High Flight

By Pilot Officer John G. Magee, Jr., RCAF

Oh, I have slipped the surly bonds of earth
And danced the skies on laughter-silvered wings;
Sunward I've climbed, and joined the tumbling mirth
Of Sun-split clouds – and done a hundred things
You have not dreamed of – wheeled and soared and swung
High in the sunlit silence. Hov'ring there.
I've chased the shouting wind along, and flung
My eager craft through footless halls of air.
Up, up the long, delirious, burning blue
I've topped the windswept heights with easy grace
Where never lark, or even eagle flew.
And, while with silent, lifting mind I've trod
The high untrespassed sanctity of space
Put out my hand, and touched the face of God.

Pilot Officer John Gillespie Magee, Jr., an American serving with the Royal Canadian Air Force, composed "High Flight." He was born in Shanghai, China in 1922, the son of missionary parents, Reverend and Mrs. John Gillespie Magee; his father was an American and his mother was originally a British citizen.

He came to the U.S. in 1939 and earned a scholarship to Yale, but in September 1940 he enlisted in the RCAF and graduated as a pilot. He was sent to England for combat duty in July 1941.

In August or September 1941, Pilot Officer Magee composed "High Flight" and sent a copy to his parents. Several months later, on December 11, 1941 his "Spitfire" airplane collided with another plane over England and Magee, only 19 years of age, crashed to his death. His remains are buried in the churchyard cemetery at Scopwick, Lincolnshire.

PREFACE

Nicolaus Copernicus and Galileo Galilei developed the scientific knowledge that became the underpinning of spaceflight. Edward Everett Hale in “The Brick Moon” and Jules Verne in “From the Earth to the Moon” dreamed and wrote about it. But finally in the last half of the twentieth century, it was the Americans and the Soviet Russians, locked in the throes of the Cold War, who accomplished it. A good case can be made that when historians look back at the twentieth century, the initial efforts of humankind to slip “the surly bonds of Earth” will play a dominant role.

Today, we call the sixteenth century the “Age of Exploration” because by combining the fore-and-aft sail rig of Arab dhows with the sturdy hull of the Baltic cog, the “caravel” was created that could safely sail all the oceans of the world. Thus, in the final years of the fifteenth century, Bartolomeo Diaz, Christopher Columbus, and Vasco da Gama opened astonishing new vistas using the caravels. In less than a century after their epochal voyages, the geography of the Earth was essentially understood and things were forever changed.

Today, because of the advent of rocket technology, we stand at the threshold of sending humans to Mars as well as to other places in the Solar System. We are within a decade of sending people back to our own Moon to establish permanent stations to exploit lunar resources and to create staging bases for the large-scale exploration of the Solar System. As was the case half a millennium ago, things will change forever when this is done.

We have both been involved in this initial exploratory effort in an intimate way. One of us (Richard H. Truly) has actually flown in space and both of us have participated in and led the organizations established in the United States to conduct space exploration. Both of us have also been touched by the brutal wars of the twentieth century, and we therefore know how these have influenced the lives of people all over the world as well.

The idea of this *Encyclopedia of Space Science and Technology* was conceived late in 1997 when one of us (Hans Mark) had a conversation with Dr. Edmund H. Immergut, who has had a long and distinguished career in scientific publishing and in the production of encyclopedias. He believed that the enterprise of space exploration was far enough along – 40 years after the first orbital flight of Sputnik I – that a good technical encyclopedia on the subject would be timely and appropriate. In developing the ideas for the encyclopedia, the following principles were established.

- The encyclopedia would be written at a high technical level, i.e., for an audience of technically literate people who were not experts in space science or technology.
- The encyclopedia would contain articles that would describe the technology of space exploration as well as the scientific results and their applications.
- The authors who would be selected to write articles would be people who are, or have been, active participants in enterprise of space exploration.

- The encyclopedia would be international and would attempt to capture the spirit that animated the enterprise for the past half century.
- The encyclopedia would have a broadly based editorial board whose members would help to select authors and assist in passing judgment on the quality of the work.

It is our hope that we have largely adhered to these principles. The *Encyclopedia of Space Science and Technology* consists of nearly 80 articles organized under eight separate categories. There is an appropriate index and a table of contents that should make it easy for readers to find the topic of interest for which they are searching.

Throughout this work, both of us have enjoyed working with old and new colleagues. We would like to extend our appreciation to everyone who participated in this effort, first and foremost, our authors for their contributions, our Associate Editors, Drs. Milton A. Silveira and Michael I. Yarymovych, and all the members of our Editorial Board for their participation and advice. Finally, special thanks are due to our Managing Editor, Ms. Maureen A. Salkin, for her tireless and highly diplomatic efforts to keep things rolling so that we can now all see the final result.

A

AIR AND SHIP-BASED SPACE LAUNCH VEHICLES

Introduction

In 1957, the Soviet Union placed the first man-made object in orbit around the earth. Since then, numerous launch vehicles have been developed to improve the performance, reliability, and cost of placing objects in orbit. By one estimate, roughly 75 active space launch vehicles either have established flight records or are planning an inaugural launch within the year. This does not include the numerous launch vehicles from around the world that are no longer operational such as the Jupiter, Redstone, Juno, Saturn, Scout, Thor, Vanguard, and Conestoga family of rockets from the United States or the N-1 from the former Soviet Union, to name just a few. Despite the many differences among all of these launch vehicles from both past and present, one common element can be found in all but four of them: they are ground-launched. Of the four exceptions, two are air-launched (NOTSNIK and Pegasus), one is ship-launched (Sea Launch), and one is submarine-launched (Shtil). It is important to keep in mind that numerous air-launched and ship-launched suborbital launch systems are in use by militaries, commercial entities, and educational institutions. However, the four mentioned are the only mobile launch systems that can place objects into a sustainable Earth orbit.

Mobile Space-Launched Vehicles

Project Pilot (NOTSNIK). NOTSNIK is the oldest and, until recently, the least well known of the four mobile space-launched systems. Following the launch of Sputnik by the Soviet Union, President Eisenhower's administration elicited proposals to launch a satellite into orbit. The Naval Ordinance Test

Station (NOTS) located at China Lake in California proposed launching a rocket from a jet fighter (1). The idea is the same as that of the current Pegasus vehicle: reduce the amount of energy needed to place a payload into orbit by launching it above the denser portion of the atmosphere. In this fashion, the engineers at NOTS designed a vehicle from existing rocket motors that could place a 2-pound satellite in a 1500-mile-high orbit. The engineers recognized the energy savings from such a launch concept and also the utility of such a flexible platform. Launching from a jet fighter could, theoretically, place a satellite into any orbit from anywhere in the world at any time.

The U.S. Navy accepted the proposal from NOTS in 1958, by some accounts as a safety net in the event that the ongoing Vanguard project was unsuccessful. The program was officially called Project Pilot, but the engineers at NOTS preferred the name NOTSNIK in direct reference to the Soviet satellite that was currently orbiting above them and the rest of the world. A Douglas Aircraft F4D-1 Skyray was the carrier aircraft for the rocket and consequently was considered the first stage. The second and third stages were modified antisubmarine missiles. The final stage was taken from a Vanguard rocket. The entire launch vehicle measured a mere 14 feet in length and had four fins at the aft end that provided a span of 5 feet.

The NOTSNIK was launched six times from an altitude of about 41,000 ft. Four of those launches ended in known failures. However, the results of two have never been verified. Some in the program insist that they achieved their goal of placing the small payload of diagnostic instruments in orbit. At least one ground station in New Zealand picked up a signal in the right place at the right time. However, confirmation that the signal was from the NOTSNIK payload was never established. Even the possibility of a success was veiled in secrecy for more than 40 years for, by all accounts, two critical reasons. The first was that in the days following the early embarrassments of Vanguard, the Eisenhower administration did not want to claim success unless it was absolutely certain. The second reason was that a mobile air-launched system that could reach orbit had extremely appealing military applications. However, the tactical advantages of such a system were far outweighed by the strategic consequences, as stated in the Antiballistic Missile (ABM) Treaty between the United States and the former Soviet Union that was concluded in 1972 (2):

Further, to decrease the pressures of technological change and its unsettling impact on the strategic balance, both sides agree to prohibit development, testing, or deployment of sea-based, air-based, or space-based ABM systems and their components, along with mobile land-based ABM systems. Should future technology bring forth new ABM systems 'based on other physical principles' than those employed in current systems, it was agreed that limiting such systems would be discussed, in accordance with the Treaty's provisions for consultation and amendment.

Pegasus. Roughly 30 years later, while NOTSNIK remained an official government secret, the idea of launching payloads into space from an airborne platform was revisited in the form of the Pegasus launch vehicle. The driving forces behind NOTSNIK and Pegasus were essentially the same. An air-launched space vehicle provides several advantages compared with ground-based counterparts.

As an example, Pegasus is launched at an altitude of 39,000 ft, which is above a significant portion of the atmosphere. As mentioned, with NOTSNIK, this eliminates the need for extra performance that would otherwise be needed to overcome atmospheric forces. This also implies that the structural components of the vehicle can be lighter, which improves the efficiency of the rocket as a whole. The energy required from the launch vehicle is also reduced by the speed already achieved by the carrier aircraft. An air-launched system also allows applying more of the impulse of the first stage along the velocity vector. This is a more efficient use of the vehicle's energy than that of ground-launched vehicles that must first apply the thrust almost perpendicular to the velocity vector already imparted by Earth's rotation. These factors combine to produce a requirement for a velocity increment that is on the order of 10% less than a comparable ground-launched rocket.

The Pegasus vehicle is a winged, three-stage, solid rocket booster (Fig. 1). It is the first space-launched vehicle developed solely with commercial funding. Three versions have been developed and flown over the years: Standard, Hybrid, and XL. The XL is the only vehicle within the Pegasus family currently in production. The XL is roughly 10,000 lbm heavier than the Standard or Hybrid models and is roughly 6 ft longer. Because the XL extends farther aft beneath the L-1011 carrier aircraft, the port and starboard fins become an obstacle to the landing gear doors. To correct this problem, the port and starboard fins were

Figure 1. Disassembled version of standard Pegasus launch vehicle.

modified to include an anhedral of 23° . To maintain commonality between the various members of the Pegasus family of vehicles, the same anhedral was introduced into the Standard vehicle, which was then given the designation Pegasus Hybrid. Other than the anhedral of the fins, the Standard and Hybrid vehicles are exactly the same. The Standard, the first Pegasus vehicle built, was flown on six missions. The Hybrid vehicle has flown four times. The XL vehicle has flown 21 times. Of 31 Pegasus launches, only three missions failed to reach orbit.

The Pegasus XL was designed and developed to provide increased performance above and beyond that provided by the Standard and Hybrid vehicles. A typical Pegasus XL vehicle weighs roughly 51,000 lbm at launch, is 55.4 ft long and 50 inches in diameter, and the wingspan is 22 ft (3). At launch, the Pegasus XL is carried aloft by the company's carrier aircraft, a modified L-1011, which originally saw commercial service with Air Canada. The vehicle is dropped from an altitude of 39,000 ft at Mach 0.8. Five seconds after release from the L-1011, the first stage ignites and the vehicle's on-board flight computer continues the sequence of events that eventually lead to orbital insertion. The brief coast period between drop and stage one ignition is designed to provide a safe distance between the L-1011 and the launch vehicle.

The Pegasus Standard vehicle was originally dropped from a NASA-owned and operated B-52. The Pegasus vehicle was attached to one of the pylons underneath the starboard wing much in the same manner as the early supersonic and hypersonic test vehicles such as the X-15. For a variety of reasons, Orbital purchased and modified the L-1011 to facilitate all future launches.

Unlike the B-52 that supported initial Pegasus launches, the L-1011 carries the Pegasus vehicle underneath the fuselage rather than underneath the wing. Once Pegasus is ready to be mated to the carrier aircraft, it is towed from Orbital's integration facility at VAFB to the plane on the Assembly and Integration Trailer (AIT). Regardless of where the launch is to take place, the Pegasus is always integrated and mated to the L-1011 at VAFB. From there, the launch system can travel to any location in the world for launch. There is enough ground clearance for the L-1011 to take off and land with Pegasus attached underneath. However, the added height of the AIT underneath Pegasus requires raising the L-1011 off the ground slightly by hydraulic jacks to mate Pegasus to the carrier aircraft (Fig. 2). While mated to the L-1011, the vertical rudder actually protrudes into the plane's fuselage in a compartment specifically designed for this purpose. When mating the Pegasus to the L-1011, the rudder is usually detached from the Pegasus vehicle and placed inside the housing first. Then the Pegasus is rolled underneath the L-1011 and attached to the rudder and then to the plane. Removing the rudder first minimizes the height to which the L-1011 needs to be raised for the mating process. The entire mating process from rollout to mating takes about 6 hours. Pegasus is attached to the L-1011 using four hooks on the center box of the wing and a fifth hook on the forward portion of the vehicle. The inside of the airplane has been stripped of all unnecessary equipment and hardware. Up front in what would normally be the first class cabin are eight seats for personnel during ferry flights from VAFB to the launch site of interest and two computer stations from which personnel can monitor the health of the vehicle and the payload. The rest of the interior of the cabin has been completely gutted. Access to the rear portion of the aircraft cabin is obtained through a galley door.

Figure 2. Fully assembled Pegasus launch vehicle being mated to the L-1011 aircraft. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Unlike most other launch vehicles in the U.S. fleet, the Pegasus launch vehicle is integrated horizontally on the AIT (Fig. 3). Horizontal integration facilitates easy access to the vehicle and eliminates the need for high bays and large cranes. Components are received as needed either from groups within Orbital Sciences or from outside vendors. To ensure that all of the major flight hardware and software is thoroughly tested before flight, Pegasus, like many other vehicles, is subjected to a series of “fly to orbit” simulations at various stages of the integration process. Four flight tests are normally performed. The first tests the three stages individually. The second test is conducted after the three stages are electrically mated together. The third test is performed after the three stages are electrically and mechanically mated and the stack is electrically mated to the payload. The fourth and final flight test is performed once the payload has been mechanically mated to the rest of the vehicle and the half of the fairing that includes the pyro devices necessary for jettisoning the shroud is

Figure 3. Horizontal integration of Pegasus launch vehicle. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

electrically mated. These tests are intended to verify that various systems function and also respond as expected to known disturbances. If the inertial measurement unit (IMU) onboard receives data to indicate that an unexpected attitude change has occurred, will the fins or thrust vector control systems respond accordingly? Are all the commands to the various subsystems appropriate, and do those subsystems respond appropriately? Once the Pegasus vehicle has been mated to the L-1011 carrier aircraft, one last test is performed, called the Combined Systems Test (CST). This test verifies that the launch vehicle and the carrier aircraft are communicating as expected. This is particularly important since the vehicle's health can be monitored both from telemetry that is broadcast from the vehicle to the ground via antennas on Pegasus and also by the computer stations inside the L-1011 via hardwired electrical connections. More importantly, some data and commands are sent to the Pegasus vehicle before launch. The only method currently available for accomplishing this transfer of data is through the electrical connections between the Pegasus vehicle and the carrier aircraft.

To be fully mobile, the Pegasus launch system must also be fully self-contained. Except for those services provided by the range (such as radar coverage), the L-1011 can transport all of the equipment required to support a launch of Pegasus, including, of course, Pegasus itself (Fig. 4). Some launches take place off the coast of California where the Western Range (based at VAFB) is the lead range. In these instances, no ferry flight is required. The L-1011 simply takes off from VAFB and flies to the designated drop point roughly 100 nmi out to sea. The checklist that is processed in the control room on the day of launch requires about 4 to 5 hours to complete. The L-1011 usually takes off an hour before the scheduled launch time. If all systems are "go," as determined by the mission team members in the control room, the launch conductor on the ground commands the pilot of the L-1011 to drop the Pegasus from the carrier aircraft.

Shtil. In a classic example of turning swords into plowshares, the Russian Navy developed a satellite delivery system for nonmilitary applications that uses a submarine-launched. The SS-N-23 (NATO's designation) is a three-stage

Figure 4. L-1011 aircraft taking off with Pegasus. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

liquid-fueled vehicle that can deliver small satellites to low Earth orbit. Very little is known about this launch vehicle service including performance to various altitudes and inclinations. What is known is that two satellites belonging to the Technical University of Berlin were successfully launched in 1998 from a Russian submarine for the stunningly low price of \$150,000 (4). Some sources indicate that the typical commercial price for a Shtil launch is actually in the neighborhood of \$500,000. There are two possible reasons for the low cost of a Shtil launch. The first is that more than 200 missiles have already been produced by the Russian military. There is also speculation that offering commercial launch services provides a way to maintain proficiency in launching missiles without using precious military funding. One disadvantage of this system is that the Shtil vehicle likely does not have enough performance to achieve circular orbits in the medium to high Low Earth Orbit (LEO) altitudes (4). This is a direct result of the Shtil's heritage as a ballistic missile first and foremost.

Sea Launch. The most recent mobile launch system is the Sea Launch vehicle which is launched from a converted oil-drilling platform along the equator (Fig. 5). Sea Launch is both the name of the launch vehicle and the name of the international joint venture that provides the launch services. The partnership is comprised of Boeing, KB Yuzhnoye of Ukraine, which provides the two Zenit stages, and RSC Energia of Russia, which provides the Block DM-SL upper stage. The launch vehicle and payload integration takes place at the vehicle's home port of Long Beach, California. Once integration is complete, the launch vehicle is loaded onto the converted oil-drilling platform and towed to a predetermined

Figure 5. Computer simulation of Sea Launch. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

launch location at the equator, specifically 154° West. Once on site, the Zenit 3SL is raised into its launch attitude (vertical) and launched. A second ship that houses mission personnel and the control room monitors the launch from nearby. The vehicle itself is a little less than 200 ft long and roughly 13 ft in diameter. The performance to Geosynchronous Transfer Orbit (GTO) is approximately 5250 kg (4). “In terms of spacecraft mass in final orbit, this would be equivalent to approximately 6000 kg of payload capability if launched from Cape Canaveral, because the spacecraft does not need to perform a plane change maneuver during the Geosynchronous Earth Orbit (GEO) circularization burn” (5).

There are three key phases in the integration of a Sea Launch vehicle (5). Phase I takes place in the Payload Processing Facility (PPF). This phase includes receipt of the spacecraft, processing of the spacecraft, testing, and enclosure within the payload fairing. Phase II takes place on the Assembly and Command Ship (ACS). This entails mating the encapsulated spacecraft to the launch vehicle and testing the integrated stack. Phase III takes place on the Launch Platform (LP) once the vehicle has been transferred from the ACS. While still in port, the integrated launch vehicle is raised to its vertical launch attitude so that a series of tests can be conducted. The launch vehicle is then lowered back into a horizontal position, stored in an environmentally controlled room, and transported to the equator while on board the launch platform. At the launch site, the launch vehicle is rolled out to the launch pad, raised to a vertical attitude again, and fueled. The launch is performed by an automated system and monitored by the Assembly and Command Ship which is moved for launch to a distance 6.5 km away (Fig. 6).

The Assembly and Command Ship for Sea Launch serves as the launch vehicle integration and testing facility. In addition to acting as the temporary home for launch crews, the ship also houses the Launch Control Center (LCC) and the equipment necessary to track the initial ascent of the rocket. Unlike the

Figure 6. Sea Launch successfully lifts DIRECTV 1-R satellite into orbit. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Pegasus carrier aircraft that was modified after serving in a different capacity, the ACS was designed and constructed specifically to suit the unique requirements of Sea Launch. The ship is roughly 660 ft long and 110 ft in beam and has an overall displacement of approximately 30,830 tonnes.

The rocket assembly facility is on the main deck of the ACS where the launch vehicle integration takes place. This activity is conducted before setting sail for the equator and simultaneously with spacecraft processing. After the spacecraft has been satisfactorily processed, it is encapsulated and transferred to the rocket assembly compartment, where it is mated to the launch vehicle. Following integration and preliminary testing, the integrated launch vehicle is transferred to the launch platform. Then both ships begin the journey to the equator, which takes roughly 12 days.

The launch platform has all of the necessary systems for positioning and fueling the launch vehicle, as well as conducting the launch operations. Once the launch vehicle has been erected and all tests are complete, personnel are evacuated from the launch platform to the ACS using a link bridge between the vessels or a helicopter. Redundant radio-frequency links between the vessels permit personnel on the ACS to control all aspects of the launch, even when the command ship has retreated to a safe distance before launch. The launch platform, which was converted from an oil drilling platform, is very stable. It is supported by a pair of large pontoons and is propelled by a four-screw propulsion system (two in each aft lower hull). Once at the launch location, the pontoons are submerged to a depth of 70.5 ft to achieve a more stable attitude for launch, level to within approximately 1° .

Advantages of Mobile Space-Launched Systems

NOTSNIK, Pegasus, Sea Launch, and Shtil were never intended to replace the existing fleet of ground-launched rockets. Rather, they effectively supplement the existing worldwide capability by providing additional services to a targeted market of payloads that benefit greatly from the mobility and flexibility of these unique space-launch systems. These vehicles can provide services similar to ground-launched vehicles for payloads within their weightclass. In fact, all four vehicles have fixed launch locations for standard services. For example, Pegasus uses the launch location of 36°N , 237°E for all high-inclination missions that originate from VAFB. In this regard, the mobile launch systems are no different from ground-launched vehicles in that they repeatedly launch from a fixed location, albeit a location that is not on land. However, they can also offer services and performance that avoid many of the restrictions inherent in being constrained to a particular launch site. Few of those restrictions are trivial. They include inclination restrictions, large plane changes required to achieve low-inclination orbits from high-latitude launch sites, large plane changes required to transfer from GTO to GEO when launching from certain ranges, and low-frequency launch opportunities for missions that require phasing such as those involving a rendezvous with another spacecraft already in orbit.

Inclination Restrictions. Inclination restrictions stem from range safety considerations. To understand these restrictions fully, it is first necessary to

understand two concepts: (1) transfer orbits and (2) instantaneous impact-point tracks.

Transfer Orbits. Transfer orbits are intermediate orbits established by the various stages of a launch vehicle that provide a path to the final desired orbit. The transfer orbits for early stages are mostly suborbital, meaning that some portion of the orbit intersects Earth's surface. The most efficient way to transfer between two orbits is to apply thrust at opposite apses. An application of thrust in the right direction at the perigee of the initial orbit will raise the apogee. Coasting to the new apogee and applying thrust (again in the appropriate direction) at this apsis will then raise the perigee. This provides a stair-step approach to raising the altitude of a vehicle's orbit. The ascent of a launch vehicle from launch to orbit follows a similar trend with one critical caveat. The impulse of initial stages is usually not sufficient, individually, to raise the perigee above Earth's surface. This means that using the optimal Hohmann transfer approach would bring the launch vehicle back to Earth before another transfer burn could be made. As a result, initial launch vehicle stages usually apply their thrust at places within a transfer orbit other than the apses and usually always on the ascending side of the orbit.

Consider a modest three stage, ground-launched rocket launching into a circular low Earth orbit as an example. Before launch, the vehicle is effectively sitting at the apogee of an orbit (Fig. 7). If the surface of Earth were not present to support the rocket, it would be drawn downward along a path that would take it closer and closer to Earth's center before swinging back to an apogee altitude equal to the radius of Earth. This is essentially the first of several transfer orbits and the rocket has not even been launched. When the rocket lifts off, it applies its thrust at an apsis, but in a direction that is perpendicular to the initial velocity vector of the rocket, which itself is in the direction of Earth's rotation. During the first burn, the vehicle slowly tilts over so that the thrust is applied in a direction that is increasingly parallel to Earth (Fig. 8). This has the effect of increasing both the apogee and perigee. The perigee will most likely still be suborbital at the end of the burn. The apogee will be increased sufficiently that the launch vehicle

Figure 7. Path of rocket without Earth's surface. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 8. Path of rocket after launch. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

can coast up to a location near the new apogee, following the first stage burnout, and ignite the second stage. The key consideration here is that the second stage will be ignited near but not at the apogee. Again, this is not the most energy-efficient way to transfer orbits, but it is necessary because the opposite apsis is still below Earth's surface, and the second stage may not have sufficient impulse to raise it above the atmosphere. Igniting the second stage at a location other than the apogee again has the effect of raising both the perigee and the apogee. In this case, because only one stage is left, the burn is designed to raise the apogee to the desired altitude of the final orbit. After the second stage burns out, the vehicle coasts up to the new apogee and ignites the third stage. This will raise the perigee up to the final orbit altitude without changing the altitude of the apogee.

Impact-Point Tracks. By always burning on the ascending side of the trajectory and iteratively raising the apogee while the transfer orbit remains suborbital, anything jettisoned before the final burn will reenter the atmosphere and either burn up or impact Earth's surface. As the burn of each stage progresses, the point at which the transfer orbit intersects the Earth extends farther and further downrange until, at some point late in the final burn, there is no longer a point of intersection. These points of intersection comprise the instantaneous impact-point track. Clearly, as the vehicle is coasting, the instantaneous impact point does not change. Conversely, during a motor burn, it is constantly changing and each point represents the location of impact on Earth if, in fact, the thrust were to be instantly terminated either by design or due to some sort of failure. It is this impact-point track and the need for it to avoid populated areas that is a primary source of inclination restrictions from various ranges.

For any rocket launch, whether it be space-based, suborbital, ground-launched, ship-launched, or air-launched, the public-safety considerations that must be satisfied are very stringent. Those stages of a rocket that are jettisoned before reaching orbit should avoid land. And no launch vehicle whose impact-point track nominally crosses land can risk a casualty among the public with a probability of greater than 30 in a million. Calculating the expectation of a

casualty depends on many factors, including the reliability of the launch vehicle (e.g., how many failures it has had in the past), the density of the population being overflown, and the speed with which the instantaneous impact-point track crosses over a populated region. Late in flight, the distance between successive impact points increases dramatically and reduces the risk to the population below. This is why it is generally more permissible to overfly populated regions far downrange than it is early in flight. For instance, the risk to a populated region in Africa from a rocket launched at the Eastern Range would, in general, be less than the risk posed to an area with the same population density overflown in the Caribbean. This is not to say that overflight of any part of Africa is acceptable. There are some extremely high population densities in Africa, especially along the west coast of northern Africa, which are avoided at all costs. And it is this very consideration that constrains the paths of many launch vehicles from the existing ranges.

The key land masses that must be avoided early in flight for vehicles launching from the Eastern Range include the entire eastern seaboard of the United States when launching on an ascending pass (northerly direction) and the Caribbean and South America when launching on a descending pass (southerly direction). For maximum performance from any given launch vehicle, this restricts the range of inclinations achievable from the Eastern Range to between roughly 28.5° and 51° for ascending passes and between 28.5° and 40° for descending passes. Clearly, inclinations outside this range would be achievable if plane changes were instituted, but that has the disadvantage of reducing the maximum available performance for any given launch vehicle. Higher inclinations are available from the Western Range but restrictions still exist there due to Hawaii, islands in the South Pacific, and the western coasts of both North and South America.

When the inclinations from both the Eastern and Western Ranges are combined (assuming direct injection), a block of inclinations is unavailable without plane changes and subsequent reductions in weight-to-orbit capabilities. For small payloads with limited budgets that require an inclination outside what is directly available from the existing ranges, the cost of launching on the heavy-lift launchers that can execute the necessary plane changes can be prohibitive. And reducing launch costs by flying as a secondary or even tertiary payload is advantageous only in the rare event that a primary payload can be found that requires the same final orbit. For these customers, Pegasus and Shtil provide an alternative due to their relatively low cost, mobility, and self-contained launch infrastructure. Sea Launch provides a similar alternative for the heaviest satellites that are intended for either GEO or low Earth orbits.

Plane Changes Required to Achieve Low Inclinations. The inclination of an orbit represents the angle between the equatorial plane and the orbital plane around Earth. This also happens to be similar to the definition of lines of latitude. It is no coincidence then that the maximum latitude of the ground track for any object in space is roughly equivalent to the inclination of the object's orbit. The only reason that the maximum latitude is not exactly equal to the inclination is because Earth is not a perfect sphere. Conversely, this implies that the minimum inclination attainable by a launch vehicle is roughly equivalent to the latitude of the location from which it is launched. The maximum is 180° minus

the latitude of the launch point. This leads to the important conclusion that the only latitude from which all inclinations are directly accessible is 0° (the equator). The Eastern Range is at a latitude of roughly 28.5° . Therefore, the minimum inclination attainable without plane changes is roughly 28.5° . Lower inclinations can be achieved by launching into any available inclination, achieving a preliminary orbit, and then making an inclination correction burn when the satellite is over the equator or at any latitude that is numerically less than the desired inclination. The significant disadvantage of this process is that inclination changes while in orbit require a great deal of energy. The larger the change in inclination required, the more energy must be expended. Depending on the final orbit desired, this usually requires an additional stage to correct the inclination and achieve the final orbit. The most common recipient of this type of orbit maneuver is a satellite headed to geosynchronous orbit. However, there are low Earth orbit payloads that require low inclinations as well. The ability of Pegasus and Shtil to move the drop point to a latitude from which such energy-intensive plane changes would not be required permits smaller launch vehicles to achieve the same orbit from lower latitudes that larger vehicles can achieve from higher latitudes. The difference in cost, complexity, and performance can often mean the difference for some customers between launching or not.

Some launch locations maintained by other countries are at significantly lower latitudes than those in the United States. For some customers, such ranges can provide the necessary services. However, many satellites in the United States, especially government sponsored, are required to contract with a U.S. launch service provider and use a U.S. controlled range.

Phasing. An object's orbit is essentially a locus of points that defines the path of the satellite. Those points define a plane that goes through the center of Earth. To define an object's precise position within an orbit, that plane and every position in it is defined with respect to both Earth and a coordinate system, one of whose axes always points toward the vernal equinox. Every position of a satellite as it orbits Earth is defined in terms of an epoch (time), the semimajor axis, and eccentricity, measured from Earth's center, inclination and argument of perigee, which are both referenced to Earth's equator, and the right ascension of the ascending node, which is referenced to the vernal equinox frame.

A rendezvous between two objects in space involves a series of maneuvers designed to make the orbital elements of both objects the same, hence confirming the fact that they have, in fact, become a single object orbiting Earth. Just as motor burns can raise or lower the perigee or apogee of an orbit or change the inclination, so too can motor burns be used to change every orbital element that defines a satellite's motion. However, changing some of those elements, especially those that require plane changes, requires large amounts of energy, and they are considered "expensive" in the parlance of orbital mechanics. One way to avoid paying the high price of actively changing the orbit of a satellite with a motor burn is to do it passively through the aid of various external forces. Several naturally occurring forces cause every orbital element to change over time. These include atmospheric drag, solar radiative pressure, the gravitational attraction of the Moon, Sun, and planets, and the nonuniform gravitational forces due to Earth's oblateness. These forces can be used to one's advantage when planning a rendezvous mission. However, some changes resulting from these forces can take

a very long time to reach significant levels. This means that the initial differences between the rendezvousing satellite and the target must be initially small to avoid spending too much unproductive time in orbit. This can be accomplished by simply timing the launch appropriately so that at the time of orbital insertion, the satellite that has newly arrived in orbit is very close to the orbital plane of the target satellite.

To accomplish this maneuver, the launch must occur when the target satellite passes almost directly overhead. It also must be passing in the same direction as the intended launch. In other words, if the satellite being launched is to head off in a southerly direction (along the descending pass), the target satellite must be overhead and also on its descending pass as well. Otherwise, the two satellites will end up with right ascensions that are 180° apart which would be excessively expensive (either in terms of time or energy) to correct once in orbit.

For ground-launched vehicles, the wait between successive passes of the target satellite could be as much as several days, depending on the target orbit because the distance between ground tracks on successive passes depends on the period of the orbit, which depends on the orbit's semimajor axis. Clearly, the ground track of an object that requires only 90 minutes to orbit Earth will be more closely spaced than the ground track of an object whose period is several hours. These ground tracks will pass to the east and west of the given launch site on a daily basis, but the distance between the ground track and the launch site will only be minimized by a periodicity of the order of days.

Mobile assets, however, can eliminate the wait by essentially choosing a launch point that is ideally suited for a rendezvous. Instead of waiting for the ground track to come to the launch point, the launch point is moved to the ground track. In this way, the launch opportunities can be reduced from one every two to three days to at least once a day if not twice a day, if the launch vehicles have the flexibility to launch on both ascending and descending passes.

Consider an example of a satellite being launched by a Pegasus XL to rendezvous with a satellite currently in orbit at an altitude of 400 km circular. A normal ground-launched vehicle would require a wait of about 2 days between successive launch attempts. However, the mobility of Pegasus permits two launch opportunities every day, which is graphically represented in Figs. 9 and 10. Two key assumptions need to be kept in mind when viewing these figures. The first is that the maximum range of the Pegasus carrier aircraft is roughly 1000 nmi. This includes a captive carry to the launch site, an aborted launch, and a return to base with Pegasus still attached. The second assumption is that for launches that do not require the full advantage of Pegasus' mobility, the standard launch point for Pegasus out of the Eastern Range is 28°N , 281.5°E . The vertical axes in Figs. 9 and 10 represent the difference in argument of latitude between the two satellites (the angular separation within the same orbital plane). The horizontal axis represents the launch point as the difference in degrees from the nominal point listed before. The diagonal lines represent the difference in argument of latitude for each day in the first week of October, which was chosen simply as an example. Figure 9 represents the difference in argument of latitude for northerly launches (launch along the ascending pass). Figure 10 represents the difference in argument of latitude for southerly launches (launch along the

Figure 9. Graph of difference in argument of latitude for northerly launches.

descending pass). The horizontal lines simply demarcate zero angular separation between the two satellites.

The intersection of a diagonal line with a horizontal line defines a drop point within the range of the Pegasus carrier aircraft from which Pegasus can be

Figure 10. Graph of difference in argument of latitude for southerly launches.

launched and effectively deliver its satellite to the front door of the target satellite at the time of orbital insertion. Realistically, this is not how a rendezvous would normally be achieved. Ideally, the satellite being launched would be placed in a temporary parking orbit slightly below and behind the target satellite. Over the course of several orbits the distance separating the two objects would be slowly decreased using several controlled burns of the satellite just placed in orbit. This would imply that a drop point is needed not to achieve 0° difference in argument of latitude but some finite value. The example is still valid. Simply shift the horizontal lines up or down until the desired difference in argument of latitude is matched. Again, an intersection between a diagonal line and the horizontal line defines a launch point within the range of the Pegasus carrier aircraft that would result in the desired difference in argument of latitude.

As can be seen from Figs. 9 and 10, every day except two in the first week of October provides two launch opportunities. A southerly launch on the 3rd does not provide a drop point within the range of the carrier aircraft that will achieve the desired result. However, a drop point can be found on that day if the launch is along the ascending pass instead. Likewise, a suitable drop point cannot be found within the range of the carrier aircraft on the 6th of October when launching along the ascending pass, but one can be found if launching in a southerly direction. The same qualitative results would be obtained for any other time frame. The quantitative results might be slightly different. For instance, instead of having only one launch opportunity on the 3rd and 6th it may be the 4th and the 7th. But the end result is the same. The mobility of Pegasus and, by definition, Sea Launch, and Shtil provides ideal rendezvous launch opportunities at least once a day and in most cases twice a day.

Clearly there are disadvantages with all of these mobile assets. Pegasus is limited in its size due to the restrictions of the L-1011 and, more importantly, the mechanical limitations of the hooks that hold the vehicle to the plane. Sea Launch has somewhat of a temporal disadvantage in that it requires almost 2 weeks to travel to the launch site. Those problems are exacerbated for Shtil because its home port is farther north. Nonetheless, for some specific missions, the mobility and flexibility that are provided by these unique space-launched assets provide valuable supplemental services to the fleet of existing ground-launched vehicles.

APOLLO 17 AND THE MOON

Apollo 17 was not the last flight of humans to the Moon. This writer was not the last human being to step on the lunar surface. More lunar exploration and even lunar settlement will occur, barring the future stagnation or disappearance of our civilization. Exploration and scientific investigations in the earth sciences are rarely complete, particularly for studies related to a specific field site. A long hiatus between field investigations may occur, but other forms of investigation, directly or indirectly related, continue. Apollo 17's field study of the Valley of Taurus-Littrow on the Moon in 1972 and subsequent examination of its significance to our understanding of the origin and evolution of that small planet and of our own constitute a good example of these facts of scientific life. As the third of the specifically "science" missions to the Moon in the twentieth century, Apollo 17 actually became the last lunar landing of the Apollo Program in September 1970 (1) rather than on 11 December 1972 when the mission reached Taurus-Littrow. The National Aeronautics and Space Administration (NASA) and the Administration of President Richard M. Nixon, with the acquiescence of the Congress, had concluded that no further planned amortization of the American taxpayer's investment in deep space exploration would be undertaken. As historically naive a political decision as this may seem today to some, it did not prevent the achievement of one of the Program's major goals—gaining a first-order understanding of the Moon and its relationships to the terrestrial planets. This became one of the primary historical legacies of the post-World War II generation.

Apollo had evolved quickly and radically toward increased scientific emphasis after Neil Armstrong first stepped on the Moon on 20 July 1969. Its purpose changed from the completed goal of meeting President John F. Kennedy's challenge (2) to land "men on the Moon and return them safely to Earth," to an objective of increasing human knowledge about the Moon and space. This would be done to the maximum extent possible using the technological and operational systems in hand and reasonable extensions of that capability. This shift in emphasis occurred smoothly and rapidly thanks to the foresight of senior NASA managers such as George M. Low, Apollo Spacecraft Program Manager; Robert Gilruth, Director of the Manned Spacecraft Center; Eugene Kranz, Chief of the Flight Control Division; Maxime Faget, Chief Engineer of the Manned Spacecraft Center; and General Samuel Phillips, Director of the Apollo Program. As early as the spring of 1969 (3), scientific packages were being enhanced, adding new experiments and improving old ones. Astronaut training in field geology, overseen by the author for the Astronaut Office, was altered to consist of field simulations (4) at geologically relevant sites using mission-specific equipment and procedures. These scientific training exercises taught pilots the art of geologic observation, sampling, and documentation and also put that learning in the context of real geologic problems related directly or indirectly to those they would encounter on the Moon. In addition to the U.S. Geological Survey's Principal Investigators for field geology, Eugene M. Shoemaker, Gordon A. Swann, and William R. Muehlberger (also of the University of Texas), world-renowned Earth scientists who doubled as outstanding teachers were given increased

access to mission planning, mission operations, and astronaut training. These new participants included Richard H. Jahns (Stanford University), Robert P. Sharp and Leon T. Silver (California Institute of Technology), James B. Thompson and James Hays (Harvard University), and Gene Simmons and William Brace (Massachusetts Institute of Technology). Also important to science was an increase in the capability of the Lunar Module (5) so later missions could include heavier scientific payloads, a lunar roving vehicle, and greater consumables, thus, longer time on the Moon. These augmentations meant a large increase both in time for exploration (22 hours for Apollo 17 versus a total of 19.4 hours for Apollo 11, 12, and 14, combined) and in distance traveled (35 km for Apollo 17 versus ~5 km combined walking distance for Apollo 11, 12, and 14).

The Apollo 11, 12, and 14 missions were flown largely under the original payload, training, and operational constraints imposed by the race to the Moon and the conservatism necessary for success in that race. These missions still managed, however, to produce remarkable suites of samples, photographs, and observations in addition to giving the Apollo team the operational confidence to land at more challenging but scientifically more interesting locations away from the lunar equator. In spite of the operational limitations, the analysis of samples and other information returned from the first three landing sites rapidly increased the understanding of the Moon and its history. Ironically, the Apollo 13 mission, which failed to land on the Moon, set the stage for the even more spectacular scientific returns from the last three landings, Apollo 15, 16, and 17. The crew and backup crew of Apollo 13 had embraced the new training emphasis on field geology and encouraged the Apollo 15 crew to follow suit. Apollo 13's backup crew, already convinced that a science focus was important, was assigned to fly the Apollo 16 mission. Finally, the designation of a scientist and geologist as the Lunar Module Pilot on Apollo 17 assured that all of the last three missions truly would be "The Great Voyages of Exploration" (6).

Due to the foreknowledge that Apollo 17 would be the last of the Apollo series, selection of its landing site became a contentious issue (7) among lunar scientists and between lunar scientists and operational planners. The usual candidates for landing sites reappeared: crater floor and central peak opportunities for deep sampling of the lunar crust, like the impact crater Copernicus; possible volcanic features, like the Davy Crater Chain and dark material in Alphonsus; and highland areas such as the rim of the crater Tycho and an area "Southwest of Crisium." Even a farside landing in the basin Tsiolkovskiy was given brief consideration due to the efforts of the author (8). Eventually, however, the scientists became increasingly interested in an unnamed, 2300-m deep, 50-km long valley, radial to the 740-km diameter circular basin, Serenitatis, that cut through the Taurus Mountain ring near the crater Littrow. This Valley of "Taurus-Littrow," however, was not a favorite of the operational mission planners. In spite of the pinpoint landing accuracy they had demonstrated on all previous missions since Apollo 11, the narrow valley, the mountainous approach, and the high valley walls gave the planners pause. Their legitimate concerns were compounded by the relatively short time, only 14 minutes, for navigational updates after acquisition of communications from the lunar module, Challenger, as its last orbit before landing carried it around the Moon from the farside. Initially, trajectory calculations indicated that three-sigma errors, the normal

Figure 1. Night launch of the Saturn V rocket carrying the Apollo 17 Mission to the Moon at 12:40 A.M., 7 December 1972 (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

extremely conservative planning limit, might result in hitting the side of the northern mountain wall. Gradually, however, refinements in navigational techniques for the mission and the inevitable synergistic give and take that so characterized Apollo interactions narrowed the three-sigma errors to about 1-km, the limit where all agreed that Taurus-Littrow could be the selected site. Thus, in late February 1972, only 9 months from launch, Taurus-Littrow was approved as the exploration site for Apollo 17 (9) (Fig. 1).

The Apollo 17 Mission

The Valley of Taurus-Littrow (Fig. 2) offered four major benefits as the last Apollo landing site, taken in the context of a final test of then current hypotheses related to the origin and evolution of the Moon. First, photogeologic analysis indicated that Taurus-Littrow provided access to a three-dimensional window into a mountain ring created by the Serenitatis large basin-forming event, by now well established as the result of a giant impact of an asteroid or comet. Second, major units of mare basalt and older nonmare rocks would be within easy reach of roving vehicle traverses. Third, a mantle of dark, possibly young volcanic debris partially covered the region as well as portions of the valley, and craters of a range of depths

Figure 2. The Valley of Taurus-Littrow as seen from the Commander's window on the left side of the Lunar Module Challenger on the orbit of the Moon before landing. The view is approximately west northwest, looking toward the Serenitatis Basin (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

penetrated this debris and the underlying basalt. And, fourth, the valley lies about 600-km north and 200-km east of the Apollo 11 and Apollo 15 sample areas, respectively, adding significantly to our exploration coverage of the Moon's nearside.

The Lunar Module crew of Apollo 17, Commander Eugene A. Cernan, and the writer as geologist and Lunar Module Pilot, conducted 22 hours of field exploration and experiment deployment in the Valley of Taurus-Littrow between 11 and 14 December 1972. During this period, the crew investigated, photographed, and sampled 11 major field locations. We traversed, observed, and sampled more than 35-km of the valley floor and obtained and documented 120-kg of samples from 97 major boulders and 75 other lunar materials. We took 2200 documentation photographs and deployed the 11 experiments of the Advanced Lunar Science Experiment Package (10). The crew had trained together for 15 months before launch, several days a month consisted of simulated traverses at field sites illustrating one or more of the types of geologic problems expected on the Moon and specifically at Taurus-Littrow. Combined with the geologic experience of the author, the organization and flexibility of the exploration plans (11–13), and the close cooperation of the science team in direct support on Earth, this training gave a stronger scientific foundation to Apollo 17's exploration that had been possible during previous Apollo missions (14,15).

The North and South Massifs constitute the major structural boundaries of the Valley of Taurus-Littrow. Slopes of an approximately constant 25° flank the Massifs, rising 2000 and 2300 m, respectively, above the valley floor. Discontinuous, but roughly horizontal exposures of thick sections of crustal rocks that predate the major mare basalt eruptions exist on the steepest upper slopes. These outcrops or near outcrops create numerous fields of exposed rock from which tracks lead downward to some of the sampled boulders at the base of the Massifs. Interlocking domes called the Sculptured Hills constitute Taurus-Littrow's northeastern wall and have concentrations of boulders apparent only on the inaccessible upper slopes of these hills. The valley floor consists of an undulating, highly cratered, relatively flat surface, covered largely by broken and pulverized basalt. One group of the cluster of craters surrounding the spot where Challenger landed, lies on a ray of secondary ejecta from the crater Tycho (16) 2000-km to the southwest. The largest of these craters is about 600-m in diameter. An older cluster of craters of about the same range of sizes cut into the floor northeast and to the west of the landing point, near the base of the North Massif. An irregular fan of material, the light mantle, projects northeast from the base of the South Massif. Finger-like projections of this fan reach out as much as 6-km from the Massif. Premission photographs suggested that a mantle of dark material covers the valley as a whole, including portions of the surrounding mountains. All surfaces are composed as pulverized debris called "regolith" (17), consisting largely of fragments of the bedrock below mixed with dark mantling material and other materials thrown into the area by more distant meteor impacts or introduced by volcanic eruptions younger than the bedrock.

Scientific activities in Taurus-Littrow (Fig. 3) began with the deployment of the experiments constituting the sixth and final Apollo Lunar Surface Experiments Package (ALSEP). This package had been enhanced to have a design life of 2 years rather than one (18). In connection with drilling holes for the heat flow experiment, two cores through the upper 3.2-m of the central valley regolith were obtained. Despite minor interruptions to work on technical problems with the ALSEP, about a third of the first excursion (extravehicular activity or EVA) and most of the second and third excursions concentrated on the planned traverses and exploration. Actual traverses followed this plan closely (19–22) except for a curtailed first traverse that only reached a point on the rim of Steno crater rather than reaching the original objective of Powell and deletion of the third traverse's Station 10 at Sherlock. Investigations of the basaltic mare materials south of the landing point began on the first excursion. On the second day, the traverse went west to sample premare materials at the base of the South Massif (Station 2). We then worked back over the light mantle deposit (Stations 2A and 3); to the dark, possibly volcanic crater, Shorty (Station 4); over the contact between light mantle and mare; and finally into the basalt boulder field surrounding the 100–150 m deep crater, Camelot (Station 5). The third day started with a long study of large boulders at the base of the North Massif (Stations 6 and 7), followed by sampling in the regolith at the base of the Sculptured Hills (Station 8), and a final stop at another possible volcanic crater, Van Serg (Station 9). Along each lunar rover traverse, we periodically sampled the surface of the regolith across various geologic units, deployed explosive charges for the active seismic profiling experiment, monitored the receiver for the surface electrical properties experiment,

and obtained readings from the traverse gravimeter (23). The principal sampling tools used included a rock hammer, a pair of long handled tongs, 35 and 70 cm core tubes, a long handled scoop (also used for trenching), and a supply of pre-numbered Teflon sample bags (Fig. 4).

Impact Cratering

Almost everything we think we know about the Moon must be viewed through the filter of impact cratering effects (Fig. 5) that have dominated lunar history from its origin to the present (24–29). The impact of comets, asteroids, meteors, micrometeors, dust, and energetic atomic and nuclear particles have modified the surface and near-surface expression of all of the internally generated processes that contributed to the present physical nature of the Moon. The secondary effects of each impact have magnified the importance of these impacts. Most comet, asteroid, meteor, and micrometeoroid impact velocities are between 13 and 18-km/s, and some are as high as 70-km/s, giving target pressures at the point of impact of several hundred Gpa (gigapascal). Extraordinary amounts of heat per unit mass are released as conversion of kinetic energy into forward and rearward shock waves takes place almost instantaneously. The amount of extralunar material that can be identified in regolith samples returned to Earth

Figure 4. The author as a well-equipped astronaut on the Moon during the Apollo 17 mission in the Valley of Taurus-Littrow. He is using “the rake” sampling device to sift rock fragments from the finer portions of the regolith and has a 70-mm Hasselblad camera mounted on his chest (courtesy of NASA). indicates that about 98% (30) to 99.7% (31) of all but the larger projectiles is melted, vaporized, or ionized, and returned to space. The general characteristics of lunar impact craters as a function of diameter are summarized in Table 1.

Processes associated with cratering and space radiation have created a well-defined zone of debris that covers essentially the entire Moon; its thickness depends on the length of exposure of a specific geologic unit or feature. This zone is called the “regolith,” a terrestrial term also used for the Moon. Essentially all the samples returned from the Moon by Apollo have come from the regolith or from rocks incorporated within it. It has been defined as “the layer or mantle of fragmental and unconsolidated rock material, whether residual or transported and of highly varied character, that nearly everywhere forms the surface of the land and overlies or covers bedrock. It includes rock debris of all kinds, including volcanic ash...lunar regolith consists [largely] of particles <1-cm in size although larger cobbles and boulders, some as much as several meters across, are commonly found...much of the pulverized material is melted and welded together to produce breccias (fragmental rocks) and impact melt rocks, which make up a significant portion of the regolith...”(32,33). A particularly important part of the lunar regolith consists of aggregates of rock, mineral, and glass fragments,

Figure 5. The 95-km diameter impact crater Copernicus as seen from the Apollo 17 Lunar Module Challenger after its departure from the Moon on 14 December 1972. Data from the Apollo 12 mission indicate that Copernicus formed about 900 m.y. ago (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

called agglutinates, held together by impact melt glass. Recently, it has been shown that on the nanometer scale, iron metal particles accreted on and formed in the rims of regolith grains significantly affect optical and magnetic properties (34–36). Further, the lunar regolith contains embedded solar wind gases, meteoritic material, and isotopic products and crystal structure damage produced by solar and cosmic radiation. The average depth of the regolith in a given area reflects the age of the underlying bedrock. Lateral mixing of material derived from adjoining bedrock units is a function of the age of the separating contact.

Origin and Evolution

A “standard” or “conventional” hypothesis for the origin and evolution of the Moon evolved significantly during the last three decades of the twentieth

Table 1. General Characteristics of Lunar Craters as a Function of Size^a

Diameter range examples	General characteristics
< 10-m	<ul style="list-style-type: none"> • Craters normally do not penetrate the regolith. • Depth to diameter ratio variable. • Glass discontinuously lines shallow pits in the center of fresh craters. • Mineral grains shattered around small craters on solid rock (zap pits). • Deep pits (~1/3 the crater diameter) in the center of some craters.
~ 10-m to ~100-m Van Serg and Shorty Craters in Taurus-Littrow	<ul style="list-style-type: none"> • Craters normally penetrate mare regolith if above 20-m diameter. • Depth to diameter ratio about 1:3 to 1:4 for fresh craters. • Inner benches common if target material stratified. • Regolith breccias present inside and on the ejecta blankets of young craters. • Ejecta blankets extend to about one crater diameter. • Target strata are overturned, but original vertical sequence is preserved in ejecta blanket.
~ 100-m to ~10-km Taruntius; Camelot Crater in Taurus-Littrow	<ul style="list-style-type: none"> • Both transient and initial steady-state craters are hemispherical and have circular and raised rims. • Depth to diameter ratio about 1:3 to 1:4 for fresh craters. • Impact breccias present inside and on the ejecta blankets of young craters. • Ejecta blankets extend to about one crater diameter. • Secondary impact cratering significantly modifies surface features out to many crater diameters from the edge of continuous ejecta. • Target strata are overturned, but their original vertical sequence is preserved in ejecta blanket.
~ 10-km to <300-km Copernicus	<ul style="list-style-type: none"> • Transient crater approaches hemisphere and has a circular raised rim and probably is lined with a shell of impact melt. • Initial steady-state crater has a flat floor and central mound or peak. • Initial steady-state crater walls have many stepwise benches (slump landslides) on walls. • Hummocky crater floors and the depressions on wall benches and near-rim ejecta blankets of larger craters have indications of pools and flows of impact melt. • Ejecta blankets extend to about one crater diameter. • Target strata are overturned, but their original vertical sequence is preserved in ejecta blanket. • Secondary impact craters, crater clusters, crater chains, and herringbone crater chains extend several thousand kilometers beyond edge of continuous ejecta.

Table 1. (Continued)

Diameter range examples	General characteristics
> 300-km (basin) Orientale	<ul style="list-style-type: none">• Transient crater depth to diameter ratio decreases with increasing size as lithostatic pressures compete with explosive pressures.• Transient crater has an increasingly flat trapezoidal crosssection and increasing diameters.• Transient crater has a flat floor, a circular raised rim, and probably is lined with a thick shell of impact melt.• Initial steady-state crater has a fractured, flat floor and central ring or partial ring of peaks.• Initial steady-state crater walls have many wide, stepwise benches (slump landslides) on walls.• Floors and depressions on wall benches and near-rim ejecta blankets have indications of large pools, mantles, and flows of impact melt. Impact melt also injected into target materials.• Ejecta and debris flow blankets extend beyond one crater diameter.• Two to six rings of mountains outside transient crater rim around basins > 400-km in diameter.• Target strata sequence is not well preserved in ejecta blanket due to extensive mixing of ejecta during flow.• Within one crater diameter of the final steady-state rim, there is a continuous deposit of melt breccia, possibly several hundred meters thick at the rim of the larger basins.• Secondary impact craters, crater clusters, crater chains, and herringbone crater chains extend beyond the edge of continuous ejecta and debris flows and reach thousands of kilometers and probably around the entire Moon to the basin antipode.

^aRef. 620.

century. This hypothesis currently holds that the Moon formed about 4.57 billion years (b.y.) ago by the aggregation of material produced during a giant impact between the very young Earth and a Mars-sized asteroid; most metallic core-forming material remained with Earth (37–43). Such an origin could explain the high angular momentum of the Earth–Moon system and at least some of the lunar geochemical constraints related to iron, volatile, and alkali elements other than potassium (44). Soon after or during lunar aggregation, lunar core formation occurred (45,46), and a Magma Ocean developed on its surface (47,48). The lunar Magma Ocean largely crystallized within 50 million years (m.y.) of the creation of the solar nebula and, at the same time, differentiated due to contrasts in mineral densities into an olivine-pyroxene dominated mantle and a 60–70-km thick Caplagioclase-rich crust (49,50). Late in this differentiation process, potassium, rare-earth elements, phosphorous, and thorium-rich residual liquid (urKREEP) (51) accumulated beneath the crust, largely in the region beneath what is now the Procellarum basin (52–56). Late ilmenite-rich cumulates (57) sank toward

the base of the less dense olivine and pyroxene cumulates carrying some urKREEP material with them (58). Intrusive and extrusive basaltic magmatic activity began soon after the Magma Ocean crystallized and, before the main sequence of mare basalt eruption began at about 3.8 b.y., produced the magnesium-rich suite of plutonic rocks (Mg-suite) (59–61), KREEP-rich basalts (62), and the cryptomaria (63–66). At about 3.85 b.y., a concentrated bombardment of the crust took place that produced most or all of the ~50 basins greater than 300-km in diameter visible today as well as most other observed cratering effects in the lunar crust (67–71). The effect of this late lunar “cataclysm” was to reset the ages of all crustal impact glasses yet studied (72,73). South Pole-Aitken basin is probably the only basin >1000-km in diameter to form during this late bombardment (74); the Procellarum basin is an artifact of the superposition of several smaller basins (75). A global magnetic field and presumably a circulating fluid metallic core were present at least between 3.9 and 3.8 b.y. (76–78). The core is now between 300 and 400-km in radius (79–81). Between 3.9 b.y. and about 1.0 b.y., mare basalts and basaltic pyroclastic materials erupted, largely on the nearside of the Moon (82–84). Major features on the Moon have been little modified subsequently other than the development of several meters of impact-generated regolith on most surfaces (85).

Although some aspects of this conventional hypothesis of lunar origin and evolution are attractive and probably correct, as will be discussed throughout this article, numerous difficulties exist in reconciling a number of its implications with everything we think we know about the Moon (86–89). Some of the major questions that can be raised with the conventional hypothesis are as follows:

1. Was the Moon formed as a result of a giant impact on Earth immediately after Earth’s accretion or was it formed independently and later captured?
2. Did core formation in the Moon and other terrestrial planets occur immediately after their accretion or was it delayed by the existence of a silicate protocore?
3. Did thermal convection and/or impact-induced splash cooling play a significant role in the crystallization and differentiation of the Magma Ocean?
4. Did the Moon’s Magma Ocean’s late ilmenite-rich cumulate sink near the base of the cumulate pile globally or only in response to local destabilization by the formation of a few extremely large impact basins?
5. Was the Moon’s Magma Ocean’s residual liquid (urKREEP) initially concentrated beneath the Procellarum Basin or distributed in a spherically uniform shell under the lunar crust?
6. Was the global thermal insulation effect of the impact-generated megaregolith of the lunar highlands critical to the later formation of the magmas that formed the basaltic maria?
7. Is the Procellarum Basin a consequence of the merging of several smaller basins or of a single extremely large impact?
8. Were the one or more extremely large impact basins and the ~50 large basins on the Moon the result of a “cataclysm” of impacts at about 3.85 b.y. or of a sustained bombardment lasting about 400 m.y.?

9. Was melting of the mantle due to pressure release (90) after large basin events significant in generating of magmas related to the Mg-suite of lunar rocks?

The scientific results of the Apollo 17 mission can now be viewed in the context of the conventional hypothesis and questions about that hypothesis from the perspective of more than 40 years of modern study of all of the Apollo missions and other lunar investigations. These later investigations have included telescopic and photogeologic mapping of the lunar surface, Apollo sample analyses, automated missions that both preceded (91) and followed Apollo, and the remarkable thought and computer modeling that has been stimulated by the collected data. Broadened multidisciplinary discussions of lunar origin and evolution are assisted by a descriptive formulation of the formative stages of lunar evolution as an augmentation of the traditional time-stratigraphic approach (92). The term “stage” is not used below in the normal time-stratigraphic sense (93). Rather “stage” is used in a more general sense for overlapping periods of lunar history that have definable but somewhat arbitrary beginnings and endings due in large part to the current incompleteness of information about the absolute ages of lunar events. Thus, the evolution of the Moon as a small planet (94–98) can be descriptively summarized as follows (Plate 1):

Plate 1. Major stages of lunar evolution. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

- Stage 1: Beginning [Pre-Nectarian (99)]—4.57 b.y. before present
- Stage 2: Magma Ocean (Pre-Nectarian)—4.57–~4.2(?) b.y.
- Stage 3: Cratered Highlands/Very Large Basins (Pre-Nectarian)—~4.4–~4.2(?) b.y.
- Stage 4: Large Basins—(Pre-Nectarian–Upper Imbrium)—~4.2(?)–3.8 b.y.
- Stage 4A: Old Large Basins/Crustal Strengthening (Pre-Nectarian)—~4.2(?)–3.92 b.y.
- Stage 4B: Young Large Basins (Nectarian–Lower Imbrium)—3.92–3.80 b.y.
- Stage 5: Basaltic Maria (Pre-Nectarian–Copernican?)—~4.2(?)–1.0(?) b.y.
- Stage 5A: Cryptomaria (Pre-Nectarian)—~4.2(?)–3.92 b.y.
- Stage 5B: Maria (Upper Imbrium–Copernican?)—~3.9–1.0(?) b.y.
- Stage 6: Mature Surface (Pre-Nectarian–Copernican)—~3.9 b.y.–Present.

Each of these formative stages overlapped significantly. The Magma Ocean began to form before the end of lunar accretion and probably was not fully solidified until after the end of the formation of old large basins. The Cratered Highlands overlapped at least the beginning of the Large Basin Stage. The Basaltic Maria magmas probably began forming initially by pressure-release (decompression) melting and then by thermal remelting of the upper mantle. Basaltic maria lavas first appeared on the lunar surface during the Large Basin Stage as cryptomaria and then partially filled many later large basins and other depressions. The regolith that underlies mature surfaces began forming on exposed units at the beginning of the Cratered Highlands Stage and continues to form today. Graphical cartoons illustrating this formulation of lunar evolution are referred to by Plate number in the following discussion.

Beginning (Stage 1). Discussion of the origin of the Moon (Plates 2 and 3) includes issues related to the origin of Earth and also to the origin of the solar system as well (100,101). One of the few undisputed scientific conclusions about the solar system as a whole is that it was formed from a concentration of interstellar dust and gas 4.567 b.y. ago. This conclusion is inferred from the radiometric ages of chondritic, eucritic, and iron meteorites (102–104) and from the initial isotopic ratios (radiometric model ages) of many lunar samples (105). Meteorites and lunar samples also preserve a record of extinct radionuclides. This record is consistent with the hypothesis that the formation of our solar system was initiated by an interstellar shock wave generated by a nearby supernova (106–108) that contributed the now extinct radionuclides and other materials to the solar nebula. The chemical similarity of carbonaceous chondrite (CI) meteorites to the composition of the Sun (109) and the current apparent abundance of such material in the solar system have led to the assumption that these meteorites closely represent the composition of primordial material that formed the Sun and the terrestrial planets. Computer models of processes in the early nebula have cast some light on what may have been happening after the shock wave during the first 10 million years or so (110–112). Once the initial angular momentum of the collapsing interstellar cloud had been dissipated and the rotating disk of the solar nebula had formed around the young Sun, particles began to stick together. This led gradually to the formation of planetesimals and then more rapidly to the

Plate 2. Apollo model of lunar evolution—Beginning ~4.567 plus b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

formation of planets. The relationship at this point between Earth and the Moon, if the Moon existed, remains unknown. Refractory element ratios (113,114) and oxygen isotope ratios (115–119) indicate, within the limits of analytical error, that the materials which accreted to form the two bodies came from the same accretionary region (feeding zone) of the solar nebula.

After the initial analysis of the results of the Apollo landings and subsequent robotic missions was completed, the question of the origin of the Moon boiled down to two competing hypotheses. As discussed before, a majority of present workers favors formation of the Moon as a result of the impact of a differentiated “Mars-sized asteroid” with a young but at least partially differentiated Earth. General computer modeling of such an origin suggests that it may explain the unusually high angular momentum of the Earth–Moon system (120,121). On the other hand, the amount of iron in the Moon (12%) in comparison to just Earth’s mantle (8%) appears to require that 90% or more of the Moon, formed in this “giant impact” model, must come from the impactor and relatively little from Earth’s mantle (122). A similar conclusion can be drawn from consideration of Hf/W systematics for Earth and the Moon (123). Thus, the giant impact model represents more of a Moon formed by impact-assisted capture of the mantle of the impactor rather than including a measurable fraction of the mantle of Earth. Increasingly, some of the geochemical inconsistencies of this computer model, particularly the evidence of an undifferentiated lower mantle discussed below, are being recognized (124–126). Other workers previously have suggested that the evidence supports the capture of the Moon by Earth after both

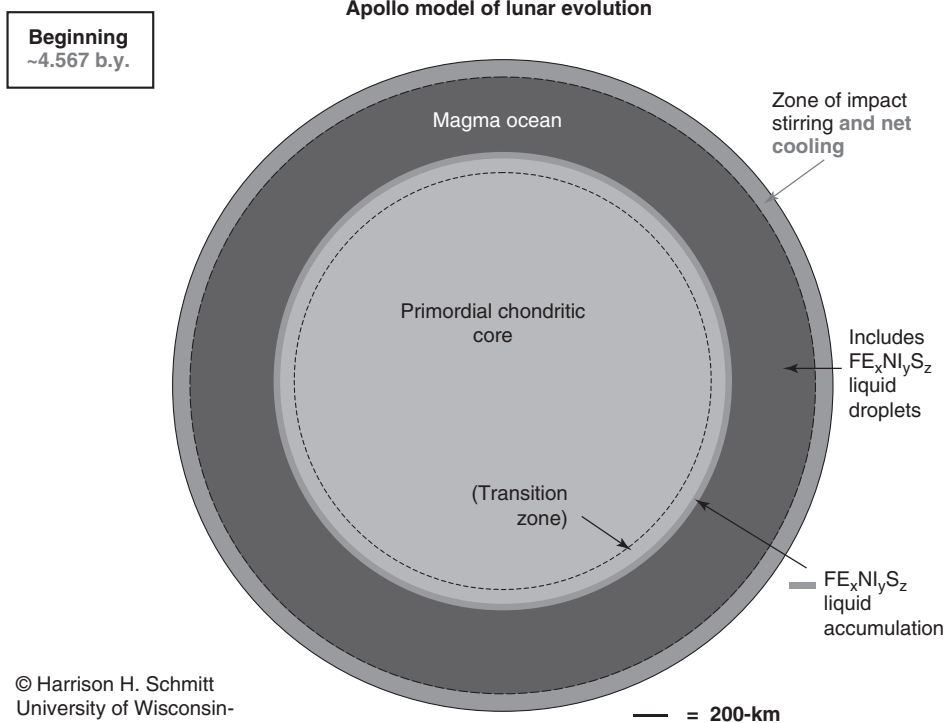

Plate 3. Apollo model of lunar evolution—Beginning ~4.567 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

formed independently as planets (127,128). In addition, models of giant impact scenarios are becoming increasingly confining in their possible initial conditions and subsequent evolutionary paths before the existing Earth–Moon system could have been created (129–136). Capture, provided that it is found compatible with the constraints of angular momentum, appears to be better than a giant impact in explaining the geochemical and geophysical structure of the lower mantle of the Moon. It has been suggested qualitatively, however, that special conditions related to a giant impact could produce the apparent undifferentiated characteristics of the lower lunar mantle (137,138). Considerations of lunar accretion from a circumterrestrial disk (139) also should receive additional attention in modeling studies (140).

No modern modeling studies of the capture hypothesis have been conducted since the early 1970s. Capture options, however, may exist that can explain the high angular momentum of the Earth–Moon system (141). Inherent in the capture hypothesis is the assumption that the Moon accreted in the inner solar system simultaneously with Earth, beginning with a cool, chondritic protocore upon which a Magma Ocean developed as the accumulated energy of accreting material increased with time. Gaining an early slight advantage in mass, co-orbiting Earth would have grown more rapidly and attracted proportionally more of the heavy element-rich planetesimals than the Moon, drawing from the same radial mixing orbital reservoir (142) in the solar nebula. The relatively

devolatilized character of the outer portions of the Moon, of which the Apollo samples are representative, would result from a much less competitive lunar gravity well relative to that of Earth both during accretion and during the impact-enhanced devolatilization of the lunar Magma Ocean. Alkali element depletions and isotopic ratios calculated for the Moon do not require the extreme devolatilization of a giant impact (143). Laboratory studies suggest that the volatility of sodium from a Magma Ocean is too low to account for the present proportion of sodium in the Moon (144). These studies, however, have not taken into account the pervasive stirring and spot high temperatures due to impacts that would enhance the efficiency of devolatilization of relatively volatile elements. Impact-generated temperatures of several thousand degrees would have existed locally near each impact point (145,146) and may have prevailed throughout the upper portions of the Magma Ocean during the last phases of extremely rapid lunar accretion. These portions of the Magma Ocean could be said to be boiling! Limits to devolatilization are indicated by the lack of fractionation between stable potassium and magnesium isotopes in the Moon; isotopic ratios of these elements are the same as Earth's (147,148). This lack of alkali isotopic fractionation and a rubidium/cesium ratio only a factor of about 2 greater than carbonaceous chondrites (149) indicate that the temperature of the impact-stirred portion of the upper Magma Ocean (although potentially several thousand degrees C) did not exceed that required for complete vaporization of alkali components. The reduced state of the Moon (150,151) also may relate to devolatilization of the Magma Ocean during which the ratio of water to iron was decreased to the point where all remaining water was disassociated by reaction with immiscible iron-rich liquid separating from the Magma Ocean.

The geochemical constraints of the lower mantle (below about 550 km), indicated by analyses of lunar pyroclastic glasses, also support the capture hypothesis. Volatiles and isotopic systems in the pyroclastic glasses that indicate largely undifferentiated source regions in the lower lunar mantle are incompatible with a Moon formed from the differentiated mantles of two impacting bodies, as required by the giant impact hypothesis of origin. Data from the Apollo 17 deposit of orange pyroclastic volcanic glasses have contributed significantly to this continuing debate over the origin of the Moon. The discovery of orange volcanic glass ("orange soil") in the rim of Shorty Crater (Station 4) and close to its original point of deposition (152), subsequent recognition of volcanic glasses as a widespread component of the lunar regolith, and detailed examination of these glasses in terrestrial laboratories established a number of new geochemical constraints on the origin of the Moon (153–155). Finding the orange glass (Figs. 6 and 7), whose geology is discussed under the Basaltic Maria Stage below, came from the convergence of a number of factors. First, one of the primary objectives of the mission to Taurus-Littrow was to search for the cause of dark mantling, possibly pyroclastic (explosive) volcanic deposits in the region. Second, premission consideration of multiple hypotheses for the origin of the dark-halo crater called Shorty included the possibility that it might be a volcanic vent, even though all evidence then available pointed to an impact origin. Finally, the writer's experience in volcanic provinces on Earth and his normal field geologist's instincts to watch one's feet probably were important factors. From the moment of discovery (156,157), it was clear that the orange glass would be significant, but

Figure 6. View of the Station 4 area, the site of the orange volcanic glass on the southern rim of the 110-m diameter Shorty Crater (to the right). The orange glass deposit lies just this side of the large boulder on the rim of Shorty, behind and to the right of the lunar roving vehicle and the author (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

how significant was not known until its return to Earth. It took detailed investigations in terrestrial laboratories before the ramifications of the glass slowly became clear. The primary importance of the pyroclastic glasses relative to lunar origin lies in the composition of the adsorbed volatiles on the surfaces of the small glass beads, and devitrified glass beads, as distinct from the glass itself. The volatiles washed from the surfaces of the beads are unlike any other lunar materials yet analyzed (158,159). A similar volatile component exists in the green volcanic glasses sampled by Apollo 15. Volatiles associated with both types of glasses are enriched over associated basalts by factors >100 in Cl, F, Br, Zn, Ge, Sc, Tl, and Ag and by factors >10 in Pb, Ga, Sb, Bi, In, Au, Ni, Se, Te, and Cu. These anomalies suggest that volatile components, otherwise depleted in lunar samples, are present in significantly higher abundances in the source areas of the volatiles accompanying pyroclastic glasses (160,161). The isotopic composition of the lead associated with the orange glass provides an even more unusual data point. It is isotopically primitive (162–166), that is, the lead had not been separated from its uranium and thorium radiogenic sources before eruption at the surface. Similarly, there is a chondritic initial tungsten value for the combined volatile and glass components, again suggesting that the lower mantle is largely undifferentiated and close to chondritic in composition (167).

Thus, the data related to volcanic glasses indicate that the source of the volatile components of the Apollo 17 orange glass lies below the devolatilized and differentiated cumulates of the Magma Ocean (see below) in a relatively

Figure 7. The Station 4 sample locality for the Apollo 17 orange volcanic glass, showing the dark, reddish orange central zone of the deposit and light-colored altered regolith at the left-hand contact (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

undifferentiated, possibly largely chondritic lower mantle. New assessments of Apollo seismic data suggest that the transition between the upper and lower mantle exists at about 550 km (168,169). A largely undifferentiated lower mantle does not fit the current model of lunar origin from debris generated by the impact of a differentiated planetesimal on a differentiated Earth. That debris would have lost much of its chondritic character prior to lunar accretion (170–172). Additionally, unlike Earth, the hafnium–tungsten isotopic system has significant variations within various categories of lunar samples (173,174) as a consequence of internal differentiation of these elements during the Magma Ocean Stage of lunar evolution (175). The mean model age (176) for the now extinct ^{182}Hf (half-life = 9 m.y.) and its stable daughter ^{182}W is about 50 m.y. in samples directly or

indirectly related to the differentiation of the majority of the lunar Magma Ocean (177). The orange glass isochron (178) also indicates an age of 54 ± 7.5 m.y. (179). These data are consistent with the idea that most of the Magma Ocean crystallized in 50 m.y. or less (180) and with theoretical analyses that Magma Oceans existed on terrestrial planets only very early in the history of the solar system (181).

Dynamical modeling and extinct isotope data (182,183) indicate that both accretion and planetary differentiation took place rapidly. A ~ 50 m.y. model age for forming major portions of the lunar mantle creates a very narrow, but not closed, window for a Mars-sized planetesimal and Earth to interact to form the Moon, considering that the total detectable life of ^{182}Hf would be ~ 90 m.y. Thus, within the first ~ 40 m.y. of ^{182}Hf 's existence, the following must occur:

1. The supernova that created ^{182}Hf and other now extinct isotopes must interact with and trigger the collapse of the interstellar gas and dust cloud to form the solar nebula.
2. Angular momentum within the solar nebula must be dissipated.
3. Planetesimals that have chondritic proto-cores must form in the inner solar nebula and aggregate into the terrestrial planets.
4. Magma oceans must form on some or all the terrestrial planets and be sufficiently stable that $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid can separate and accumulate at the base of the magma oceans.
5. Magma oceans must cool to a temperature where silicate crystallization and differentiation can begin.
6. $\text{Fe}_x\text{Ni}_y\text{S}_z$ metallic cores must displace the chondritic protocores of Earth and the impacting Mars-sized planetesimal if the Moon is to result from their impact interaction.
7. Sufficient silicate cumulates must form in the lunar magma ocean to isolate that portion of the Hf/W system in the source region of future mare basalts from the residual Magma Ocean.

Because steps 1–4 probably took 20–100 m.y. (184,185), then Hf/W systematics indicate that the formation of the Moon by a giant impact of another planet on the Earth must have occurred within a very narrow window of time—the first 30 m.y. or less. In spite of the narrowness of the opportunity, current modeling suggests that this is the most likely period for a giant impact to have occurred in the inner solar system (186,187). If such interaction did occur in this window and magma oceans existed on both objects at the time of impact (188), metallic core formation and initial mantle differentiation would have been incomplete. This would be inconsistent with what is known about the chemistry of the Moon and would require subsequent large accretionary impacts to adjust that chemistry to what is observed (189). Additionally, as discussed above, the apparent $^{182}\text{Hf}/^{182}\text{W}$ isochron age for the orange volcanic glass and its volatile component is 54 ± 7.5 m.y. This suggests that the deep source regions for the volatiles associated with the orange glass became closed systems for Hf and W when the volatiles' source areas in the more primitive lower mantle were no longer exposed to downwardly migrating $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid (see Magma Ocean discussion below).

Such migration would have kept the system temporarily open relative to tungsten. Thus, until the giant impact model for lunar origin or even an impact-assisted capture model or a circumterrestrial disk model can accommodate these geochemical and geophysical constraints, none of these models represent reality. At this time, the writer favors an origin by relatively passive Earth capture (190); however, most workers in lunar science favor origin by giant impact. No evidence has been recognized that would suggest when capture might have occurred; however, apparent lunar tidal signatures in 2.0 b.y. (191) and 3.2 b.y. (192) old terrestrial sedimentary rocks indicate a lunar influence on Earth's oceans by at least that time. The 3.2 b.y. tidal signature also has been interpreted to indicate that the lunar orbital shape at that point was similar to the current shape. If tidal interaction between Earth and the Moon's iron-rich core were necessary to produce a dynamo-generated lunar magnetic field (193), then the Moon had been captured by ~ 3.85 b.y. ago. This is the age of the large impact basin Imbrium (194), the oldest large basin that has a clearly identified remnant magnetic field (195) antipodal to it.

Magma Ocean (Stage 2). A consensus has developed from the data from all of the Apollo missions that, as accretion of the Moon accelerated, a silicate Magma Ocean was created (196–201) (Plate 2). Although debate continues as to the depth of the lunar Magma Ocean, the geophysical constraints (202–204) appear to indicate that only the outer ~ 500 -km melted, another 50–100-km partially melted, and a “primitive accretion core” (205), of roughly 1200-km radius, remained relatively cool and solid. Melting of the accreting material was accomplished by the conversion of accretionary kinetic and potential energy to heat and by the decay of short-lived radioisotopes such as aluminum-26 (206). As the Magma Ocean formed, the dynamic heating, splashing, and stirring of the global melt would have delayed differentiation (relative separation of the elements) due to fractional crystallization, a process by which minerals more dense and less dense than the parent melt sink or float, respectively, as they crystallize. As discussed before, some volatile differentiation, due to the thermal escape of elements too light and thermally energetic to be held by lunar gravity, would occur during this formative period, provided that the temperature of the Magma Ocean exposed to space reached several thousand degrees C. Thus, water, carbon dioxide, nitrogen, noble gases, and highly volatile elements, such as bismuth (Bi), thallium (Tl), indium (In), and cadmium (Cd) (207), are strongly depleted in the outer Moon relative to solar and carbonaceous chondritic abundances (208). Moderately volatile elements, such as lithium (Li), sodium (Na), potassium (K), rubidium (Rb), and cesium (Cs), are somewhat depleted as well (209). Sodium is depleted by a factor of 3–5 compared to Earth (210). The rare-earth elements, however, do not show evidence of selective loss based on their range of volatility (211). This suggests that at least some of the apparent elemental depletion patterns in lunar materials were inherited from the materials from which it was formed (212,213), either the differentiated mantle of a large impactor (giant impact), a circumterrestrial postaccretion disk, or differentiated planetesimals elsewhere in the inner solar system (capture). Also, as the materials from which the Moon formed probably consisted of largely oxidized phases that had chondritic affinities, initial separation of liquid metallic iron may not have occurred in the early Magma Ocean. Rather, as accreting material began to melt, iron and

nickel, along with sulfur, would be concentrated in an immiscible (214) metal-rich liquid ($\text{Fe}_x\text{Ni}_y\text{S}_z$) (215,216) accompanied by some portion of other siderophilic elements (217), including cobalt, precious metals, and platinum group elements (PGE). The actual cobalt and nickel contents for the Moon as a whole and for the lunar mantle in particular are still uncertain (218,219) and cannot yet be relied upon to help unravel the question of lunar origin. An iron and sulfur-rich liquid would have been an immiscible in the predominantly silicate liquid of the Magma Ocean. As iron-rich liquids are very dense, $>4.5\text{-gm/cm}^3$, a rain of small droplets would aggregate rapidly on the floor of the Magma Ocean (density $\sim 3.3\text{-gm/cm}^3$) and ultimately move toward the center of the Moon through the cooler lower mantle. In the process of nucleation in the Magma Ocean, the immiscible $\text{Fe}_x\text{Ni}_y\text{S}_z$ droplets would react with any remaining water to form hydrogen and iron oxide (wustite). Hydrogen would be dissolved in the silicate liquid, maintaining a reducing environment in the Magma Ocean early in its differentiation history. That this occurred is consistent with the necessarily reduced state of europium ions in the Magma Ocean during differentiation (220) and with experimental work (221) relative to chromium abundances in volcanic glasses. Both facts indicate low oxygen fugacities (measures of the tendency toward oxidation) in the Magma Ocean.

The next major change in the Magma Ocean began with the sequential crystallization of silicate minerals (222–224) and their separation from the liquid in relation to contrasting densities, that is, fractional crystallization (Plate 4). This critical chemical differentiation process started when the rate of heat addition due to accretion and radioactive decay became less than the rate of heat loss, and the temperature of at least portions of the Magma Ocean decreased to about 1300°C . Minerals forming in a silicate liquid have compositions different from that liquid, so chemical change in the liquid, that is, differentiation, results when those minerals are separated from the liquid. Assuming that the composition of the Magma Ocean resembled an iron, nickel, sulfur, and volatile-depleted carbonaceous chondrite, the first silicate mineral to begin to crystallize was probably magnesium-rich olivine [$(\text{Mg},\text{Fe})_2\text{SiO}_4$], followed closely by magnesium-rich orthopyroxene [$(\text{Mg},\text{Fe})\text{SiO}_3$] (225) (Plate 4). Olivine and orthopyroxene crystals below the zone of likely continued impact-induced turbulence sank to the floor of the Magma Ocean as cumulates. There, they were immersed in the ocean's residual silicate liquid which ultimately solidified interstitially, forming more olivine and pyroxene but eventually crystallizing calcium-rich plagioclase [$(\text{Ca},\text{Na})\text{Al}(\text{Al},\text{Si})\text{Si}_2\text{O}_8$], ilmenite [FeTiO_3], and other minor minerals. These interstitial minerals make up only a few percent of the final cumulate mantle rock but included trace amounts of radioactive isotopes of potassium, uranium, and thorium, important in the later remelting of the upper mantle to generate the mare basalts (see mare basalt discussion below). Above the roughly 500-km deep presumed base of the cumulate zone, seismic velocities (226) are consistent with those measured for a mixture of magnesium-rich olivine (75–85% forsterite component) and pyroxene. Mare basalt melting experiments suggest that pyroxene in the upper mantle probably varies upward from orthopyroxene dominant to pigeonite [$(\text{Ca},\text{Mg},\text{Fe})(\text{Mg},\text{Fe})\text{Si}_2\text{O}_6$] dominant to calcium clinopyroxene [$\text{Ca}(\text{Mg},\text{Fe})\text{Si}_2\text{O}_6$] dominant. These minerals and their compositions are consistent with phases found in equilibrium with the mare basalt magmas at

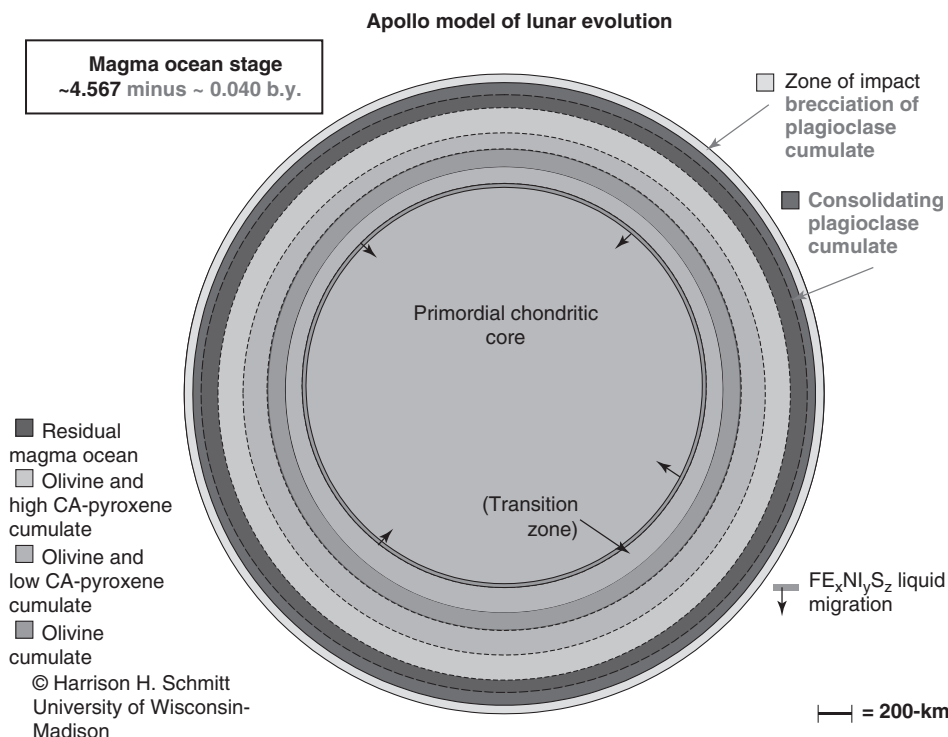

Plate 4. Apollo model of lunar evolution—Magma Ocean Stage ~4.567 minus ~0.040 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

pressures corresponding to their apparent depths of origin (227). The consistent relation between seismic data and the experimental work on mare basalt melting suggests that the combined effects of convective circulation (228) in the crystallizing Magma Ocean were minimal. In fact, impact-related mixing and splashing plus conduction of heat probably contributed more to early cooling than convection. Thus, early crystallization may have taken place in the upper, more rapidly cooled portions of the Magma Ocean, causing incorporation of relatively undifferentiated Magma Ocean liquid as interstitial material in early cumulates.

Crystallization of calcium-rich plagioclase feldspar, anorthite [(Ca,Na)(Al,Si)Si₂O₈], joined the formation of olivine and pyroxene in the Magma Ocean after sufficiently large volumes of such cumulates had separated to raise the aluminum concentration in the remaining liquid to the level required for plagioclase nucleation (229). Assuming chondritic concentrations of aluminum (<5% Al₂O₃), this point of plagioclase saturation in the residual Magma Ocean would have been reached after about 80% of the original magma had crystallized or Al₂O₃ concentration had reached about 15% (230). One consequence of plagioclase separation from the Magma Ocean was depletion of divalent europium relative to other rare-earth elements in the residual magma; the evidence for this was apparent in the first analyses of lunar basalts (231,232) and lunar anorthosites (233). Europium depletion in basalts and concentration in anorthosites constitutes one of the major pieces of evidence that there had been a lunar Magma

Ocean (234). Slight depletion of europium in pyroclastic orange and green glasses (235,236), however, and the evidence that these glasses were partial melts of deep (early) cumulates (237,238) indicate that there may have been some convective interchange with the residual Magma Ocean during the period of early plagioclase separation. The early formed plagioclase had probably less than 2–3% (239,240) of the albite component $[\text{NaAlSi}_2\text{O}_8]$ in solid solution. The albite component would be expected to increase gradually with time to more than 25% in plagioclase (241) forming from the Magma Oceans' residual liquid, as sodium and aluminum concentrations in the remaining liquid increased, relative to calcium, and olivine and pyroxene continued to separate. So far, examples of relatively sodium-rich ferroan anorthosite are rare, and those that have been found in the sample collections are less iron-rich than would be expected (242,243). Plagioclase crystals (density 2.9-gm/cm^3) would tend to float toward the top of the Magma Ocean; however, if there were continued impacts of debris into the Magma Ocean and some downward convective currents, their aggregation into a coherent lunar crust would have been slowed significantly. Plagioclase-rich samples from Apollo 15, 16, and 17 highland breccias also contain pigeonite (an iron-bearing clinopyroxene) and appear to represent an impact-modified version of this primitive crust (244). The detailed evolution of ferroan anorthosite crustal rocks and their mineralogical and geochemical variability remain unclear (245).

The overall crust, commonly referred to as "ferroan anorthosite," contains about 85% plagioclase by volume, and the rest is mostly pigeonite (246). Recent examination of feldspathic lunar meteorites and their comparison with Clementine optical remote sensing data suggest that the uppermost crust may be about 83% plagioclase and remainder is about 4.2% FeO, 5% MgO, and less than 0.5% TiO_2 (247). Apollo seismic data and gravity data from Clementine orbital perturbations (248,249) indicate that the anorthositic crust has an average thickness of about 60–70-km. Thickness ranges from a maximum of about 120-km in the farside region between the giant Procellarum and South-Pole Aitken Basins to a minimum of about 20-km in several of the young, large basins on the nearside. Such extreme variations, although model dependent and constrained primarily by Apollo nearside seismic data, may be largely if not entirely the result of the globally asymmetrical redistribution of crustal material by large basin-forming events (see below). It can be argued that the term ferroan anorthosite should be modified to ferroan "gabbroic or noritic" anorthosite (250) as a more appropriate designation for the upper crustal composition, given the content of less than 90% plagioclase (251). There may be another important type of lunar crustal rock, referred to as "granulitic breccia" (252) and identified in Apollo 16 and 17 samples (253–256). In fact, these rocks could be called "magnesian gabbroic anorthosite" as they have $\text{Mg}/(\text{Mg} + \text{Fe})$ ratios up to 75 or five points greater than the <70 of the ferroan anorthosites. These rocks may have genetic affinities with the Mg-suite of rocks (see below), although that is not clearly apparent at this time. Continued refinement of the relative distribution of magnesium and iron in the crust through Lunar Prospector and Clementine data synthesis may ultimately provide a better definition of global relationships involving magnesium granulitic breccias (257). In summary, a synthesis of current data and interpretations suggest that there are three major zones in the lunar crust. The upper 10–30-km is ferroan

gabbroic anorthosite that represents an original ferroan anorthosite with plagioclase >95% contaminated by (1) early splash from impacts penetrating into the residual Magma Ocean and/or (2) more pyroxene-rich material excavated from the lowest zone of the crust by large impacts. The middle 10–20-km is ferroan anorthosite that represents a largely unmodified plagioclase floating cumulate from the Magma Ocean (258). The lower 20–100-km is ferroan anorthosite that contains numerous Mg-suite intrusions (259) possibly associated with magnesium anorthosite, the so-called granulitic breccias.

Analyses of samples of Apollo 17 rocks consisting of fragments of Mg-suite rocks, or breccias, at Stations 2, 6, and 7, have provided new, but complicated insights into processes related to the lunar Magma Ocean and possibly to the formation of the lunar crust. A particular class of nonmare rock fragments that contain magnesium-rich mafic minerals and calcium-rich plagioclase exist in these breccias (260) and are composed of only one to three principal minerals, namely, olivine (dunites) (Fig. 8), pyroxene (pyroxenites), plagioclase and orthopyroxene (norite), and plagioclase and olivine (troctolites). These rocks, and similar rocks sampled at other Apollo sites, are known as the “Mg-suite.” Some rocks composed largely of plagioclase (anorthosites but not ferroan anorthosites) and possibly some alkali-rich rocks (261), appear to be related to this group. Although this is a very complex suite of rocks and subject to much debate, they probably are at least the result of the relatively undisturbed fractional crystallization of magnesium and calcium-rich silicate magmas, possibly of a variety of initial origins, that solidified in large chambers within the early crust. Multiple origins for the Mg-suite are suggested by their contrasting chemical characteristics (262) as well as their range of ages. Early remelting of Magma Ocean cumulates due to impact-induced, pressure-release (decompression) melting caused by cumulate overturn and/or impact removal of crust may have resulted in the formation of the oldest Mg-suite magmas (263) (Plate 5). Impact-induced remelting of magnesium-rich cumulates is consistent with the 4.4–4.5 b.y. crystallization ages (264) of a dunite (olivine) from Station 2 and a troctolite (plagioclase + olivine) from Station 8. Alternatively, the Mg-suite may be related to the materials that constitute the Procellarum KREEP Terrain (265–270) and not a broadly distributed, intrusive component of the lunar crust. The geographical limitation of Apollo and Luna samples to eight sites in a relatively small portion of the lunar nearside prevents full evaluation of this suggestion. On the other hand, the global distribution of apparent Mg-suite materials exposed by relatively young impact craters in the crust suggests no such geographical limitation (271). Another suggestion (272) that some of the older examples of the Mg-suite may be the consequence of impact induced “splash intrusions” of unsolidified Magma Ocean is not compatible with the increasingly higher iron content that would be present in such residual Magma Ocean liquids. The chemical characteristics of the younger examples of the Mg-suite of rocks, (>3.9 and <4.4 b.y.) also may indicate complex scenarios of partial melting of selected portions of the upper mantle, assimilation of crustal materials, and subsequent fractional crystallization in the crust (273,274). Recent work (275) has suggested that the source materials for some of the Mg-suite that contain particularly Mg-rich olivine are zones of intermediate depth in the mantle, rich in olivine and calcium-poor pyroxene. These cumulate zones, never very cool and

Figure 8. The clast of nearly pure olivine rock (dunite) sampled by the Apollo 17 crew at Station 2 at the base of the South Massif and dated as having crystallized 4.5 b.y. ago. The clast is enclosed in a blue-gray impact breccia and is a member of the Mg-suite of lunar rocks (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

beginning to reheat under an increasingly insulating crust (see the Cratered Highlands Stage below), may have partially melted due to the release of pressure during the formation of the earliest of the old, large basins (see below). Intrusion of such pressure-release melts into the crust, assimilation of some crustal debris, and subsequent fractional crystallization may explain the younger examples of the Mg-suite. The restricted mineralogical makeup of the rocks of the Mg-suite is consistent with initial solidification as fractionally crystallized, probably layered bodies. These layered intrusives would have been broken up and excavated by repeated large impacts until clasts in the breccias are all that remain to be sampled at the lunar surface. Mg-suite intrusions, however, may remain as coherent bodies in the lower crust, as evidenced by masses of apparently related material identified by remote sensing in the central peaks, walls, and ejecta

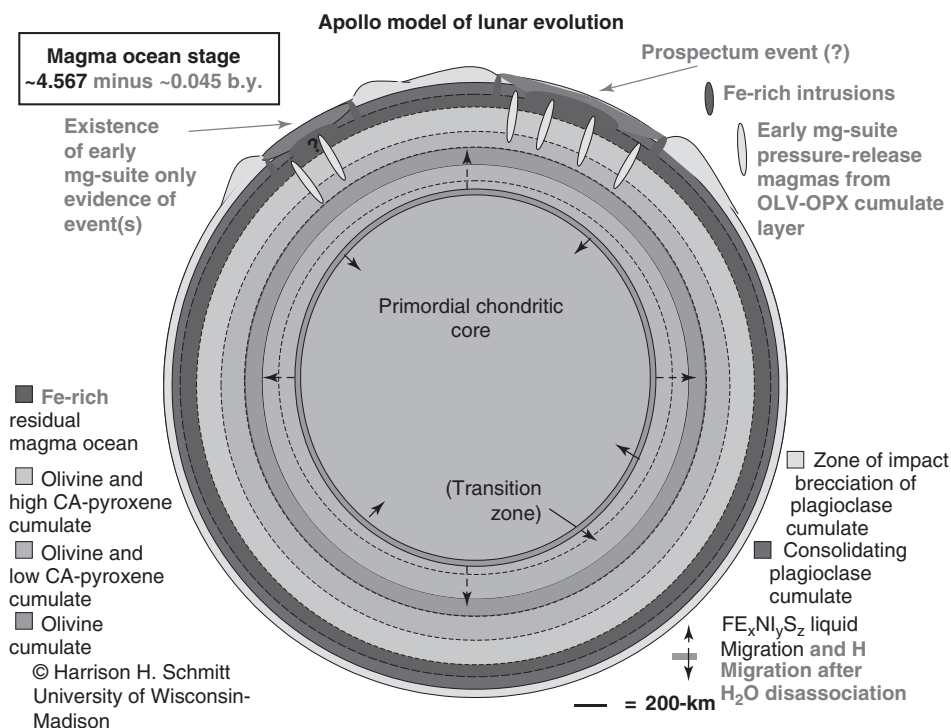

Plate 5. Apollo model of lunar evolution—Magma Ocean Stage ~4.567 minus ~0.045 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

blankets of many impact craters (276–278) and by the increase in seismic velocities in the lower crust (279). Many characteristics of these remotely sensed masses, such as their magnesium to iron ratios, have not yet been determined, so it cannot be conclusively said that some or all are related to the Mg-suite, but rather may be related to the ferroan anorthosite or magnesium granulitic breccia magma systems (280).

When the crystallization of the Magma Ocean was about 90–95% complete (281,282) and as iron and titanium concentrations in the residual Magma Ocean increased, ilmenite [$FeTiO_3$] became the last major mineral to crystallize and settle from the residual magma (Plate 6). Ilmenite-rich cumulates (3–12% ilmenite), accompanied by continuing formation of increasingly iron-rich olivine and pyroxene and increasingly sodium-rich calcium plagioclase, became an important constituent of the upper portion of the lunar mantle. For example, high-titanium mare basalt magmas produced by later partial melting of the mantle appear to have originated at depths between 100 and 200-km below the surface (283), plausibly a region of ilmenite-rich cumulates. The trace element ratios of such basalts also support their origin from partial melting of late ilmenite-rich cumulates. Europium depletion in the titanium-rich basalts, as in all mare basalts (284–286), indicates extensive previous plagioclase separation from the parent Magma Ocean. Further, ilmenite's precipitation from the Magma Ocean would deplete niobium in the residual liquid (287). High Nb/U and Nb/Th

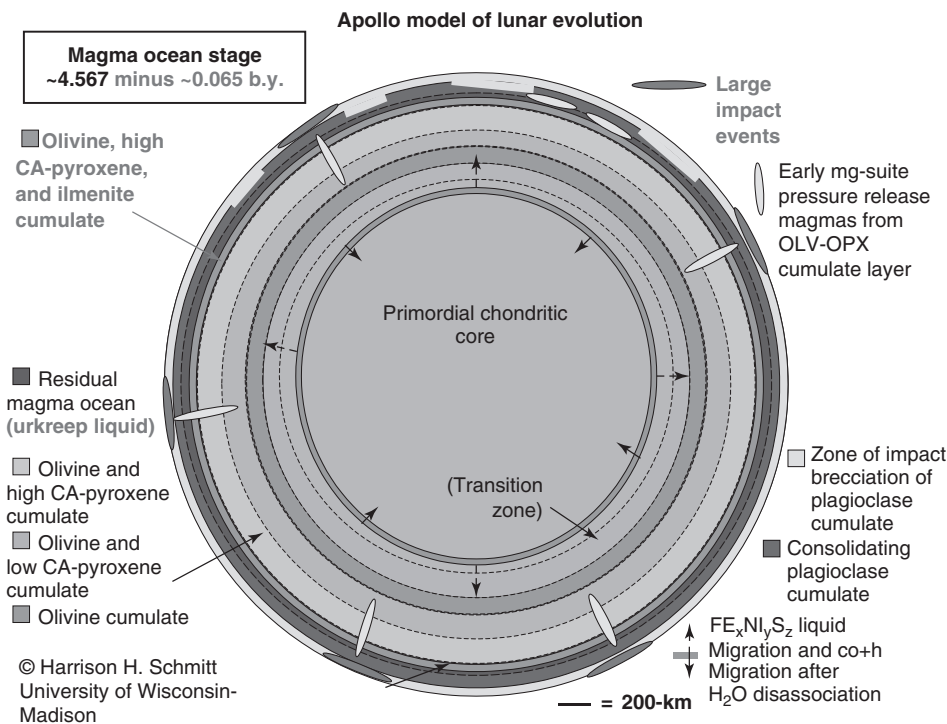

Plate 6. Apollo model of lunar evolution—Magma Ocean Stage ~4.567 minus ~0.065 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

ratios in high-titanium Apollo 17 basalts (288) reflect the consequent enrichment of this element in the ilmenite-rich cumulates and are consistent with an origin for these basalts through partial melting of such cumulates. Ilmenite crystallization also depleted hafnium in the remaining liquid (289). The high-titanium basalts sampled by Apollo 17 (see discussion of the Basaltic Maria Stage, below) have high radiogenic ^{182}W and high Hf/W ratios (290). This is consistent with ilmenite cumulate crystallization while significant ^{182}Hf (half-life 9 m.y.) existed, probably less than ~50 m.y. after the origin of the solar system (291). There have been recent suggestions that the late ilmenite-rich cumulates, once formed, sank to greater depths in the other cumulates of the upper mantle (292–294) because of ilmenite's high density relative to the underlying olivine–pyroxene cumulates (4.7 gm/cm^3 vs. $\sim 3.5 \text{ gm/cm}^3$, respectively). The average density of the ilmenite cumulate, however, would be only slightly higher than the olivine–pyroxene combination. The apparent relatively shallow depth of origin of titanium-rich basalts sampled by Apollos 11 and 17 would also contradict this hypothesis, at least for the eastern regions of the lunar nearside.

When ilmenite appeared, the continued crystallization of the four major minerals produced by the Magma Ocean (olivine, pyroxene, plagioclase, and ilmenite) largely completed the formation of the upper lunar mantle (that is, the mantle above about 500-km and below the base of the crust). After about 99% of the Magma Ocean had solidified (295), however, a geochemically significant

amount of residual silicate liquid would have remained below the crust. Fractional crystallization of the major minerals would have enriched this liquid in silicon (Si), potassium (K), and incompatible elements (296), that is, most rare-earth elements (REE), phosphorus (P), uranium (U), and thorium (Th). Dissolved volatiles, including hydrogen (H) and carbon monoxide (CO), also would be concentrated in this remaining magma. This residuum has been named “urKREEP” to distinguish it from an apparently related component in Apollo samples that was originally called just “KREEP.” Tungsten (W) also would be enriched in urKREEP and represents a special case. After the early separation of much of the siderophilic trace elements by the rapid precipitation of $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid, any residual such elements, including tungsten and subsequently formed radiogenic ^{182}W , would be gradually concentrated in the residual Magma Ocean as incompatible elements. As a residual silica-rich liquid, urKREEP would have existed as a liquid at temperatures lower than those of the original Magma Ocean. Such a liquid would have potentially stayed molten as a result of the concentration of radioactive, heat-producing isotopes and the insulating effects of the Cratered Highlands forming on the upper crust (see discussion below).

Some outward transfer of heat by convection in the cooling Magma Ocean seems likely during much of the Magma Ocean Stage (297–299). On the other hand, as solidification proceeded, potential convection cells would have been increasingly restricted. Convective tendencies also would have been reduced by cooling of the young Magma Ocean through continued impact splashing in its upper portions, a major factor not yet included in models of thermal evolution. The importance of splash cooling may be suggested by indications, discussed before, that the Magma Ocean largely solidified in 50 m.y. or less. Subsequently and throughout lunar history, there is no direct evidence that mantle convection was a significant thermal transfer process. That convection was not important is indicated by recent thermal modeling investigations (300). Further, little or no evidence of mantle convection exists at the surface unless the $\sim 2000\text{-km}$ long, north–south volcanic ridge system in the western portion of the Procellarum Basin implies that such activity existed beneath this region (301). (Alternatively, this Procellarum ridge system may reflect a cryptic crustal structure associated with the transient crater of the Procellarum basin-forming event discussed below.) After the Magma Ocean crystallized to become the upper mantle, conduction and upward migration of partial melts were probably sufficient to prevent any major density instabilities that would lead to solid or nearly solid-state convection in the one-sixth gravity environment of the Moon. Cooling sufficient for the solidification of all but the radioisotope-rich, late residual liquid of the Magma Ocean took place in about 150 ± 70 m.y. after accretion, based on Sr/Rb model ages for closure of the isotopic systems in KREEP (302). The hafnium–tungsten isotopic system (303) indicates that of the majority of the Magma Ocean solidified within 50 m.y., a time close to the lower limit of the Sr/Rb system closure uncertainty.

Cratered Highlands/Very Large Basins (Stage 3—Pre-Nectarian). The Cratered Highlands/Very Large Basin Stage of lunar evolution (Plate 7) represents the early Pre-Nectarian of the US Geological Survey time-stratigraphic system (304) and records the sustained violence of the first few hundred million years in the history of the Moon and the terrestrial planets. The stage commenced

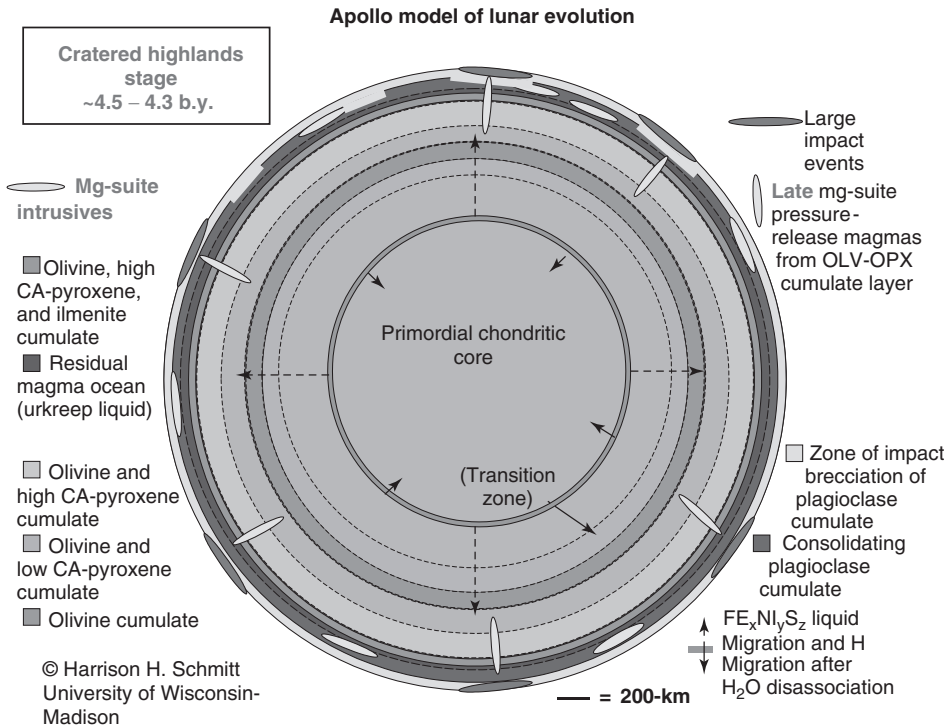

Plate 7. Apollo model of lunar evolution—Cratered Highlands Stage ~4.5–4.3 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

as the developing lunar crust gained consistent stability and coherence sufficient to retain the imprint of craters excavated largely by the continuing in-fall of residual, preaccretion debris and/or meteors, as well as comets ejected from the outer solar system. Crystallization ages of several Apollo 17 samples of the Mg-suite of rocks and Sr–Rb model ages, as discussed before, suggest that this period began about 4.5 b.y. ago and overlapped the previous Magma Ocean Stage as the last residua of the Magma Ocean continued to crystallize and differentiate. Similarly, recent Sm–Nd isochron ages for two ferroan anorthosite clasts from an Apollo 16 highland breccia are ~4.54 and 4.40 b.y. (305). A possible lower limit for the duration of the stage is 4.2 b.y. (306) at which time most K–Ar radiometric clocks in Apollo 16 breccias of apparent Pre-Nectarian age were reset. The sustained high rate of impact probably resulted from preaccretion debris remaining in crossing orbits (307,308) and the ejection of material from orbital bands in resonance with the gas-giant planets (309). There also remains a possibility for the accretion of any original moons or rings of Earth after capture of the present Moon (310) or its aggregation from a circumterrestrial disk (311). As the Cratered Highlands formed, the crust saturated with craters at a saturation size (measured by curves of crater size vs. frequency that approach a slope of -1) of 60–70-km in diameter (312) (Fig. 9). This means that a relatively uniform megaregolith, including any heterogeneities introduced into the crust by Mg-suite magmatic intrusions, developed to a depth of at least 25 km, the approximate depth to which Apollo passive seismic interpretations indicate that intense

Figure 9. Typical Cratered Highlands on the farside of the Moon (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

fracturing of the upper crust exists (313). Although average depths of about 20-km for the megaregolith have been proposed (314), brecciation to the greater depths suggested by seismic data is plausible due to the near superposition of many large craters and impact-generated fractures that extend below the transient floor of each crater. The superposition of ejecta blankets from large basins, on the other hand, will have produced much thicker regional zones of megaregolith, even though lithostatic pressure may have closed most fractures below 25 km. During this stage, regional textural homogenization of the upper crust down to the base of the megaregolith was indicated by the pre-Apollo lunar mapping program (315) and by the sample suites from Apollo 16 (316). Apollo 17's impact breccias related to the Serenitatus event (boulders at Stations 2, 6, and 7) also record crustal recycling by many earlier basin-forming and cratering events. These breccias further illustrate the processes and incomplete degree of mixing (317,318). The

regional nature of the compositional homogenization process during this period has now become broadly defined by remote sensing of the lunar highlands from the more recent Galileo (319–321), Clementine (322), and Lunar Prospector (323) spacecraft. This process, however, appears to have added less than 0.3% of an extralunar component to the Cratered Highlands (324) if iridium is considered a surrogate for that component.

The creation of the majority of large basins, discussed in the next section, followed the Cratered Highland Stage as a distinct period in lunar evolution. Two and possibly four extremely large impacts events (325–327), however, upon which later large basins are superimposed, may have occurred during this stage. Two of these formed the nearside Procellarum Basin and the farside South Pole-Aitken Basin (Fig. 10). These two basins are about 3200-km (transient crater ~ 2100 -km) and 2500-km (transient crater ~ 2000 -km [?]) in diameter, respectively. An older, third structure or cryptic basin ~ 3000 -km in diameter, centered roughly on Mare Tranquillitatis, is indicated by a partial ring of anomalously high iron plus titanium seen in the Lunar Prospector thermal neutron data between latitude $+30^\circ$ and -45° and longitude $+60^\circ$ and $+120^\circ$ (328) (Plate 5). The center of the transient crater of this very large cryptic basin, tentatively referred to as the Prospector Basin, coincides roughly with the global selenopotential low at the lunar surface. Prospector may have been responsible for the

Figure 10. Topographic map of the Moon from Clementine data showing the Procellarum Basin in the upper left of the nearside image, the South Pole-Aitken Basin in the lower portion of the farside image, and the Cratered Highlands of the farside and southern nearside (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

present ~ 2 -km offset in the center of the figure from the center of mass (329) that produces this low. The lack of physiographic and strong geochemical definition of Prospector suggests that it would have been formed before full consolidation of the anorthositic crust ~ 4.5 b.y. ago and before a signature of the concentration of KREEP components in the residual Magma Ocean could be left in the crust. Without other distinguishing geochemical signatures, Prospector's ring of anomalous iron plus titanium in the crust, now nearly homogenized with the Cratered Highlands of the region, may represent a trace of partially differentiated Magma Ocean brought to the surface around the transient crater.

The Procellarum event (Plate 8) may have taken place in the midportion of the Cratered Highlands Stage, possibly about 4.3 b.y. ago, if the impact degradation of its surrounding rings is any indication. Crystallization ages near 4.3 b.y. for some of the Apollo 14 KREEP-related samples may be related to the Procellarum event. In response to such an event, KREEP-rich basalt intrusions and extrusions might have been emplaced throughout the Procellarum region (330). However, 700 m.y. later, extensive eruptions of mare basalt partially filled the Procellarum Basin and other basins contained within it (see below) and covered most materials created or emplaced as a consequence of the Procellarum event. Beneath the transient Procellarum crater, pressure-release melting of olivine and low calcium–pyroxene cumulates (harzburgite), if those cumulates were near their partial melting temperature, would have produced intrusive magmas that may have crystallized the relatively young members of the Mg-suite of samples (331). The Procellarum impact also would have removed the early formed

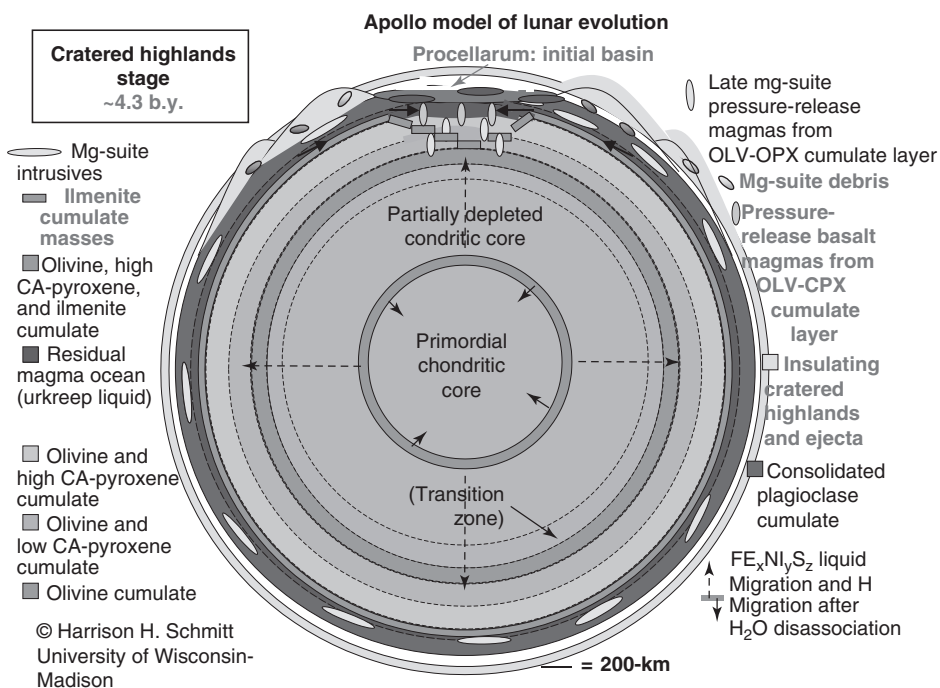

Plate 8. Apollo model of lunar evolution—Cratered Highlands Stage ~ 4.3 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Cratered Highlands from the region. Present crustal thickness modeling for the region is consistent with thinning of the crust from about 70-km to about 40-km thick (332,333). By removing a large area of insulating megaregolith and requiring that a new zone of insulating crust develop subsequently, the event also may have delayed future remelting of the underlying upper mantle to produce mare basalt magmas. Crystallization ages of mare basalts (334,335) sampled by Apollo 12 and 15 within the Procellarum Basin are younger (3.1–3.4 b.y.) than mare basalts to the east (3.6–3.9 b.y.) sampled by Apollo 11 and 17. On the other hand, the ages of mare basalts fragments in the more limited Luna 16 and 24 samples from Mare Fecunditatis and Mare Crisium, respectively, east of the Apollo 11 and 17 sites, are in the 3.3–3.6 b.y. range. An Ar–Ar age from Mare Fecunditatis basalt is 3.41 ± 0.04 b.y. (336), and two Ar–Ar ages from Crisium basalt fragments are 3.30 ± 0.04 b.y. (337) and 3.61 ± 0.12 b.y. (338). These relatively young ages may be the result of basaltic maria appearing first at the selenopotential low and then progressively away from that low (339) or of an as yet unrecognized, very large basin-forming event in that region removing older Cratered Highlands, as suggested before for Procellarum. Some suggestion for such a very large event centered on the equator southeast of Crisium is apparent in the gravity models based on Lunar Prospector data (340,341) and in the albedo maps from Clementine (342) (Clementine may be an appropriate name for this possible basin). Mare Australus consists of the basaltic lava fill of many craters and low areas in a ~1200-km diameter basin that also may indicate a very large impact.

The largely farside South Pole-Aitken Basin is the largest and oldest unambiguous impact basin on the Moon (343–348). It can be argued that the South Pole-Aitken event (Plate 9) took place near the end of the Cratered Highland Stage. For example, this event removed most of the insulating megaregolith of the Cratered Highlands and also thinned the total crust thickness to about 40 km (349); however, little new insulating megaregolith formed afterward. Gravity modeling also indicates that the lunar crust has been thickened by ejecta on the highlands surrounding South Pole-Aitken. If the Procellarum Basin is also the result of an impact, the combination of ejecta of Cratered Highlands material from South Pole-Aitken and Procellarum thickened the crust between them to about 120 km. The Galileo, Clementine, and Lunar Prospector remote sensing data have produced additional insights about South Pole-Aitken. Although actual magnesium to iron ratios have not been determined, these data suggest that most of the dark albedo surfaces in that basin, where iron, titanium, and potassium are lower than in mare basalts, may be related to impact melting of noritic or gabbroic Mg-suite rocks within the lower ferroan anorthosite crust. As in the Procellarum, Mg-suite related lavas may have been generated by pressure-release melting of the mantle's olivine–orthopyroxene cumulates beneath South Pole-Aitken. The presence of a weak KREEP signature in the South Pole-Aitken Basin may indicate that deep Mg-suite masses included some intrusives derived from Magma Ocean residual liquids of intermediate maturity. Imbrium ejecta in this region, however, cannot be eliminated as a source of KREEP-bearing material (350,351). In spite of a basin depth of 12 km below the mean lunar radius, mare basalt appears to be rare in the basin (352). South Pole-Aitken removed essentially all of the insulating surface layer without time for replenishing it, as indicated by the better definition of related physiographic

Plate 9. Apollo model of lunar evolution—Cratered Highlands Stage ~4.2 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

features relative to Procellarum. The South Pole-Aitken event thus appears to have prevented the later large-scale remelting of underlying upper mantle cumulates and the subsequent regional eruption of mare basalt, even though significant heat-producing, KREEP-related materials may be present in the underlying crust. Some local mare basalt signatures, however, have been identified in the northern portions of the basin (353), suggesting late partial melting of the underlying mantle, as occurred elsewhere on the farside of the Moon.

Thermal neutron spectra obtained by Lunar Prospector disclose a zone of high iron plus titanium, relative to other nearby crustal elemental signatures, just outside the rim of both the Procellarum and South Pole-Aitken Basins (354). These annuli suggest that material at and immediately outside of the now exposed rims of the Procellarum and South Pole-Aitken Basins came from deep crustal or upper mantle rocks. Until the magnesium content of these annuli is determined, their full significance will be uncertain; however, both events may have excavated levels of the lower crust that included abundant mafic material, possibly Mg-suite intrusives. This conclusion is consistent with new assessments of Apollo passive seismic data (355) which indicate a gradual increase in crustal density from 2.9-gm/cm³ in the upper crust to 3.4-gm/cm³ at the crust-mantle boundary. Lunar Prospector gamma-ray spectrometer data (356), on the other hand, indicate that neither of these enormous events excavated significant material related to urKREEP. This strongly suggests that urKREEP magmas had yet to move into the Moon's lower crust at the time of each event, a magmatic

episode discussed further later in connection with the Old Large Basin Substage when urKREEP apparently did move upward on a global scale.

The extensive movement of residual Magma Ocean liquids across and possibly along the crust–mantle boundary region may well have occurred beneath both Procellarum and South Pole-Aitken in response to the regional reduction in lithostatic pressure that would coincide with their formation (357–359). The coincidental formation of another large basin, the 1160-km diameter Imbrium basin near the center of Procellarum, further resulted in the redistribution of KREEP-related materials in and roughly radial to Imbrium (360). This scenario for urKREEP migration after a postulated Procellarum event provides an alternative to recent proposals of chemically asymmetrical differentiation of the Moon (361–365) to explain the present surface concentration of KREEP-related material around Imbrium. In this regard, an extreme concentration of KREEP-related material in the Procellarum region has been postulated in the form of the “Great Lunar Hot Spot” (366) now generally referred to as the “Procellarum KREEP Terrane (367). Asymmetry by the end of Magma Ocean solidification is also inherent in suggestions of the overturn of ilmenite cumulates (368) and overall mantle instabilities (369). On the other hand, if the Magma Ocean solidified in a roughly spherically symmetrical manner, such a KREEP-related concentration would not be expected as a consequence of differentiation. Like any fluid in orbital space, a Magma Ocean would tend to form a spherical shell subject to rotational, tidal, and convectional stresses. A generally spherically symmetrical solidification of this shell on the Moon is suggested strongly by (1) the pervasive evidence of both an originally global anorthositic crust, as discussed previously, and (2) globally distributed eruptions of mare basalts derived by partial melting from mantle cumulates (see Basaltic Maria discussion below). What asymmetries, if any, may have been introduced by rotational, tidal, and convectional stresses are not yet clear.

As implied before, one of the most important effects of the formation of the Cratered Highlands was a reduction in the thermal conductivity of the crust. As indicated by Apollo passive seismic data (370,371), low thermal conductivity corresponds to the high scattering and low attenuation of seismic waves that exist in this upper zone or megaregolith of the lunar crust. Thus, individual rock particles in the outer 25 km of the crust would be dominantly in point contact with each other and can be expected to be highly insulating thermally. Thermal transfer would be largely by radiation between particles rather than by conduction. The increasingly insulating character of the pulverized upper crust over that which would have prevailed during the crystallization of most of the Magma Ocean would arrest the cooling of the residual Magma Ocean during the Cratered Highlands Stage. It allowed the gradual accumulation of radiogenic heat necessary eventually to remelt partially the source regions in the upper mantle that subsequently produced the mare basalts and various pyroclastic volcanic eruptions. The resulting downward wave of heating would proceed into the upper mantle from the still molten and significantly radioisotopic urKREEP residual liquid at the base of the crust. This heating would be augmented by radioactivity retained interstitially within the deeper Magma Ocean cumulates. Proposals related to a Procellarum “hot spot” discussed before have led to a suggestion that a radiogenic heating mechanism by itself could explain the concentration of

basaltic maria on the lunar nearside (372). The thermal models developed in support of this proposal indicate that such a concentration of radiogenic heating would have kept the urKREEP zone beneath the crust molten for a few billion years. Maintaining urKREEP in a molten state only beneath Procellarum, however, does not explain the presence of isolated basaltic maria in deep farside craters (373,374). More critically, it cannot explain the persistence of gravitational anomalies due to mass concentrations (mascons) in the Procellarum Basin after 3.9 b.y. ago (see following Large Basin Stage discussion). The evidence is strong that the residual Magma Ocean had fully solidified in the crust by the time the young, mascon basins had formed. Although some significant migration of urKREEP liquids toward the Procellarum region may have occurred after the Procellarum basin-forming event, mare basalt magmas probably were prevented by the thicker farside crust from reaching the surface on the farside to the extent seen on the nearside. In the specific case of South Pole-Aitken, the loss of the insulating Cratered Highlands would have limited the remelting of the underlying upper mantle.

Large Basins (Stage 4—Pre-Nectarian–Lower Imbrium). Apollo 17 and Apollo 15 landed in the proximity of major structural features related to the formation of Serenitatis and Imbrium, respectively, two of the approximately 50 large circular basins on the Moon (Fig. 11). The extreme, but less than ~ 100 -km diameter scale cratering intensity that characterized the Cratered Highland Stage of lunar evolution had waned significantly before these and most other large basins were formed by extremely large and energetic impacts (375). This conclusion is consistent with the relatively good preservation of the concentric ring structures and some features of the surrounding ejecta blankets of most basins defined as “large,” whose diameters are greater than 300-km (376). In aggregate, crustal thickness determinations (377) indicate that these basins have redistributed large volumes of the upper 10–30-km of the fragmental debris (megaregolith) of the Cratered Highlands, particularly on the nearside of the Moon. Preservation of many of the physiographic features of the majority of large basins contrasts sharply with the vagueness or absence of similar features related to the very large basins (Procellarum, South Pole-Aitken, and possibly Prospector and Clementine) that formed during the Cratered Highlands Stage. These earlier very large basins may indicate that many more such basins formed, possibly about 14 (378), only to be destroyed by the combined effects of later basin forming and the overall, very high cratering rate during the Cratered Highlands Stage. As noted before, the Cratered Highlands are saturated with craters 60–70-km in diameter (379), a size–frequency parameter that requires a much higher rate of cratering than recorded in subsequent lunar history. Although little direct evidence of more than a few, very large “cryptic” or hidden basins yet exists and analyses of the uniformity of anorthosite distribution suggest that few actually formed (380), the previous existence of at least some cannot be ruled out, such as the possibility of Clementine, southeast of Crisium, discussed previously. One other such cryptic basin may encompass the roughly 2000-km diameter farside region that includes the smaller basins Mendeleev, Moscoviense, and Freundlich-Sharonov. This region appears to have a crustal thickness 20–30-km less than surrounding highlands (381) but no other indications of a very large basin event.

Figure 11. Near full Moon view showing examples of old and young, large basins both containing basaltic maria. The irregular basin at the lower left of center is Tranquillitatis, whose southern portion contains the Apollo 11 landing site. The circular basin at the lower left is Serenitatis. The Apollo 17 landing site is located in the lower right portion of the surrounding ring of mountains. The farside mare basin, Tsiolkovskiy, is visible just right of the top (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Large crater-forming events that formed a specific period in solar system history may have continued for several hundred million years after the less energetic background impacts of the Cratered Highlands Stage had largely ceased. A strong presumption can be made that a source of objects discrete from that which caused the earlier intense cratering was responsible for most large basins in the period between 4.2 and 3.8 billion years (382,383) or was part of a “cataclysm” at about 3.85 billion years (384,385). A discrete source is required even if a short-lived cataclysm is assumed. How long the large basin impact period lasted will be discussed further later; however, this discrete source supplied far fewer, but far more energetic objects (more massive and/or higher velocities) than the source responsible for the intense, postaccretion cratering that created the Cratered Highlands. Four possibilities for sources of the impactors of the Large Basin Stage appear plausible at this time: (1) the proto-Kuiper Belt of cometary objects whose injection into the inner solar system was the result of orbital resonance with Neptune (386); (2) the injection of Öort cloud cometary

objects at rates greater than during the last 3.9 b.y. as a consequence of perturbations by a passing stellar body (387); (3) large protomoons of Earth, swept up by the Moon during and after capture (388); and (4) Jupiter's initial interaction with the Main Belt Asteroids, or its induced breakup of the Belt's planetesimal precursor, and injection of fragments into inner solar-system-crossing orbits by orbital resonance (389). Of these possibilities, Jupiter's initial interaction with Main Belt Asteroids and/or the breakup of the original Main Belt planetesimals or ejection of Kuiper Belt objects due to interaction with Neptune appear to be the best present choices as discrete impactor sources. Modeling studies suggest that interactions between Neptune and Kuiper Belt objects probably would be completed over time frames of about 10 million years, although time frames of the order of hundreds of millions of years may be involved in the formation of the Kuiper Belt itself (390). An Öort Cloud source is currently unconstrained by modeling studies, but it seems likely that it continued to supply similar objects off and on indefinitely, given its postulated large total mass. Assimilation of protomoons of Earth, if any existed, would have involved objects of low kinetic energy relative to a coorbiting Moon, would occur over a shorttime interval, and would not explain large basin formation on other planets. At this stage of knowledge, however, it does not appear that any of these possibilities can be totally eliminated. Conversely, future studies of potential interactions of the gas giants with the Kuiper Belt and of passing stellar neighbors with the Öort Cloud might include the hypothetical constraint of large basin formation on the inner planets between about 4.3 and 3.8 billion years ago or of a short cataclysm.

Old Large Basins/Crustal Strengthening (Stage 4a—Pre-Nectarian). Globally, comparison of the old large basins with younger large basins (391) indicates that major strengthening of the lunar crust occurred during the early portion of the Large Basin Stage (392). The younger basins of the Nectarian and Lower Imbrium Systems, including Serenitatis, are circular and sharply defined structurally and physiographically. Central mass concentrations (mascons) underlie the young basins and are surrounded by mass deficiencies under mountainous rims several thousand meters high (393–395). Analysis and modeling indicate that most of the mascon signal comes from thick plates of basalt that partially fill the young basins in contrast to relatively thin basalt fill in older basins. A small part of the mascon signal may come from upward bulges in the crust–mantle boundary. A very large amount of mare basalt as hidden intrusions in the megaregolith beneath the basins may also contribute. On the other hand, the old basins are only irregularly circular, have relatively low mountainous rims, underlie ejecta from young basins, and today are largely compensated for gravitationally, that is, they have no mass concentrations or deficiencies associated with them. Thus, old large basins have adjusted isostatically, but young large basins have not (396) (Plate 10), leaving the latter with deep holes for mare fill and uncompensated for mass deficiencies beneath their ejecta rims. This suggests that the fracturing of the lunar crust by the older basin-forming events permitted urKREEP liquids to migrate into the crust. When these liquids moved upward and solidified, the potential was lost for rapid, postimpact isostatic adjustment by urKREEP magma movement at the crust–mantle boundary. A strengthening boxwork of solidified KREEP-rich intrusions also would be created

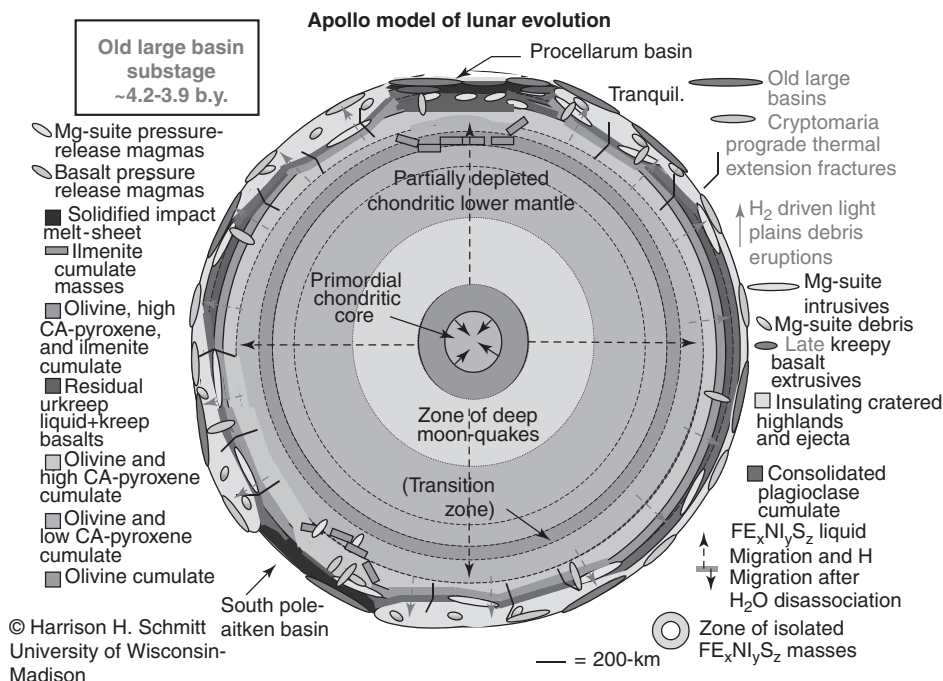

Plate 10. Apollo model of lunar evolution—Old Large Basin Substage ~4.2–3.9 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

in the lower crust. Although old basins also have some mare fill, higher basin floors would result in thinner mare basalt plates than in younger, unadjusted basins. If this hypothesis is correct, the remnants of the Magma Ocean remained in liquid form until about 3.92 ± 0.03 b.y. ago. This is the apparent age of Nectaris (397,398), apparently the oldest basin that has an uncompensated for mascon (399). The Apollo sample suite lacks clear-cut examples of ferroan anorthosite in association with material that might be interpreted as urKREEP intrusive. Except for Apollo 15 KREEP basalts, rocks that have a strong KREEP chemical component have been found only as impact melt breccias. These two observations (400,401) suggest that urKREEP intrusives are confined to the lower crust and have been exposed only in a single deep excavation, namely, Imbrium, where impact melting predominated. Probably because of the thinning of the upper crust by coincidence of the Imbrium transient crater with that of the Procellarum event, 3.83–3.86 b.y. old mare basalts (402) mixed with older KREEP-rich material may have reached the surface in that region roughly coincident with the Imbrium event at 3.82 b.y. (403).

Recent studies (404) have increasingly extended the areas of the Moon in which craters that penetrated young large basin eject deposits have exposed older dark materials that have basaltic characteristics, the so-called “cryptomaria” (405–408). The cryptomaria are related in age to the old, large basins because they also lie under ejecta from the young, large basins which is why they are “cryptic.” The volume of these apparently basaltic lavas of pre-Young Large Basin age is uncertain, but may be of the order of 10^6 -km³ (409) compared with basaltic

maria volume estimates of the order of 10^7 -km³ (410). Cryptomaria may be represented in the Apollo samples by basalts of ages clearly greater than 3.92 b.y. (411,412) or by KREEP-related basalts whose model ages are 4.2–4.4 b.y. (413). Most pre-3.92 b.y. basalts have high aluminum content, and others have KREEP affiliations and a variety of unusual chemical combinations (414). This chemistry may be explained by derivation from either urKREEP residual liquids or pressure-release partial melts of shallow Magma Ocean cumulates positioned between 100-km and 200-km depth and just below the radioisotope-rich, residual liquids of the Magma Ocean. Movement, intrusion, and eruption of magmas derived from residual liquids at the crust–mantle boundary and deeper pressure-release melting of a mantle near its partial melting point would occur in response to structural disruptions and the removal of tens of kilometers of overlying Cratered Highlands megaregolith. Such disruptions would accompany extraordinary events like those that created Procellarum, South Pole-Aitken, and other old, large basins. Future comparisons of the details of Lunar Prospector's gamma-ray spectrometer data and of relatively large areas of identified cryptomaria exposure may help further discriminate and define their source or sources, particularly if a KREEP signature becomes apparent. Such a signature would be expected for magmas from or passing through zones near the base of the crust. If it turns out that the compositions of cryptomaria are not significantly related to KREEP, it would suggest very rapid ascent of their magmas or their eruption in the narrow time window before the formation of young large basins and after the solidification of urKREEP liquids in the lower crust. The identification of cryptomaria on a global scale has other implications. The eruptions of early partial melts or urKREEP residual liquids from beneath the lunar highlands may have included significant residual volatiles and been at least partially pyroclastic. As a consequence, they may have contributed to the formation of light plains deposits or Cayley Formation units (415,416). Such smooth, light colored units in the lunar highlands actually may have several origins. In nearside regions affected most by young large basin events, they may be largely the result of the uniform settling of material in fluidized debris flows that extended beyond zones of continuous ejecta. On the other hand, those deposits observed by the author in old craters in the farside highlands may be the result of internal processes. An origin by pyroclastic eruptions dominated by entrained, fine-grained crustal debris is suggested by the smoothness of these plains, their similarity in albedo to other highland surfaces, irregular rimless depressions in their surfaces, and the absence of nearby young, large basins as sources of fluidized debris.

The formation of each of at least 29 old, large basins, including Procellarum and South Pole-Aitken, had five, essentially global effects. First, upper crustal material was redistributed regionally as ejecta blankets, debris flows, and impact melt flows and intrusions. Second, excavation and broad distribution of Mg-suite rocks and impact melts from solidified intrusions in the lower crust occurred. Third, regional thinning and thickening of the crust took place. Fourth, the lower crust beneath each basin was fractured extensively. And fifth, local areas of temporarily low lithostatic pressure were created under each basin, and mantle material at or near its partial melting point was commensurately mobilized. After each large basin formed, the relatively low-density, immediately underlying, urKREEP liquids would tend to move upward into the fractured lower crust

and brecciated upper crust. In the process, those liquids, probably with small amounts of superheat due to pressure release, would assimilate and mix with both ferroan anorthosite and differentiated Mg-suite masses, creating the diversity of parent magmas indicated by KREEP-rich samples from the Apollo landing sites (417). As they cooled, significantly contaminated KREEP-related magmas crystallized into networks of compositionally varied intrusions. In the Procellarum and possibly other deep old basins, KREEP-related magmas and pressure-release magmas may have reached the floor of the basins only to be largely buried by younger, large basin ejecta and mare basalt eruptions. Pre-Nectaris crystallization ages of 4.2 b.y. (418) for some olivine-rich and aluminous KREEP-related basalts are consistent with this scenario.

Apollo 17 sampled some of these effects of the Old Large Basin Stage during the examination of boulders at the base of the Massifs of the Valley of Taurus-Littrow. The Serenitatis basin-forming impact partially exposed a complex sequence of roughly layered ejecta blankets (Table 2, Plate 11) in the massif walls. Layers probably include significant ejecta from at least three, old Pre-Nectarian basin-forming events, Procellarum, Fecunditatis, and Tranquillitatis, as well as the younger basins, Serenitatis and Imbrium. It is possible that samples from these ejecta units are included in those collected at Stations 2, 3, 6, and 7 at the bases of the South and North Massifs. The most likely possibilities are samples from Boulder 1 at Station 2 (419). Rb–Sr isochron ages between 4.2 and 4.0 b.y. for some of the clasts in this boulder suggest that the probably older Procellarum ejecta is not represented unless that event was the source of the fine-grained plagioclase clasts whose Rb–Sr isochron ages are about 4.4 b.y. (420).

Young Large Basins (Stage 4b—Nectarian–Lower Imbrium). Between 3.92 ± 0.03 b.y. (Nectaris event) and 3.80 ± 0.05 b.y. (Orientale event), 14 large basins formed (421,422) in a lunar crust that could support significant mass concentrations and deficiencies indefinitely (Plate 12). Alternatively, it has been suggested (423–425) that a lunar cataclysm between 3.9 and 3.8 b.y. created these basins and also the 29 or more older, nonmascon basins and the Cratered Highlands as well. This latter hypothesis rests on the predominance of ages in that range that have been measured for impact glasses in Apollo, Luna, and lunar meteorite samples from the highlands and from basin-related materials. In this context, note that all Apollo and Luna sampling took place within the regions most affected by young, large, basin-forming events and a predominance of ages related to those events would be expected. This influence also may have extended globally to affect the lunar meteorite samples. Advocates for a cataclysm argue that the influence of impact melting and thus the resetting of radiometric ages is limited to the near vicinity of the basins. This may not be the case as lunar mapping (426) and experimental results (427) suggest that very large amounts of impact melt form within the transient crater of a basin, and also such melt is widely distributed on and in ejecta. Ejected melt particles of the highest energies will have a global reach in large basins. Even so, impact melts from the highlands sampled by Apollo 16 show formation ages up to 4.2 b.y. (428), and, as noted before, Rb–Sr ages for clasts in breccias sampled by Apollo 17 also show ages up to 4.2 b.y. The question whether 50 or more large basins formed in about 100 million years or less or in about 400 million years will ultimately be determined by more extensive sampling of the lunar highlands.

Table 2. Local Sequence from Younger to Older of Pre-Mare Basalt Stage Events in the Vicinity of the Valley of Taurus-Littrow (For Regolith Depth: Shallow = 0.01–1 Meters, Moderate = 1–10 Meters, and Deep = 10–100 Meters)

Depth or thickness	Characteristics	Age or duration, b.y., Δ = time interval
~ 10-m	<i>In situ</i> brecciation and gardening from primary and secondary impacts.	$\Delta 3.87$ b.y.
~ 100-m (621)	Overtured, late-stage Cratered Highlands ejecta and/or debris flow deposits from the Imbrium event, consisting of ferroan anorthosite fragmental breccia with KREEP-related and Mg-suite clasts (Boulder 1 at Station 2) (622). Seismic velocities of ~4000-m/s (623) for the material below the basalt fill of the valley indicate relatively unconsolidated debris.	3.85 ± 0.02 (624)
Shallow	<i>In situ</i> brecciation and gardening from primary and secondary impacts.	$\Delta \sim 0.050$ b.y.
< 100-m ^a	Crystallized melt breccia from the Serenitatis event both as an extrusive sheet and as intrusives (Boulder 2 at Station 6) (625).	3.87 ± 0.08 (626)
~ 700-m ^a (627)	Overtured, late stage Cratered Highlands ejecta and/or debris flow deposits from the Serenitatis event, consisting of ferroan anorthosite fragmental breccia that contains lower crustal Mg-suite materials (Boulder 1 at Station 6) (628).	3.87 ± 0.08 (629)
Moderate	<i>In situ</i> brecciation and gardening from primary and secondary impacts.	$< \Delta 0.1$ b.y.
< 100-m ^a	Debris flow deposits of late Cratered Highlands ejecta from the Crisium event, consisting of ferroan anorthosite fragmental breccia that possibly contains KREEP and Mg-suite materials.	3.9–4.0 b.y.
Deep	<i>In situ</i> brecciation and gardening from primary and pre-Crisium secondary impacts, particularly secondaries from Smythii and Nectaris.	$< \Delta 0.2$ b.y.
< 100-m ^b	Overtured, late stage Cratered Highlands ejecta and Procellarum ejecta units from the Fecunditatis event, consisting of ferroan anorthosite fragmental breccia that possibly contains lower crustal materials including the Mg-suite (Boulder 1 at Station 2?).	(?)
Shallow	<i>In situ</i> brecciation and gardening from primary and pre-Fecunditatis secondary impacts.	$< \Delta 0.1$ b.y.

^aRelative age relationships between Crisium and Serenitatis not established.

^bRelative age relationships between Tranquillitatis and Fecunditatis not established.

The vast majority of the nonmare materials accessible to Apollo 17 in the Valley of Taurus-Littrow represents large basin ejecta derived from the Cratered Highlands or the upper lunar crust. Using the relative ages of the large basins (429), approximate ejecta thickness expected from such basins (430), and radiometric ages determined for specific impact-related events near Taurus-Littrow, the general characteristics of the local sequence of events are given in Table 2 and Plate. 11. Investigations of the large boulders of impact melt breccia at Station 6 and 7 at the base of the North Massif in the Taurus-Littrow area documented the complexity of processes associated with large basin-forming events. The prevalence of melt breccia in the boulders suggests that they tie genetically to the 740-km diameter Serenitatis basin whose rim is 15–20-km to the west. The track to the largest of the boulders (Fig. 12) indicated that it had rolled down from a break in the slope $\sim 500\text{-m}$ above the valley floor, $\sim 1000\text{-m}$ below the top of the North Massif (431), and probably near the base of Serenitatis ejecta. The higher, $\sim 25^\circ$ slopes include outcrops or near-outcrops; some appear roughly horizontal in aspect. For the first time on the Moon, this boulder permitted observations and sampling across a major lithologic and structural contact related to a large impact (Fig. 13). A finely crystalline melt breccia—tan-gray and highly vesicular (Fig. 14)—intrudes, is in, or was laid down in contact with crystalline nonmelt breccia—blue-gray, nonvesicular and clast-rich (Fig. 15). An approximately 1-m wide

zone in the nonmelt breccia contains small vesicles at and near the contact with the melt breccia. At Station 7, a vein of crystalline melt breccia cuts across the contact zone and through a clast, suggesting that the melt breccia may be largely intrusive. Laboratory investigations of the samples from these boulders indicate an age of crystallization for the melt breccia of 3.87 ± 0.08 b.y. (432), giving the probable age of the Serenitatis basin-forming event. The petrographic and chemical characteristics of the melt and nonmelt breccias indicate that each is polymict (multiple types of fragments) and have crystalline matrices. The matrices show a continuum in texture between very finely crystalline to poikilitic (433), reflecting the extreme brecciation, heating, melting, and mixing effects of large basin formation (434). No materials, related to the post-Serenitatis, Imbrium basin-forming event, were obvious at the base of the North Massif, although other crystalline breccias similar to the two types discussed before are present. Elsewhere, a

boulder of layered, relatively unmetamorphosed and less coherent blue-gray breccia investigated at the base of the South Massif appeared to have been derived from sources in the blue-gray unit at the top of this mountain. The apparent several hundred meter thickness of that unit (435,436) is consistent with the ejecta thickness estimated for points at this distance from the Imbrium Basin (437). Further, the presence of a KREEP component in the boulder's chemistry (438) suggests an Imbrium source area because most KREEP-related materials at the lunar surface appear to be associated with ejecta from that basin. The study of Boulder 1 at Station 2 suggests that the 3.85 ± 0.02 b.y. old Imbrium event (439) deposited material from the ~ 4.3 b.y. old Procellarum basin as well as recycled ejecta derived from the old large basin, Tranquillitatis, to the south, dated at 3.94 ± 0.06 b.y. (440,441).

One of the questions raised about the crystalline melt breccias (442) investigated at Stations 6 and 7 in the Valley of Taurus-Littrow relates to the vesicles or smooth-walled holes they contain. The holes formed when the breccia was partially molten and an immiscible fluid phase separated and coalesced to shape them. Elongation of the vesicles indicates that the melt breccia was still flowing when this phase was present but not at temperatures sufficient to melt all silicate clasts. Vesicles also formed in the more solid rock in contact with the melt breccia. Vesicles are common phenomena in terrestrial lavas where a variety of

Figure 12. The large boulders investigated at Station 6 at the base of the North Massif. The five boulders accessible for examination and sampling are apparently all part of one boulder that broke apart as it came to rest after rolling ~ 1.5 km down the side of the valley (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

volatile components, particularly water and carbon dioxide, are available to form the immiscible fluid. The chemical nature of the vesicle phase in lunar breccias, however, is constrained (1) by the lack of evidence that water or carbon dioxide ever existed in these lunar rocks, (2) by the absence of any discernible alteration of the minerals lining the vesicles, and (3) by the absence of anomalous mineral precipitates on the vesicle walls. A number of lines of reasoning suggest that the apparently inert fluid in question consisted largely of hydrogen and/or carbon monoxide; some helium and volatile nitrogen and other carbon compounds were possibly included. Throughout the formation of the Cratered Highlands, much of the pulverized ferroan anorthosite would have been as fine as the present-day surface regolith due to oversaturation with impacts smaller than those that formed the saturation size, 60–70 km diameter craters. This fine regolith would have been exposed to the solar wind of that time. Today, the solar wind is 96% protons (443) and may have been much more intense during the early history of the solar system, although the particularly intense T-tauri phase of solar evolution probably preceded the Cratered Highlands Stage (~ 4.4 – 4.2 b.y. ago) of lunar history (444,445). Plagioclase, the mineral phase comprising about 85% of the lunar highlands, is a mineral known to be capable of incorporating hydrogen ions in its crystal lattice (446). Epithermal neutron spectra from Lunar

Figure 13. Prospector (447) indicate an average of about 30 ppm hydrogen in the present-day highland regolith (448). Thus, there is the potential for retaining significant hydrogen, as well as impactor-derived volatiles, throughout the fine portions of the crustal megaregolith. Until it is possible to sample the fines of the deep megaregolith directly, it will remain uncertain whether there was sufficient solar wind exposure during the Cratered Highland Stage to provide the volatiles necessary to create the observed vesicles. A possible alternative source of vesicle-forming fluids may be the volatiles derived from impactors or material volatilized upon impact; however, most evidence indicates that such extremely high temperature material is lost to space (449–451) or would be expected to condense

Figure 14. Tan-gray, vesicular impact melt breccia of the boulder at Station 6 shown in Fig. 12 (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

very quickly into solid material. Thus, solar wind hydrogen and lesser amounts of solar wind helium and carbon monoxide from the fine fraction of the megaregolith could be incorporated into impact melts and form the observed vesicles. Such hydrogen also may be mobilized in the crater ejecta, lowering the overall viscosity and contributing to the mobility of debris flows (452).

An additional effect of young, large basin formation appears to have been the creation of bright swirls (Fig. 16) antipodal to at least the four youngest basins, Crisium, Serenitatis, Imbrium, and Orientale (453). Another, less precise correlation, may be the large bright swirl, Reiner Gamma, which is roughly antipodal (approximately 50°W, 20°N) to the young basin, Tsiolkovskiy. The extensive region of swirls east of the Crisium basin and antipodal to Orientale were observed and photographed in detail during the Apollo 17 orbital mission. Bright swirls have no apparent topographic relief or texture, are

Figure 15. Blue-gray, clast-rich impact breccia of the boulder at Station 6 shown in Fig. 13 (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

diffusely bordered, and have local dark cores. There have been recent suggestions that bright swirls represent variations in proton-induced darkening of surface materials. These variations might be caused by deflections of solar wind associated with remnant magnetic anomalies that are also roughly antipodal to at least four and possibly six of the young basins (454–456). Alternatively, the swirls may be the result of an internally originated process that causes changes in the relative abundance of fine and coarse particles in the regolith (more coarse particles give a brighter albedo). This change may possibly be related to gas flow from the crust or deeper interior of the Moon that moves fine particles upward to the surface in response to seismic shaking at antipodes from large impacts. Such an origin would account for the reported lower maturity index for the Reiner Gamma swirl relative to the host mare basalt (457), although magnetization of thick, underlying Imbrium ejecta has

Figure 16. Light-colored swirls on the surface of the farside of the Moon, east of the Smythii Basin and antipodal to the Orientale Basin (courtesy of NASA).

also been suggested as the basis of this and two other swirls in the region (458). On the other hand, the antipodal association of magnetic anomalies, if genetically related to basin formation, would provide a constraint on the duration of a past lunar dipole field. As anomalies do not appear to be antipodal to the old large basins and are of lower intensity antipodal to Orientale, then the dipole may have been active only between about 3.92 and 3.80 b.y., the span of apparent ages of these young basins. If this suggestion survives further scrutiny, these dates may indicate the approximate times of lunar core formation and termination of core circulation, respectively. If it took about 600 m.y. for the $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid that formed the lunar core to migrate through the lower mantle and coalesce as a core, then this would be further support for the hypothesis that the whole Moon never melted during the Magma Ocean Stage. Otherwise, $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid would have formed a core nearly simultaneously with melting of the whole Moon.

Basaltic Maria (Stage 5—Upper Imbrium). Considerable evidence exists of eruptions of basaltic lavas on the Moon (Plate 13) as early as 4.2 b.y, the cryptomaria (459), and as late as 1.3 b.y. in Oceanus Procellarum (460). The majority of the partial filling of many of the large basins by mare basalt (see Fig. 11), however, particularly on the nearside of the Moon, appears to have begun about 3.8 b.y. ago and lasted for about 800 m.y. years. This period constitutes the bulk of the Basaltic Maria Stage of lunar evolution (461–463) (Fig. 17). Recent estimates of the volume of mare basalt range up to 10^7-km^3 (464), and the mean volume per eruption was about 200-km^3 (465). These volume estimates do not include potentially abundant intrusions in the pervasively fractured lunar crust. Hidden intrusives in the thick crust may account for the “missing” mare basalt on the lunar farside. The fundamental characteristics of the samples of mare basalts collected by the Apollo astronauts are their chemical and mineralogical diversity (466–469). The mare basalt sample suites from the Apollo 12 and Apollo 17 sites, however, contain many samples that appear to be largely derived from one or two individual flows or cooling units (470–472) and are discussed in more detail later. The variety of mare basalt compositions attests to the comparable variety of depths, mineral assemblages, and degrees of partial melting involved in the lunar mantle, as the mare basalt magmas formed (473,474). This variety probably was further enhanced by the differing degrees of internal differentiation that resulted from fractional crystallization and devolatilization during ascent and

Plate 13. Apollo model of lunar evolution—Basaltic Maria Stage 3.8–3.7 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

solidification which it has been noted, also took place in the Apollo 12 basalt flows (475) (Plates 14–16).

The insulating nature of the Cratered Highlands and the heat sources in KREEP-related intrusives within and beneath the crust would have resulted in a downward wave of partial melting, progressing through the Magma Ocean cumulates of the upper mantle. This constitutes the simplest and currently most plausible scenario for the generation of mare basalt magmas during their peak eruptive period. Additional sources of heat would have included interstitial radioisotopes within the cumulates. Partial melting at increasing depths would partially reverse the sequence of cumulate formation in the cooling Magma Ocean, initially producing primary magmas rich in titanium and KREEP-related components at about a 200-km depth, followed by melting at increasing depths to

Plate 14. Apollo model of lunar evolution—Basaltic Maria Stage 3.7–3.5 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

below 400 km (476,477). These would be reflected in magmas that had progressively less titanium, less KREEP-related components, and more magnesium as deeper olivine and orthopyroxene-rich cumulates reached equilibrium with the very earliest partial melts derived from interstitial plagioclase, ilmenite, and other minor minerals. This sequence can be verified only in a general sense; the oldest samples of mapped lavas are titanium-rich (Apollos 11 and 17), and the youngest are magnesium-rich (Apollos 12 and 15 and Lunas 16 and 24). Analysis indicating that platinum group elements have higher concentrations in the older, titanium-rich basalts than in the younger, magnesium-rich basalts, is consistent with this sequence as well. Due to the early separation of iron-rich liquid from the Magma Ocean (see the previous discussion of the Magma Ocean Stage), the remaining siderophilic platinum group elements, most of which would have gone into the iron-rich liquid, would have been reconcentrated in the residual liquid from which ilmenite ultimately crystallized (478). Clearly, there are great uncertainties in attempts to correlate source region compositions and ages among various maria on the Moon. For example, in the Oceanus Procellarum maria west of Imbrium there appears to be a reversal of the sequence of old and titanium-rich to young and magnesium-rich. Many of the youngest lavas in Oceanus Procellarum that have been identified by remote sensing and dated by crater statistics (479) are also titanium-rich. This reversal may be explained by an earlier migration of dense ilmenite cumulates to deeper portions of the mantle in response to the disruption of the Procellarum basin-forming event. Such a

Plate 15. Apollo model of lunar evolution—Basaltic Maria Stage 3.5–3.0 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

gravitational destabilization of ilmenite cumulates has been suggested for the entire Moon (480); however, the distribution and ages of Ti-rich mare basalts are not consistent with this more global hypothesis.

Samples of basalts in the older to younger age sequence, Apollo 11 > Apollo 17 > Luna 16 > Luna 24/Apollo 15 > Apollo 12 (481–483), appear to follow this melting sequence scenario reasonably well. Greater amounts of incompatible, KREEP-related elements are also noted in older basalts (484) due to the close association of late ilmenite cumulates with the residual melt of the Magma Ocean. Although Apollo sample analyses suggest a bimodal distribution of titanium in mare basalts, remote sensing data indicate that the majority of mare surfaces show a few percent TiO₂ and smooth decreases in abundance on either side of this peak (485). Except for the old titanium-rich basalts noted, variations in major element compositions, particularly in titanium, potassium, and aluminum, can be attributed to fractional crystallization of basaltic magmas and/or melting varying proportions of ilmenite-, KREEP, and plagioclase-bearing interstitial material, respectively, in the source cumulates (486–488). Significant assimilation of crustal material is ruled out by geochemical and isotopic considerations (489). Rare-earth patterns also follow a compatible sequence; the greatest europium depletion occurred in the oldest primary mare magmas (490), magmas produced from cumulates subject to the longest interval of plagioclase crystallization. A proposed alternative scenario for producing the primary magmas for the basaltic maria through partial melting of a hybridized upper mantle

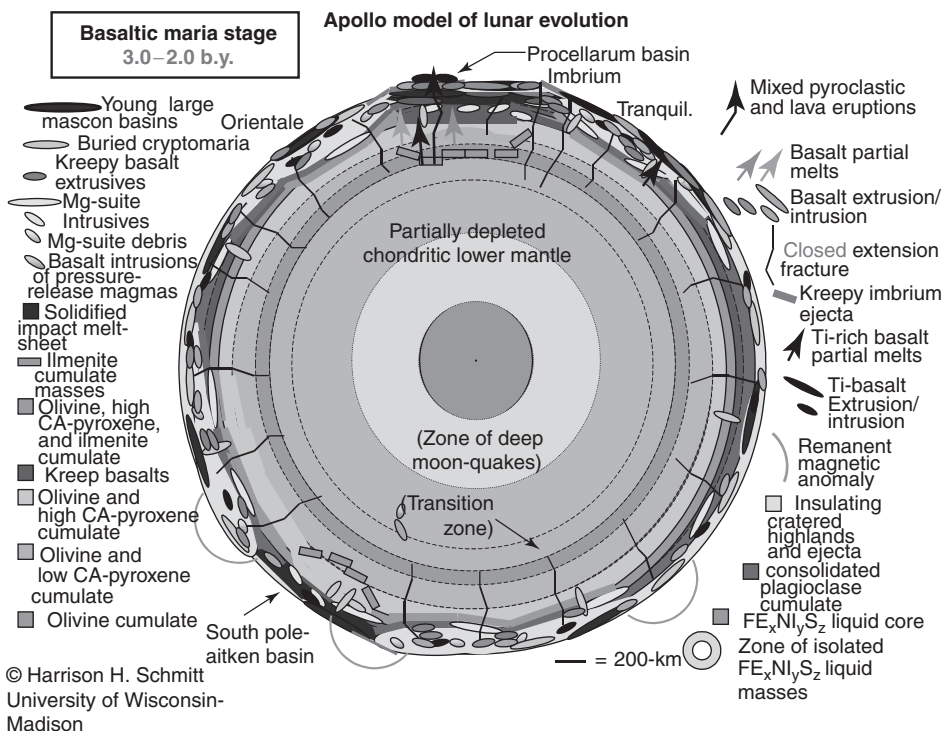

Plate 16. Apollo model of lunar evolution—Basaltic Maria Stage 3.0–2.0 b.y. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

plus assimilation of various materials (491) suffers from inconsistency with the apparent depths of partial melting as a function of time. Also, models for mantle hybridization (492) are inconsistent with the concept of the generally compositionally concentric structure of the mantle discussed before and with the improbability of overturn in the lunar mantle when fully solidified. The apparent exception to the lack of mantle hybridization, as noted before, consists of the region beneath the Procellarum Basin and possibly beneath the South Pole-Aitken Basin. Very large basin-forming events would have had the potential to destabilize the underlying mantle though pressure-release melting and may have allowed relatively dense ilmenite-rich cumulates to migrate downward.

Apollo samples and age estimates by crater statistics suggest that surface flows during the main phase of mare basalt eruption appeared first in the Serenitatis–Tranquillitatis region of the Moon. This spatial association probably exists for three reasons. First, after the formation of the Procellarum Basin and before the Serenitatis and Tranquillitatis events, as discussed previously, a thick portion of insulating megaregolith and ejecta lay over this region, accelerating reheating of the mantle. Second, due to the offset of the Moon's center of mass from its center of figure toward this region (493), a selenopotential low existed that facilitated magma access to the surface. Third, younger magmas would be forced progressively away from the area of preceding eruptions as they encountered a largely permeated and sealed crust. Although the distribution of basins

and highlands would perturb this idealized pattern, some indications of a roughly concentric color and age pattern of mare distribution around the selenopotential low have been observed (494,495). On the other hand, by 3.92 b.y. ago, the beginning of the Young Large Basin Substage, fractional remelting of the outermost cumulates of the Magma Ocean probably had progressed in many regions, if not globally, to the point of incipient eruption. The Serenitatis event (3.87 ± 0.08 b.y.) and other large events on the nearside of the Moon may have accelerated regional mantle melting by the release of lithostatic pressure resulting from the instantaneous removal of 10–20 km or more of crustal material (496). No specific evidence, however, indicates that this significantly affected the eruptive history of the maria (497). Elimination of most of the initial pressure change might have occurred through rapid rebound of the basin floors as partially fluidized mantle material moved inward and upward to compensate (498). Additionally, nearly contemporaneous movement of large fault blocks of basin rim masses into the transient crater cavity may have taken place (499).

Nonetheless, the oldest known lavas spatially associated with the Serenitatis basin crystallized about 3.82 ± 0.25 b.y. ago (500). These old, high-titanium lavas were sampled during Apollo 17 at the rim of Camelot Crater (Fig. 18). Because these mare basalts lie above Imbrium ejecta deposits and Apollo 14 and 15 samples date the Imbrium event at 3.85 ± 0.03 b.y. ago (501), the

Figure 18. Mare basalt boulders at Station 5 on the rim of Camelot Crater excavated from a depth of about 150 m. The author is moving toward the Lunar Rover (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

oldest basalt ages can be constrained even more to about $3.82 \pm_{0.25}^{0.06}$ b.y. The Taurus-Littrow lava, or rather the regolith formed on them, is contiguous with a dark blue-gray annulus about 50 to 100 km wide around Serenitatis and is roughly contiguous with the titanium-rich basalts of Mare Tranquillitatus to the south. The annulus of dark blue-gray regolith underlies younger mare basalts covered with brown-gray regolith in the central portion of the southern Serenitatis Basin (502,503), regolith low in titanium, as determined by remote sensing (504). The younger, central basin lavas may be represented in the Apollo 17 sample suite by small fragments of low-titanium basalt in the regolith that have ages of 3.74 ± 0.20 b.y. (505). The most common types of titanium-rich basalts (Types A and B) sampled in the Valley of Taurus-Littrow are of a differentiated continuum between high-titanium, olivine-rich basalt and a low-potassium, olivine-poor basalt that can be produced by fractional crystallization of a single magma (506). Consideration of the depths of the craters that excavated the Type A and B samples suggests that these basalts represent most of the upper 100–150 m of the basalt section. Active seismic measurements made just after the Apollo 17 mission determined that approximately 1.175 km of basaltic rock partially filled the valley (507). *In situ* gravity measurements showing a basalt depth of ~ 1.4 km (508) roughly confirms the seismic estimate. No direct field evidence exists for the thickness of individual flows in this basalt section. The rate of extrusion may have been high enough that individual eruptions coalesced to create a few thick cooling units, possibly only one, as suggested by the chemical trends between basalt Types A and B. Field observations support this conclusion in that they disclosed only limited textural or mineralogical variability among the basalt boulders other than in vesicle concentration and grain size. The seismic profiles further suggest only two major units, one 248-m thick zone that had a seismic velocity of 250 m/s underlain by a 927-m thick zone that had a velocity of 1200 m/s, both consistent with known basalt velocities (509). The upper unit may be an intensely fractured portion of a single cooling unit because the profiles were measured largely under the highly cratered central portion of the valley. In contrast to these apparently thick Apollo 17 basalt units, samples from around craters in the basalt flows at the Apollo 12 site provided conclusive field and chemical evidence of fractional crystallization in flows only a few tens of meters thick, primarily through the settling of olivine (510,511). Olivine fractionation also seems dominant in the differentiation of the apparently much thicker Apollo 17 flows; however, ilmenite, armalcolite $[(\text{Mg,Fe})\text{Ti}_2\text{O}_5]$, and chromian spinel may be involved as well (512). On the other hand, many mare basalt flows extruded late in other eruptive areas appear to be only 10–60 m thick (513). Photographs by the Apollo 15 crew of flows exposed in Hadley Rille (514), photogeologic evidence of relatively thin flows at the surface of other basins, and the thin flow that must have protected the integrity of the orange volcanic glass deposit in Taurus-Littrow (515) indicate that this often has been the case.

Apollo 17 radar data taken from orbit (516) are consistent with a 3-km thick basalt section in the central portion of the southern Serenitatis Basin. Analysis of impact craters penetrating this mare (517) gives an estimated thickness of 4 km. A number of factors indicate that the lunar basaltic eruptions that created the maria in general occurred at high rates from many centers across wide regions. Such rapid and pervasive eruptions would result in dense plates and

possibly thick cooling units in the central portions of confining basins. For example, the innumerable deep fractures in the crust and upper mantle associated with Serenitatis and previous impacts provide a vast number of potential magma conduits. Gravity one-sixth that of Earth's and a lunar magma viscosity 10 times lower than that of the average terrestrial basaltic magma will result in a flow rate from source regions possibly 50% faster than that in Earth (518). This may lead as well to a propagation rate in the crust as much as ten times faster. The increase in volume of a partial melt compared to its crystalline equivalent would have created overpressures and/or buoyant forces (519) necessary to drive magma from the mantle and into and through the crust, accompanied by intensified microfracturing and refracturing of the lower crust. A significant likelihood also exists that the crust was in overall tension during the Basaltic Maria Stage as a result of volume increase due to thermal expansion and partial melting of the upper mantle. Such tension would have tended to keep fractures open until filled by solidified magma. All of these factors may have produced a volume of intrusive basalt dikes beneath the central portions of mare basins like Serenitatis that is great enough to contribute to the spatially associated mascon. If such a mass contribution is significant, then the degree to which modeling of mascons depends on an elevation of the crust-mantle boundary would be correspondingly reduced. The fact that the youngest flows in a given region are low volume flows can be best explained by decreasing magma production and/or the constriction or closing of most conduits by preceding eruptions. Many late eruptions, particularly of regional deposits of pyroclastic volcanic glasses, are closely associated with large, graben-forming fractures related to major basin margin structures. The very deep source regions indicated for such glasses and their associated volatiles strongly suggest that these fractures penetrate more than 500 km into the lower mantle (520), again indicating an upper mantle in structural tension at the time of eruption.

Major basalt units in the Apollo 17 suite are vesicular, as are basalts from other mare landing sites. The variability of associated mineral linings and phase equilibrium implications of these relics of an immiscible fluid phase were first studied in Apollo 11 basalts from Tranquillity Base (521). As in crystalline melt breccias, is a likely candidate for a vesicle fluid phase, although carbon monoxide is another strong possibility (522–524). Unlike the probable solar wind origin of the hydrogen in melt breccias, however, hydrogen or carbon monoxide in the mare basalt magmas would need to be derived from primordial sources (525). In the case of hydrogen, primordial water would be decomposed by downwardly migrating $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid separated from the Magma Ocean and would produce FeO and hydrogen. The total absence of any indication of water associated with the vesicle fluid phase demonstrates that all primordial water in the source materials for the Magma Ocean has been lost to space or has decomposed. Further, the lack of evidence that water was associated with the adsorbed volatiles in pyroclastic volcanic glasses indicates that no water remains in the lower, more primitive mantle and supports the hypothesis of a broadly disseminated migration of $\text{Fe}_x\text{Ni}_y\text{S}_z$ liquid through this material to form the lunar core. The presence of hydrogen as a component of lunar magmas would affect other aspects of magmatic activity, including, density, viscosity, fractional flotation of minerals adhering to vesicle walls, and the dynamics of late-stage eruptions from cooling intrusives.

Fluorine is slightly concentrated on the walls of basalt vesicles relative to the rock as a whole (526). Fluorine constitutes an important component of the volatile fraction of the orange and green volcanic glasses, so a broader attempt to characterize the vesicle fluids in lunar basalts might be of significant interest.

Regional dark mantle deposits have been mapped around the southern edge of the Serenitatis Basin (527,528) (Fig. 19) as well as in many other locations on the Moon (529). These deposits and similar pyroclastic materials sampled by Apollo 17 characterize late-stage mare volcanism at the edges of a few other large basins, including Imbrium (green volcanic glasses sampled by Apollo 15). As previously discussed, the volcanic glasses associated with these deposits and found ubiquitously as a component of mare regolith at all of the Apollo sites have

Figure 19. Regional deposit of dark mantle material near the southwestern edge of Serenitatis. Orbital observation during the Apollo 17 mission indicated that these deposits contain extensive layers of orange, red, and black glasses (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

continued to grow in significance relative to the origin, evolution, and internal structure of the Moon (530,531). The continuing interest in such glasses was catalyzed by the Apollo 17 discovery of the nearly pristine orange volcanic glass and its black, partially devitrified equivalent in the rim of Shorty Crater (532,533). Table 3 summarizes the geologic history of the area near Shorty Crater. Another type of basalt sampled in the Valley of Taurus-Littrow (Type C), a very high titanium, vesicular olivine-rich basalt, apparently formed a protective unit above the original, pre-Shorty orange and black volcanic glass deposit. Type C basalt has an unusually low Ba/Rb ratio that also distinguishes it from other basalts in the valley (534). Some such lava flow necessarily covered the deposit at Shorty soon after it was formed during a pyroclastic eruption (535) about 3.48 ± 0.03 b.y. ago (536), or about 300 m.y. after the major mare basalt eruptive activity in the valley. Orange glass argon exposure ages of 30 ± 6 m.y. (537) indicate that the original pyroclastic deposit lay unprotected on the Moon's surface for about that length of time. Further, cosmic ray track data indicate that the event that formed Shorty and exposed the orange glass occurred between about 10 ± 3 (538) and 19 m.y. ago (539). This Type C basalt made up a unit of limited lateral extent because samples of it were obtained only at Station 4 on the rim of Shorty Crater (540). No other evidence of protected orange glass was observed, even though beads of this glass are important constituents of the valley regolith (541). The Type C unit also was apparently quite thin as it, several meters of the underlying pyroclastic deposits, and a meter or so of light mantle debris (see below) must fit into a section about 14 m thick, the depth of Shorty Crater below the precrater surface. No pyroclastic material was observed on the floor of Shorty, only large blocks of fractured basalt. Most of the Type C basalt would have been pulverized and incorporated in the approximately 10 m of regolith developed in the valley during the 3.5 billion years since its eruption.

These orange pyroclastic glasses (see Figs. 6 and 7), independent of their adsorbed volatiles, appear to have originated from melting of the deep portions of the upper mantle, possibly as deep as 400 km or more below the surface (542,543). Even deeper origins are indicated for the low-titanium green glasses sampled by Apollo 15 (544). The small europium depletion in the Apollo 15 green volcanic glasses (545) suggests a deep (early) cumulate source region less affected than mare basalt source regions by the loss of europium during plagioclase separation from the Magma Ocean. On the other hand, the larger europium depletion and generally higher rare-earth concentrations in the Apollo 17 orange glasses suggest a relatively shallow (late) cumulate source region from which plagioclase has crystallized. Clearly, there is much more to be learned from the pyroclastic glasses. For example, the high-titanium orange glass turned out to be high in iron and magnesium relative to high-titanium mare basalts (546), also consistent with a source distinct from those basalts. Interpretations of analyses of trace elements (547) indicate that the source regions for some pyroclastic glasses have some chondritic characteristics with regard to these elements and include garnet as a mineral phase. These data suggest that some of the source regions of the pyroclastic glasses lie below 550 km, the apparent base, on seismic grounds, of the largely or entirely molten Magma Ocean (548,549). Further, the light gray regolith on either side of the orange glass deposit, apparently altered from the darker gray of the nearby regolith due to volatile migration, contains

Table 3. Sequence of Geologic Events in the Vicinity of Shorty Crater

Event	Thickness or dimension	Age or Δ time
Deposition of Serenitatis ejecta and faulting to form the proto-Valley of Taurus Littrow	~ 700 m (635)	3.87 ± 0.08 b.y. (636)
Development of regolith	(?)	$< \Delta 0.1$ b.y.
Deposition of Imbrium ejecta	~ 100 m (637)	3.85 ± 0.03 b.y. (638)
Development of regolith	(?)	$< \Delta 0.31$ b.y.
Eruption of basal mare basalt unit (?)	$927 \text{ m} \pm 10\%$ (639)	Between 3.88 and 3.57 b.y. (between the oldest limit on age for Imbrium and the youngest limit on oldest sampled Taurus-Littrow basalt)
Development of regolith (?)	(?)	
Eruption and <i>in situ</i> differentiation of Types A and B, high-titanium olivine basalt flows (Stations 1 and 5)	$248 \text{ m} \pm 10\%$ (640)	3.82 ± 0.05 0.25 b.y (641)
Development of regolith (74240–49? and 74260?)	A few cm	$\Delta \sim 6\text{--}41$ m.y.
Pyroclastic eruption of orange glass and black, partially devitrified glass beads (double drive tube 74001/2 and 74220)	2–4 m (Visual estimate from photographs showing a dark layer in west rim of Shorty Crater; (642)	3.48 ± 0.03 (643)
Development of regolith (no known sample)	$\sim 2\text{--}5$ cm	$\Delta \sim 20 \pm 6$ m.y. (644)
Eruption of basalt lava deposit (74245, 74255 and 74275) (Type C?) that covered the pyroclastic deposit and protected much of it from regolith formation (645) and cosmic ray exposure (646)	~ 10 m	3.45 b.y.?
Development of regolith (no known sample)	$\sim 5\text{--}10$ m (647–649)	$\Delta \sim 3.34$ b.y.
Avalanche of South Massif regolith Stations 2, 2a, and 3) to create the light mantle unit (650). Probably related to the impact of ejecta from the crater Tycho (651)	~ 1 m (at Station 4)	95 ± 6 m.y. (652)
Development of regolith (LRV-5 and 6)	$\sim 5\text{--}10$ cm (653)	$\Delta \sim 75$ m.y.
Impact creating 110-m diameter Shorty Crater and excavating to a depth of 20–25 m	~ 14 m below the Preexisting surface (654), including a few meters into the Type A/B basalt unit	10 ± 3 (655) to 19 m.y. (656)

Table 3. (Continued)

Event	Thickness or dimension	Age or Δ time
Pressure-driven eruption of gas/ bead mixtures along conduits in the radial and circumferential fractures around Shorty Crater (657) and volatile migration, particularly Na (658), into surrounding regolith or deposition of portions of orange and black pyroclastic ejecta in the rim and wall of Shorty (659)	> 70 cm	Δ seconds to minutes
Development of regolith (top of drive tube 74001)	~ 0.5 cm (660)	$\Delta 7$ –19 m.y.

unusually high Na (550), which is otherwise depleted in crustal mare basalts relative to carbonaceous chondrites (551).

After mare basalt eruptions, and associated with many if not most eruptions of regional pyroclastics (552–554), normal faulting (555) occurred in nearby mare-filled basins. These faults produced many long, often arcuate graben valleys (556) (see Fig. 19). As discussed before, this phenomenon suggests that the stress regime of the lunar crust was tensional during the Basaltic Maria Stage and for some time before. Such a tensional stress field would be expected because thermal expansion and partial melting of the upper mantle began soon after the formation of the Cratered Highland Stage's insulating megaregolith. The more slowly expanding lower mantle may have maintained this global tensional field, long after heating and partial melting of the upper mantle ceased due to mare basalt eruption and consequent heat transfer to the surface. Long duration crustal tension may explain the existence of a structural moat or trough rather than the normal talus apron between the base of the Apollo 17's South Massif and the mare basalt fill in the Valley of Taurus-Littrow (557). A sporadic but continuous widening of the fault boundary that defines the south side of the valley (558) apparently has provided space for talus accumulation. Later regional relaxation of crustal tension would have contributed to the formation of the abundant mare ridges (559). These ridges, also called wrinkle ridges, constitute common features on the exposed surfaces of the lunar maria (560). They are apparently produced by regional compressive stresses associated with eruptive episodes of basalt of an age younger than the lavas affected or with the cooling of the upper mantle after eruptive activity ceased in a given region. The east–west to north–south Jefferson-Lincoln-Lee scarp that crosses the lower slope North Massif and the Valley of Taurus-Littrow appears to be such a ridge. It probably expresses the trace of a thrust fault (561). The absence of strike-slip faults (562) in this region as well as elsewhere on the Moon probably reflects the very low shear strength of the intensely fractured and brecciated outer lunar crust. That

some shear stress can be present in the Moon is indicated by local en echelon displacement of a few graben valleys (563). The greater curvature of the Moon relative to other planets may also contribute to the lack of significant regional shear stress (564).

Mature Surface (Stage 6—Pre-Nectarian—Present). Maturation of the surface of a lunar geologic unit begins with stabilization of the unit's upper surface. Primary and secondary impacts and space radiation cause some degree of modification on every surface formed on the Moon, however transitory its exposure may be to the space environment. A quantitative maturity index has been developed (565); however, it has become increasingly clear that factors other than age can effect the measured "maturity." Although the index is useful in comparing similar units, relative iron, and titanium contents of the original materials (566), and initial particle size and volcanic glass content (567) will affect its values significantly. For most of the lunar highlands, there was a continuous process of megaregolith development followed by normal regolith development beginning with the formation of the first coherent solid surface on the Magma Ocean. At a more detailed level, regolith development began region by region, area by area with the emplacement of the last ejecta derived from a large basin-forming event or from a crater that fully penetrated older regolith. Similarly, for the lunar maria, regolith development began basin by basin with the solidification of the last mare basalt unit at the surface. Thus, the Mature Surface Stage for the lunar maria overlaps much of the Large Basin Stage on the highlands and began in a staggered sequence between 3.8 and 3.0 b.y. ago on most of the maria, depending on the age of flow surfaces.

Regolith makes up the dominant maturation product (see Figs. 4, 8, 12 and 18). This layer of pulverized debris is developed largely through impacts, the largest producing fairly sharp, irregularly cupped contact on fractured bedrock. The regolith constitutes the upper tens of meters of surface materials in the highlands; however, over the oldest of the lunar maria, such as at Apollo 11's Tranquillity Base, the regolith reaches an average maximum depth of only about 6 m. Near contacts between the maria and steep highland slopes or where pyroclastic glasses have been added to the surface of earlier formed regolith, the overall depth of largely fine-grained debris increases. This has been studied best in the Valley of Taurus-Littrow. Here, highland debris from the North and South Massifs and glass beads from pyroclastic deposits have added several meters of thickness to the regolith (568). Cosmic rays and solar wind particles also modify the lunar regolith. Cosmic rays produce a variety of spallation isotopes useful in measuring the length of time materials have been exposed at or near the lunar surface (569). They induce the production of neutrons whose energy or temperature can be measured in lunar orbit and used to determine remotely the concentrations of some interacting elements in the regolith (570). High-energy solar wind ions, largely hydrogen and helium but containing significant carbon and nitrogen and minor noble gases as well, stream continuously from the sun, guided by solar magnetic lines of force. The flux of solar wind ions at the lunar surface varies with the quantity ejected from the Sun and because of interactions with Earth's magnetosphere. Upon impinging on the lunar surface, these ions are embedded continuously in the near surface mineral and glass constituents of the regolith, are partially released later by micrometeoroid impact and diurnal

heating, and are partially retained by burial under ejecta from impacts. To some degree, released species will be entrained in the passing solar wind ("pickup ions") and are either lost entirely or reimplanted elsewhere on the Moon. For any given regolith deposit, a steady state of solar wind concentration develops that depends on the overall length of exposure, so that the measured amount of retained solar wind increases roughly with the age of the underlying unit. A definitive model of this overall process has not been published; however, the analysis of lunar soils has disclosed the approximate steady-state concentrations of solar wind volatiles in samples and cores from the various Apollo landing sites (571,572). Most sampling, bagging, transporting, splitting, and distribution of Apollo samples was not designed to prevent the loss of contained solar wind volatiles. As a consequence, the vast majority of quantitative measurements of solar wind components in the lunar regolith samples must be viewed as minimum amounts, possibly in error by as much as 50 to 100%.

Evidence is strong that solar wind hydrogen and helium are retained selectively by feldspar and ilmenite, respectively. In the earlier discussion of the origin of vesicles in crystalline melt breccias, it was noted that epithermal neutron spectra, measured by Lunar Prospector (573), indicate variations in concentrations of protons (hydrogen) in the lunar regolith. Significant concentrations by factors of 2–3 exist in the lunar maria relative to the highlands. The feldspar crystal lattice can hold hydrogen in a cation position (574); however, the specifics of retention in lunar feldspars have not yet been addressed. Hydrogen's affinity for titanium, present in the mineral ilmenite [FeTiO_3] in most maria, may contribute to the retention of solar wind hydrogen in basaltic regolith. The Prospector data also show that hydrogen, specifically protons, are concentrated by factors of 3–10 at the lunar poles, apparently related to the generally colder regolith and to approximately 20,000 km² of permanent shadow in those two areas (575,576). The temperature of surfaces in permanent shadow is a constant -230°C in contrast to the maximum daytime temperature at the equator of $+123^\circ\text{C}$ (577). The Prospector Team (578) and others using data from Clementine (579) interpreted the epithermal neutron spectra to indicate the presence of large quantities of water ice. The Clementine data have been disputed vigorously (580). Still others have suggested that most if not all the signal in the polar regions is related to solar wind hydrogen (581,582). Water ice might be deposited as a consequence of cometary impacts on the Moon, as predicted theoretically (583). The interpretation of the Lunar Prospector neutron spectrometer data indicating water appears premature, however, in the face of the proven presence of more than 100 ppm solar wind hydrogen in many soil and regolith breccia samples (584). Solar wind hydrogen would also be concentrated and preserved as a distributed regolith component in the colder polar regions as well as in permanent shadow. In permanent shadow, no significant amount of implanted solar wind hydrogen would be lost to thermal cycling and both primary and pickup ions would be continuously deposited in such areas, albeit at a slower rate due to geometric factors. Further, a continuous blanket of cometary water ice, precipitated on rare occasions in permanent shadow, would remain subject to micrometeoroid erosion comparable to that which gardens the upper few centimeters of the regolith approximately every 10 million years (see data summarized in Table 3). Unless covered by protective ejecta from impacts or deposited in one of the few extremely

deep craters near the South Pole, as now postulated by the Lunar Prospector Team (585), the water ice blanket may erode and be dispersed in a geologically short interval. Some water ice and other cometary volatiles may be preserved beneath scattered ejecta blankets or in deep craters in permanently shadowed areas, depending on the frequency of cometary impacts relative to the rate of water ice erosion. Solar wind hydrogen, however, probably accounts for most if not all of Lunar Prospector's epithermal neutron signal.

The high-titanium regolith in the Valley of Taurus-Littrow has helped to quantify the correlation of solar wind helium content with TiO_2 in Apollo samples of regolith derived primarily from mare basalt. This relationship had been well-documented in samples from other Apollo sites (586). Because ilmenite is the only significant titanium mineral in the regolith, it appears to accommodate helium in its lattice better than other minerals and glasses. Helium release signatures from lunar samples containing ilmenite have been duplicated in terrestrial ilmenite irradiated with helium ions at solar wind energies (587). Significantly, the light isotope of helium, ^3He , holds great promise as a lunar resource export to supply future fusion power plants on Earth (588,589). Although the regolith in the valley of Taurus-Littrow has concentrations of ^3He , early resource production probably would concentrate on much larger areas in the Mare Tranquillitatis (590,591). The 2000-km long volcanic province of central Oceanus Procellarum constitutes another high-titanium region of the Moon; however, until direct evaluation of the strength of the titanium-helium correlation can be made specifically for this province, Tranquillitatis probably will remain the preferred target area for early production. If it is shown that the proton signal at the lunar poles is largely the result of a 3- to 10-fold concentration of solar wind hydrogen, then helium may be concentrated there as well. Whether such a concentration advantage can offset the higher cost of mining, living, and transportation inherent in any resource recovery at the lunar poles remains to future study.

During the Mature Surface Stage, impacts continued and declined to approximately present frequency levels (592) with some recently detected variability (593). They did not, however, change the face of the Moon significantly. Three billion years ago, the full Moon would have looked very familiar to a time traveler from our day. The type example of one of the few major impacts of this stage has been that which formed the 95-km diameter crater Copernicus (594,595) about 0.85 b.y. ago (596). Secondary projectiles from another such crater, Tycho, appear to have formed the cluster of craters in the central portion of the Valley of Taurus-Littrow and triggered the avalanche or landslide that produced the light mantle deposit (597) (see Fig. 3). This association, if valid, places an age of ~ 100 m.y. on the Tycho event (598). The plume-like avalanche deposit, essentially identical mineralogically and chemically to the regolith on the slopes of the South Massif, was investigated and sampled at Stations 2, 2A, and 3. An avalanche-related origin of the light mantle deposit is supported by an apparent vertical separation of rock fragments by size within the deposit (599). *In situ* screening of near-surface debris from both South Massif talus and light-mantle, produced a significantly lower frequency of rock fragments larger than 2 cm in samples from the light mantle. Additionally, visual comparisons of the size of boulders excavated by impacts into the deposit correlated roughly with the

diameter of craters, and thus with the depth of excavation. Sorting by size and the potential availability of hydrogen released by particle interaction in the flowing feldspathic regolith further suggests that the avalanche was gas lubricated. The liberation of solar wind gases by particle abrasion in regolith samples was demonstrated during soil mechanics experiments on returned samples (600).

Possible Implications

Apollo 17 had both the privilege and the sadness to be the capstone on humankind's first venture into deep space. The privilege came in contributing to the reemphasis of the potential of free men and women when given a challenge they believe must be met. The sadness lay in not continuing to amortize the investment of human lives, families, energy, and resources that made Apollo possible. Science, however, owes much to the explorations of the Moon and became the second major objective of this technological race into the future. As a consequence of obtaining an understanding of the evolution of a second planet, we now can look at other terrestrial planets with far greater insight than ever would have been possible otherwise (Fig. 20). The record of impact activity on the Moon, particularly that between about 4.4 and 3.8 b.y. ago, represents a period of Earth history that spans the time when complex organic molecules became replicating life forms (601–603) and continents began to form. During the first 200 m.y. of this period, the Moon's dry anorthositic crust was saturated with impacts capable of forming craters 60–70 km in diameter. On Earth, the pulverized and partially vitrified crust created by a similar saturation would have continuously reacted with water to create a wide spectrum of clay species (604), whose crystal structure may have been important as templates for organic synthesis. During this same interval, two and possibly more very large impact basins formed on the Moon; their terrestrial equivalent would have been larger and had thick interior melt-sheets. The differentiation of these melt-sheets would have yielded silica-rich disks thousands of kilometers in diameter and possibly tens of kilometers thick that became potential seeds for the aggregation of early continents. The existence of a continental crust on Earth has now been placed at least at 4.3 b.y. ago (605,606) and consistent in time with the formation of very large lunar basins. The next 400 m.y. on the Moon saw about 50 large impacts that created basins at least 300 km in diameter plus many more smaller. On Earth, a much larger number of similar events may have delivered additional organic components as well as augmented the initial continental material. The global effect, however, of such highly energetic and repeated impacts potentially would have assisted and disturbed the final development of replicating life forms. In addition to formation of complex molecules in terrestrial environments (607), a continuing influx of organic chemicals may also have arrived as constituents of comets (608). Recent isotopic evidence of terrestrial biological processes about 3.8 b.y. years ago (609) is consistent with the end of large basin formation in the inner solar system. Thus, the Moon gave us a window into the first 1.5 b.y. of Earth history, a period that culminated in the first isotopic indications of biological processes by life forms on our home planet.

Figure 20. Apollo 17's view of a nearly full Earth, photographed by the author from a distance of about 34,000 miles (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Other scientific implications of lunar exploration and research relative to understanding the other terrestrial planets and the asteroids are also profound. The Moon forms one end member in the planetary mass series Earth–Venus–Mars–Mercury–Asteroids–Moon (610). Having a detailed understanding of the nature and evolution of the two end members of this series, rather than of just Earth, has increased the value of remotely sensed data about the others by orders of magnitude. For example, new questions can be asked about the sequence of events during the formation of Earth's core (611). Discrepancies between the apparent ages of Earth and the Moon (612) can be approached from new directions (613). Evidence indicating that primitive lead isotopic ratios, chondritic tungsten isotopic ratios, and increased aluminum exist in the lunar mantle below about 550 km strongly suggests that the Moon had an original chondritic core of about 1200 km in radius. Further, $^{182}\text{HF}/^{182}\text{W}$ systematics constrain the crystallization of most of the lunar Magma Ocean to within the first ~40 million years of solar system history. These data may indicate that the

Moon evolved separately from Earth and was captured rather than originating as a consequence of a giant terrestrial impact. They also suggest that the original core of Earth, as well as those of Mars, Venus, and Mercury, would have been chondritic and comparable in size to the 1200-km protocore of the Moon. Initially, cool cores would have delayed metallic core formation resulting from the downward migration of iron-nickel-sulfur liquid separates from Magma Oceans. Age correlation of the start of global magnetism on the Moon with young, large impact basins indicates a delay of about 700 million years in lunar core formation. Prelarge-basin magnetic striping detected in highland units on Mars (614) suggests a shorter, possibly ~ 300 to 400 million year delay on that planet. On Earth, the delay may have been long enough to isolate radiogenic isotopic systems temporarily from magma ocean isotopic systems in an initially chondritic core. A delay in the mixing of these two systems after core formation may explain the paradox of model radioisotopic systems giving ages for Earth that are ~ 100 million years younger than the age of the Moon and meteorites.

Figure 21. Apollo 17's view of the rising crescent Earth from behind the Moon (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

The nature of Earth's crust when plate tectonic processes first began to assemble continents can be illuminated by joint consideration of the evolution of the Moon and Mars (615). Further, interpretations of spacecraft images and data from the other terrestrial planets invariably are considered first in the context of what we know about Earth and the Moon. The Asteroids, sampled by many meteorites and imaged by several spacecraft, can now be viewed confidently as largely the remains of a Moon-like planet, broken apart by interactions with Jupiter (616). Although our remotely sensed information about Mercury is limited compared to the other planets, Mariner 10 images and other data can be interpreted as disclosing a somewhat larger version of the Moon (617), but one that evolved much nearer the Sun and had a much larger metallic core. Global photography, orbiting sensors, and telerobotic landers have begun to illuminate the geologic history of Mars. Martian history now can be organized with reference to the sequence of major stages of lunar evolution, modified by our terrestrial experience with the effect of water and an atmosphere (618). Venus still holds many mysteries about its resurfaced crust in spite of the remarkable global coverage by the Magellan spacecraft's radar system (619). Using that imagery, however, and our knowledge of Earth and the Moon, we know the questions to ask about underlying materials and structures and about samples when they can be obtained from the surface of Earth's sister planet. Finally, the discovery of solar wind resources in the lunar regolith, particularly ^3He as a potential terrestrial fusion energy fuel, has joined

Figure 22. The Lunar Module Challenger at rest in the Valley of Taurus-Littrow on the Moon (courtesy of NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Earth and the Moon together as one environmental system for the future (Fig. 21). Our ability to be a truly spacefaring species in the foreseeable future may rest on the availability in space of lunar consumables, hydrogen, oxygen, water, and food. Ultimately, the returns on America's investment in Apollo (Fig. 22) will turn out to be as large and immeasurable as they were for those stimulated by Thomas Jefferson in the Louisiana Territory, Abraham Lincoln in Alaska, and many other public and private commitments to exploration and science.

ACKNOWLEDGMENTS

The author is profoundly indebted to the thousands of researchers who studied the Moon and planets through the ages and particularly since President John F. Kennedy issued his challenge for Americans to go to the Moon. The frequent citing of general review references in part acknowledges the vast numbers of individuals who contributed to any given area of investigation, and the reader is referred to these works to pursue the history of the development of particular data sets or interpretations. The author is also indebted beyond expression to the late Graham Ryder and to R. L. Korotev who provided extraordinarily valuable reviews of the technical portions of the manuscript that pertain to the origin and evolution of the Moon and were submitted for publication elsewhere. Their reviews improved the quality of those discussions immeasurably; however, the author takes full responsibility for any errors of omission or commission that remain in those or other sections.

ARIANE ROCKET PROGRAM

This article describes the circumstances that led Europe to go ahead with the Ariane Program in 1973 and subsequently to decide on a series of follow-up versions, up to and including Ariane 5. The article also describes the main management principles adopted that have varied little in 20 years and includes brief details of the successive launcher configurations from Ariane 1 to Ariane 5.

Page of History

In 1972, the European space community was in a state of crisis. It is interesting to look back at the situation which preceded this crisis to understand the reasons that led to the decision to proceed with the Ariane program and have subsequently guided the program up to the present time.

The first European initiative in the launcher field was taken by the United Kingdom in 1961, which put forward proposals to France, and later Germany, for manufacturing a launcher based on the Blue Streak, roughly similar to the American Atlas, designed and developed up to that time as a first missile stage. The Blue Streak stage was available, following a change of British policy in this domain. This was the basis for the Europa 1 project that was designed to place payloads of 1 metric ton into low orbit.

Unfortunately, the organization set up already contained the seeds of failure because the United Kingdom was supplying a first stage, whose characteristics were frozen, whereas France took on responsibility for the second stage, and Germany for the third stage. Each adopted its own technology and retained an autonomous stage, creating a total absence of anything resembling a system study or an attempt at general optimization. Furthermore, the program was created by cooperation among sovereign states, coordinated by a secretariat under the direction of a diplomat.

By 1966, there was no lack of technical and financial problems. The British threatened to withdraw from the project, which they did two years later. Therefore, the program was obliged to buy the first stage directly from United Kingdom industrial firms. The program was redirected toward geostationary orbit launches

(a satellite placed into geostationary orbit appears to be in a fixed position with respect to Earth), and a solid propellant fourth stage was added. At the same time, the Australian launch range was abandoned in favor of a new launch center to be constructed in French Guiana. The payload specification was then 270 kg in geostationary orbit, and the new program was dubbed Europa 2.

At the same time, geostationary orbit application prospects became clearer, and in 1970, Europe decided to commence studies and predevelopment work on a more powerful launcher (Europa 3) that could place 1500 kg payloads into geostationary transfer orbit (GTO). Unfortunately, the lessons to be learned from the Europa 1 failures were ignored insofar as program organization was concerned. Furthermore, although the first-stage technical configuration remained prudent, based on experience acquired by France from its Diamant program (first unit acquired in November 1965), the second stage was much too ambitious for Europe and involved a high-pressure liquid hydrogen/liquid oxygen topping cycle engine delivering 200 kN of thrust.

The period from 1969 to July 1973 was difficult for the European space community for the following reasons:

- In the technical context, Europa 1 launches F7, F8, and F9, made from the Australian base, all failed. The launcher on flight F11, the first launch Europa 2 made from the new range in French Guiana, exploded 150 seconds after lift-off on 5 November 1971.
- In the political sphere, Germany decided to withdraw from the Europa 2 program in December 1972 (which led to stopping that program in April 1973) and temporarily suspend its participation in the Europa 3 program. The Germans were also considerably attracted by collaborative proposals made by a NASA glowing from the success of the Apollo program. Germany considered that European efforts in the space transportation sector could be limited essentially to technological development, in parallel with major participation in the post-Apollo program. Nevertheless, negotiations between NASA and European representatives on that subject were difficult and engendered frustrations in Europe. At first invited to be involved in developing specific Shuttle hardware, the European contribution progressively narrowed to a science module that would fit into the Shuttle cargo bay.

France adopted a different approach that expressed a triple objective:

- acquisition of absolute control of space applications;
- founding of this control on an autonomous launch capability, with particular reference to geostationary satellites; and
- adoption of these first two objectives by its European partners to assemble sufficient financial capacity and sufficient volume to make production feasible.

However, these French ambitions were momentarily weakened by two launch failures in the Diamant national program in 1971 and 1973, despite the fact that they followed a run of six successful launches.

Finally, the Ariane program may well owe its very existence to the difficult negotiations undertaken with NASA in connection with the launch of the two “Symphonie” experimental telecommunications satellites. The extremely harsh conditions imposed on the German and French negotiators, including an embargo on using these two satellites for any commercial purpose in particular strengthened the determination to achieve the autonomy proposed by France. European agreement was finally achieved in July 1973, following a period of intensive negotiation.

It was decided to embark on three simultaneous programs:

- the “L3S” heavy launch program proposed by France at the end of 1972 (this program was renamed “Ariane” shortly afterward);
- the Spacelab program in cooperation with NASA, backed by Germany; and
- the “Marecs” maritime telecommunications program backed by the United Kingdom.

The principles of setting up the European Space Agency were also defined, and the Agency was officially formed in 1975.

The commitment made by France in connection with this agreement was very considerable and corresponded to more than 60% funding for the program, plus an undertaking to fund excess cost above 120% of the initial figure of MFF 2,060 (about \$ 447 M 1973) up to a maximum of 15% of this figure. In exchange, France obtained agreement that the European Space Agency (ESA) would delegate management of the program to the French Space Agency (CNES). The obligation to ensure a workload return for each participating country in proportion to its contribution was and is indeed a particular aspect of the ESA programs to be emphasized (Fig. 1).

The Early Days of Ariane

The performance objective for the L3S launcher was rather ambitious, based on the conviction that telecommunication satellites mass values would continue to increase and that Europe had to prepare itself for this evolution. Although the view was unanimous that the geostationary orbit was the most promising for application satellites, the figure of 1500 kg had already been the subject of arguments which were to be reopened at regular intervals when performance enhancements were proposed. The conflict was (and still is) between those who predicted a reduction in satellite mass values under the combined effect of electronic circuit miniaturization and the enhanced performance characteristics of satellite onboard propulsion systems and those who predicted a continued increase in mass values under the effect of traffic growth, congestion of the geostationary orbit, and the resultant reduction in in-orbit transponder cost. Finally, the payload mass objective adopted for the Europa 3 launcher was confirmed. It was set at 800 kg for geostationary orbits, corresponding to about 1500 kg in geostationary transfer orbit (about 200 km by 36,000 km). This represented almost twice the performance of the American Delta launcher, which had previously launched most application satellites for the Western world. This

Country	Contribution %	
	Initial	Final
France	63.87	73.55
Germany	20.12	11.47
Belgium	5.00	4.71
United Kingdom	2.47	2.27
Spain	2.00	2.38
Netherlands	2.00	1.64
Italy	1.74	1.58
Switzerland	1.2	0.83
Sweden	1.1	1.05
Denmark	0.5	0.52

Figure 1. National financial contributions. Financial management of the Ariane program had to ensure a fair return. This meant that each country was to receive a volume of business in proportion to its financial contribution. It was also expected that these figures would remain at the same level for the subsequent production phase. Already difficult to apply because it concerns an objective which is both final—including contingencies—and subject to examination when budgets are voted on for the following year, this constraint was further complicated for Ariane 1 by updating rules which varied from one country to another. For example, Belgium, France, and Switzerland made commitments based on a percentage of initial development cost, whereas Germany undertook to make an annual contribution, expressed in its national currency, which would be revised only once in midprogram, according to monetary parities and observed inflation rates. The United Kingdom was involved only through a specific agreement with France. Furthermore, inflation rates at the time were in double digits, and application of the rule of fair return, while fully understandable in principle, was far from easy. The figure compares the financial contributions at the start of the program with the final contributions.

performance was comparable with that of the Atlas-Centaur, which was used at the time only for few heavy satellites. This decision provided a substantial growth potential for European satellites and demonstrated a determination to design the Ariane launcher for an extended lifetime.

Past experience, as mentioned at the beginning of this article, demonstrated the absolute need for imposing three major principles at the very start of the program, namely, a genuine system approach, strong management, and a simple design.

The System Approach. This made it necessary to regard the Ariane launcher (and its ground support facilities) as a single entity, not merely a stack of independently designed stages; to base the development of these stages and other subsystems on the results of studies conducted at the highest level (trajectory, flight mechanics, general loads, thermal, guidance and control, etc.); to

design electrical systems in terms of the complete launcher, installing only actuator devices and equipment specific to its flight phase in each stage; and to impose design rules common to each discipline. For example, it was in this way that the need for POGO control systems was demonstrated at the beginning of the development phase. This meant that corrector devices could be designed and integrated into the propulsion systems at the outset. This was of even greater interest because Ariane was the first launcher designed entirely for geostationary orbit missions, in contrast to the other launchers existing at the time that derived to a greater or lesser degree from ballistic missiles. CNES entrusted a specific contractor (Aérospatiale) with this task and also associated Aérospatiale with the reviews conducted during the development of the various launcher systems and subsystems.

Strong Management. After obtaining delegated management authority, CNES spent the first year of the program establishing the basis for a strong management structure founded on a number of specific principles:

- unique management link between CNES, main contractors and other contractors;
- clearly defined industrial organization, with precise definition of the tasks allocated to each party. For the Ariane 1 program, CNES used the same French level 1 contractors as for its Diamant program, thus ensuring design unity in the main disciplines. These were Aérospatiale for the launcher stages, SEP (Société Européenne de Propulsion) for the propulsion systems, Matra for the vehicle equipment bay, and Air Liquide for the cryogenic third-stage tanks. Other contractors subsequently achieved level 1 status, including Contraves (Switzerland) for the fairing, DASA (Germany) for the second-stage and then the Ariane 4 liquid propellant boosters, Fiat-BPD (Italy) for the Ariane 3 and 4 boosters, etc.;
- a common understanding of the content of work to be done by each contractor, including achievements expected and reports to be submitted.

These principles led CNES to issue a set of management specifications applicable to each launcher system, subsystem and component, and also its ground facilities. These specifications covered overall planning and milestones, work breakdown structure, industrial organization, technical work coordination, schedule and cost reporting, monitoring of the development of critical elements, quality, and reliability. Application of such specifications in the context of a program involving 10 countries that differ in language and culture was a new departure for Europe and generated initial difficulties with companies each of which had their own particular methods of working. Nevertheless, this proved essential to maintain both visibility and coherence. These basic principles were also applied to the Ariane complementary development programs. They proved their effectiveness and made it possible to achieve effective control of technical development, costs, and time schedules.

Simple Design. This final point meant that the Ariane design should be based only on technologies which were either already available or involved only low development risks. The Europa 3 first stage had been designed on this principle,

applying technologies and experience acquired with the first stage of the French Diamant launcher. This stage was powered by four rugged “Viking” storable propellant engines, for which the prototype, designed in France, had been tested with very encouraging results before this program was terminated. Therefore, the Europa 3 stage was selected as the basis for the first stage of the Ariane launcher.

This could not be the case for the Europa 3 second stage that was considered much too ambitious for Europe in 1973. However, although a number of difficulties were to be anticipated if liquid hydrogen and liquid oxygen were used, the efficiency of these propellants would make it possible to reduce the lift-off mass of the launcher by a factor of almost 2. Furthermore, a certain amount of experience had been acquired on a low-thrust gas generator cycle prototype engine developed within the French national program. Work conducted in France and Germany during the Europa 3 program meant that this approach could be adopted with a satisfactory level of confidence, provided that there was no major deviation from the experience acquired from the engine and propellant and fluid system. Thus, the tanks were designed for 8 tons of propellant and a maximum possible diameter using available tooling not to exceed 2.6 m. Having made this choice, it was found necessary to add a second, intermediate stage to achieve the performance target. This stage was designed on the basis of elements and technologies developed for the first or third stage, including the Viking engine used in the first stage (with a suitably adapted nozzle) and the light alloy tanks of the third stage.

Ariane 1 Launcher

Ariane 1 was a three-stage launcher that had a total height of 47.8 m and a lift-off mass of 210 tons. The first stage had a dry mass of 13.3 tons, a height of 18.4 m and a diameter of 3.8 m. It had four Viking 5 engines (Fig. 2) that developed 2500 kN thrust on lift-off. Burn-time in flight was 146 s. The 148 tons of propellant (UDMH and N_2O_4) were contained in two identical steel tanks protected against internal corrosion by an aluminum layer and connected via a cylindrical skirt. The four turbopump Viking engines were mounted symmetrically on a

Figure 2. Viking engine flow diagram. The Viking engine uses the gas generator cycle, and the gas generator itself operates at a stoichiometric ratio. The gas produced is cooled by injecting water to reduce gas temperature to values compatible with the turbopump turbine, pressurization of the main propellant tanks, and operation of the power pack for the hydraulic servoactuators. The three pumps (UDMH, N_2O_4 , and water) are mounted on a single shaft that rotates at 10,000 rpm. (For Ariane 1, the chamber pressure was limited to 53.5 bars.) The hydropneumatic regulation system slaves the combustion pressure to a reference pressure value by adjusting the gas generator feed and, thus, the rotational speed of the turbopump. The mixture ratio is maintained at a constant level by a regulator that equalizes propellant pressures before injection into the combustion chamber. Engine ignition is induced by the pressure in the propellant tanks. When the valves open, the propellants, which are hypergolic, are delivered to the combustion chamber and gas generator and ignite spontaneously. The turbopump speed then builds up to the value set by the regulating system in 1.3 s. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

thrust frame and articulated in pairs on two orthogonal axes to provide for three-axis attitude control. An annular water tank, located inside the propulsion bay, provided for cooling the gas obtained from the engine gas generators that was used to pressurize the propellant tanks and supply the hydraulic motors of the attitude control actuator systems. Four fins with a surface area of 2 m^2 provided aerodynamic stability. This first stage was designed to destruct approximately 30 seconds after stage one to two separation.

The second stage had a dry mass of 3.13 tons (excluding the interstage conical skirt and the jettisonable acceleration rockets), its height was 11.6 m, and its diameter was 2.6 m. It had a single Viking 4 engine that developed 740 kN thrust in vacuum for a burn-time of 136 s. The motor was linked to the conical thrust frame via a gimbal with two degrees of freedom, that provided pitch and yaw control. Auxiliary nozzles supplied with hot gas from the engine gas generator provided the roll control function. The two aluminum alloy tanks that had a common intermediate bulkhead were pressurized with helium gas (3.5 bars) and contained 34.1 tons of propellant (UDMH and N_2O_4). The second stage was also designed to destruct about 30 seconds after stage two to three separation. During the prelaunch waiting period on the pad, a thermal shroud, ventilated with cold air, which restricted heat exchange between the propellants and the environment, protected the second-stage tanks. This shroud was jettisoned on launcher lift-off.

The third stage weighed 1.164 tons dry, was 9.08 m high, and had a diameter of 2.6 m. This was the first cryogenic stage produced in Europe. It was equipped with a type HM7A engine that developed 62 kN thrust in vacuum for a burn-time of 545 s. This engine was designed by Société Européenne de Propulsion (SEP), based on experience acquired with an earlier cryogenic engine, the HM 4, which delivered 40 kN thrust, and tested over the period 1962–1969. The HM 7a engine uses the conventional gas generator cycle technology, and achieves a specific impulse of 443 s with a mixture ratio of 4.43 at pump inlet. The combustion chamber is supplied with propellants pressurized by a turbopump, via a set of injection valves. The pump turbine is driven by gas supplied by a generator, the latter receiving a small proportion of propellant tapped off at the pump outlet. The liquid hydrogen and liquid oxygen tanks that contained a total of 8.23 tons of propellant were made of an aluminum alloy and had a common intermediate bulkhead (double skin under vacuum). The tanks were covered with external thermal protection to avoid warming the propellant. Both tanks were pressurized in flight, using hydrogen gas tapped at the outlet from the regenerative chamber and helium. The motor was linked to the conical thrust frame via a gimbal that provided pitch and yaw control. Auxiliary nozzles ejecting hydrogen gas were used for roll control.

The stages were separated by pyrotechnic cutter devices fitted on the rear skirts of the second and third stages. The separating stages were distanced from each other by retrorockets incorporated in the lower stage and acceleration rockets mounted on the upper stage. Stage 1 to stage 2 separation was controlled by the onboard computer, on detection of first-stage thrust decay (propellant exhaustion). Stage 2 to stage 3 separation was controlled by the onboard computer when the second-stage speed increase reached 1500 m/s.

The vehicle equipment bay (VEB) weighed 316 kg, had a diameter of 2.6 m, and was of 1.15 m high. Mounted on the third stage, the VEB contained the

electronic equipment of the launcher and also served as a base for the payload and fairing. In addition to the onboard computer, the VEB housed all of the electrical equipment required for executing the launcher mission, namely, the sequencing unit, guidance and navigation control, and the location, safety, and telemetry systems. Only the power systems and actuator devices were located elsewhere in the launcher stages.

The two half-fairings were ejected parallel to the main axis of the launcher under the control of the onboard computer, as soon as the calculated thermal flux dropped below the specified level. The fairing was jettisoned by two pyrotechnic systems, a horizontal system at the interface with the VEB and a vertical system which also served to impart horizontal velocity to each half-fairing. The fairing was 3 m in diameter and was compatible with Atlas-Centaur class satellites.

The launch facilities in French Guiana (ELA 1: Ariane launch site No1) were designed to make use of the earlier investment for the Europa 2 launcher. The stages were erected and assembled directly on the launch pad. A mobile gantry sheltered the launcher and provided for assembly of the payload with the launcher and closure of the fairing under clean room conditions. The gantry withdrawal commenced 6 hours before lift-off. The main fueling of the third stage with liquid hydrogen and liquid oxygen and final topping off were performed using a cryogenic arm system carrying a set of umbilical valve plates. Disconnection and retraction of the arms commenced at time $T - 3$ s. Control of the launcher on the pad was fully automatic from time $T - 6$ minutes. The launcher was then controlled by two ground computers, one for the electrical systems and the other for the propellant and fluid systems. The two computers also cross-checked each other. The first stage engine was ignited at time T , and the lift-off command signal was sent at $T + 3$ s, following satisfactory verification of the Viking engines. The first flight took place on Christmas eve 1979 (Fig. 3).

When the Ariane program was first initiated in 1973, few imagined a commercial career for the launcher. Things began to move in 1976 and led to a series of actions relating to launcher performance, production, and marketing. As regards performance, the idea was to propose Ariane for launching the Intelsat satellites. The success of such a venture would represent both an exceptional reference for the program and strong motivation for the players involved. However, the first task was to augment performance objectives up to 1600 kg minimum in GTO. Fortunately the prudent approach adopted for the basic definition of the launcher, combined with the results of the first flight, demonstrated propulsion performance in excess of specifications and made it possible to exceed the initial objective and achieve a figure of 1850 kg.

As far as production was concerned, it was obvious that there was no hope of selling the launcher if one waited to receive orders before commencing manufacture. It was on these lines that discussions were opened at the European Space Agency, and a promotional phase was duly adopted. Apart from the production of six launchers, the objective of this phase was to achieve full operational qualification, develop and validate the dual launch capability, and adapt the launcher comprehensively to meet user needs by providing for the construction of payload preparation facilities in French Guiana. Analysis of marketing aspects led to two actions: initiation of the Ariane 3 program and formation of Arianespace.

Ariane 3 Program

At the end of the 1970s, the application satellite market was organized around two launcher groups. These were the Delta launchers, for which GTO performance in 1978 was around 1200 kg and the Atlas-Centaur launchers whose performance figure was close to 1800 kg. Apart from the Intelsat satellites, all other payloads corresponded to the Delta class, for which Ariane could not pretend to be competitive in its actual state. The idea then emerged to adapt the launcher to enable it to launch two Delta class satellites simultaneously, thus raising the performance objective to twice 1200 kg, plus the mass of the dual launch structure designed to isolate the two satellites from each other. This corresponded to a total GTO mass of 2500 kg. The launcher also had to be competitive with the Atlas-Centaur.

This program was proposed by France to the European Space Agency and was approved in July 1980, despite the failure of the second Ariane flight (L02) in May of that year. CNES was charged with managing the Ariane 3 program, under conditions very similar to those for Ariane 1.

Analysis conducted from 1976 and aimed at increasing the performance of Ariane 1, had in fact identified modifications whose feasibility was checked out during the final development test phase. These modifications were adopted in part or in full for the Ariane 3 program, in accordance with the policy of minimizing development risks. The addition of two solid propellant boosters achieved

Figure 3. Launch L0 1 (24 December 1979). The decision to proceed directly to flight tests, using three active stages in the final flight configuration, was made following very lengthy discussions at the start of the Ariane program. This was in total opposition to the highly progressive, but also extremely costly approach adopted for the Europa 2 program. Initial ignition occurred on 15 December 1979, following a faultless countdown. Unfortunately, the ground computers did not authorize liftoff, and the engines shut down automatically at time $T + 10$ s and aborted the launch. Subsequent analysis showed that an explosion in a small measurement pipe had damaged the sensors, whose signals were used for operational diagnosis of the engines. The case of an aborted launch, for which the probability was infinitely small, had, nevertheless, been taken into account during the development phase. Procedures for return to flight configuration had been written and validated by tests conducted in Europe. This allowed restarting the count on 23 December, following 8 days of round-the-clock work. Technical problems, combined with adverse meteorological conditions, prevented a launch on 23 December. On the following day, Ariane made a practically faultless launch. Only two anomalies were identified, and these were corrected before the following flight. These concerned minor pollution of the payload, caused by the second-stage retrorockets and low amplitude vibrations (POGO effect) at the end of the second-stage flight. The first Ariane launch thus took place only 6 months after the initial target date set in 1973.

The second launch in May 1980 resulted in a failure. Destruction of the launcher occurred at $T + 63.75$ s, as a result of high frequency combustion instability in one of the first-stage Viking engines, 2.75 seconds after liftoff. Corrective measures essentially comprised modifying the propellant injection orifices in the combustion chamber. A total of 95 tests that represented 4300 seconds of burn-time were conducted to qualify the new injector under conditions substantially more severe than those encountered in actual flight. The Ariane 1 development phase terminated in December 1981, following three successes out of the four launches made. The total cost of the program was within 120% of the initial estimate. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

the objective of competitiveness, with Ariane 3 for two satellites of 1200 kg each, and Ariane 2, with no boosters, for satellites of 2000 kg.

These performance objectives were achieved on the basis of the Ariane 1 launcher by introducing the following modifications:

- increased thrust for the first- and second-stage Viking engines by augmenting combustion pressure by 10% (53.5 bar to 58.5 bar). This was obtained mainly by adding hydrazine hydrate to UDMH;
- adding two solid propellant boosters with a unit thrust of 600 kN and a burn-time of about 40 seconds. The low level of performance sensitivity to the structural mass of the boosters made it possible to adopt extremely prudent technical solutions;
- increase in the third-stage propellant load from 8 to 10 tons;
- enhancement of Stage 3 performance by increasing combustion chamber pressure by 5 bar and stretching the nozzle by 200 mm (HM7 B);
- adaptation of the SYLDA dual-launch system and the fairing to the volume required for 1200 kg-class-satellites.

Figure 4 shows a SYLDA dual-launch structure and half a fairing. The lower satellite is placed inside an egg-shaped compartment. Protected by the fairing, this carbon fiber structure is subject to reduced loads by comparison with an external structure. Furthermore, the operational constraints induced by the need to carry two satellites remain within acceptable limits.

The SYLDA structure makes it possible to achieve complete separation of the two payloads. The long orientation sequence, spin-up phase and separation of the satellites and upper part of the SYLDA, are achieved by the SCAR attitude and roll control system, using third stage pressurization hydrogen gas to operate this system.

Tested successfully on the sixth launch, this concept was unquestionably one of the keys to the success of Ariane. The cost of a launcher is not proportional to its size, and a number of functions must exist whether the launcher is small or large. A dual-launch capability, taking advantage of this scale effect, represents a major competitive plus factor.

The industrial organization was the same as that for the Ariane 1 program; the only main modification was an increase in the Italian contribution, which led to entrusting the development of the solid propellant boosters to FIAT-BPD. The first Ariane 3 was launched successfully in mid-1984.

Arianespace

The lengthy discussions which took place at the European Space Agency and led to the decision to go ahead with production of six Ariane 1 launchers, also demonstrated that this multinational organization, whose basic purpose was research and development, was not suitable for engaging in commercial and production activities. At the same time, the promoters of Ariane reached another paramount conclusion. For European autonomy to be effective in access to the geostationary orbit, the Ariane launcher had to be credible. To this end, it had to be both reliable

Figure 4. SYLDA, Ariane dual-launch system. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

and available, in other words produced in sufficient quantities and in advance of actual launch needs. This called for world-scale marketing, and at the same time made it possible to spread the fixed production costs over a larger production volume, and thus reduce the cost of the autonomy-related strategy (in contrast to its American competitors, Ariane did not have a major captive market for launching governmental satellites, to which all or part of the fixed costs could be allocated). Only a private commercial entity, responsible for both Ariane production, marketing, and launch operations, could take up this challenge.

In December 1977, Frédéric d'Allest, then head of the CNES launcher division and future Chairman and CEO of Arianespace, proposed forming a company to market the Ariane launcher. *Arianespace* was incorporated on 26 March 1980, well before qualification of the Ariane 1 program. *Arianespace* is a French business corporation. Its capital is held by CNES, the leading European manufacturers that participate in Ariane production, and a number of banks. *Arianespace* is responsible for producing, launching, and marketing the Ariane launcher or launchers, whose development and qualification have been, are, or will be conducted by the European Space Agency.

The first Arianespace commercial launch was made successfully on 22 May 1984, inaugurating the very first commercial space transportation service.

Quality

A number of technical difficulties were encountered during the early days of the Ariane program, resulting from residual design problems or omissions in the production files. The European launcher industry was in its infancy was in the process of discovering the problems inherent in launcher batch production, and had to acquire expertise in this demanding discipline. Major efforts were made during the 1980s to amplify and correct the production files, identify and analyze all defects irrespective of their importance, and carry out regular tests on equipment sampled from the production line. The severity of these tests frequently exceeded the levels specified for the qualification tests. The flight data measurement plan that covered more than 700 parameters for which results were transmitted to the ground during the qualification flights—this figure was reduced to 400 for operational flights—made it possible to analyze each flight in the finest detail and thus acquire in-depth knowledge of the launcher. This unprecedented quality construction program, conducted by a European team highly motivated at all levels, meant that the 90% reliability objective assigned to the Ariane in 1973 was quickly exceeded. By the end of October 1999, a total of 118 Ariane launchers (versions 1 to 4 inclusive) had flown, and the reliability figure for Ariane 4 exceeded 97% after a string of 48 consecutive successful flights.

Marketing

Ariane marketing operations achieved rapid success, despite a number of technical difficulties encountered at the start of the program. The success of the development plan, combined with the appraisals conducted by potential customers, bred a high degree of confidence in the European launcher and the French Guiana ground facilities. The first non-European customer to place an order for Ariane launch services in 1978 was Intelsat (International Telecommunications Satellite organization), well known in the satellite world for its technical expertise. This choice was extremely important for Ariane and induced confidence on the part of other customers, who then decided to regard the Ariane launch system objectively. Apart from its own inherent merits, Ariane had the advantage of a favorable market situation. Commissioning of the American Space Shuttle led NASA to stop producing its conventional Delta and Atlas-Centaur launchers. Delays with the Shuttle, due to technical difficulties, discouraged satellite operators, obliging them to seek other launch possibilities. Furthermore, the high U.S. dollar exchange rate during the early 1980s made Ariane prices extremely attractive compared with the American launch systems. This marketing success grew further with the passage of time. The first Ariane 3 flight in August 1984 qualified the dual-launch capability of two Delta class spacecraft and significantly increased both the launch capacity and competitiveness of the Ariane system.

In 1985, Ariane launched the same number of commercial satellites as the Space Shuttle, and in the following year, *Arianespace* signed no fewer than 16

launch contracts. By 1987, Arianespace had 57 contracts (satellites to be launched or already launched) from the European Space Agency, the member countries of the European space community, international organizations, national organizations in non-European countries and private companies, representing a total sales value exceeding FF 16 billion (about \$2.25 billion). *Arianespace* had acquired a share of more than 50% of the open satellite market, a position that the company has succeeded in maintaining despite increasingly severe competition.

Ariane Launch Site No. 2 (ELA 2)

France decided to construct a launch range in French Guiana in April 1964, after the deciding to discontinue launch operations from the Hammaguir range in southern Algeria. The French Guiana site was chosen as a result of a comparative study of a number of possible locations. Paradoxically, if we compare the 1964 situation with that of today, equatorial launches, if they were even mentioned, did not initially constitute a priority criterion. However, this view was quick to change, and in July 1966, the European launcher organization accepted the French proposal to contribute to constructing an equatorial launch base in French Guiana, initially intended for Europa 2. It should be noted that at that time, 33 years ahead of the Sea Launch project, the French Guiana site was in competition with a floating marine platform project proposed by Italy, similar to the San Marco platform which it was then operating offshore from Kenya.

A decision was quickly made in favor of the Kourou site (the population of the village of Kourou was 660 in 1964) on the Atlantic seaboard 70 km northwest of Cayenne in a sparsely populated region. The exceptional geographical characteristics of this site combined a wide launch arc over the ocean and favorable climatic conditions (infrequent storms, no cyclonic or seismic activity, and temperatures varying only slightly round a mean figure of 25°C). All types of mission (polar and equatorial orbits in the range -10.5° to $+93.5^\circ$) could be planned in complete safety, an advantage that no other operational base possessed then. The closeness of Kourou to the equator ($5^\circ 2' \text{N}$) is ideal for placing telecommunications satellites into geostationary orbit. At this latitude, the slingshot effect induced by the rotation of Earth is near its maximum, and propellant consumption for adjusting the plane of the geostationary orbit is minimum. In global terms, the mass gain achieved with a launch from Kourou is approximately 17% compared with a launch from the Cape Canaveral, using an identical launcher.

The Guiana Space Centre (CSG) facilities were first operationally tested in April 1968 with the launch of a Véronique sounding rocket, and the Centre was inaugurated officially in 1969. The first satellite was launched on 10 March 1970 with the French Diamant B launcher. The first Europa 2 flight was in November 1971, using the new CSG launch pad. The failure of this launch had a series of consequences already mentioned at the beginning of this article. For both economic and political reasons, it was essential for the Ariane 1 launcher to make the best possible use of the heavy investments made in Europa 2. Nevertheless, certain facilities were unsuitable for launch operations with Ariane because of insufficient capacity and lack of operational flexibility and due to an absence of

any growth potential. This made these facilities largely incompatible with the Ariane performance enhancements already under study. After proposals from the French Space Agency (CNES), the European Space Agency (ESA) decided to construct Ariane launch site No. 2 (ELA 2) in July 1980. This new facility was required to meet the following specifications:

- provision for 10 launches per year (Ariane 2, 3, or 4) and execution of two launches within an interval of less than one month;
- provision for replacing a launcher already on the pad, in case of need, by the launcher scheduled for the next flight;
- provision for preparing larger payloads with improved facilities for payload/launcher integration.

The design of the new launch site differed from that of ELA 1. The time spent by the launcher on the pad had to be reduced to a minimum to allow for executing launch operations and postlaunch rehabilitation of the pad within a maximum 1 month. This assumed locating a launcher preparation zone on the edge of the safety perimeter.

Following their arrival from Europe, the stages are erected, assembled, and tested in the rear preparation zone. Then, the launcher on its mobile launch table is transferred to the pad via a dual rail track (Fig. 5). There it is connected to the propellant and fuel circuits and undergoes a launch rehearsal procedure, including filling of the third stage with liquid hydrogen and liquid oxygen to check the absence of ground and onboard leakage. The success of this operation authorizes assembly of the upper part (payloads, adaptors, and fairing were integrated beforehand in a dedicated building) with the launcher. The principles of

Figure 5. ELA 1 and ELA 2 launch sites. ELA 1 site (foreground): Ariane 3 launcher during third-stage fueling tests on day D – 9. At rear: Ariane 4 launcher recently arrived on the ELA 2 pad. Note the double rail track between the pad and the preparation zone (background). The white circle midway down the rail track is a turntable, used to allow two launchers to pass each other if necessary. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

the launch sequence qualified on the ELA 1 site have been retained. The ELA 2 pad uses many of the support facilities previously used for ELA 1.

Ariane 4 Program

Ariane 3 represented a short-term response that enabled the Ariane launcher to position rapidly vis à vis its two American competitors, Thor Delta and Atlas-Centaur. The arrival of the Space Shuttle at the end of the 70s and the policy adopted by NASA of marketing Shuttle flights at extremely attractive prices required a more comprehensive response from the Ariane program.

It was obvious that the NASA price policy would lead to a profound change in satellite design, broadly on the following lines:

- increase in Delta class satellite size and mass, up to the point of occupying, in a vertical position, the maximum volume available in the Shuttle cargo bay. This led to satellites of between 1400 and 1500 kg for injection into geostationary transfer orbit;
- appearance of a family of satellites installed in a longitudinal position in the Shuttle cargo bay, designed to take advantage of the large diameter available and reduce launch cost (dependent on the height of the satellite). Corresponding changes, that involved problems of both mass and diameter were more difficult to predict.

As regards satellite mass, there were some projects for TV satellites of 2500 kg. However, these were rare and still only moderately credible at the end of 1980, in particular among those who predicted a reduction in satellite mass values from miniaturization of satellite electronics. However, things moved in 1981, and the objective of 2500 kg was finally adopted.

The diameter problem was even more delicate. The Ariane program team foresaw major aerodynamic problems if the fairing diameter exceeded by too great an extent the 2.6 m diameter of the third stage on which it was mounted. However, determination of this value required aerodynamic tests that were too lengthy to conduct before making the decision. The diameter of 3.65 m finally available for payloads was in fact the result of a compromise between what the program team considered possible at the least risk and the sacrifice which satellite customers were prepared to accept for the advantage of a second launch service source.

Competitiveness requirements dictated the pursuit of the dual-launch policy implemented for Ariane 3. The GTO performance objective assigned to Ariane 4 was consequently an ability to execute simultaneous orbit injection of two payloads, one of 1400 kg and the other of 2500 kg, giving a total of 4300 kg, including the mass of the dual-launch structure. (Note that this objective had increased from 3400 to 4300 kg in 1981 and that the maximum performance demonstrated in 1999 exceeded 4900 kg.)

This program was to be regarded as a continuation of the Ariane family, in other words as a complementary performance enhancement phase, taking full advantage of work carried out for Ariane 2 and 3, and innovating as little as possible in propulsion. This was decided to take the fullest advantage of

experience already acquired and to improve the reliability target from 0.90 to 0.92. Given the ambitious performance objective that had been set, the configuration adopted was required to embody a certain degree of flexibility with regard to lower mass payloads to apply an attractive pricing structure for a wide range of satellites. Single launches of heavier satellites like Intelsat 6—3600 kg—had to be possible, of course.

These performance objectives were achieved on the basis of Ariane 3 by introducing the following modifications:

- First stage propellant load increased from 147 to 227 tons, while retaining the same operating point for the Viking engines as qualified for the Ariane 3 program. Stage 1 burn-time was increased to 205 s.
- Development of a liquid propellant booster, corresponding to a reduced scale copy of the first stage as it uses the same engine with an appropriately adapted pressure ratio, and the same tank pressurization system. Identical stainless steel tanks carry 39 tons of propellant.
- Adaptation of the Ariane 3 solid propellant boosters. Carrying 9.5 tons of propellant, these boosters burn for 36 s and deliver 650 kN thrust each.
- Development of a new water tank, located on top of the UDMH tank. This tank is constructed in composite materials, and supplies the first stage and liquid propellant boosters in blow-down mode.
- Modification of the vehicle equipment bay structure, to achieve better payload integration flexibility and easier transition to the new fairing diameter.
- Development of an external Ariane dual-launch carrier structure (SPEL-DA), providing for dual launches of large-diameter satellites.
- Development of a new fairing with a useful diameter of 3.65 m.

This program was proposed by France to the European Space Agency and formally accepted in January 1982. The same program management principles were adopted as those for Ariane 1 and 3.

Launcher Development. The development phase did not introduce any major innovations in propulsion. First, the first-stage propulsion bay had performed extremely satisfactorily on the test bed in the Ariane 3 development program for burn-times very close to those required for Ariane 4. Furthermore, the booster propulsion system was based on a configuration already used to develop the Viking engine. Consequently, insofar as propulsion was concerned, the task was one of optimization or of demonstrating new operating margins because the burn-time for the Viking engine had been increased substantially. On the other hand, work relating to the launcher system was substantially more complicated than first thought. It was found necessary to adopt the complete system approach for each lower composite configuration. Furthermore, the increase in the height of the launcher and the size of the upper composite were reflected in a considerable increase in general loads that required substantial modification of a number of structures, including connecting flanges, in particular. Furthermore, first-stage in-flight stability was a major source of concern during the first few years of the program. Digital control was adopted to introduce a large degree of flexibility in the development time schedule and also with actual operation of the

launcher by making it possible to finalize the configuration of each launcher only 2 months before lift-off. Today, Ariane 4 can place from 2.1 to 4.9 tons in a typical GTO orbit, depending on the number of liquid (L) or solid (P) propellant boosters fitted on the first stage (AR 40,42P,42L,44P,44LP,44L). Nine different configurations of SYLDA, SPELDA, and fairings were available for payload accommodation. The Ariane 4 maiden flight, initially planned for late 1985, took place successfully on 15 June 1988.

The Birth of Ariane 5

Initial reflection at CNES on Ariane 5 dates back to 1978. At that time, the Ariane 5 launcher was regarded more as a means to access low-orbit, manned-flight missions. Nevertheless, the launching of application satellites into geostationary transfer orbit continued as an objective, in particular in triple-launch mode, to pursue the Ariane scale effect competitiveness approach. The two missions rapidly acquired identical importance.

In contrast to the approach adopted for the American Space Shuttle, the primary principle adopted was that priority should be given to competitiveness for commercial flights. Manned spaceflight induces substantial costs that it is absurd to impose on operations that can be conducted by an unmanned vehicle. The system proposed had to be capable of manned flight and unmanned flight missions without increasing the cost of the latter. Consequently, the new launcher had to be regarded and optimized as a single entity at the design stage to ensure optimum use of available resources, and the manned flight aspect had to benefit from lessons learnt from unmanned missions, while also providing for substantially dissociated use when the operational phase was reached. The manned module was consequently designed as a “special payload” mounted on top of the launcher. The capsule and spaceplane concepts were then analyzed in parallel. The latter presented the advantage of a considerable reentry cross-range and a high degree of orbit return flexibility that provided for a soft landing and consequent reuse. The onboard intelligence provided launcher “brain” functions during the ascent phase and thus eliminated the need for a vehicle equipment bay required for unmanned flight. This, then, was the Ariane 5 - Hermes concept at the end of 1979.

At that time, Ariane 5 comprised the Ariane 4 first stage, and a new second stage burning liquid hydrogen and liquid oxygen (H 55), carrying Hermes for manned missions or the Ariane 4 third stage (H 10), the vehicle equipment bay, and fairing for unmanned flight. This study, which emphasized the need for a large cryogenic engine for future Ariane improvements, made it possible to propose and obtain funding for a 3-year French national program in 1980 and to commence work on the basis of design for an engine to deliver 600 kN thrust. Germany, Sweden, and Belgium joined this project under the terms of bilateral agreements.

Partially Reusable Concept Studies. In 1980, the impact of the Space Shuttle and its price policy led to strong criticism of the conservative characteristics of the Ariane 5 configuration. As a matter of principle, reusable concepts were regarded as more economical, the more so because the maintenance costs for such systems were ignored and operating costs were substantially underestimated. Considerable attention was then paid during that year to improving the

cost levels and analyzing the operating costs announced for the Space Shuttle and those observed for the early stages of the Ariane operational phase. In parallel, the problems induced by the rehabilitation of equipment used during the Ariane 1 development phase demonstrated the importance of the corresponding work and the complementary qualification cost that would be required.

A number of concepts were considered:

- recovery of the first stage by parachutes. This was tried unsuccessfully with the first stage of the Ariane launcher used for flight 14. The liquid propellant boosters for Ariane 4 were also initially designed to facilitate this type of recovery.
- design of a first stage comprising a stack of several H 55 stages, recovered individually using a delta wing;
- consideration of a winged first stage, etc.

This line of approach failed to produce any attractive, realistic solutions, and was abandoned early in 1982.

Comparative Configuration Studies. A systematic review of all possible concepts that matched the performance objectives was then undertaken. More than 24 different configurations were drawn and assessed for performance and cost. A configuration involving a large cryogenic core stage flanked by two large solid propellant boosters was examined and then abandoned because it was impossible to identify a derivative solution, with reduced performance, which would have made it possible to adapt a launcher configuration to the mission model in the same way as with Ariane 4. This configuration was looked at again, when the desired degree of flexibility had been introduced by offering the choice of an Ariane 4 third stage (H 10), or alternatively a highly simplified storable propellant stage, and after further studies had made it possible to set an acceptable price objective for manufacturing the solid propellant.

Finally, these three configurations were selected for more detailed comparative analysis in mid-1983:

- a solution that corresponded to direct continuity with Ariane 4 but introduced a cryogenic second stage. This solution was derived directly from experience acquired from Ariane 4 and made it possible to evaluate cost and performance extremely precisely.
- a solution based on the above, replacing the Ariane 4 first stage with a cryogenic stage equipped with four or five engines identical to that used for the second stage. This solution had the advantage of requiring only development of a single propulsion engine, namely a high-thrust LOX/LH₂ engine.
- a solution involving a large cryogenic core stage, flanked by two large solid propellant boosters. This basic composite carried a simple storable propellant upper stage for low-performance missions or a cryogenic stage that carried 10 tons of LOX/LH₂ (Ariane 4 third stage) for high-performance missions.

All three configurations required developing of a new LOX/LH₂ engine. This conclusion led France to propose the development of an engine of this type, based

on the project commenced in 1980, to the European Space Agency. A further year was then devoted to a detailed comparative study of the three configurations.

The configuration that had large solid propellant boosters was finally selected on the basis of intrinsic reliability, recurrent cost, greater potential, and development time schedule control criteria. Only the safety criterion remained questionable. Compared with the abrupt failure of solid propellant boosters, their liquid propellant counterparts are always presented as easy to control. Nevertheless, in-depth analysis of the complete system demonstrates that this is not always the case, and that even in this favorable situation, there are still flight phases where the spaceplane (in contrast to a capsule) simply cannot accomplish its true rescue mission. (Long after this choice had been made, this frequently impassioned discussion was stimulated once more following the Challenger failure.)

Therefore, the configuration that incorporated two solid propellant boosters was finally presented in 1985 and adopted as a European Space Agency program in 1986 and 1987. Further optimization led to incorporating the following aspects:

- abandonment of the triple-launch concept in a basic mission context due to the excessive operational constraints relating to the satellites (availability);
- increase in payload mass values: the nominal performance objective was then dual launches into geostationary transfer orbit for satellites of 2950 kg each;
- mass problems encountered with the Hermes program. This led to an increase in the performance of the lower composite and abandonment of the cryogenic upper stage.

Ariane 5 Specifications. Final specifications for the Ariane 5 program were as follows:

- simultaneous launch of two satellites of 2950 kg and a diameter of 4.53 m into geostationary transfer orbit under environmental conditions and with a degree of precision, etc., comparable with Ariane 4 launches, representing a single-launch performance equivalent of 6800 kg;
- launch of an 18-ton payload into a circular orbit of 550 km, inclined at $28^{\circ}5'$;
- Hermes launch: this mission was not to introduce constraints liable to penalize unmanned flight. Consequently, performance requirements for this mission were deduced from those specified for unmanned flight, taking due account of safety constraints;
- Reliability of unmanned flight was set at 0.98, almost 10 times higher than the initial specification for Ariane 1. This ambitious target was justified by the high cost of insurance for both launcher and satellites (over 20% in 1988) and the major consequences of a flight failure. The safety of the crew was consequently provided for by ejection of the Hermes spaceplane on detection of an operating anomaly. The safety objective for the crew was set at a figure of $1 - 10^{-3}$.
- Cost objective per launch, on the basis of eight launches per year, was set at 90% of the figure for an Ariane 44 L. Given the respective performance of the two launchers, this corresponded to a reduction of 45% in the cost per kilogram in orbit for an equivalent fill factor.

- The target for a maiden flight was initially set for April 1995. It was subsequently put back by one year due to a number of economic constraints.

As for earlier Ariane programs, management was delegated to the French Space Agency (CNES) by the European Space Agency. The conditions for this delegation of authority were more restrictive in this case, however, due to the need for close coordination with the Hermes program and the now powerful image of the Ariane program.

The three main management principles stated at the beginning of this article with regard to Ariane 1 were retained and in fact strengthened in two areas:

- Management specifications incorporated a design-to-cost objective.
- The safety/reliability approach was further emphasized through systematic integration of past experience, both from incidents and accidents that occurred during testing, in the course of previous Ariane flights, or in the context of other programs (Challenger, etc.).

Furthermore, faced with an identified failure mode, the principle of a dual approach, involving simultaneous reduction of the probability of that failure and improvement of system tolerance was imposed.

Ariane 5 Launcher

The Ariane 5 launcher stands approximately 51.5 m high; the actual figure depends on the upper composite configuration, and the lift-off mass is 740 tons. Lift-off thrust is 11,660 kN. On the ground, the central core vehicle that has an outside diameter of 5.46 m is suspended at the level of the first-stage forward skirt between two solid propellant boosters. This connection, through which the thrust of each booster is introduced in the core stage, is made of alternate elastomer and metallic shims, designed to provide a damping effect on vibrations induced by booster combustion (Fig. 6).

The cryogenic main stage, developed under Aérospatiale as the prime contractor, is 30.5 m, and its dry mass is 12.2 tons. This stage contains 158 tons of liquid hydrogen and liquid oxygen. The Vulcain engine (Fig. 7) is mounted on a thrust cone that distributes thrust evenly at the base of the liquid hydrogen tank. The engine can be oriented along two orthogonal axes by hydraulic actuators operating on the lost fluid principle. This fluid is stored in tanks operating in the blowdown mode. Connecting struts between the main stage and the solid propellant boosters provide rigidity for the rear part. The light alloy propellant tanks have a common bulkhead, insulated with expanded polyurethane. The hydrogen tank has a volume of 390 m³ and is pressurized at values that vary according to the flight phase (between 2.15 and 2.35 bar), using hydrogen tapped at the outlet from the engine regenerative circuit. The oxygen tank (120 m³) is in the upper position and is pressurized with helium gas (3.5 dropping to 2.85 bar), obtained by heating liquid helium in a heat exchanger located in the oxygen turbine exhaust line. This helium (1.15 m³) is stored in a superinsulated tank mounted on the thrust frame. The engine control system is supplied with helium

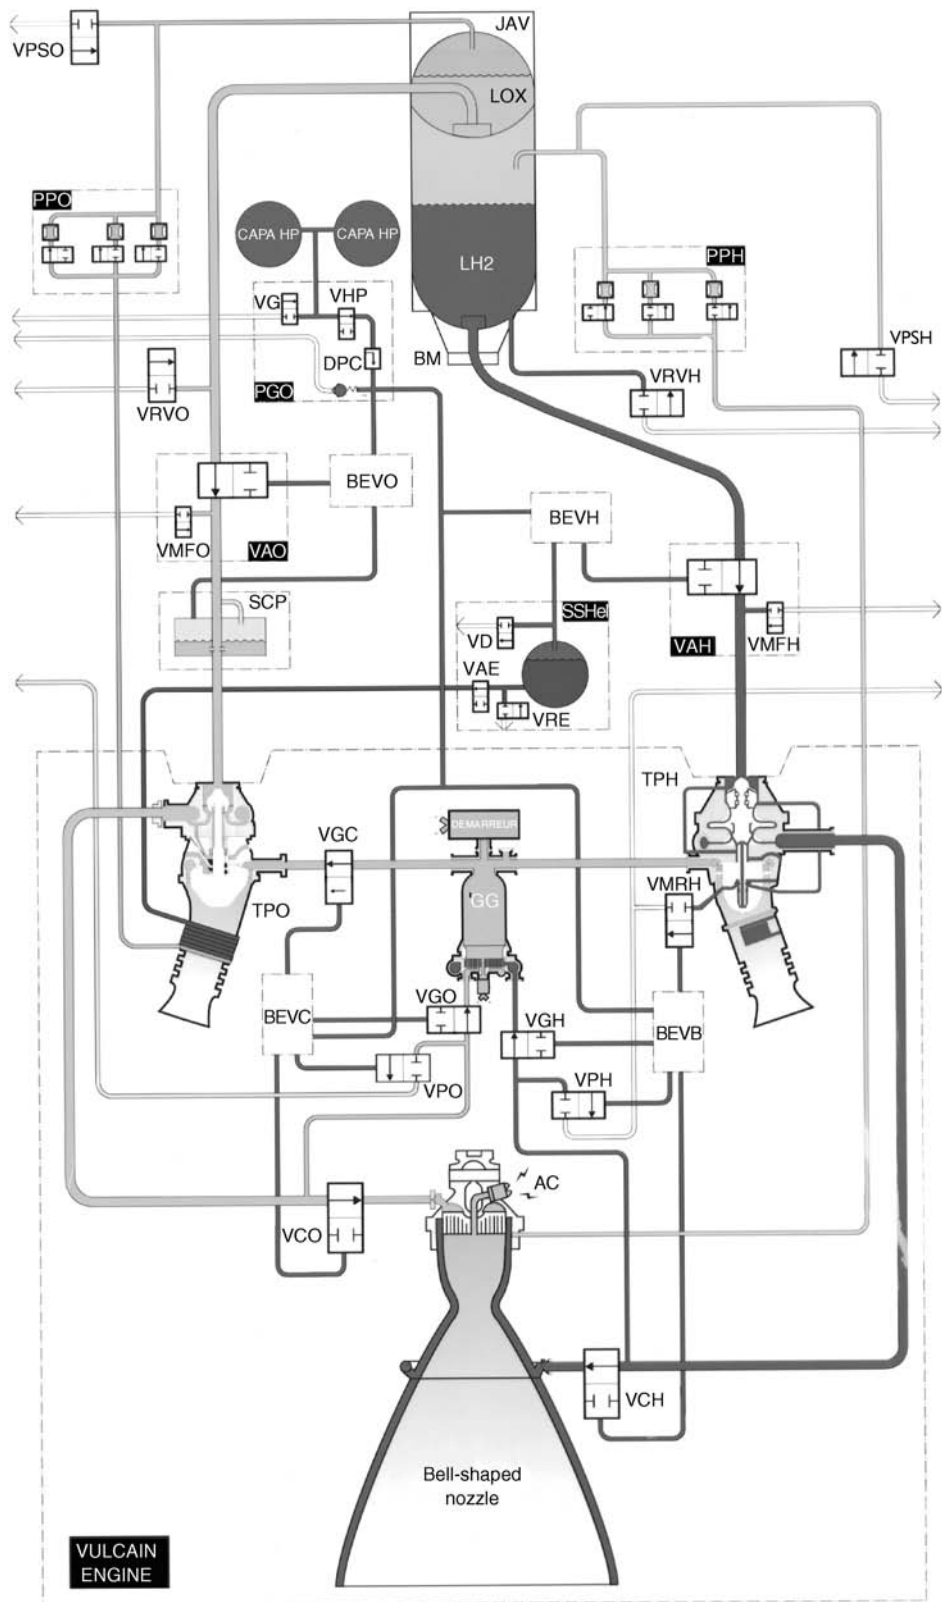

Figure 6. This is a cutaway drawing of Ariane 5. The core is the Vulcain Engine with a payload of two satellites shown above the fuel tanks. The two solid strap-on motors are shown on either side of the core. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

gas stored under pressure in separate tanks. A thrust frame, secured to the upper part of the oxygen tank, receives the thrust of the solid propellant boosters, which is then distributed evenly toward the upper composite.

Europropulsion (joint subsidiary of SNECMA/SEP and FIAT/BPD) was the prime contractor for development of the Ariane 5 solid propellant boosters.

Each booster is 31.16 m high, with a diameter of 3.05 m and a post-combustion mass of 39.3 tons. It contains 238 tons of solid propellant grain, a composite with an ammonium perchlorate and polybutadiene base charged with aluminum. The booster casing is made of a high-strength low-alloy carbon steel and comprises seven cylindrical sections and two bulkheads. The sections are flowturned to a thickness of 8 mm from forged preforms and then assembled using a tang and clevis connection. The sections and bulkheads are assembled to form three segments, each of which is loaded independently with propellant. Internal thermal insulation, made of rubber-based, silica or fiber-filled material, protects the structure from hot combustion gasses. The forward segment is loaded with a 20 tons, star-shaped solid propellant block in Italy. In view of the mass and size of the boosters, a dedicated plant has been constructed in French Guyana for fuelling the central and rear segments (approximately 110 tons of propellant each).

The nozzle, with a flexible bearing made of alternate elastomer and metallic shims, can be steered up to 6° to control the thrust vector. The hydraulic actuators are driven by fluid stored within high pressurized, carbon-fiber vessels operating in blow-down. This fluid is ejected at the nozzle exit. The nozzle, which is highly integrated with the motor, represents a prudent extrapolation of the nozzles developed and qualified for defense applications. The throat in carbon/carbon material ensures minimum erosion during flight. The exit cone is composed of a light alloy housing, with phenolic carbon and silica insulation.

Figure 7. ARIANE 5—Vulcain flow diagram. The Vulcain engine delivers 1140 kN thrust in vacuum and has a specific impulse of 432 sec. It uses conventional gas generator cycle technology. The propellants are delivered by two independent turbopumps. The liquid hydrogen unit operates at 34,000 rpm and comprises a two-stage centrifugal pump, preceded by an inducer that ensures favorable intake characteristics. This pump is driven by a 12-MW, two-stage turbine. The pump delivers up to 560 L/s of liquid hydrogen at a pressure of 17 MPa. The single-stage liquid oxygen turbopump operates at 13,400 rpm and delivers 177 L/s of propellant at 13 MPa (3.7 MW). The two turbines are driven in parallel by a single radial injection gas generator, that operates at a combustion pressure of 8 MPa. The generator is supplied with propellant tapped off at the pump outlet. The combustion chamber pressure is 110 bar. The liquid hydrogen enters the propulsion chamber via an annular distributor. Most of this flow is routed through channels integrated in the double-walled structure of the combustion chamber and throat assembly. The nozzle is cooled by a simple process known as dump cooling: the remaining hydrogen flow is routed through 460 spirally welded iconel tubes, whose diameters increase to give a continuous, bell-shaped surface, then escapes through micronozzles set along the bottom rim of the main nozzle. Although these gases do not undergo combustion, they are heated during the trip and contribute to overall thrust. The turbopumps, gas generator, and combustion chamber ignitions are started by pyrotechnic cartridges. The mixture ratio (mean value 5.25) is adjusted by a two-way valve, used to modify this ratio to terminate combustion on quasi-simultaneous depletion of the two propellants. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

The boosters are jettisoned from the core stage by means of pyrotechnic cords. Solid fuel thrusters located in the rear part and in the forward cone are used to distance the boosters from the launcher in a radial plane.

The booster thrust evolves in flight in order to limit general loads, with a maximum of 6,700 kN and an average value of 4,900 kN in vacuum. It must remain within very tight tolerances to limit any thrust differential between the two boosters at any moment. The maximum combustion pressure is 60 bar, and the specific impulse in vacuum is 270 s.

The vehicle equipment bay is 1.56 m high and constitutes a linkage structure between the first stage, second stage, and fairing.

Developed under the prime contractorship of DASA, the second stage is fitted inside the vehicle equipment bay. This is an internal and relatively compact stage, with a diameter of only 3.94 m and a height of 3.36 m. The dry mass is about 1,250 kg. This second stage carries the payload adaptor (Fig. 8).

The propulsion system comprises an “Aestus” engine, burning storable hypergolic propellants (MMH and N2O4), loaded in helium-pressurized tanks and consequently requiring no turbopump. This technological solution was adopted for its reliability, and its simple operation and re-ignition. A total of 6,550 kg of N2O4 and 3,200 kg of MMH (maximum load mass) are contained in two pairs of identical cylindrico-spherical tanks, arranged axisymmetrically two by two. The lift-off mass is 11 tons.

The engine combustion chamber, extended by a nozzle in refractory steel, is cooled by an MMH circuit. The mixture ratio is adjusted to a value of 2.05 by calibration on acceptance testing. The engine can be oriented through an arc of $\pm 4.8^\circ$ on two axes, using electrical servo actuators. The Aestus engine

Figure 8. Ariane 5 second stage. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

develops 29.1 kN thrust and has a specific impulse of 324 s. The burn-time is about 19 min.

Other details of Aestus engine are as follows:

Propellant feed rate: 8.77

Nozzle expansion ratio: 84

Mass: 111 kg.

The bay carries all functional electrical equipment used throughout the mission and a hydrazine attitude control system operating in the "blowdown" mode. This system is used to control roll throughout the propulsive flight, except during the solid booster burn phase, and during the attitude control phase after shutdown of the second-stage engine. By comparison with the Ariane 1 to 4 programs, the functional electrical systems have been fully duplicated and operate in the full active redundancy mode. This might allow for progressive incorporation of standard electrical components.

The vehicle equipment bay is separated from the main stage by dilation of a sealed pyrotechnic tube, which causes a fragile flange to rupture. The upper composite is then distanced by pyrotechnic actuators.

The assembly sequence and facilities in French Guiana (Launch site N° 3 : ELA3) are based totally on experience with Ariane 4, taking due account of the new mass and dimensional values involved, and carrying the policy of stripping the pad down to the bare minimum a step further.

As for the previous Ariane launchers, the synchronized sequence commences at time $T - 6$ min, 30 s. It is subdivided into two separate automatic procedures that involve the fluid systems, on the one hand, and the electrical systems, on the other. At $T - 4.5$ s, an execution command signal is sent to the onboard computer, which then activates the inertial guidance systems and authorizes ignition of the Vulcain engine at time T . Following verification of correct engine combustion at $T + 6.2$ s, the solid propellant boosters are ignited at $T + 7$ s. The boosters burn for about 130 s. They are jettisoned after burnout, when an acceleration limit of about 5.2 ms^{-2} is detected. For a typical GTO launch, booster separation occurs at an altitude of approximately 60 km at about $T + 140$ s. By this time the launcher relative speed has reached approximately 2000 m/s. The fairing is jettisoned on the basis of a thermal flux calculation, at about $T + 3$ min 10 s. Shutdown of the Vulcain engine is initiated by measuring propellant depletion at about $T + 9$ min 46 s. Launcher speed is then approximately 7600 m/s. After separation, fallback of the main stage is controlled so that the stage hits the ocean approximately 1800 km from the Colombian coast. The upper stage is ignited at about $T + 10$ minutes. During the launch, onboard telemetry is transmitted to Kourou via ground stations located at Natal (Brazil), Ascension Island, Libreville (Gabon), Hartbeesthoek (South Africa) and Malindi (Kenya). The upper stage is fully passivated after separation of the payloads to minimize orbital pollution.

The first Ariane 5 flight was a failure due to a software fault. The second flight (502) took place on 3 October 1997. During the second flight, the only anomaly observed was an excessive roll torque at the limit of acceptability, following jettisoning of the solid propellant boosters and during the Vulcain engine burn phase. This fault was corrected very simply by a minor modification to the orientation of the turbine exhaust nozzles.

The third flight demonstrated the exceptional flexibility of the launcher, based on the simultaneous execution of two largely different missions. The first involved placing a reentry capsule into a suborbital trajectory. The precision of the point of impact in the Pacific was excellent. The other mission involved injecting a payload into a geostationary transfer orbit, again achieved with excellent precision and followed by a second-stage maneuver. This mission involved several successive reignitions and shutdowns of the second stage.

Comparison Between Ariane 44 L And Ariane 5

Unquestionably, Ariane 5 marks a technical break with earlier members of the Ariane family. However, continuity in human resources, management principles, and industrial organization ensured that the Ariane 5 program benefited from all experience previously acquired and made it possible to improve the intrinsic reliability by one order of magnitude. The Ariane 5 launcher has four active stages, whereas Ariane 44 L has seven. The number of separation sequences has thus been reduced. Ariane 5 does not have a launch table that is active in positive time, as is the case with Ariane 4. Nor does Ariane 5 have cryogenic fuelling arms that retract at the last moment before ignition and lift-off. Ariane 5 fluid connections are passive and are pulled free on lift-off. The aborted launch case, which requires extremely complex revalidation operations for Ariane 4, is thus simplified to the extreme. Vulcain engine ignition on the ground was deliberately chosen (following ignition failures observed on Ariane 3 flights 15 and 18), as was also the decision to wait to establish a stationary regime for the complete stage (following the flight 36 failure) before checking the engine and authorizing ignition of the solid propellant boosters. The price of this option is a loss of performance (Vulcain engine thrust was set to ensure minimum acceleration of the launcher after boosters were jettisoned. On the other hand, the Vulcain nozzle could have been adapted more efficiently in the case of in-flight ignition). The production of hydraulic power required to operate the booster and first-stage attitude control actuators is obtained from simple pressurized tanks on Ariane 5, compared with the hot-gas-fed engines used for Ariane 4. This list, which covers only simplifications visible at launcher system level, can be extended for each subsystem and component.

Ariane 5 and Hermes

It has frequently been said or written that the Hermes project led to the design of a launcher which was too large, or nonoptimum, in stage configuration. The need to improve performance yet again, to face up to the competition and remain competitive, clearly demonstrates that the first criticism was foundless.

No choice was made to the detriment of optimization for GTO launches. On the other hand, where a number of possibilities were equivalent for this optimization, choices were based on a Hermes criterion. Speaking in 1999, one can be

thankful that this approach was adopted for at least three reasons:

- The Ariane 5 launcher is fully adapted for all types of missions, from constellations to heavy GEO spacecraft and servicing of the Space Station. The 503 flight demonstrated a high degree of flexibility during a single mission.
- The growth potential of Ariane 5 is very substantial, including replacement of the existing upper stage by a cryogenic stage.
- Manned spaceflight represented an excellent stimulus for the construction of launcher reliability. In this area again, the approach adopted was in no way unfavorable for unmanned missions. Abandonment of the Hermes program changed none of the choices made before this decision.

Ariane 5 Evolution Program

The increase in individual mass values of satellites in the *Arianespace* order book continued steadily throughout the 1980s. Extrapolation of this growth demonstrated that Ariane 5 performance was likely to be insufficient by about one ton shortly after qualification of the new launcher. However, this demonstration failed to convince at the beginning of the 1990s. The Hermes spaceplane program was encountering difficulties, including mass-related problems, and the proposal to increase the performance of the Ariane 5 lower composite was consequently regarded as a subterfuge for increasing the size of a launcher, still regarded as too big for launching commercial satellites. Furthermore, the multiplication of constellation projects involving small satellites in LEO and the increased credibility of plasma propulsion techniques for satellite orbit control provided ammunition for those who supported stopping further increases in the mass of geostationary satellites. When the decision to go ahead with the proposed enhancement program was finally made in 1995, this was based more on the desire to preserve cryogenic propulsion expertise than on a genuine need to enhance Ariane 5 performance, even with no change in production costs. The new enhancement program, designated “Ariane 5 Evolution” is aimed at achieving capacity for simultaneous launch of two 3300-kg-class satellites into geostationary transfer orbit.

The following modifications were adopted to meet this specification:

- Increase in Vulcain engine thrust from 1140 to 1350 kN, while changing the mixture ratio from 5.3 to 6, but without modifying the external dimensions of the first-stage tank (although the position of the intermediate bulkhead changed). First-stage mass is increased up to 170 tons of liquid hydrogen and liquid oxygen.
- To recover the specific impulse lost through this modification of the mixture ratio, the turbine exhaust gases are injected into the nozzle, whose expansion ratio area is increased. This technical solution, not adopted for the basic Vulcain program to avoid excessive integration of elements supplied by different contractors, was validated by a technological program in parallel with the main development program.

- Replacement of connections within the three main segments of the solid propellant boosters by welds. In addition to a substantial booster mass gain and lower costs, this simplifies application of internal thermal protection.
- Adaptation of the dual-launch system (SYLDA) used with Ariane 2, 3, and 4 to the dimensions of Ariane 5.

In parallel with the Ariane 5 Evolution program, Arianespace is proceeding with a number of optimization actions (lightening of the vehicle equipment bay, increasing the solid propellant loading of the booster forward segment) based on experience acquired during the development phase. Combined with Ariane 5 Evolution, this will increase the performance in GTO up to 8 tons in single-launch configuration. These enhancements should be operational late mid 2002.

New Phase: Ariane 5 Plus

Changes in the launch service supply situation due to the upcoming availability of Atlas 3, Delta 3, and the American EELVs (Delta 4 and Atlas 5) will further intensify competition and induce a new trend in satellite mass values toward 5 tons for multimedia spacecraft.

Figure 9. The Ariane rocket family. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

To preserve the competitive advantage achieved with dual launches, the performance of Ariane 5 must exceed 10 tons for GTO injection. This objective will be achieved in two phases:

- For mid 2002 horizon, a second stage will be developed with a propellant load of 14 tons LH₂ and LOX, using the current Ariane 4 third-stage propulsion system. This, combined with Ariane 5 evolution, will take payload capacity up to 10.4 tons in single-launch configuration.
- For a late 2005 horizon, the HM 7 engine will be replaced by the new Vinci motor that delivers 15 tons of thrust and designed for repeated reignition. Tank capacity will be increased to 23 tons of LH₂ and LOX.

This will provide geostationary transfer orbit performance of 11.9 tons in single-launch configuration.

The existing storable liquid propellant upper stage will also be retained but will be adapted to be capable of multiple ignition, with long ballistic phases, to have the flexibility required for all type of missions.

Phase 1 and 2 of this evolution program were decided in the European Space Agency Council in 1998 and 1999. Work on the new engine has been authorized so that the relevant decision can be made in 2001.

Conclusion

Figure 9 briefly summarizes the successive changes in the Ariane launcher and the policy of addressing each new phase takes fullest advantage of experience acquired in the preceding phases. Indeed, Ariane 5 shows a break in this process, and has more the air of the start of a new family. However, the actual break is substantially less pronounced than appears to be the case because the same teams, strengthened by working together for 20 years, have developed and will manufacture Ariane 5.

The technical solutions adopted have frequently been criticized for a lack of initiative because there is sometimes a tendency to confuse efficiency with the technologies applied. But a launcher provides a service, and the only thing that counts is the quality of service provided to the satellite owner. This service is judged in performance, operating cost, reliability, availability, appropriateness of satellite preparation facilities, etc. These are the criteria on which the program's efforts primarily were focused.

ARTIFICIAL GRAVITY

Definition

Artificial gravity (AG) is not gravity at all. It is not a field force or a “force at a distance.” Neither does its strength obey the inverse square law of attraction that determines the orbital motion of planets. However, in terms of its action on any mass, it is indistinguishable from “real gravity.” Instead of gravitational pull, it exerts a centrifugal force, proportional to the mass that is being accelerated centripetally in a rotating device. Although the effect of AG on an extended body differs from that of true gravity, the effects on any given mass are equivalent. Thus AG is simply the imposition of acceleration on a body to recover the forces that are eliminated by the free fall of orbital flight. (Of course, real gravity is not eliminated in orbit. The pull toward Earth in Earth orbit and toward the Sun in interplanetary orbit is balanced by the “free fall” acceleration of the spacecraft and its contents toward Earth or the Sun. To an observer or instrument onboard the spacecraft, it *feels* as though the pull of gravity were removed.)

Provision of AG

In principle, AG could be provided by various means. A continuously thrusting rocket that accelerated a spacecraft halfway to Mars would generate AG equal to the acceleration level. Intermittent impulsive AG would be imposed on an astronaut who jumps back and forth between two opposing trampolines or even between two stationary walls in a spacecraft. However, the term *artificial gravity* is generally reserved for a rotating spacecraft or a centrifuge within the spacecraft. Every stationary object within the centrifuge is forced away from the axis of rotation toward the outer “floor” by a force proportional to the mass of the object, its distance from the center of rotation, and the square of the angular velocity of the device.

Why AG May Be Necessary

Probably the most serious health threat to humans during interplanetary flight comes from radiation exposure en route and on some extraterrestrial surface. Beyond that, prolonged exposure to weightlessness itself can result in deconditioning many of the body’s systems. For space voyages of several years, such as those envisioned for exploration of Mars, the human requires some sort of “countermeasure” to reduce or eliminate this deconditioning. Intensive and sustained exercise on a treadmill, bicycle, or rowing machine was used on the U.S. and Russian spacecraft to minimize the problems of weightlessness. The procedure is uncomfortable and excessively time-consuming for most astronauts. Furthermore, its effectiveness is not proven for all users. Other kinds of countermeasures, including diet, fluid loading before reentry, lower body negative pressure, or wearing a “penguin suit” to force joint extension against a resistive force are either marginally effective or present an inconvenience or hazard.

The *physiological effects* of weightlessness are generally adaptive to space flight and present a hazard only upon return to Earth or landing on another planet (1). However, they may present hazards in flight in the event of a bone fracture, a vigorous muscle contraction, or alterations in the heart's rhythm.

Aside from the severe danger of space radiation, the principal physiological risk of long flight is deterioration of the skeleton. Bones are living tissue, constantly being strengthened by calcium extracted from the blood and destroyed by returning calcium to the blood. Bone maintenance requires a compressive load along the axis of the bone and some high-force impulsive loading. In the absence of these loads that are normally provided by gravity and walking, the major bones that support body weight begin to deteriorate, and a net loss of body calcium occurs, independent of the amount taken in with food or supplements. The long bones in the legs and the vertebrae in the spine lose crucial size and strength during prolonged bed rest. Similarly, they lose strength in spaceflight. Calcium is lost at a rate of about 1/2% per month, and the losses are reflected in the density and size of weight-bearing bones. For a spaceflight of two years, a 25% decrease in bone size might occur (unless the process reaches a plateau), thus increasing the risk of fracture and severely hampering the bone's ability to mend.

Muscles involved in weight bearing, as well as bones, begin to weaken with disuse in weightlessness. The major muscle groups in the legs and back that normally support weight lose mass and are also "reprogrammed," so that fibers previously devoted to slow steady tension are used for brief bursts instead. The shifting of fluid from the legs and lower trunk to the head and chest that produces the first symptoms of head-fullness discomfort on orbit initiates an early loss of body fluid, including blood plasma. The relative excess of red blood cells is countered by stopping their production in the bone marrow and additionally by destroying young red blood cells. The cardiovascular regulating system that acts to maintain adequate blood pressure when we stand up, is no longer needed in space and shows signs of deterioration. Neither the fluid loss and resulting "space anemia," nor the loss of cardiovascular regulation and tone normally cause any difficulty in orbit. During reentry and back on Earth, however, the renewed exposure to gravity can cause weakness and fainting.

The balance system that keeps humans from falling depends on the detection of gravity by the otolith organs in the inner ear. Because the only stimulus to the organs in weightlessness is linear acceleration, considerable reinterpretation of vestibular signals takes place. A consequence of this process is the common occurrence of space sickness early in flight and postural disturbances and vertigo after return.

The immune system that fights infection may also be compromised by space flight, although it is unclear whether weightlessness alone is the major factor.

In addition, a variety of *human factor* problems arise in weightlessness, including the constant need for handholds or footholds for stabilization and the possibility of disorientation within a spacecraft. However, these problems are often balanced by the ease of moving heavy objects, the use of three-dimensional space, and the shear pleasure of floating in weightlessness.

History of AG

The notion of creating a substitute for gravity through centrifugation was introduced early in the conception of human space travel. Tsiolkovsky, the influential Russian space visionary, discussed the idea in 1911, and his concepts were picked up 50 years later by Korolev, who designed a flexible tether system for the Voskhod manned missions (2). It was, however, never built. A detailed engineering proposal for an AG station was introduced by Noodhung in 1927, a full 50 years before the first satellite was launched. When Von Braun described his vision of space exploration in 1953, he included a large rotating torus to deal with weightlessness (Fig. 1) (3).

The popularization of AG, however, is attributable to the science fiction community. The large rotating torus in Clarke and Kubrick's *2001: A Space Odyssey* presented an idealized version of life in space, free of health problems and the negative effects usually associated with transiting from the rotating to the stationary parts of the station. By 1965, preliminary tests on a short-radius centrifuge first showed that subjects who were deconditioned by bed rest could be protected against cardiovascular deconditioning by periodic centrifugation (4).

Experience with AG in space has been quite limited. Rats were centrifuged continuously at 1 g for several days and showed no deconditioning. Human experiments, however, have not been conducted to date. Early attempts to test AG by tethering a Gemini spacecraft to an Agena rocket were inconclusive and nearly led to disaster when the thruster nozzle stuck on Gemini 8, sending the pair of space vehicles into an uncontrollable spin. The 2.5-m-radius centrifuge on the International Space Station should afford the opportunity to examine the adequacy of various levels of AG in protecting rodents during spaceflight.

Design Boundaries

The envelope of operation for AG is limited by several factors, as pointed out by Von Braun and adapted by others. The “comfort zone” for AG with a rotational radius of up to 1000 feet is bounded by several constraints (5). In one presentation, the nominal design point was for a 734-foot radius architecture, spinning

Figure 1. Von Braun's rotating space station (reprinted from Reference 3). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

at approximately 1.8 rpm. This large radius creates less than a 1% gravitational gradient from head to foot under a 4% ratio of Coriolis force to apparent weight for a crew moving at 3 ft/s. The rim velocity would exceed 200 ft/s. The basic design space is normally shown on a graph of rotational rate versus radius; the acceleration level appears as a derived parameter according to the equation $A = r\omega^2$. The design boundaries have generally been stated for continuous rotation but are also shown here for intermittent centrifugation (Figs. 2a,b).

Figure 2. (a) Comfort zone for continuous AG (adapted from Reference 5). (b) Centrifuge zone for intermittent AG (adapted from Reference 5).

The *minimum gravitational level*, normally measured at the rim of a centrifuge, is the key parameter in the design space. The limited animal tests in orbit confirm that continuous rotation to yield 1 g at the feet of a small rodent is sufficient to maintain normal growth. However, it remains to be determined whether a lesser g level will suffice. Based on centrifuge studies of long duration, Russian scientists suggest that the minimum level of effective AG is about 0.3 g and recommend a level of 0.5 g to increase a feeling of well-being and normal performance.

The *maximum gravitational acceleration level* is also a factor if short-radius intermittent AG is used. Levels up to 2 g are probably useful, especially if combined with exercise, but a level as high as 3 g's is likely to produce ill effects if maintained for more than 20 minutes.

The *maximum angular velocity* of the AG device is limited by the Coriolis forces encountered when walking or when moving objects, and by the motion sickness and disorientation experienced with certain kinds of head movements. Coriolis accelerations are real inertial accelerations that occur when moving within a rotating framework. Any movement in a straight line with respect to the rotating frame, except for one parallel to the axis of rotation, is in fact a curved motion in inertial space. The curve reflects acceleration sideways and entails a sideways inertial reaction force (Fig. 3).

People trying to walk radially outward on a spinning carousel will feel a surprising force pushing them sideways, parallel to the circumference. As seen by an observer stationed outside the carousel, the walker's path is really curved in the direction of the carousel's spin. The sideward inertial acceleration requires a sideward force (*Coriolis force*), according to Newton's second law, and the subjects need to apply that unexpected force to avoid walking a path that is curved relative to the carousel. They also must apply an unexpected postural reaction to avoid falling over.

Additionally, anyone trying to walk along the rim of the AG spinning vehicle in the direction of the spin is subject to an unexpected radial inertial acceleration inward, which entails a downward Coriolis force, making the space walker feel heavier. If the astronaut were to turn around and walk along the rim in the direction opposite to the spin, the Coriolis force would be upward and the apparent weight of the astronaut would be reduced. The magnitude of the Coriolis force is given by the equation $|F_c| = |m\omega \times v|$. From considerations of human factors, the Coriolis accelerations should be kept to less than some fraction of the AG gravity level. Stone (5,6) suggests that this be no higher than one-fourth. For radial movement at velocity v , this is given by

$$\text{Coriolis acceleration/artificial gravity} = \omega v_{\max}/r\omega^2 = v_{\max}/v_{\text{rim}},$$

where v_{rim} is ω times r and is the speed of the outer rim of the AG centrifuge. The *minimum rim velocity* is limited only by the need to maintain enough friction for locomotion when walking against the direction of spin. For walking, v_{\max} is about 1 m/s, and it has been assumed that the estimated minimum rim velocity is 6 m/s.

The most disturbing aspect of AG rotation is probably the Coriolis cross-coupling accelerations detected by the semicircular canals in the vestibular systems of the inner ear. The organs function to detect angular velocity of the

Gravity gradient. (a) Object of mass M "weighs" $MR\omega^2$ on the rim. (b) Object of mass M "weighs" $Mr\omega^2$ at radius r .

head relative to inertial space for most normal head movements. However, because of their mechanical structure, they fail to register long-lasting constant velocity motion and, instead, indicate that one is stationary in a turn that lasts more than 10–20 s. In AG, these vestibular signals are apparently inconsistent with what one sees in the spacecraft and also with the linear acceleration registered by the otolithic organs in the labyrinth. This conflict, before adaptation, produces both motion sickness and spatial disorientation.

When subjects in AG suddenly move their heads about an axis that is not parallel to the spin axis, two unexpected angular accelerations occur. First, during the head movement a “cross-coupled acceleration” occurs, equal to the product of the spin rate and the head angular velocity that produces transient acceleration about a third orthogonal axis. This is given by the equation $A = \omega_y \times \omega_s$. Second, when the head is turned, the spin angular velocity is moved from one head plane to another, producing a sensation of deceleration about the first axis and acceleration about the second one. A sensation of rotation with components around both axes usually occurs for up to 10 sec, as the semicircular canals return to their neutral position. The directions of both the Coriolis force and the cross-coupled accelerations depends on the direction the subject is facing in the rotating spacecraft, as well as the direction of head movement, thereby complicating the process of general adaptation to the unusual environment.

All of the unexpected Coriolis sensations are proportional to the AG spin rate. Although further adaptative schedules might increase the tolerable rate, the *maximum spin rate* for continuous rotation has been estimated at 6 rpm, with possible elevation to 10 rpm. Almost all subjects can adapt quickly to work in a 2-rpm rotating environment. It is believed that most could tolerate increased rotational rates to 6–10 rpm, providing that they are built up slowly in steps of 1–2 rpm with a period of 12–24 h at each increment (7).

The *gravitational gradient* refers to the change in AG level with radius and can affect both physiological function and the ease of handling materials in space. Since the “g level” is proportional to the radius, the gravitational gradient from head to foot is simply the ratio of height to radius: $Gradient = h/R$. For continuous rotation at smaller radii, comparable to the astronaut’s height, the gravitational gradient may become more of a problem. For a 2-m astronaut, the radius would be at least 4 m for a 50% maximum gradient.

Experimental Results

Space Experiments. Despite the long-standing interest in artificial gravity, experimental evidence from space is very limited. Only two space missions early in the space program were devoted to animal studies, and all of the human in-flight results were anecdotal.

Flight Animal Experiments. The Soviet space research community expressed an early and intense interest in AG and, in 1961, began testing rats and mice in the 25-s weightless periods of parabolic flight. Animals showed normal appearing locomotion during these brief periods if they were housed in a centrifuge producing at least 0.3 g, thus setting this as a minimum g requirement (8). The first animals to be centrifuged in space were on the Cosmos 782 mission

in 1975, when fish and turtles centrifuged at 1 g were found indistinguishable from their ground controls. Furthermore, turtles centrifuged at levels as low as 0.3 g showed none of the muscle wasting typical of weightlessness. A much more extensive investigation was carried out on rats centrifuged during the 20-day mission of Cosmos 936 in 1977. These animals, housed in a small-radius (32-cm), high-speed (53.5-rpm) 1-g centrifuge, showed deficits in equilibrium and postural control postflight, consistent with the observed reduction in vestibular sensitivity. Faring less well than their ground controls, they also failed to counter fully the usual effects of weightlessness on loss of muscle and bone, circumstances that may have been the result of the small cage size and the high-g gradient. The large animal centrifuge planned for the International Space Station is designed to provide a range of AG levels, above and below 1 g, to a large variety of fish, plants, and small animals.

Human Space Experience with AG. No formal human AG experiments were performed in space during the first 40 years of the space age. During the earliest years of human spaceflight, the major physiological disturbances involved “space adaptation syndrome” and were of concern only for the first few days in orbit. The debilitating effects of weightlessness on the bone, muscle, and cardiovascular system were demonstrated on the Skylab missions in the early 1970s and later on the long-duration Salyut and Mir flights. However, it was believed that in-flight exercise, augmented by resistance training and fluid loading, would solve the problem. As time passed, the opportunities for human centrifuges or rotating spacecraft in orbit disappeared. During a 1966 Gemini mission, an orbiting Agena rocket casing was tethered to the spacecraft, and the two were put into a slow spin. No data were taken. On Gemini 8, when Gemini was docked to the Agena, a planned slow rotation got out of control because of a stuck thruster, and the crew was saved only by the skillful use of an orbital maneuvering engine. No further spacecraft AG tests have been conducted. Since then, the only opportunities for investigation have come from uncontrolled, anecdotal reports.

During the Skylab missions, the crew took advantage of the large open compartment to run around the curved circumference. They produced a self-generated AG by running. The crew reported no difficulty with either locomotion or motion sickness.

Although no specific AG human experiments have been performed, some centrifugation for other purposes has produced a measure of centripetal acceleration. During the Spacelab International Microgravity Laboratory (IML-1) mission, subjects were spun on a rotator in which the head was 0.5 m off center, experiencing an acceleration of $-0.22 g_z$, and the feet were on the other side of the axis, experiencing an acceleration of $+0.36 g_z$ (9). No unusual inversion phenomena were reported. Similarly, in the Neurolab Spacelab mission, four subjects received periodic rotation in a similar situation without reorientation. In that case, however, those subjects seemed to have achieved some measure of resistance to postflight orthostatic instability and did not show the usual decrease in vestibular sensitivity to tilt (10).

Ground Centrifuge Experiments. Despite the absence of flight-test opportunities, several laboratories worldwide have continued ground-based studies of the efficacy and acceptability of human horizontal centrifugation. Of course, all of these investigations are hampered by the presence of the steady gravitational

pull. Gravity adds to the centrifugal force vectorially and produces a net specific gravito-inertial force $F = g - a$ directed between vertical and horizontal.

The earliest of the extensive tests of sustained rotation were conducted in Pensacola (11), beginning in 1958. The "slow rotating room" (SRR) exposed volunteers to prolonged rotation (12). This 3-m-radius room that has a horizontal floor permitted subjects to adapt to rotation during several days (13,14). Initially, most subjects developed motion sickness symptoms when they made head movements at room rotational rates in excess of 3 rpm and, through that experience, learned to restrict them. Incremental increase in the speed of the room was employed. After several days, most subjects were able to make head movements without symptoms at rotational rates up to 6 rpm. Only some of the subjects could go further to move comfortably at 10 rpm. When the rotation was stopped, subjects felt an aftereffect and an erroneous motion sensation during head movements. They were maladapted to rotation in the opposite direction.

Beginning in the 1960s a major ground research program on AG was conducted at the Institute for Biomedical Problems in Moscow (IBMP). Their earliest tests in the MVK-1 small rotating chamber at speeds up to 6.6 rpm allowed rotating one or two subjects for up to a week. It was followed by the roomier 10-m-radius "Orbita" centrifuge, capable of rotating two to three people for several weeks at speeds up to 12 rpm. The longest tests were for 25 days at 6 rpm. The initial exposures produced the expected disturbance of equilibrium and coordination. Within an hour, the usual pattern of motion sickness symptoms occurred, including vomiting in some cases (15). In 4–5 hours, subjects also complained of listlessness, sleepiness, and headache—similar to the Sopite syndrome identified by Graybiel. Three periods of vestibular adaptation were distinguished for these long-duration exposures. The first 1–2 days were characterized by severe motion sickness. This was followed by a week during which the nausea and related acute symptoms disappeared, but listlessness and headache remained. Finally, after the first 7–10 days, subjects showed immunity to motion sickness, even when additional vestibular stimulation was imposed. The generalizability of this adaptation has not been determined. The Soviet centrifuge tests indicated an absence of any motion sickness symptoms at 1 rpm, moderate symptoms at 1.8 rpm, and marked symptoms at 3.5 rpm. Head movements brought on discomfort in all cases.

More recent investigations have assessed the ability of subjects to avoid motion sickness during head movements while rotating at the high speeds associated with short-radius centrifugation. Antonutto and colleagues in Udine, Italy, found that subjects who were pedaling on a bicycle-powered short centrifuge were able to make head movements without acute motion sickness while rotating at 19–21 rpm. Young, Hecht, and colleagues used the 2-m-radius centrifuge at MIT to show that most subjects could adapt both their eye movements and their motion sickness symptoms to accommodate head movements while rotating at 23 rpm (16). Both the Udine and the MIT studies were conducted at speeds sufficient to produce 1 g of horizontal centripetal acceleration or a net gravito-inertial acceleration of 1.4 g's. In the Udine centrifuge, it was aligned with the subject's, head-to-foot axis, whereas in the more provocative MIT studies, the subject remained horizontal.

The Coriolis forces associated with limb movements, head movements, and walking in a rotating environment are initially both surprising and disturbing.

However, in almost all cases, appropriate new motor control strategies are developed, so that subjects can adapt to the new environment and no longer are even aware of the unusual forces. Extensive experiments in the Brandeis University rotating room demonstrate the remarkable ability to adapt to unusual environments (17). A measure of dual adaptation apparently exists, so that subjects can switch from the rotating to the nonrotating environment with minimal relearning.

The adequacy of artificial gravity in stimulating the cardiovascular system has been investigated in ground studies. In most studies, the debilitating effects of weightlessness are simulated by sustained bed rest, often at 6° of head-down tilt and occasionally by partial submersion in water to approximate the fluid shift better that occurs in space. In a pioneering study in 1966, White and his colleagues at Douglas (18) showed that intermittent exposure to 1g or 4g's on a 1.8-m-radius centrifuge was effective in alleviating the usual decrease in tolerance to standing (orthostatic intolerance). Exercise produced little additional benefit. The principal cardiovascular reactions of interest for centrifugation are the venous tone, especially in the legs, and the baroreflex regulation of blood pressure. For a short-radius centrifuge small enough to accommodate a subject only in a squatting position, the centrifugation does little to encourage venous return by stimulating the muscles. The IBMP ground centrifuge tests (19) demonstrated that subjects who were deconditioned by 2 weeks of water immersion could increase their post-immersion tolerance to +3 g_z by intermittent acceleration on a 7-m-radius centrifuge. For some time, it was debated whether the intermittent centrifugation conditioned only the passive motor tone or whether the body's active baroreflex to counter the effects of gravity on blood pressure was also affected. Burton and Meeker (20), using a 1.5-m-radius centrifuge intermittently, showed that the baroreceptors are adequately stimulated during AG. Their slow compensation for the hydrostatic pressure drop during rotation permits the g tolerance to gradual onset acceleration to exceed that to rapid onset acceleration. Beyond even the benefit of intermittent acceleration on cardiovascular responses is the effect on blood volume. Normally, weightlessness or head-down bed rest produces a fluid shift toward the head that in turn leads to fluid loss, including plasma, and a resulting increase in hematocrit. However, Yajima and his colleagues from Nihon University School of Medicine in Tokyo (21) showed that 1 hour per day of 2g_z exposure of their subjects, using a 1.8-m-radius centrifuge, was sufficient to prevent hematocrit from increasing during a 4-day bed rest period. In other studies, they confirmed the effectiveness of intermittent centrifugation on maintaining baroreflex and parasympathetic activity (22). To prevent motion sickness, the Nihon investigators stabilized the head during these centrifuge runs.

The interaction between the cardiovascular fitness enhancement of regular exercise and the tolerance built up during centrifugation remains unclear. Certainly the two countermeasures are individually effective, but whether they contribute more in combination is still under study (23,24).

Artificial Gravity Design Options

The choice of AG design depends on a basic decision whether the crew is to be transported with *continuous* AG, requiring a large-radius device, or exposed to

intermittent AG, in which case a small rotator can be employed. The classical large *spinning space station*, as epitomized by the von Braun torus, was the basis for early designs in the Apollo era (25). At one time, a large toroid 150 feet in diameter and constructed of six rigid modules joined by an inflatable material, was envisioned. The large mass and excess volume of a torus or hexagon forced consideration of other ways of generating centrifugal forces at large radii. The two that emerged are the rigid truss, or boom, and the tether concept. A *rigid truss* design typically would have the crew quarters and operations module at one end and a large counterweight at the other end. The counterweight might be an expended fuel tank or an active element such as a nuclear power source. In most cases a counterrotating hub is present at the center of rotation to provide both a nonspinning docking port and to allow for a zero-g workspace for experiments. A variation on the rigid truss is the extendable or telescoped boom concept, in which the radius of the AG systems could be varied more easily than with a fixed truss and slider. However, both of these designs imply considerably more mass and power requirements than a tether system. A variable length *tether* that could be unreeled in orbit and used to connect a spacecraft to a counterweight has emerged as the most acceptable design for a large AG system. As envisioned for a Mars mission (26), it would consist of a 80,000 kg habitat module 225 m from the center of mass, with a 44,000 kg counterweight 400 m beyond. The two are connected by a tether, weighing 2400 kg, reeled out by a deployer weighing 1700 kg. All told, the additional weight for accommodating a tethered AG system for a human Mars mission is about 21,000 kg, or about 5% of the 0-g weight, plus about 1400 kg of propellant (Fig. 4).

One of the obvious concerns about a tethered AG system is its vulnerability to tether breakage. For the Mars mission design, a tether in the form of a band $0.5\text{ cm} \times 46\text{ cm} \times 750\text{ m}$ would provide a dynamic load safety factor of 7, offering a working strength of (630,000 N). That concern has otherwise been addressed by using webbing or braided cable to maintain tether integrity, even in the event of a meteoroid collision. (The probability of tether impact with a micrometeoroid of mass greater than 0.1 gm was calculated as .001 for a mission of 420 days.) A second concern about a tethered system lies in its dynamic stability, especially during unreeling and during spin up and spin down. The interaction with orbital maneuvers is complex, whether the spin axis is inertially fixed or tracking the Sun to facilitate the use of solar panels.

The alternative approach to AG is to use a *short-arm centrifuge* intermittently. In this case, the exposure would not be limited to less than 1 g, but might be as high as 2 or 3 g's to deliver adequate acceleration in exposures of perhaps 1 h daily or several times per week. Of course, such a short device would have to spin much faster than the 6 rpm limit envisioned for a large continuous system—and would produce significant Coriolis forces and motion sickness stimuli if the head is moved, at least until adaptation occurs. The short-radius centrifuge becomes particularly attractive when its dimensions shrink to the point that intermittent centrifugation could be carried out within the confines of a spacecraft, rather than entailing rotation of the entire complex. A 2-m-radius AG device permits subjects to stand upright and even walk within its limited confines. Of course, the head is then close to the center of rotation, and a significant gravitational gradient appears as one goes from head to toe. Many of the ground

Figure 4. Tether design. (Reference 26).

studies of intermittent short-radius centrifugation have been conducted with rotators of radius from 1.8–2.0 m. As the radius shrinks even further to less than 1.5 m, the taller subjects can no longer stand erect but must assume a squatting or crouching posture. For many such designs, the subject would also provide the power to turn the device and perform valuable exercise by bicycling the centrifuge into rotation (Fig. 5).

Figure 5. Bicycle-driven centrifuge courtesy of Dava Newman (photo by William Litant, Massachusetts Institute of Technology). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Although the power saving may be trivial, or not even used, the importance of active exercise while exposed to intermittent centrifugation might lie in its protection against syncope, or fainting, as the body is exposed to the unaccustomed footward forces that tend to pool blood in the lower extremities.

ASTEROIDS

Asteroids are small members of the solar system in heliocentric orbits concentrated between Jupiter and Mars. Since most of them have orbits that are roughly similar to those of the planets (low inclination and eccentricity), they have sometimes been called minor planets, although this term is no longer in common use. More important is the distinction between asteroids and comets, where the primary difference is one of composition. Most asteroids are rocky objects, composed of the same sorts of materials as the inner planets. Comets, in contrast, contain a substantial quantity of water ice and other frozen volatiles

in addition to silicates and organic compounds. However, there are ambiguities in terminology. Comets that make frequent passes around the Sun may lose their volatiles and become indistinguishable from rocky asteroids. In addition, there are many volatile-rich objects being discovered in the outer solar system (beyond Neptune) that resist classification as either asteroids or comets. These are the Kuiper Belt Objects (KBOs), discussed in this Encyclopedia in the entry for Comets.

The most comprehensive references for asteroids are the large multiauthor textbooks published in the Space Science Series of the University of Arizona Press. See especially *Asteroids II* (1989) edited by R. Binzel and others, and *Hazards Due to Comets and Asteroids* (1994) edited by T. Gehrels. Soon to be published in the same series is *Asteroids III* (2002), edited by W. Bottke and others.

Discovery of Asteroids

Asteroids are too faint to be visible to the unaided eye, so their discovery belongs to the era of telescopic astronomy. On New Year's Day in 1801, Giuseppe Piazzi at Palermo Observatory found the first asteroid, which he named Ceres for the Roman patron goddess of Sicily. This faint object (now known as the largest asteroid) orbited the Sun at a distance of 2.8 astronomical units (AU). It was at first hailed as the "missing planet" in the large gap between the orbits of Mars and Jupiter. In the following few years, three more asteroids—Pallas, Juno, and Vesta—were found, also orbiting between Mars and Jupiter. These were even smaller than Ceres, although Vesta is slightly brighter due to its more reflective surface. Even combined, the masses of these four objects came nowhere near that of a real planet. Most of the asteroids are located in what is defined as the main asteroid belt, at distances from the Sun are between 2.2 and 3.3 AU, corresponding to orbital periods between 3.3 and 6.0 years.

The next asteroid was not discovered until 1845, but from then on, they were found regularly by visual observers who scanned the sky looking for them. By 1890, the total number had risen to 300. At that time, photographic patrols began, and the number of known objects rapidly increased and reached 1000 in 1923, 3000 in 1984, 5000 in 1990, and 20,000 in 2001. To be entered on the official list of asteroids, an object must be well enough observed to establish its orbit and permit its motion to be accurately calculated many years into the future. The responsibility for cataloging asteroids and approving new discoveries is assigned to the International Astronomical Union Minor Planet Center in Cambridge, Massachusetts (1). It is an interesting indication of growing interest that 198 years were required to find the first 10,000, but only two years were needed to find the second 10,000. Most recent discoveries are a by-product of the Spaceguard Survey, a concerted search for near-Earth Asteroids (NEAs) that will be discussed in detail at the end of this article.

In addition to numerical designations (e.g., 4 Vesta, 1000 Piazzia), which are given in chronological order of determination of an adequate orbit, most asteroids have names, usually suggested by the discoverer. Initially, these were the names of Greek and Roman goddesses, such as Ceres and Vesta, and later

expanded to include female names of any kind. When masculine names were applied, they were given the feminine Latin ending. More recently, the requirement of female gender has been dropped, and today asteroids are named for a bewildering variety of persons and places, famous or obscure. This article uses names rather than numbers to refer to specific asteroids.

Basic Asteroid Statistics

Our census of the larger asteroids is fairly complete by now, based primarily on ground-based surveys, complemented by infrared space observations, such as those from the Infrared Astronomy Satellite (IRAS) in 1983. It is likely that we have discovered all main-belt asteroids 25 km or more in diameter, and discovery should be more than 50% complete for diameters down to 10 km. Ceres, the largest, has a diameter just under 1000 km. The next largest asteroids are about half this size (see Table 1 for a listing of the dozen largest asteroids). The total mass of all of the asteroids amounts to only 1/2000 of the mass of Earth (less than 1/20 the mass of the Moon). Our knowledge is better for the closer asteroids in the inner part of the asteroid belt, and most of the larger undiscovered bodies are probably beyond 3 AU from the Sun.

There are many more small than large asteroids. An estimate of the relative numbers of objects of each size is interesting as a characterization of the asteroid population, and it is also closely related to the distribution of craters caused by the collision of asteroids with the planets and satellites in the inner solar system.

As a rule, many processes in nature, including those of fragmentation, result in approximately equal masses of material in each size range. Applying such a power law to the asteroids, we would find that there should be 1000 times more 10-km objects than 100-km ones, and a million more at 1 km than 100 km. In other words, the number of objects of a given diameter is inversely proportional to the cube of their diameter. However, measurements of the asteroids indicate that the numbers do not rise this fast as size declines but increase more nearly as the inverse square of the diameter, resulting in a distribution where most of the

Table 1. **The Largest Asteroids**

Name	Year of discovery	Distance from Sun, AU	Diameters, km	Class
Ceres	1801	2.77	940	C
Pallas	1802	2.77	540	C
Vesta	1807	2.36	510	V
Hygeia	1849	3.14	410	C
Ineramnia	1910	3.06	310	C
Davida	1903	3.18	310	C
Cybele	1861	3.43	280	C
Europa	1868	3.10	280	C
Sylvia	1866	3.48	275	C
Juno	1804	2.67	265	S
Psyche	1852	2.92	265	M
Patientia	1899	3.07	260	C

mass is in the larger objects. This is why we are relatively certain of the total mass of the asteroids, even without having counted all of the small ones.

From the observed distribution of sizes, we can estimate that there are more than 100,000 asteroids down to a diameter of 1 km. Although 100,000 sounds like a lot of objects, space in the asteroid belt is still empty. The belt asteroids occupy a very large volume, roughly doughnut shaped, about 100 million km thick and nearly 200 million km across. Typically the asteroids 1 km or larger are separated from each other by millions of kilometers. They pose no danger to passing spacecraft. In fact, it was challenging to locate asteroids near enough to the trajectory of outward-bound spacecraft (such as Galileo and Cassini) to allow close asteroid flybys on the way to Jupiter.

Physical and Chemical Properties

As seen through a telescope without special image compensation (adaptive optics), an individual asteroid is an unresolved starlike point. The word asteroid means starlike. Before about 1970, almost nothing was known about the physical nature of asteroids, and research was confined to discovering and charting orbits and determining rotational rates from observations of periodic variations in brightness. In the past 30 years, however, new observing techniques used with large telescopes have revealed a great deal about the physical and chemical nature of the asteroids (2). These astronomical observations have been supplemented by key studies of meteorites and by close-up spacecraft observations of a few asteroids, including Gaspra, Ida, Mathilde, and Eros—the latter involved both orbital and landed investigations.

Asteroid sizes and shapes are determined directly from imaging with modern adaptive optics or from the Hubble Space Telescope (although the resolution, even with the largest telescopes, leaves much to be desired). High-precision radar imaging is also a powerful tool if the object comes sufficiently close to Earth. Size can also be measured by timing the passage of an asteroid in front of a star. Because we know exactly how fast the asteroid is moving against the stellar background, measuring how long the star is obscured yields a chord length for the asteroid that can be accurate to a few kilometers. If timings of the same event made from different locations on Earth are combined, the profile of the asteroid can be derived. Unfortunately, however, suitable events are rare, and only a dozen asteroids have been measured successfully by this method.

Most asteroid sizes have been estimated indirectly from their visible or infrared brightness. Given only the apparent visible-light brightness of the object, we can roughly estimate its size by assuming a reflectivity or albedo that is characteristic of average asteroids. Such diameters are typically uncertain by a factor of 2, implying an order-of-magnitude uncertainty in mass. Much more accurate are reflectivities determined by combining visible-band measurement of reflected light with infrared-band measurement of emitted heat radiation. Such diameters are good to 10% or better, and they require no arbitrary assumptions about reflectivity.

It is clear that the asteroids have a variety of surface compositions, as discussed further later. This variety leads to a wide range of surface reflectivity.

The majority of the asteroids are very dark, roughly the brightness of charcoal. Other types can have reflectance as high as white terrestrial rocks. To make sense of this diversity of material, one must add information on the spectral reflectance of the asteroids. It is particularly useful to compare the asteroids with extraterrestrial samples that reach Earth as meteorites. A few meteorites come from the Moon or Mars, but the great majority of them are fragments from asteroids. Unfortunately, the chaotic dynamic processes that deliver meteorites to our planet do not include traceable return addresses. One of the major challenges of meteoritics is to connect the samples we have to their parent bodies (or class of parent bodies) among the asteroids.

The use of spectral data to characterize asteroids has yielded preliminary determinations of composition for approximately 1500 objects. These include a few asteroids that have metallic surfaces, presumably representing the surviving cores of objects that melted, differentiated chemically, and subsequently lost their stony crusts and mantles. Most, however, have rocky surfaces, that compare to the majority of meteorites, which are also rocky. Exact identifications are difficult, however, and usually we cannot specify the unique properties that identify an individual. With some notable exceptions, contemporary asteroid research, therefore, tends toward broad statistical studies rather than detailed investigation of particular objects. The exceptions are the handful of asteroids that have been visited by spacecraft or imaged at close range by radar, to be discussed further later.

Most of the well-observed asteroids fall into one of two classes based on their reflectivity (3). They are either very dark (reflecting only 3–5% of incident sunlight) or moderately bright (15–25% reflectivity). A similar distinction exists in their spectra. The dark asteroids are fairly neutral reflectors and do not have major absorption bands in the visible range to reveal their compositions, although some of them show spectral evidence of chemically bound water in the infrared. Most of the lighter asteroids are reddish and have the spectral signatures of common silicate minerals such as olivine and pyroxene. The dark gray asteroids have spectra similar to the carbonaceous meteorites, so they are called C-type asteroids. The lighter class is named the S-type, indicating silicate or stony composition. A third major group appears to be metallic (like the iron meteorites) and is called the M-type. There is also a variety of subclasses based on spectra and reflectivity, especially among the dark C-type objects. It is also increasingly clear that some process of “space weathering” alters the optical properties of surface materials; it partially masks identification with specific meteorite types on Earth and blurs the distinctions that might otherwise be seen among asteroids of different subgroups.

Using the classification of the asteroids, we can look at the distribution in space of the broad C, S, and M types. At the inner edge of the belt, the S asteroids predominate. Moving outward, the fraction of C-type objects increases steadily, and in the main asteroid belt as a whole, the dark, carbonaceous objects make up 75% of the population, compared to 15% S and 10% of M and other types.

Beyond the main belt, all asteroids are very dark, but their colors are redder than the belt objects, and they do not look like any known carbonaceous meteorite (4). Because these objects are not represented in our meteorite collections, scientists hesitate to commit themselves concerning their composition. It is

generally thought, however, that they are primitive objects and that a fragment from one of them would be classed as a carbonaceous meteorite, although of a kind different from those already encountered.

If the asteroids are still near the locations where they formed, we can use the distribution of asteroid types to map out the composition of the solar nebula, the original circumsolar assemblage of gas and dust from which the planetary system formed (5). Carbonaceous meteorites formed at lower temperatures than the other primitive stones, so we infer that the concentration of similarly composed C-type asteroids in the outer belt is consistent with their formation farther from the Sun, where the nebular temperatures were lower. It is also possible, however, that the asteroids formed elsewhere and were herded into their present positions by the gravity of Jupiter and the other planets. In that case, the C-type asteroids could have formed far beyond Jupiter and subsequently diffused inward to their present positions in the outer part of the asteroid belt. Similarly, the S-type asteroids near the inner edge of the belt could either have formed where we see them today, or they could have been gravitationally scattered to their present locations from still closer to the Sun. The solar nebula temperatures that we would deduce by applying these two alternative models are quite different. So far, however, we have not been able to settle on which model is preferred for the origin of the asteroids.

Orbits

The orbits of the belt asteroids are for the most part stable, their eccentricities are less than 0.3, and inclinations are below 20° . In the past, when presumably there were more asteroids, collisions may have been common, but by now the population has thinned to the point where each individual asteroid can expect to survive for billions of years between collisions. Still, with 100,000 objects 1 kilometer or more in size, a major collision somewhere in the belt is expected every few tens of thousands of years. Such collisions, as well as lesser cratering events, presumably yield some of the fragments that develop Earth-crossing orbits and eventually reach Earth as meteorites. In contrast, Earth-approaching NEAs have unstable orbits and typical dynamic lifetimes of only about 100 million years. Their numbers represent an equilibrium between inward scattering from the main belt and elimination either by colliding with the terrestrial planets or the Sun or by gravitational ejection from the solar system.

Given their history of collisions, there is no reason to expect that most asteroids are monoliths. Many may be rubble piles, consisting of loosely bound, low-density accumulations of debris that has reaccreted after a catastrophic disruption (6). In general, the energy required to disperse such debris completely is substantially greater than the energy needed to break up a target. One line of evidence for the existence of rubble piles comes from the highly elongated shapes of some small, rapidly spinning asteroids. These shapes are nearly what one might expect for an equipotential fluid and suggest such a reaccretion process. However, conclusive evidence of rubble piles awaited the first close-up spacecraft investigations, as recounted later.

The orbits of asteroids within the main belt are not evenly distributed. As shown in Fig. 1, some orbital periods are preferred, and others are nearly

Figure 1. Histogram of orbital periods of the known asteroids. The deep minima are the Kirkwood gaps that correspond to periods that are in resonance with Jupiter (courtesy of Jet Propulsion Laboratory and NASA). Source: http://ssd.jpl.nasa.gov/a_histo.html. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

unpopulated. These unpopulated sections of the belt are resonance gaps, also known as the Kirkwood gaps for the nineteenth-century astronomer who discovered them. These gaps occur at orbital periods that correspond to resonances between these periods and the orbital period of Jupiter. Resonance takes place when the orbital period of one body is an exact fraction of the period of another. In this case, the underpopulated asteroid orbits correspond to periods that are one-half, one-third, one-quarter, etc., that of the 12-year orbital period of Jupiter. The Kirkwood gaps provide a clue to the origin of the asteroids or rather to the absence of a single large planet in the region between Mars and Jupiter. Presumably the dominant gravitational presence of Jupiter interrupted the accretionary process and dispersed the planetesimals in this part of the solar system. Most of the material ended up striking the inner planets or was ejected from the system, and only a small remnant remains in the asteroid belt today.

Asteroidal orbits display other patterns in addition to the resonance gaps. An asteroidal family is defined as a group of objects that have similar orbits that suggest a common origin. These were first identified by Kiyotsuga Hirayama early in the twentieth century. About half of the known belt asteroids are members of families, nearly 10% belong to just three: the Koronos, Eos, and Themis families. Although not clustered together in space at present, the members of an asteroid family were all at the same place at some undetermined time in the past. Members of the same family tend to have similar reflectivities and spectra.

Apparently, the family members are fragments of broken asteroids, shattered in some ancient collision, and still follow similar orbital paths. According to some estimates, almost all asteroids smaller than about 200 km in diameter were probably disrupted in earlier times, when the population of asteroids was larger. The families we see today may be remnants of the most recent of these inter-asteroidal collisions.

Asteroids up Close

Radar Studies. One of the most powerful tools for investigating asteroids is radar. There are two major planetary radar facilities, both of which were upgraded in the late 1990s. NASA operates the Goldstone (California) planetary radar facility as part of the Deep Space Net, and the 1000-foot Arecibo dish in Puerto Rico is operated by the National Astronomical and Ionospheric Center with NSF and NASA support. The two facilities are complementary—Arecibo has greater sensitivity, but Goldstone has greater sky coverage. Radar allows measuring range and velocity and permits us to define the rotational state precisely and to constrain the object's internal density distribution. In addition, radar astronomers used measurements of echo power in time delay (range) and Doppler frequency (radial velocity) to construct geologically detailed three-dimensional models that sometimes rival the resolution of spacecraft imaging systems (7).

By 2001, radar had detected more than 120 asteroids, whose sizes are as small as 30 m. These include large objects in the main belt as well as more than 80 of the smaller NEAs. One of the early radar contributions was to search for direct evidence of metallic surfaces for a few asteroids from their high microwave reflectivity. Observations of M asteroids Psyche and Kleopatra provide the best evidence linking the M class to metallic composition. However, these two asteroids have provided numerous surprises. In spite of its apparently metallic surface, Psyche has a density of only about 2 g/cm^3 , suggesting that its interior has extremely high porosity if composed of metal. Kleopatra is even stranger; it has a remarkable “dog-bone” shape that suggests reaccretion of material after a catastrophic impact. There is also evidence of a low-density surface of unconsolidated rubble on Kleopatra—again not what we would have expected by comparison with the lumps of iron-nickel in our meteorite collections (8).

The highest-resolution imaging has been achieved for asteroids that come very close to Earth. The largest of these is Toutatis, an elongated lumpy asteroid that provided early evidence that asteroids might not be monolithic (Fig. 2). At

Figure 2. Shape model from radar images of Toutatis. Analysis of the delay-Doppler imaging sequence established that Toutatis is in a non-principal-axis spin state, and accurate determination of the asteroid's rotation required inverting of the image sequence with a realistic physical model. These four views of the Toutatis computer model show shallow craters, linear ridges, and a deep topographic “neck” whose geologic origin is not known. It may have been sculpted by impacts into a single, coherent body, or this asteroid might actually consist of two separate objects that came together in a gentle collision. Toutatis is about 5 km long (images courtesy of Steve Ostro, NASA Jet Propulsion Lab and Scott Hudson, Washington State University). Source: four images labeled as “computer model” at http://echo.jpl.nasa.gov/asteroids/4179_Toutatis/toutatis.html.

5 km long, Toutatis is among the largest of the NEAs. Toutatis is also one of three asteroids found so far that are in slow, non-principal-axis spin states—perhaps evidence that they have received recent impacts (9). Among the interesting results of radar has been the discovery of three bifurcated objects (Castalia, Mithra, and Bacchus) that appear to be contact binaries. In several other cases, there is evidence of satellites orbiting asteroids. Satellites provide a way to calculate densities of the primary objects. Since the late 1990s, several asteroidal satellites (including the large C-type main-belt asteroids Eugenia and Antiope) have been discovered by using ground-based optical telescopes, and densities have also been measured for three of the asteroids visited by spacecraft. Most of the densities turn out to be surprisingly low (less than 2 g/cm^3), suggesting rather high interior porosity.

Spacecraft Flybys. Table 2 summarizes the four detailed spacecraft studies of asteroids. The main-belt asteroids Gaspra and Ida were flyby targets for Galileo on its way to Jupiter, and Mathilde was visited by the NEAR-Shoemaker spacecraft on its way to its primary target, Eros. The NEAR studies of Eros are discussed in the next subsection. Figure 3 illustrates these spacecraft targets on the same scale.

The Galileo flybys of two main-belt S-type asteroids revealed that both are highly irregular in shape, heavily cratered, and have only slight differences in color or reflectivity across their surfaces. Gaspra is undersaturated with craters, indicating a relatively young age (where age is the time since the last global-scale impact). In contrast, Ida is saturated with craters, and it appears to have a broken-up surface layer (a regolith) that is tens of meters thick (similar to that of the Moon). The discovery of a small satellite (Dactyl) in orbit around Ida permitted measuring its mass and density. The density is 2.6 g/cm^3 , similar to that of primitive rocks. Partly on this basis, it appears that these two S-type asteroids are probably coherent and are composed of materials similar to ordinary chondrite primitive meteorites. However, the spectral mismatch between these objects and known chondrites in our meteorite collections continued to baffle investigators after these two flybys. In addition, the presence of large families of grooves or lineaments on both asteroids suggested that they had global-scale cracks resulting from past impacts.

Mathilde was the first main-belt C-type asteroid to be examined at close range. NEAR-Shoemaker found a unique shape for this asteroid, dominated by several apparent craters whose diameters are greater than the radius of the asteroid. Such a configuration is not possible for a “normal” rocky target because the formation of the most recent of these craters would have been expected to destroy preexisting giant craters or perhaps even to disrupt the target entirely.

Table 2. Spacecraft Encounters with Asteroids

Asteroid	Class	Date	Dimensions, km	Density, g/cm^3	Best resolution, m
Gaspra	S	1991	$18 \times 11 \times 9$	—	50
Ida	S	1993	$60 \times 25 \times 19$	2.6	25
Mathilde	C	1997	$66 \times 48 \times 46$	1.3	160
Eros	S	2000	$31 \times 13 \times 13$	2.67	0.1

Figure 3. Family portrait of spacecraft images of asteroids Gaspra, Ida, Mathilde, and Eros, shown to scale. Gaspra and Ida (both main-belt asteroids) were imaged by the Galileo spacecraft. Mathilda (main-belt) and Eros (near-Earth) were imaged by NEAR-Shoemaker (Images courtesy of NASA, the Caltech Jet Propulsion Laboratory, and the JHU Applied Physics Laboratory.) Source: <http://junior.apk.net/~matto/comparison_mathild_ida_gaspra_eros.jpg>.

Only a “soft” target that has a less competent interior can absorb great shocks without internal disruption. This interpretation was reinforced by the measured density of 1.3 g/cm^3 , indicative of about 50% porosity. Thus, Mathilde became the first confirmed rubble-pile asteroid.

The NEAR-Shoemaker Mission to Eros. The most ambitious and successful spacecraft investigation of the asteroids was carried out by a small (Discovery-class) NASA spacecraft called the Near Earth Asteroid Rendezvous (NEAR) mission. It was further christened NEAR-Shoemaker in honor of Eugene Shoemaker, the father of asteroid geology. NEAR-Shoemaker missed its original rendezvous date with Eros in December 1998 due to a malfunction, but it recovered after one more trip around the Sun and finally arrived in February 2000. It achieved an initial high orbit, then gradually lowered its altitude during the next year, and studied Eros with a variety of instruments. The spacecraft obtained thousands of multispectral images and more than 10 million laser altimetry measurements, making Eros one of the best-mapped objects in the solar system (10,11).

After 1 year in orbit, NEAR-Shoemaker began a staged descent to the surface, taking pictures of ever-increasing resolution (Fig. 4). It landed on 12 February 2001 at an impact velocity of 1.6 m/s. Fortunately, the spacecraft was not damaged, even though it had not been designed for such a maneuver. Using its low-gain antenna, it continued radioing data from the surface for more than a week, providing the best measurements of elemental composition. The mission ended on 28 February when a command from Earth turned off the spacecraft (12).

The quantitative measurement of radioactivity from K, Th, and U, as well as gamma-ray lines of Fe, O, Si, and Mg, demonstrated that Eros has a primitive composition equivalent to the low-iron group of ordinary chondrite meteorites. Eros is a normal class-S asteroid, so this *in situ* result finally settled questions that had remained open for decades concerning the nature (primitive or

Figure 4. Close-up of near-Earth asteroid Eros as seen from the NEAR-Shoemaker cameras at a range of just 7 km. Most of the scene (about 350 meters across) is covered by rocks of all sizes and shapes, but the floors of some craters are smooth, suggesting accumulation of fine mobile material. The smallest visible features are about 1 meter across. (Image courtesy of NASA and the JHU Applied Physics Laboratory.) Source: <http://photojournal.jpl.nasa.gov/cgi-bin/PIAGenCatalogPage.pl?PIA03118>.

differentiated) of the S asteroids. The density of Eros (2.67 g/cm^3) is also generally consistent with this meteorite identification, although it still implies a substantial bulk porosity of about 25%. Evidently asteroids, like many terrestrial sediments, are consistently less dense than the individual rocks of which they are composed.

Long ridges seen in some of the images demonstrate that Eros is a consolidated and coherent body that has global-scale tectonics. As suspected for several other asteroids, Eros is a solid collisional fragment of a larger parent body (not a rubble pile), but it is also not a monolith because its interior has been heavily fractured. The surface is cratered, but there is a surprising deficiency of small craters, combined with an excess of boulders up to the 100-m size. There are actually more boulders than craters in the tens-of-meters sizes. Some measured slopes are greater than the angle of repose. Dark material has flowed down-slope, exposing underlying bright material. The effects of space weathering are evident in the different spectral reflectivity of exposures of differing age. Apparently Eros has a complex, mobile regolith, whose small-scale surface roughness is similar to that of lunar regolith (somewhat surprising because the gravity is so much less).

As noted in summer 2001 by MIT scientist Richard Binzel, “We’re getting to know asteroids as tangible objects, on the same scale and geologic sense that we know mountains on Earth.” And like terrestrial mountains, their interiors can be highly fragmented.

Trojan Asteroids

A particularly interesting group of dark, distant asteroids is orbitally associated with Jupiter. Although the gravitational attraction of this giant planet generally

makes nearby asteroidal orbits unstable, exceptions exist for objects of the same orbital period as Jupiter, while leading or trailing it by 60° . These two stable regions are called the leading and trailing Lagrangian points, named for the mathematician who demonstrated their existence in 1772. While he was mathematically examining the possible motions of three mutually gravitating bodies, Lagrange found two regions where a small object could occupy a stable orbit within the gravitational fields of two larger objects. If the larger objects are Jupiter and the Sun, a small object in one of the Lagrangian points occupies one corner of an equilateral triangle, and the Sun and Jupiter are at the other two points.

The regions of stability around the two Lagrangian points are quite large: each contains several hundred known asteroids. The first of these Lagrangian asteroids was named Hektor when it was discovered in 1907. All of them are named for the heroes of the *Iliad* who fought in the Trojan War, and collectively they are known as the Trojan asteroids. Their spectra are distinctive, suggesting that they represent a group of special, primitive objects that have been trapped in this region of space since the birth of Jupiter. If we could detect the fainter members of these Trojan clouds, we might find that the Trojan asteroids are nearly as numerous as those in the main asteroid belt.

Near-Earth Asteroids

Asteroid populations that can impact Earth are of special interest to us. They are generally referred to as Near-Earth Asteroids (NEAs) or Earth-crossing asteroids (ECAs). Because of their unstable, planet-approaching orbits, the NEAs have impacted the surfaces of the planets in the inner solar system (including Earth) and have influenced both geologic and biological evolution. There is reason to expect further impacts in the future, so the NEAs are a topic that has profound political and societal overtones. The impact hazard represents the intersection of asteroid science and public welfare and governmental policy (13).

It is highly improbable that a large (diameter > 1 km) NEA will hit the Earth within our lifetimes, but such an event is entirely possible. In the absence of specific information, such a catastrophe is equally likely at any time, including next year. Recognition that Earth (and Moon) are impacted by asteroids and comets is less than a century old, and it was not even securely proven that the prominent Meteor Crater (Arizona) was of impact origin until the work of Eugene Shoemaker in 1960. The fortunate fact that the atmosphere protects us from impacting bodies smaller than a few tens of meters in diameter (except for the rare iron meteorites) has the perhaps unfortunate consequence that we have almost no direct experience with cosmic impacts.

Tunguska and Meteor Crater. On the timescale of a human lifetime, the 1908 Tunguska impact in Siberia is the most notable. It was estimated (primarily from barographic and seismic records) that it had an explosive energy of ~ 15 megaton (TNT equivalent) when it disintegrated about 8 km above the ground. The impactor had the force of a large contemporary nuclear weapon. The explosion affected an unusually remote part of the world, and the first expedition to study Tunguska was delayed by two decades. At the time, before the existence of

an Earth-crossing asteroid population was recognized, it was naturally suggested that the culprit was a small comet. Other fringe-science explanations included the impact of a mini black hole and the crash of a UFO spacecraft. Not until the 1990s did numerical modeling of the entry physics clearly indicate that a comet (low-density, friable material) of this kinetic energy would disintegrate at very high altitudes and could not penetrate into the troposphere (14). Now we recognize that the event in Tunguska was simply the most recent example of an ongoing bombardment of Earth by NEAs.

A better known site of asteroidal impact is Meteor Crater (also called Barringer Crater) in northern Arizona. In this case, an iron asteroid about 40–50 meters in diameter struck about 50,000 years ago and formed a crater slightly more than 1 km in diameter. The energy of this impact was approximately the same as that of Tunguska (about 15 megaton), but because of the greater strength and density of the projectile, the explosion occurred at or below the surface, and a crater was formed.

Impacts and Extinctions. NEAs entered the scientific and popular mainstream in the 1980s when they were identified as the possible agents of biological mass extinctions. Alvarez and others (15) proposed that the dinosaur-killing KT mass extinction was due to an impact by a comet or asteroid, inferred from the chemical signature of extraterrestrial material in the boundary layer at the end of the Cretaceous. This bold hypothesis received general acceptance after the 200-km-diameter Chicxulub crater in Mexico (still among the largest craters identified on Earth) was discovered and it was dated exactly to the age of the KT extinction.

The most revolutionary insight of Alvarez and his colleagues was not that impacts take place on Earth (which was obvious), but that even small impacts (on a geological or astronomical scale) can severely damage the fragile terrestrial ecosystem. From the size of the Chicxulub crater, the energy of the KT impact is estimated at about 100 million megaton, and a consistent value of the size of the impactor (10–15 km in diameter) is derived from the observed extraterrestrial component in the boundary layer. Immediate effects of the impact included blast and the generation of a tsunami (because the impact occurred in a shallow sea). However, the primary agents of global stress appear to have been a short-lived firestorm from atmospheric heating of ejecta followed by a persistent (months to years) blackout due to particulates suspended in the stratosphere (16). Large land animals (such as the dinosaurs) were incinerated within a few minutes of the impact, and the marine ecosystem collapsed a few weeks later as a result of the global blackout. Fortunately, impacts of this size are exceedingly rare; they occur at average intervals of the order of a hundred million years. Today, there is no NEA comparable to the KT impactor that can hit Earth. However, we have no such assurance of immunity from smaller impacts.

Impacts from asteroids and comets have influenced the biological history of our planet in a variety of ways. It is widely thought that carbonaceous asteroids have been the dominant source of Earth's water and other volatiles, including many organic compounds required for originating life. At the same time, the impact environment of early Earth must have challenged the development of life and may have led to short episodes in which the oceans boiled away and the planet was sterilized. The phenomenon has been called the "impact frustration of life" (17). After the end of the heavy bombardment of Earth about 3.8 billion

years ago, impact catastrophes of this dimension were not possible. However, the Earth must have experienced dozens (or more) of impacts of the size of the KT event that punctuated biological evolution with occasional episodes of dramatic environmental stress. Impacts have been suspected in several other mass extinctions besides the KT, but in no other case is the evidence truly compelling. However, we know that these impacts have happened, and it is entirely plausible that they played a major role in biological evolution.

The Asteroid Impact Hazard

The average frequency of impacts by NEAs as a function of kinetic energy is illustrated in Fig. 5, adapted from a graph published in 1983 by Shoemaker (18). Comparison of this size–frequency distribution with the expected environmental damage caused by impacts of different energy leads to the conclusion (19) that the greatest risk is from large impacts, those that create a global ecological catastrophe. The threshold for global catastrophe is in the vicinity of 1 million megatons of energy, corresponding to an NEA whose diameter is about 2 km. Below this threshold, impacts create regional or local disasters, but the population (and social stability) of the planet are not threatened.

Although impacts below this million-megaton threshold are much more frequent, the total hazard from the sum of all such smaller impacts is less. Unlike more familiar natural hazards, the impact risk is primarily from extremely

Figure 5. Plot of frequency of impacts on Earth vs. impact energy for near-Earth asteroids (NEAs). The power law is a long-term average derived primarily from lunar cratering and the current number and distribution of known NEAs. Shown plotted at their estimated energies are the Hiroshima nuclear bomb, the Tunguska impact of a small asteroid in Siberia (1908), and the KT impact that led to the extinction of the dinosaurs (65 million years ago). (Figure courtesy of David Morrison and NASA Ames Research Center.)

rare events—literally unprecedented in human history. The impact hazard represents the extreme case of a calamity of low probability but high consequences, including the possible end of civilization as we know it. It is logical to concentrate first on mitigating the risk from global catastrophes. Later, it may be desirable to extend mitigation efforts to smaller impacts that are much more likely to happen within our lifetimes, although they do not threaten society as a whole.

The preceding discussion treats impacts as if they are random statistical events, but they are in fact clearly deterministic. There either is or is not an NEA on a trajectory to collide with the Earth within, say, the next century. Any discussion of mitigation must recognize that these events can be predicted and even eliminated by deflecting a threatening NEA. The key requirement is adequate warning time. This is the philosophy behind the international “Spaceguard Survey” being carried out by ground-based optical telescopes equipped with state-of-the-art wide-field detectors and automated search capability (20). The NEAs are found as they repeatedly fly past Earth at typical distances of tens of millions of kilometers. If one of them should be on course for a future collision, it should be discovered decades (or more) in advance. The initial goal of Spaceguard is to discover and catalog at least 90% of all NEAs larger than 1 km in diameter within 10 years (by 2008). The focus is on NEAs of this size because 1 km is near the lower bound for an impact that can cause a global catastrophe. However, the observers continue to discover more NEAs below 1 km than above it, and over time the survey will extend completeness to smaller sizes.

The threat of impacts and the requirement to survey the NEAs have been recognized by the governments of the United States, the United Kingdom, Japan, and the Council of Europe, as well as by many *ad hoc* technical panels. The current Spaceguard Survey is being carried out by half a dozen observing teams primarily supported by NASA and the USAF. More than half the discoveries are being made by the Lincoln Lab/MIT group called LINEAR. As of the end of 2001, more than 500 of the estimated 1000 NEAs larger than 1 km have been found, and their orbits have been calculated. We can say with assurance that none of the discovered NEAs poses any threat on the timescale of a human lifetime, but of course we still cannot speak for the objects not yet discovered (21). How far the survey will be extended, and what plans will be developed for possible planetary protection against impacts, are questions for society as a whole, not just the small number of scientists who are currently studying NEAs.

Glossary

Asteroid. A small (diameter less than 1000 km) rocky or metallic solar system object in heliocentric orbit, generally of moderate or low orbital eccentricity and inclination. The majority are located in the asteroid belt between Mars and Jupiter. Sometimes called minor planet.

Asteroid Belt. The region in the solar system where most asteroids are found, between Mars and Jupiter. Specifically, objects in the main asteroid belt have orbital periods between 2.2 and 3.3 years.

Astronomical unit (AU). The mean distance of Earth from the Sun, approximately 150 million km.

Megaton (MT). Unit of energy equivalent to one million tons of TNT, 4.3×10^{15} joule.

Meteorite. Any extraterrestrial material that survives passage through the atmosphere and falls to Earth's surface. Most meteorites are fragments of asteroidal parent bodies.

Near-Earth Asteroid (NEA). An asteroid whose orbit brings it close to Earth (perihelion distance less than 1.3 AU) or, especially, an asteroid in an Earth-crossing orbit. Sometimes subdivided into Amor, Apollo, and Aten subgroups.

Regolith. The fragmented, dusty, porous, upper layer of material on a planetary surface; essentially the equivalent of Earth's soil for an object like the Moon that has little or no atmosphere or water.

ASTROBIOLOGY

Astrobiology is a relatively new term that embraces the multidisciplinary study of the living Universe. It is the investigation of the origin, evolution, distribution, and destiny of life in the Universe. Astrobiology addresses some of the most profound questions of humankind: How did life begin? Are there other planets like Earth? What is our future as terrestrial life expands beyond the home planet? These questions are age-old. In the twenty-first century, however, advances in biological sciences, informatics, and space technology may make it possible for us to provide some answers.

Although the term had been used occasionally during previous decades as a synonym for “exobiology,” astrobiology in its present incarnation was proposed by NASA Associate Administrator for Space Science Wesley Huntress in 1995. NASA encouraged this new discipline by organizing workshops and technical meetings, establishing a NASA Astrobiology Institute, providing research funds to individual investigators, ensuring that astrobiology goals are incorporated in NASA flight missions, and initiating a program of public outreach and education. NASA’s role is derived from its history of studying the origin of life and searching for evidence of life on Mars or elsewhere in our solar system. Under the umbrella of astrobiology, these efforts are expanded to include the search for life within other planetary systems, as well as investigating the response of terrestrial life to global changes on Earth and to exposure to conditions in space and in other worlds. Astrobiology addresses our origins and also our aspirations to become a space-faring civilization.

Science Goals

The NASA Astrobiology road map (1) provides an initial description of the technical content of astrobiology. This road map was formulated through a series of workshops and discussions involving more than 400 people, primarily academic scientists who are interested in this new discipline. The road map represents a snapshot of a developing science and defines its content as perceived by scientists in 1998.

Astrobiology addresses three basic questions, which have been asked in some form for generations.

- How does life begin and evolve? (Where did we come from?)
- Does life exist elsewhere in the Universe? (Are we alone?)
- What is life’s future on Earth and beyond? (Where are we going in space?)

These are very general questions, and no one expects that definitive answers will be found easily. More specific is the analysis of astrobiology in terms of 10 long-term science goals.

1. Understand How Life Arose On Earth. Terrestrial life is the only form of life that we know, and it appears to have arisen from a common ancestor. How and where did this remarkable event occur? The question can be approached using historical, observational, and experimental investigations to understand the origin of life on our planet. We can describe the conditions on Earth when life began, use phylogenetic information to study our earliest ancestors, and also assess the possibility that life formed elsewhere and subsequently migrated to Earth.

2. Determine the General Principles Governing the Organization of Matter into Living Systems. To understand the full potential of life in the Universe, we must establish the general physical and chemical principles of life. We ask if terrestrial biochemistry and molecular biology are the only such phenomena that can support life. Having only one example, we do not know which properties of life are general and necessary and which are the result of specific

circumstances or historical accident. We seek these answers by pursuing laboratory experimental approaches and computational theoretical approaches.

3. Explore How Life Evolves on the Molecular, Organic, and Ecosystemic Levels. Life is a dynamic process of changes in energy and composition that occurs at all levels of assemblage from individual molecules to ecosystemic interactions. Modern genetic analysis, using novel laboratory and computational methods, allows new insights into the diversity of life and evolution at all levels. Complementary to such studies are investigations of the evolution of ecosystems consisting of many interdependent species, especially microbial communities.

4. Determine How the Terrestrial Biosphere Has Coevolved with Earth. Just as life evolves in response to changing environments, changing ecosystems alter Earth's environment. Astrobiologists seek to understand the diversity and distribution of our ancient ancestors by developing technology to read the record of life as captured in biomolecules and in rocks (fossils), to identify specific chemical interactions between the living components of Earth (its biosphere) and other planetary subsystems, and to trace the history of Earth's changing environment in response to external driving forces and to biological modifications.

5. Establish Limits For Life in Environments That Provide Analogs for Conditions in Other Worlds. Life is found on Earth anywhere liquid water is present, including such extreme environments as the interior of nuclear reactors, ice-covered Antarctic lakes, suboceanic hydrothermal vents, and deep subsurface rocks. To understand the possible environments for life in other worlds, we must investigate the full range of habitable environments on our own planet, for what they can tell us about the adaptability of life and also as analogs for conditions on other bodies in our solar system, such as Mars or Europa.

6. Determine What Makes a Planet Habitable and How Common These Worlds are in the Universe. Where should we look for extraterrestrial life? Based on our only example (life on Earth), liquid water is a requirement. Therefore, we must determine which sorts of planets are likely to have liquid water and how common they might be. Studying the processes of planet formation and surveying a representative sample of planetary systems will determine which planets are present and how they are distributed, essential knowledge for judging the frequency of habitable planets.

7. Determine How to Recognize the Signature of Life in Other Worlds. Astrobiologists need to learn to recognize extraterrestrial biospheres and to detect the signatures of extraterrestrial life. Within our own solar system, we must learn to recognize structural fossils or chemical traces of extinct life that may be found in extraterrestrial rocks or other samples (such as Martian meteorite ALH84001). To understand remotely sensed information from planets circling other stars, we should develop a catalog of possible spectral signatures of life. (See article on Extraterrestrial Life, Searching for in this Encyclopedia.)

8. Determine Whether There Is (or Once Was) Life Elsewhere in Our Solar System, Particularly on Mars and Europa. Exciting data have presented us with the possibility that at least two other worlds in our solar system have (or have had) liquid water present. On Mars, there is evidence for stable flowing water early in that planet's history. Both *in situ* investigations and the analysis of returned samples will be necessary to understand Mars' historical

climates and its potential for life. Because their surfaces are inhospitable, exploration of the subsurface probably offers the only credible opportunity to find extant life on either Mars or Europa.

9. Determine How Ecosystems Respond to Environmental Change on Timescales Relevant to Human Life on Earth. Research at the level of the whole biosphere is needed to examine the habitability of our planet over time in the face of both natural and human-induced environmental changes. To help ensure that continuing health of this planet and to understand the potential long-term habitability of other planets, we need to assess the role of rapid changes in the environment and develop our knowledge base to enable predictive models of environment–ecosystem interaction.

10. Understand the Response of Terrestrial Life to Conditions in Space or on Other Planets. All terrestrial life has developed in a one-gravity field, protected by Earth’s atmosphere and magnetic field. What happens when terrestrial life is moved off its home planet and into space or to the Moon or Mars, where the environment is very different from that of Earth? Can organisms and ecosystems adapt to a completely novel environment and live successfully for multiple generations? Are alternative strategies practical, such as bioengineering organisms for specific environments? The results from attempting to answer such questions will determine whether Earth’s life can expand its evolutionary trajectory beyond its place of origin.

Programmatic and Institutional Foundations

Astrobiology began as an effort within NASA to organize its space research programs around the theme of life in the Universe. It was given impetus by missions to Mars and Europa, by plans for telescopes in space to detect other planetary systems and measure the spectra of distant planets, and by the launch of the International Space Station and its planned suite of experimental facilities for life science. Within the NASA hierarchy, astrobiology has elements in the Space Science, Earth Science, and Human Exploration and Development of Space Enterprises. The lead management and coordination role was assigned to the Office of Space Science, and the lead NASA Center role was assigned to the Ames Research Center in California.

One of the early commitments to the development of astrobiology was the creation of a NASA Astrobiology Institute (NAI). This organization has the multiple objectives of encouraging commitments to astrobiology in the academic community, stimulating multidisciplinary research, and providing advice and technical input to NASA flight missions. Its member institutions are built around multidisciplinary research teams selected competitively. The central offices of the Astrobiology Institute are located at Ames Research Center, but the participating scientists (nearly 400 of them in 2001) remain employed in their own home institutions. Thus the NAI is a “virtual institute” or “collaboratory” in structure, using communications technology, together with an annual science meeting, postdoctoral fellows, and a number of cross-institutional “focus groups” to bind its geographically dispersed teams together. The first Director of the Astrobiology Institute is Nobel laureate Baruch Blumberg. Eleven

member institutions were selected in 1998: Harvard University, Marine Biological Laboratory at Woods Hole, Carnegie Institution of Washington, Pennsylvania State University, Arizona State University, Scripps Research Institute, University of California at Los Angeles, University of Colorado, NASA Ames Research Center, NASA Jet Propulsion Laboratory, and NASA Johnson Space Center. To these, the following were added in 2001: University of Rhode Island, Michigan State University, and University of Washington. Also associated with the NAI are the Center for Astrobiology in Madrid Spain and astrobiology teams in the United Kingdom and Australia. There is also a great opportunity for public access, as indicated by such popular web-sites as <astrobiology.arc.nasa.gov>, <nai.arc.nasa.gov>, and <www.astrobiology.com>.

The NASA astrobiology science goals bear a relationship to the search for extraterrestrial intelligence (SETI). Indeed, the detection of signals from an intelligent civilization on a distant planet would provide one of the most unambiguous signatures of extraterrestrial life (Goal 7 above). Historically, however, the SETI efforts have been separated from NASA since congressional action in 1993 terminated all NASA support for SETI programs. Intellectually, however, the two efforts represent complementary ways of addressing some of the same objectives.

Astrobiology is a science that has wide public appeal, as well as potential public concern. The search for life beyond Earth and the eventual expansion of terrestrial life to Mars or other planets in our solar system carry responsibility for protecting planetary ecosystems. Astrobiologists must ensure that these programs are carried out according to generally understood ethical and scientific principles. We will not endanger terrestrial life by introducing alien life-forms, and we will consider the broad ethical and cultural implications before we undertake to change the climate and surface conditions to make another world more hospitable to terrestrial life. Astrobiologists realize that their research has implications that are felt beyond the confines of the laboratory. As our understanding of living systems and the physical universe increases, we will confront the implications of this knowledge in more than just the scientific and technical realms. To understand the consequences will require multidisciplinary consideration of areas such as economics, environment, health, theology, ethics, quality of life, the sociopolitical realm, and education.

Summary

Astrobiology deals with a broad spectrum of disciplines, working together to use space technology to answer fundamental questions about life. Recent developments suggest that astrobiology is here to stay. But its success as a field will depend primarily on the quality of research carried out and on its contributions to space missions. If (or when) life is discovered on Mars or Europa, or the signature of life is detected in the light from an Earth-like planet circling another star, or commitments are made to human visits to other planets, then we can anticipate that astrobiology will hold center stage within space science.

Glossary

Astrobiology. The multidisciplinary study of the living universe, investigating the origin, evolution, distribution, and destiny of life in the Universe (term coined by Wesley Huntress in 1995). The term is somewhat broader than exobiology and includes studies of terrestrial life as it migrates into space.

Exobiology. The study of the origin, evolution, and distribution of life in the universe (term coined by Joshua Lederberg in 1960). In the United States, the term does not include studies of terrestrial life in space, but in Europe, “exobiology” sometimes takes on this broader meaning (which is essentially the same as “astrobiology”).

ASTRONAUTS AND THE PEOPLE WHO SELECTED THEM: A COMPENDIUM

The National Aeronautics and Space Administration's (NASA) Lyndon B. Johnson Space Center (JSC), located in Houston, Texas, has been responsible for conducting the astronaut recruiting and selection process. This includes

- establishing the astronaut staffing and selection requirements.
- issuing and releasing public announcements advertising the qualification requirements.
- appointing qualified members for rating panels and selection committees established for each recruiting campaign:
 - to review and perform the initial screening of applicants;
 - to conduct personal interviews of those applicants who satisfy initial screening requirements; and
 - to make final recommendations for selecting of applicants who qualify for the astronaut training program.

From the outset of human spaceflight, prospective candidates for the astronaut training program have been recruited on the basis of selection criteria dictated by the requirements of the missions to which they would be assigned. These mission requirements have grown in complexity; each follow-on program is responsible for advancing the state of the art of human space explorations. Such requirements have evolved from the pioneering effort in Project Mercury to those of far-reaching ramifications demonstrated in Project Apollo for landing humans on the Moon and more in the Space Shuttle and International Space Station Program for sustaining human life and supporting human productivity for flights of long duration.

In December 1958, President Dwight D. Eisenhower issued an edict limiting the pool of candidates for Project Mercury astronauts to military test pilots. Critics argued that this requirement excluded women, given the absence of female test pilots in the armed services to choose from and that the use of all military personnel in this highly visible position ran contrary to NASA's status as a civilian agency. However, Eisenhower's decision simplified and expedited NASA's selection process, eliminated the potential publicity blitz associated with an open call for applicants, and fit well with the highly technical and classified nature of certain aspects of the job. Screening boards for the Navy, Air Force, and Marines and a review by three aviation medicine specialists deemed 110 test pilots suitably qualified for further evaluation by the NASA Space Task Group, the organization charged with putting America's first human in space. Robert R. Gilruth, the Space Task Group Director, delegated all authority for selecting the Mercury astronauts to his deputy, Charles J. Donlan, and his handpicked board. Though rigorous medical and psychological tests provided a wealth of information on each potential astronaut, this first selection committee also weighed its impressions gained through personal interviews with each candidate. The committee regarded individual initiative and complementary technical expertise within the group as the deciding factors in March 1959 when they chose the seven test pilots who would be America's first men in space. In the following month, after approval by Gilruth and NASA management, the space agency publicly announced the names of the Mercury Seven astronauts.

The Original Seven

The initial astronaut selection began in January 1959, before human spaceflight operations began, when NASA asked the military services to screen personnel

records for prospective candidates who met the qualifications outlined in Table 1. This preliminary review produced 508 military test pilots, of whom 110 satisfied all of the basic requirements. A subsequent examination of military and medical records reduced the total eligible to 69, all of whom were invited to Washington for a briefing on Project Mercury and a personal interview. It was on the basis of these interviews, that 32 men were chosen to undergo detailed physical examination and stress testing; however, it became apparent during this phase that all of the candidates surpassed the established medical standards. Consequently, final screening concentrated on individual engineering and operational performance, and the seven best technically qualified were selected in April 1959 for the Mercury Program.

Note: All ranks for military and uniformed services officers referenced indicate the rank held when the individual was selected for the astronaut program.

M. Scott Carpenter, Lt., USN. Born May 1, 1925. B.S. in Aeronautical Engineering from the University of Colorado.

L. Gordon Cooper, Capt., USAF. Born March 6, 1927. B.S. in Aeronautical Engineering from the Air Force Institute of Technology.

John H. Glenn, Jr., Lt. Col., USMC. Born July 18, 1921. B.S. in Engineering from Muskingum College.

Virgil I. Grissom, Capt., USAF. Born April 3, 1926. B.S. in Mechanical Engineering from Purdue University.

Walter M. Schirra, Jr., Lt. Comdr., USN. Born March 12, 1923. B.S. from the U.S. Naval Academy.

Alan B. Shepard, Lt. Comdr., USN. Born November 18, 1923. B.S. from the U.S. Naval Academy.

Donald K. Slayton, Capt., USAF. Born March 1, 1924. B.S. in Aeronautical Engineering from the University of Minnesota.

An ad hoc selection committee was appointed for each recruiting effort conducted in the search for candidates who qualified for the astronaut training program. Participating in the selection of the original seven were Charles J. Donlan, NASA Space Task Group; A. O. Gamble, NASA Headquarters; Robert R. Gilruth, NASA Space Task Group; and Warren J. North, NASA Headquarters.

Group 2

In April 1962, an announcement was issued from Houston to recruit a second group of astronauts to train for the Gemini and Apollo Programs. Minimum qualification standards were published and disseminated to aircraft companies, government agencies, military services, the Society of Experimental Test Pilots, and the news media (see Table 1). A total of 250 applications was received from civilian and military sources. Each candidate who satisfied the five basic standards was asked to complete a variety of forms describing academic credentials and flight and work experience in detail. Each was also asked to submit to a thorough physical/medical examination and to forward the results to the Johnson Space

Table 1. **Astronaut Selection History^a 1958 to 2000**

Group	Date	Number selected	Max age	Max height	Min degree level	Jet pilot	TPS grad	Flying time	Experience	Outside help
1	Apr. 59	7	39	5'-10"	B.S.	Yes	Yes	1500		
2	Sept. 62	9	34	6'-0"	B.S.	Yes	Yes	1500

^bNAS is the National Academy of Science.

Center (then the Manned Spacecraft Center) in Houston, Texas. In June 1962, a preliminary selection committee reviewed this additional information submitted by the individual candidates and selected 32 of the most qualified applicants to participate in further examinations, tests, and personal interviews. Nine pilot astronauts comprised the group finally selected in September 1962:

Neil A. Armstrong, civilian. Born August 5, 1930. B.S. in Aeronautical Engineering from Purdue University and attended graduate school at the University of Southern California.

Frank Borman, Maj., USAF. Born March 14, 1928. B.S. in Aeronautical Engineering from the U.S. Military Academy and M.S. in Aeronautical Engineering from the California Institute of Technology.

Charles Conrad, Jr., Lt., USN. Born June 2, 1930. B.S. in Aeronautical Engineering from Princeton University.

James A. Lovell, Jr., Lt. Comdr., USN. Born March 25, 1928. B.S. from the U.S. Naval Academy.

James A. McDivitt, Capt., USAF. Born June 10, 1929. B.S. in Aeronautical Engineering from the University of Michigan.

Elliot M. See, Jr., civilian. Born July 23, 1927. B.S. from the U.S. Merchant Marine Academy and M.S. in Engineering from the University of California at Los Angeles.

Thomas P. Stafford, Capt., USAF. Born September 17, 1930. B.S. from the U.S. Naval Academy.

Edward H. White II, Capt., USAF. Born November 14, 1930. B.S. from the U.S. Military Academy and M.S. in Aeronautical Engineering from the University of Michigan.

John W. Young, Lt. Comdr., USN. Born September 24, 1930. B.S. in Aeronautical Engineering from Georgia Institute of Technology.

The committee for the selection of Group 2 included Warren J. North, NASA JSC; Alan B. Shepard, Jr., NASA JSC; and Donald K. Slayton, NASA JSC.

Group 3

A third call for applications for the astronaut process was issued in June 1963. For this group, the requirement for test pilot school was optional (see Table 1), and the required jet pilot time was reduced to 1000 hours. With this decrease in actual flying requirements, increased emphasis was given to academic areas. A total of 720 applications was received—228 from civilians and 492 from military personnel. Of the 490 certified eligibles, 136 were referred for final screening by the NASA selection board. Fourteen new astronauts were named in October 1963. Two civilians, seven Air Force pilots, four Navy aviators, and one Marine Corps aviator comprised this third group of trainees:

Edwin E. Aldrin, Jr., Maj., USAF. Born January 20, 1930. B.S. from the U.S. Military Academy and Sc.D. in Astronautics from Massachusetts Institute of Technology.

William A. Anders, Capt., USAF. Born October 17, 1933. B.S. from U.S. Naval Academy and M.S. in Nuclear Engineering from the Air Force Institute of Technology.

Charles A. Bassett II, Capt., USAF. Born December 30, 1931. B.S. in Electrical Engineering from Texas Technological University.

Alan L. Bean, Lt., USN. Born March 15, 1932. B.S. in Aeronautical Engineering from the University of Texas.

Eugene A. Cernan, Lt., USN. Born March 14, 1934. B.S. in Electrical Engineering from Purdue University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Roger B. Chaffee, Lt., USN. Born February 15, 1935. B.S. in Aeronautical Engineering from Purdue University.

Michael Collins, Capt., USAF. Born October 31, 1930. B.S. from the U.S. Military Academy.

R. Walter Cunningham, civilian. Born March 16, 1932. B.A. and M.A. in Physics from the University of California at Los Angeles.

Donn F. Eisele, Capt., USAF. Born June 23, 1930. B.S. from the U.S. Naval Academy and M.S. in Astronautics from the Air Force Institute of Technology.

Theodore C. Freeman, Capt., USAF. Born February 18, 1930. B.S. from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the University of Michigan.

Richard F. Gordon, Lt. Comdr., USN. Born October 5, 1929. B.S. in Chemistry from the University of Washington.

Russell L. Schweickart, civilian. Born October 25, 1935. B.S. in Aeronautical Engineering and M.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology.

David R. Scott, Capt., USAF. Born June 6, 1932. B.S. from the U.S. Military Academy, and M.S. and M.E. in Aeronautics and Astronautics from Massachusetts Institute of Technology.

Clifton C. Williams, Jr., Capt., USMC. Born September 26, 1932. B.S. in Mechanical Engineering from Auburn University.

The selection committee members for Group 3 were John H. Glenn, Jr., NASA JSC; Warren J. North, NASA JSC; Walter M. Schirra, Jr., NASA JSC; Alan B. Shepard, Jr., NASA JSC; and Donald K. Slayton, NASA JSC.

Group 4 (Scientist-Astronauts)

NASA began recruiting for its first group of scientist-astronauts in October 1964. For this group, flying status was desirable but not a mandatory prerequisite for selection (see Table 1). However, each of those selected was required to pass a Class I military flight physical examination before acceptance to the training program. Emphasis was on graduate work in the natural sciences, such as physics, medicine, engineering, or comparable occupational experience. A total

of 1492 letters of interest was received in Houston by January 1965. Some were informal inquiries, but 909 were formal applications. Of the latter, 424 qualified under the minimum criteria established and were forwarded to the National Academy of Sciences in Washington DC for evaluation. The Academy evaluated these applications for conformity with scientific criteria developed cooperatively with the NASA Office of Space and Applications and recommended 16 candidates for final consideration. These 16 applicants underwent thorough physical examinations and stress testing, and six were selected in June 1965 for training as scientist-astronauts. One geologist, two physicians, and three physicists comprised the group, and two in the group were qualified jet pilots. Those without jet pilot experience underwent one year's flight training before entering the regular astronaut training program. The following were selected:

Owen K. Garriott, civilian. Born November 22, 1930. B.S. in Electrical Engineering from the University of Oklahoma and M.S. and Ph.D. in Electrical Engineering from Stanford University.

Edward G. Gibson, civilian. Born November 8, 1936. B.S. in Engineering from the University of Rochester and M.S. in Engineering and Ph.D. in Engineering and Physics from California Institute of Technology.

Duane E. Graveline, civilian. Born March 2, 1931. Ph.D./M.D. from the University of Vermont and M.S. in Public Health from Walter Reed Army Medical Center.

Joseph P. Kerwin, Lt. Comdr., USN. Born February 19, 1932. B.A. in Philosophy from the College of the Holy Cross and M.D. from Northwestern University Medical School.

F. Curtis Michel, civilian. Born June 5, 1934. B.S. and Ph.D. in Physics from California Institute of Technology.

Harrison H. Schmitt, civilian. Born July 3, 1935. B.S. in Science from California Institute of Technology and Ph.D. in Geology from Harvard University.

The selection committee for Group 4 consisted of the following members from the National Academy of Sciences Board: Dr. Allan H. Brown, Department of Biology, Joseph Leidy Laboratory of Biology, University of Pennsylvania; Professor L.D. Carlson, Department of Physiology, University of California Medical School; Professor Frederick L. Ferris, Jr., Educational Services, Inc.; Dr. Thomas Gold, Chairman, Astronomy Department, Director, Center for Radio, Physics and Space Research, Cornell University; Dr. H. Keffer Hartline, Rockefeller University; Dr. Clifford T. Morgan, Department of Psychology, University of California; Dr. Eugene M. Shoemaker, Astrogeology Branch, U.S. Geological Survey; Dr. Robert Speed, Department of Geology, Northwestern University; and Professor Aaron C. Waters, Department of Geology, University of California.

The NASA Board consisted of the following individuals: Charles A. Berry, M.D., NASA JSC; John F. Clark, NASA Goddard Space Flight Center (GSFC); Maxime A. Faget, NASA JSC; Warren J. North, NASA JSC; Alan B. Shepard, Jr., NASA JSC; and Donald K. Slayton, NASA JSC.

Group 5

The Johnson Space Center launched its fifth recruiting drive in September 1965. Eligibility requirements were basically the same as those used in selecting the third group of astronaut trainees (see Table 1). A total of 510 applications was received, of which 158 (100 military and 58 civilians) met basic requirements. The previously established screening procedures were followed, yielding 19 pilot-astronauts who were selected in April 1966. Selectees were:

Vance D. Brand, civilian. Born May 9, 1931. B.S. in Business and Aeronautical Engineering from the University of Colorado and MBA from the University of California at Los Angeles.

John S. Bull, Lt., USN. Born September 25, 1934. B.S. in Mechanical Engineering from Rice University.

Gerald P. Carr, Maj., USMC. Born August 22, 1932. B.S. in Mechanical Engineering from the University of Southern California, B.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School, and M.S. in Aeronautical Engineering from Princeton University.

Charles M. Duke, Jr., Capt., USAF. Born October 3, 1935. B.S. in Naval Sciences from the U.S. Naval Academy and M.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology.

Joe H. Engle, Capt., USAF. Born August 26, 1932. B.S. in Aeronautical Engineering from the University of Kansas.

Ronald E. Evans, Lt. Comdr., USN. Born November 10, 1933. B.S. in Electrical Engineering from the University of Kansas and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Edward G. Givens, Jr., Maj., USAF. Born January 5, 1930. B.S. in Naval Sciences from the U.S. Naval Academy.

Fred W. Haise, Jr., civilian. Born November 14, 1933. B.S. in Aeronautical Engineering from the University of Oklahoma.

James B. Irwin, Maj., USAF. Born March 17, 1930. B.S. in Naval Sciences from the U.S. Naval Academy and M.S. in Aeronautical Engineering and Instrumentation Engineering from the University of Michigan.

Don L. Lind, civilian. Born May 18, 1930. B.S. in Physics from the University of Utah and Ph.D. in High Energy Nuclear Physics from the University of California at Berkeley.

Jack R. Lousma, Capt., USMC. Born February 29, 1936. B.S. in Aeronautical Engineering from the University of Michigan and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Thomas K. Mattingly II, Lt., USN. Born March 17, 1936. B.S. in Aeronautical Engineering from Auburn University.

Bruce McCandless II, Lt., USN. Born June 8, 1937. B.S. in Naval Sciences from the U.S. Naval Academy and M.S. in Electrical Engineering from Stanford University.

Edgar D. Mitchell, Comdr., USN. Born September 17, 1930. B.S. in Industrial Management from Carnegie Institute of Technology, B.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School, and Sc.D. in Aeronautics and Astronautics from Massachusetts Institute of Technology.

William R. Pogue, Maj., USAF. Born January 23, 1930. B.S. in Education from Oklahoma Baptist University and M.S. in Mathematics from Oklahoma State University.

Stuart A. Roosa, Capt., USAF. Born August 16, 1933. B.S. in Aeronautical Engineering from the University of Colorado.

John L. Swigert, Jr., civilian. Born August 30, 1931. B.S. in Mechanical Engineering from the University of Colorado, M.S. in Aerospace Science from Rensselaer Polytechnic Institute, and M.S. in Business Administration from the University of Hartford.

Paul J. Weitz, Lt. Comdr., USN. Born July 25, 1932. B.S. in Aeronautical Engineering from Pennsylvania State University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Alfred M. Worden, Capt., USAF. Born February 7, 1932. B.S. from the U.S. Military Academy and M.S. in Aeronautical/Astronautical Engineering and Instrumentation Engineering from the University of Michigan.

The selection committee members for Group 5 were Charles Conrad, Jr., NASA JSC; L. Gordon Cooper, Jr., NASA JSC; Virgil I. Grissom, NASA JSC; Warren J. North, NASA JSC; Donald K. Slayton, NASA JSC; Clifton C. Williams, Jr., NASA JSC; and John W. Young, NASA JSC.

Group 6 (Scientist-Astronauts)

In September 1966, NASA requested the National Academy of Sciences to nominate a second group of scientist-astronauts. NASA encouraged the Academy to seek experienced scientists of exceptional ability “to conduct scientific experiments in manned orbiting satellites and to observe and investigate the lunar surface and circumterrestrial space.” The Academy then issued its announcement stating: “The quality most needed by a scientist serving as an astronaut might be summed up by the single word “perspicacity.” The task requires an exceptionally astute and imaginative observer but also one whose observations are accurate and impartial. He must, from among the thousands of items he might observe, quickly pick out those that are significant, spot the anomalies, and investigate them. He must discriminate fine detail and subtle insight into a general pattern, and select and devise key observations to test working hypotheses. The selection criteria and procedures were comparable to those used in choosing the first group of scientist-astronauts (see Table 1). Nine-hundred applicants responded, but the Academy recommended only 69 for NASA’s final consideration. Of this number, 11 were chosen:

Joseph P. Allen IV, civilian. Born June 27, 1937. B.A. in Math-Physics from De Pauw University and M.S. and Ph.D. in Physics from Yale University.

- Philip K. Chapman, civilian. Born March 5, 1935. B.S. in Physics and Mathematics from Sydney University; M.S. in Aeronautics and Astronautics and Sc.D. in Instrumentation from Massachusetts Institute of Technology.
- Anthony W. England, civilian. Born May 15, 1942. B.S. and M.S. in Geology and Physics from Massachusetts Institute of Technology.
- Karl G. Henize, civilian. Born October 17, 1926. B.A. in Mathematics and M.A. in Astronomy from the University of Virginia and Ph.D. in Astronomy from the University of Michigan.
- Donald L. Holmquest, civilian. Born April 7, 1939. B.S. in Electrical Engineering from Southern Methodist University and doctorates in Medicine and Physiology from Baylor University.
- William B. Lenoir, civilian. Born March 14, 1939. B.S., M.S., and Ph.D. in Electrical Engineering from Massachusetts Institute of Technology.
- John A. Llewellyn, civilian. Born April 22, 1933. B.S. and Ph.D. in Chemistry from the University College of Cardiff.
- F. Story Musgrave, civilian. Born August 19, 1935. B.S. in Mathematics and Statistics from Syracuse University, M.B.A. in Operations Analysis and Computer Programming from the University of California at Los Angeles, B.A. in Chemistry from Marietta College, M.D. from Columbia University, and M.S. in Biophysics from the University of Kentucky.
- Brian T. O'Leary, civilian. Born January 27, 1940. B.A. in Physics from Williams College, M.A. in Astronomy from Georgetown University, and Ph.D. in Astronomy from the University of California at Berkeley.
- Robert A. R. Parker, civilian. Born December 14, 1936. B.A. in Astronomy and Physics from Amherst College and Ph.D. in Astronomy from California Institute of Technology.
- William E. Thornton, civilian. Born April 14, 1929. B.S. in Physics and M.D. from the University of North Carolina.

The Group 6 selection committee members from the National Academy of Sciences Board were Dr. Allan H. Brown, Department of Biology, Joseph Leidy Laboratory of Biology, University of Pennsylvania; Professor L.D. Carlson, Department of Physiology, University of California Medical School; Dr. Arthur B. Dubois, Division of Graduate Medicine, Department of Physiology, University of Pennsylvania; and Dr. H. Keffer Hartline, Rockefeller University.

The Life Sciences Subpanel members were Dr. George V. LeRoy, Medical Director, Metropolitan Hospital, Detroit, Michigan; Dr. Clifford T. Morgan, Department of Psychology, University of California; and Dr. Norton Nelson, Provost, University Heights Center, New York University.

The Physical Sciences Subpanel members were Dr. Edward W. Cannon, Chief, Applied Mathematics Division, National Bureau of Standards; Professor Frederick L. Ferris, Jr., Educational Services, Inc.; Dr. Harry H. Hess, Department of Geology, Princeton University; Dr. John D. Hoffmann, Chief, Polymers Division, National Bureau of Standards; Dr. Phillip Mange, Naval Research Laboratory; Dr. Eberhardt Rechtin, Assistant Director for Tracking and Data Acquisition, NASA JPL; Dr. Eugene M. Shoemaker, Astrogeology Branch, U.S. Geological Survey;

Dr. Shirleigh Silverman, Associate Director of Academics Liaison, National Bureau of Standards; Professor Philip N. Slater, Research Professor, Stewart Observatories, University of Arizona; Dr. Robert Speed, Department of Geology, Northwestern University; Professor Edward C. Stevenson, Professor of Electrical Engineering, University of Virginia; Professor Aaron C. Waters, Department of Geology, University of California; and Dr. Arthur H. Waynick, Director, Ionosphere Research Laboratory, Pennsylvania State University.

The NASA Board members were Charles A. Berry, M.D., NASA JSC; Maxime A. Faget, NASA JSC; Owen K. Garriott, Ph.D., NASA JSC; Wilmot N. Hess, NASA JSC; Alan B. Shepard, Jr., NASA JSC; Donald K. Slayton, NASA JSC; and Robert F. Thompson, NASA JSC.

Group 7

This group of seven pilot astronauts, transferred to NASA from the USAF Manned Orbiting Laboratory (MOL) Program when it was cancelled in August 1969. Although there were 13 in the MOL contingent, NASA absorbed only those under the age of 35:

Karol J. Bobko, Maj., USAF. Born December 23, 1937. B.S. from the U.S. Air Force Academy and M.S. in Aerospace Engineering from the University of Southern California.

Robert L. Crippen, Lt. Comdr., USN. Born September 11, 1937. B.S. in Aerospace Engineering from the University of Texas.

C. Gordon Fullerton, Maj., USAF. Born October 11, 1936. B.S. and M.S. in Mechanical Engineering from California Institute of Technology.

Henry W. Hartsfield, Maj., USAF. Born November 21, 1933. B.S. in Physics from Auburn University.

Robert F. Overmyer, Maj., USMC. Born July 14, 1936. B.S. in Physics from Baldwin-Wallace College and M.S. in Aeronautics from the U.S. Naval Postgraduate School.

Donald H. Peterson, Maj., USAF. Born October 22, 1933. B.S. from the U.S. Military Academy and M.S. in Nuclear Engineering from the Air Force Institute of Technology.

Richard H. Truly, Lt. Comdr., USN. Born November 12, 1937. B.S. in Aeronautical Engineering from Georgia Institute of Technology.

Group 8—Space Shuttle Astronauts

In 1978, NASA selected 35 astronaut candidates as the first group to support the Space Shuttle program. One of the 15 pilots was African-American. Six females, two African-Americans, and one Asian-Pacific Islander were among the 20 mission specialists. The candidates reported to the Johnson Space Center on July 1, 1978 to begin a challenging training and evaluation program that included Orbiter Systems training, science and enrichment briefings, and T-38 flight training. After successfully completing this program,

the following candidates were qualified as astronauts and received technical assignments within the Astronaut Office to prepare them further for an assignment to a Space Shuttle mission:

Guion S. Bluford, Jr., Maj., USAF. Born November 22, 1942. B.S. in Aerospace Engineering from Pennsylvania State University, M.S. in Aerospace Engineering from the Air Force Institute of Technology, and Ph.D. in Aerospace Engineering from the Air Force Institute of Technology.

Daniel C. Brandenstein, Lt. Comdr., USN. Born January 17, 1943. B.S. in Mathematics and Physics from the University of Wisconsin-River Falls.

James F. Buchli, Lt. Col., USMC. Born June 20, 1945. B.S. from U.S. Naval Academy and M.S. in Aeronautical Systems from the University of West Florida.

Michael L. Coats, Lt. Comdr., USN. Born January 16, 1946. B.S. from the U.S. Naval Academy, M.S. in the Administration of Science and Technology from George Washington University, and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Richard O. Covey, Maj., USAF. Born August 1, 1946. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Aeronautics and Astronautics from Purdue University.

John O. Creighton, Lt. Comdr., USN. Born April 28, 1943. B.S. from the U.S. Naval Academy and M.S. in the Administration of Science and Technology from George Washington University.

John M. Fabian, Maj., USAF. Born January 28, 1939. B.S. in Mechanical Engineering from Washington State University, M.S. in Aerospace Engineering from the Air Force Institute of Technology, and Ph.D. in Aeronautics/Astronautics from the University of Washington.

Anna L. Fisher. Born August 24, 1949. B.S. in Chemistry from the University of California, Los Angeles and M.D. from the University of California, Los Angeles, School of Medicine.

Dale A. Gardner, Lt., USN. Born November 8, 1948. B.S. in Engineering Physics from the University of Illinois.

Robert L. Gibson, Lt., USN. Born October 30, 1946. B.S. in Aeronautical Engineering from California Polytechnic State University.

Frederick D. Gregory, Maj., USAF. Born January 7, 1941. B.S. from the U.S. Air Force Academy and M.S. in Information Systems from George Washington University.

Stanley D. Griggs. Born September 7, 1939. B.S. from U.S. Naval Academy and M.S.A. in Management Engineering from George Washington University.

Terry J. Hart. Born October 27, 1946. B.S. in Mechanical Engineering from Lehigh University, and M.S. in Mechanical Engineering from Massachusetts Institute of Technology.

Frederick H. Hauck, Comdr., USN. Born April 11, 1941. B.S. in General Physics from Tufts University and M.S. in Nuclear Engineering from Massachusetts Institute of Technology.

Steven A. Hawley. Born December 12, 1951. B.A. in Astronomy and Physics from the University of Kansas, and Ph.D. in Astronomy from the University of California, Santa Cruz.

Jeffrey A. Hoffman. Born November 2, 1944. B.A. in Astronomy from Amherst College, and Ph.D. in Astrophysics from Harvard University.

Shannon W. Lucid. Born January 14, 1943. B.S. in Chemistry from the University of Oklahoma, M.S. in Biochemistry from the University of Oklahoma, and Ph.D. in Biochemistry from the University of Oklahoma.

Jon A. McBride, Lt. Comdr., USN. Born August 14, 1943. B.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Ronald E. McNair. Born October 21, 1950. B.S. in Physics from the North Carolina A&T University and Ph.D. in Physics from Massachusetts Institute of Technology.

Richard M. Mullane, Capt., USAF. Born September 10, 1945. B.S. from the U.S. Military Academy and M.S. in Aeronautical Engineering from the Air Force Institute of Technology.

Steven R. Nagel, Capt., USAF. Born October 27, 1946. B.S. in Aeronautical/Astronautical Engineering from the University of Illinois.

George D. Nelson. Born July 13, 1950. B.S. in Physics from Harvey Mudd University, M.S. in Astronomy from the University of Washington, and Ph.D. in Astronomy from the University of Washington.

Ellison S. Onizuka, Capt., USAF. Born June 24, 1946. B.S. in Aerospace Engineering from the University of Colorado and M.S. in Aerospace Engineering from the University of Colorado.

Judith A. Resnik. Born April 5, 1949. B.S. in Electrical Engineering from Carnegie-Mellon University and Ph.D. in Electrical Engineering from the University of Maryland.

Sally K. Ride. Born May 26, 1951. B.S. in Physics from Stanford University, B.A. in English from Stanford University, and Ph.D. in Physics from Stanford University.

Francis R. Scobee, Maj., USAF. Born May 19, 1939. B.S. in Aerospace Engineering from the University of Arizona.

Margaret R. Seddon. Born November 8, 1947. B.A. in Physiology from the University of California, Berkeley, and M.D. from the University of Tennessee College of Medicine.

Brewster H. Shaw, Capt., USAF. Born May 16, 1945. B.S. in Engineering Mechanics from the University of Wisconsin and M.S. in Engineering Mechanics from the University of Wisconsin.

Loren J. Shriver, Capt., USAF. Born September 23, 1944. B.S. from the U.S. Air Force Academy and M.S. in Astronautics from Purdue University.

Robert L. Stewart, Maj., U.S. Army. Born August 13, 1942. B.S. in Mathematics from the University of Southern Mississippi and M.S. in Aerospace Engineering from the University of Texas, Arlington.

Kathryn D. Sullivan. Born October 3, 1951. B.S. in Earth Sciences from the University of California, Santa Cruz, and Ph.D. in Geology from Dalhousie University.

Norman E. Thagard. Born July 3, 1943. B.S. in Engineering Science from Florida State University, M.S. in Engineering Science from Florida State University, and M.D. from the University of Texas Southwestern Medical School.

James D. van Hoften. Born June 11, 1944. B.S. in Civil Engineering from the University of California, Berkeley, M.S. in Hydraulic Engineering from Colorado State University, and Ph.D. in Fluid Mechanics from Colorado State University.

David M. Walker, Lt. Comdr., USN. Born May 20, 1944. B.S. from the U.S. Naval Academy.

Donald E. Williams, Lt. Comdr., USN. Born February 13, 1942. B.S. in Mechanical Engineering from Purdue University.

The following individuals were on the rating and selection board for Group 8: George W.S. Abbey, Joseph D. Atkinson, Jr., Ph.D.; Vance D. Brand; Edward Gibson, Ph.D.; Carolyn Huntoon, Ph.D.; Joseph P. Kerwin, M.D.; Jack R. Lister; Glynn S. Lunney; Robert A. Parker; Robert O. Piland; Martin L. Raines; Duane L. Ross; Donald K. Slayton; James H. Trainor, Ph.D.; and John W. Young. Dr. James Tainor was from the NASA GSFC; the remainder were from NASA JSC.

Group 9

NASA selected 19 astronaut candidates for the Space Shuttle program in 1980. The eight pilots and 11 mission specialists included the first Hispanic mission specialist and the first candidate selected from the U.S. Army. The candidates reported to the Johnson Space Center on July 7, 1980 to begin their training and evaluation program. The 1980 astronaut candidate class included:

James P. Bagian. Born February 22, 1952. B.S. in Mechanical Engineering from Drexel University and M.D. from Thomas Jefferson University.

John E. Blaha, Lt. Col., USAF. Born August 26, 1942. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.S. in Astronautical Engineering from Purdue University.

Charles F. Bolden, Jr., Maj., USMC. Born August 19, 1946. B.S. in Electrical Engineering from the U.S. Naval Academy and M.S. in Systems Management from the University of California.

Roy D. Bridges, Jr., Maj., USAF. Born July 19, 1943. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Astronautics from Purdue University.

Franklin R. Chang. Born April 5, 1950. B.S. in Mechanical Engineering from the University of Connecticut and Ph.D. in Physics from Massachusetts Institute of Technology.

- Mary L. Cleave. Born February 5, 1947. B.S. in Biology from Colorado State University, M.S. in Botany from Utah State University, and Ph.D. in Civil Engineering from Utah State University.
- Bonnie J. Dunbar. Born March 3, 1949. B.S. in Ceramic Engineering from the University of Washington and M.S. in Ceramic Engineering from the University of Washington.
- William F. Fisher. Born April 1, 1946. B.S. in Psychology from Stanford University, M.S. in Engineering Science from the University of Houston and M.D. from the University of Florida College of Medicine.
- Guy S. Gardner, Maj., USAF. Born January 6, 1948. B.S. in Aeronautical Engineering from the U.S. Air Force Academy and M.S. in Aeronautical Engineering from Purdue University.
- Ronald J. Grabe, Maj., USAF. Born June 13, 1945. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Aeronautics from the Technische Hochschule, Darmstadt, Germany.
- David C. Hilmers, Capt., USMC. Born January 28, 1950. B.S. in Mathematics from Cornell College and M.S. in Electrical Engineering from the U.S. Naval Postgraduate School.
- David C. Leestma, Lt. Comdr., USN. Born May 6, 1949. B.S. in Aeronautical Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.
- John M. Lounge. Born June 28, 1946. B.S. in Mathematics from the U.S. Naval Academy and M.S. in Astrophysics from the University of Colorado.
- Bryan D. O'Connor, Maj., USMC. Born September 6, 1946. B.S. in Naval Science from the U.S. Naval Academy and M.S. in Aeronautical Systems from the University of West Florida.
- Richard N. Richards, Lt. Comdr., USN. Born August 24, 1946. B.S. in Chemical Engineering from the University of Missouri and M.S. in Aeronautical Systems from the University of West Florida.
- Jerry L. Ross, Capt., USAF. Born January 20, 1948. B.S. in Mechanical Engineering from Purdue University and M.S. in Mechanical Engineering from Purdue University.
- Michael J. Smith, Lt. Comdr., USN. Born April 30, 1945. B.S. in Aeronautical Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.
- Sherwood C. Spring, Maj., U.S. Army. Born September 3, 1944. B.S. in Engineering from the U.S. Military Academy and M.S. in Aerospace Engineering from the University of Arizona.
- Robert C. Springer, Maj., USMC. Born May 21, 1942. B.S. in Naval Science from the U.S. Naval Academy, and M.S. in Operations Research from the U.S. Naval Postgraduate School.

The following individuals served on the rating panel and the astronaut candidate selection board for Group 9: George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Joseph P. Allen, IV, Ph.D.; Vance D. Brand; Harvey L. Hartman; Gregory W.

Hayes; Jay F. Honeycutt; Carolyn L. Huntoon Ph.D.; William B. Lenoir, Ph.D.; Robert O. Piland; James H. Trainor, Ph.D.; Paul J. Weitz; and John W. Young. Dr. Trainor was from NASA GSFC, and the remainder were from NASA JSC.

Group 10

In 1984, NASA selected 17 astronaut candidates for the Space Shuttle program. One of the seven pilots was Hispanic, and three of the 10 mission specialists were female. The astronaut candidates who began training at the Johnson Space Center on July 1, 1984 included:

James C. Adamson, Maj., U.S. Army. Born March 3, 1946. B.S. in Engineering from the U.S. Military Academy and M.S. in Aeronautical and Mechanical Engineering from Princeton University.

Mark N. Brown, Capt., USAF. Born November 18, 1951. B.S. in Aeronautical and Astronautical Engineering from Purdue University and M.S. in Engineering from the Air Force Institute of Technology.

Kenneth D. Cameron, Maj., USMC. Born November 29, 1949. B.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology and M.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology.

Manley L. Carter, Jr., Comdr., USN. Born August 15, 1947. B.A. in Chemistry from Emory University and M.D. from Emory University.

John H. Casper, Lt. Col., USAF. Born July 9, 1943. B.S. in Astronautics and Engineering Science from the U.S. Airforce Academy and M.S. in Astronautics from Purdue University.

Frank L. Culbertson, Jr., Lt. Comdr., USN. Born May 15, 1949. B.S. in Aerospace Engineering from the U.S. Naval Academy.

Sidney M. Gutierrez, Capt., USAF. Born June 27, 1951. B.S. in Aerospace Engineering from the U.S. Air Force Academy and M.A. in Management from Webster College.

Lloyd B. Hammond, Jr., Capt., USAF. Born January 16, 1952. B.S. in Engineering Mechanics from the U.S. Air Force Academy and M.S. in Engineering Mechanics from Georgia Institute of Technology.

Marsha S. Ivins. Born April 15, 1951. B.S. in Aerospace Engineering from the University of Colorado.

Mark C. Lee, Capt., USAF. Born August 14, 1952. B.S. in Civil Engineering from the U.S. Air Force Academy and M.S. in Mechanical Engineering from Massachusetts Institute of Technology.

George D. Low. Born February 19, 1956. B.S. in Physics from Washington and Lee University, B.S. in Mechanical Engineering from Cornell University and M.S. in Aeronautics and Astronautics from Stanford University.

Michael J. McCulley, Lt. Comdr., USN. Born August 4, 1943. B.S. in Metallurgical Engineering from Purdue University and M.S. in Metallurgical Engineering from Purdue University.

William M. Shepherd, Lt. Comdr., USN. Born July 26, 1949. B.S. in Aerospace Engineering from the U.S. Naval Academy, M.S. in Mechanical Engineering from Massachusetts Institute of Technology, and M.S. in Ocean Engineering from Massachusetts Institute of Technology.

Ellen L. Shulman. Born April 27, 1953. B.A. in Geology from the State University of New York at Buffalo and M.D. from Cornell University.

Kathryn C. Thornton. Born August 17, 1952. B.S. in Physics from Auburn University, M.S. in Physics from the University of Virginia, and Ph.D. in Physics from the University of Virginia.

Charles L. Veach. Born September, 18, 1944. B.S. in Engineering Management from the U.S. Air Force Academy.

James D. Wetherbee, Lt., USN. Born November 27, 1952. B.S. in Aerospace Engineering from the University of Notre Dame.

The members of the rating panel and selection committee for Group 10 included George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Joseph P. Allen IV, Ph.D.; Gregory W. Hayes; Jay F. Honeycutt; Carolyn L. Huntoon, Ph.D.; Robert A.R. Parker, Ph.D.; Duane L. Ross; Paul J. Weitz; and John W. Young. All were from NASA JSC.

Group 11

An additional 13 candidates were selected to train for the astronaut corps in 1985. This group of six pilots and seven mission specialists included two females. They reported to the Johnson Space Center on August 1, 1985. The astronaut candidates were:

Jerome Apt. Born April 28, 1949. B.S. in Physics from Harvard College and Ph.D. in Physics from the Massachusetts Institute of Technology.

Michael A. Baker, Lt. Comdr., USN. Born October 27, 1953. B.S. in Aerospace Engineering from the University of Texas.

Robert D. Cabana, Maj., USMC. Born January 23, 1949. B.S. in Mathematics from the U.S. Naval Academy.

Brian Duffy, Capt., USAF. Born June 20, 1953. B.S. in Mathematics from the U.S. Air Force Academy and M.S. in Systems Management from the University of Southern California.

Charles D. Gemar, Capt., U.S. Army. Born August 4, 1955. B.S. in Engineering from the U.S. Military Academy.

Linda M. Godwin. Born July 2, 1952. B.S. in Mathematics from Southeast Missouri State, M.S. in Physics from the University of Missouri, and Ph.D. in Physics from the University of Missouri.

Terence T. Henricks, Maj., USAF. Born July 5, 1952. B.S. in Civil Engineering from the U.S. Air Force Academy and M.S. in Public Administration from Golden Gate University.

Richard J. Hieb. Born Sept 21, 1955. B.S. in Mathematics and Physics from Northwest Nazarene College and M.S. in Aerospace Engineering from the University of Colorado.

Tamara E. Jernigan. Born May 7, 1959. B.S. in Physics from Stanford University, M.S. in Engineering Science from Stanford University, and M.S. in Astronomy from the University of California at Berkeley.

Carl J. Meade, Capt., USAF. Born November 16, 1950. B.S. in Electronics Engineering from the University of Texas and M.S. in Electronics Engineering from California Institute of Technology.

Stephen S. Oswald. Born June 30, 1951. B.S. in Aerospace Engineering from the U.S. Naval Academy.

Stephen D. Thorne, Lt. Comdr., USN. Born February 11, 1953. B.S. in Engineering from the U.S. Naval Academy.

Pierre J. Thuot, Lt., USN. Born May 19, 1955. B.S. in Physics from the U.S. Naval Academy and M.S. in Systems Management from the University of Southern California.

The Group 11 rating panel and selection committee members were George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Karol J. Bobko; Daniel C. Brandenstein; Mary L. Cleave, Ph.D.; Richard O. Covey; Anna L. Fisher, M.D.; David C. Leestma; George D. Nelson, Ph.D.; Ellison S. Onizuka; Sally K. Ride, Ph.D.; Duane L. Ross; Loren J. Shriver; Paul J. Weitz; Donald E. Williams; and John W. Young. All were from NASA JSC.

Group 12

The 15 astronaut candidates selected in 1987 consisted of seven pilots and eight mission specialists, including the first African-American female and the first candidate from the U.S. Coast Guard. The following astronaut candidates reported to Johnson Space Center on August 17, 1987, to begin training:

Thomas D. Akers, Capt., USAF. Born May 20, 1951. B.S. in Applied Mathematics from the University of Missouri-Rolla and M.S. in Applied Mathematics from the University of Missouri-Rolla.

Andrew M. Allen, Capt., USMC. Born August 4, 1955. B.S. in Mechanical Engineering from Villanova University.

Kenneth D. Bowersox, Lt., USN. Born November 14, 1956. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Mechanical Engineering from Columbia University.

Curtis L. Brown, Capt., USAF. Born March 11, 1956. B.S. in Electrical Engineering from the U.S. Air Force Academy.

Kevin P. Chilton, Maj., USAF. Born November 3, 1954. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Engineering Mechanics from Columbia University.

Jan D. Dozier. Born November 1, 1953. B.S. in Biology from the Georgia Institute of Technology, B.S. in Mechanical Engineering from Auburn University, M.S. in Mechanical Engineering from the University of Alabama and Ph.D. in Mechanical Engineering from the University of Alabama.

C. Michael Foale. Born January 6, 1957. B.A. in Physics from Cambridge University, M.A. in Physics from Cambridge University and Ph.D. in Physics from Cambridge University (England).

Gregory J. Harbaugh. Born January 15, 1956. B.S. in Aeronautical and Astronautical Engineering from Purdue University and M.S. in Physical Science from the University of Houston-Clear Lake.

Mae C. Jemison. Born October 17, 1956. B.S. in Chemical Engineering from Stanford University and M.D. from Cornell University.

Donald R. McMonagle, Maj., USAF. Born May 14, 1952. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.S. in Mechanical Engineering from California State University-Fresno.

Bruce E. Melnick, Lt. Comdr., USCG. Born December 5, 1949. B.S. in Ocean Engineering from the U.S. Coast Guard Academy and M.S. in Aeronautical Systems from the University of West Florida.

William F. Readdy, Lt. Comdr., USN. Born January 24, 1952. B.S. in Aeronautical Engineering from the U.S. Naval Academy.

Kenneth S. Reightler, Jr., Lt. Comdr., USN. Born March 24, 1951. B.S. in Aerospace Engineering from the U.S. Naval Academy, M.S. in Systems Management from the University of Southern California, and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Mario Runco, Jr., Lt. Comdr., USN. Born January 26, 1952. B.S. in Meteorology from City College of New York and M.S. in Meteorology from Rutgers University.

James S. Voss, Maj., U.S. Army. Born March 3, 1949. B.S. in Aerospace Engineering from Auburn University and M.S. in Aerospace Engineering from the University of Colorado.

The following individuals served on the rating panel and selection board for Group 12: George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Daniel C. Brandenstein; Anna L. Fisher, M.D.; Carolyn L. Huntoon, Ph.D.; David C. Leestma; George D. Nelson, Ph.D.; Duane L. Ross; Loren J. Shriver; Paul J. Weitz; and John W. Young. All were from NASA JSC.

Group 13

The 23 astronaut candidates selected in 1990 included 7 pilots and 16 mission specialists. Among the candidates was the first female selected as a pilot and the first Hispanic female selected as a mission specialist. The following astronaut candidates began training at the Johnson Space Center on July 15, 1990:

Daniel W. Bursch, Lt. Comdr., USN. Born July 25, 1957. B.S. in Physics from the U.S. Naval Academy.

- Leroy Chiao. Born August 28, 1960. B.S. in Chemical Engineering from the University of California-Berkeley, M.S. in Chemical Engineering from the University of California-Santa Barbara, and Ph.D. in Chemical Engineering from the University of California-Santa Barbara.
- Michael R.U. Clifford, Maj., U.S. Army. Born October 13, 1952. B.S. in Basic Science from the U.S. Military Academy and M.S. in Aerospace Engineering from the Georgia Institute of Technology.
- Kenneth D. Cockrell. Born April 9, 1950. B.S. in Mechanical Engineering from the University of Texas and M.S. in Aeronautical Systems from the University of Florida.
- Eileen M. Collins, Maj., USAF. Born November 19, 1956. B.A. in Mathematics from Syracuse University, M.S. in Operations Research from Stanford University, and M.A. in Space Systems Management from Webster University.
- William G. Gregory, Capt., USAF. Born May 14, 1957. B.S. in Engineering Science from the U.S. Air Force Academy, M.S. in Engineering Mechanics from Columbia University, and M.S. in Management from Troy State.
- James D. Halsell, Maj., USAF. Born September 29, 1956. B.S. in Engineering from the U.S. Air Force Academy, M.S. in Management from Troy State, and M.S. in Space Operations from the Air Force Institute of Technology.
- Bernard A. Harris, Jr. Born June 26, 1956. B.S. in Biology from the University of Houston and M.D. from Texas Tech University.
- Susan J. Helms, Capt., USAF. Born February 26, 1958. B.S. in Aerospace Engineering from the U.S. Air Force Academy and M.S. in Aeronautics/Astronautics from Stanford University.
- Thomas D. Jones. Born January 22, 1955. B.S. in Basic Science from the U.S. Air Force Academy and Ph.D. in Planetary Science from the University of Arizona.
- William S. McArthur, Jr., Maj., U.S. Army. Born July 26, 1951. B.S. in Applied Sciences and Engineering from the U.S. Military Academy and M.S. in Aerospace Engineering from the Georgia Institute of Technology.
- James H. Newman. Born October 16, 1956. B.A. in Physics from Dartmouth College, M.A. in Physics from Rice University, and Ph.D. in Physics from Rice University.
- Ellen Ochoa. Born May 10, 1958. B.S. in Physics from San Diego State, M.S. in Electrical Engineering from Stanford University, and Ph.D. in Electrical Engineering from Stanford University.
- Charles J. Precourt, Maj., USAF. Born June 29, 1955. B.S. in Aeronautical Engineering from the U.S. Air Force Academy and M.S. in Management from Golden Gate University.
- Richard A. Searfoss, Maj., USAF. Born June 6, 1956. B.S. in Aerospace Engineering from the U.S. Air Force Academy and M.S. in Aerospace Engineering from the California Institute of Technology.
- Ronald M. Sega. Born December 4, 1952. B.S. in Physics and Mathematics from the U.S. Air Force Academy, M.S. in Physics from Ohio State, and Ph.D. in Electrical Engineering from the University of Colorado.

Nancy J. Sherlock, Capt., U.S. Army. Born December 29, 1958. B.A. in Biological Science from Ohio State and M.S. in Safety Engineering from the University of Southern California.

Donald A. Thomas. Born May 6, 1955. B.S. in Physics from Case Western University, M.S. in Materials Science from Cornell University, and Ph.D. in Materials Science from Cornell University.

Janice E. Voss. Born October 8, 1956. B.S. in Engineering Science from Purdue University, M.S. in Electrical Engineering from Massachusetts Institute of Technology, and Ph.D. in Aeronautics/Astronautics from Massachusetts Institute of Technology.

Carl E. Walz, Capt., USAF. Born September 6, 1955. B.S. in Physics from Kent State and M.S. in Physics from John Carroll University.

Terrence W. Wilcutt, Maj., USMC. Born October 31, 1949. B.A. in Mathematics from Western Kentucky University.

Peter J. K. Wisoff. Born August 16, 1958. B.S. in Physics from the University of Virginia, M.S. in Physics from Stanford University, and Ph.D. in Applied Physics from Stanford University.

David A. Wolf. Born August 23, 1956. B.S. in Electrical Engineering from Purdue University and M.D. from Indiana University.

The rating panel and selection board members for the 1990 astronaut candidate class were Joseph D. Atkinson, Jr., Ph.D.; Charles F. Bolden; Daniel C. Brandenstein; Mary L. Cleave, Ph.D.; Michael L. Coats; Richard O. Covey; Steven A. Hawley, Ph.D.; Jeffrey A. Hoffman, Ph.D.; Carolyn L. Huntoon, Ph.D.; Robert A.R. Parker, Ph.D.; Donald R. Puddy; Duane L. Ross; Jerry L. Ross; Rhea Seddon, M.D.; and John W. Young. All were from NASA JSC.

Group 14

In 1992, NASA selected 19 new astronaut candidates in support of the Space Shuttle program. The group consisted of four pilots and 15 mission specialists, including nine civilians and 10 military officers. The following astronaut candidates reported to the Johnson Space Center on August 3, 1992 to begin their training and evaluation program:

Daniel T. Barry. Born December 30, 1953. B.S. in Electrical Engineering from Cornell University, M.S.E. in Electrical Engineering and Computer Science from Princeton University, M.A. in Electrical Engineering and Computer Science from Princeton University, Ph.D. in Electrical Engineering and Computer Science from Princeton University, and M.D. from the University of Miami.

Charles E. Brady, Jr., M.D., Comdr., USN. Born August 12, 1951. Premed at the University of North Carolina at Chapel Hill and M.D. from Duke University.

- Catherine G. Coleman, Ph.D., Capt., USAF. Born December 14, 1960. B.S. in Chemistry from Massachusetts Institute of Technology and Ph.D. in Polymer Science and Engineering from the University of Massachusetts.
- Michael L. Gernhardt. Born May 4, 1956. B.S. in Physics from Vanderbilt University, M.S. in Bioengineering from the University of Pennsylvania, and Ph.D. in Bioengineering from the University of Pennsylvania.
- John M. Grunsfeld. Born October 10, 1958. B.S. in Physics from the Massachusetts Institute of Technology, M.S. in Physics from the University of Chicago, and Ph.D. in Physics from the University of Chicago.
- Scott J. Horowitz, Ph.D., Capt., USAF. Born March 24, 1957. B.S. in Engineering from California State University at Northridge, M.S. in Aerospace Engineering from Georgia Tech, and Ph.D. in Aerospace Engineering from the Georgia Institute of Technology.
- Brent W. Jett, Jr., Lt. Comdr., USN. Born October 5, 1958. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.
- Kevin R. Kregel. Born September 16, 1956. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.P.A. in Public Administration from Troy State University.
- Wendy B. Lawrence, Lt. Comdr., USN. Born July 2, 1959. B.S. in Ocean Engineering from the U.S. Naval Academy and M.S. in Ocean Engineering from Massachusetts Institute of Technology.
- Jerry M. Linenger, Comdr., USN. Born January 16, 1955. B.S. in Bioscience from the U.S. Naval Academy, M.D. from Wayne State University, M.S. in Systems Management, M.P.H. from the University of North Carolina, and Ph.D. in Epidemiology from the University of North Carolina.
- Richard M. Linnehan, D.V.M., Capt., U.S. Army. Born September 19, 1957. B.S. in Zoology from the University of New Hampshire and D.V.M. from Ohio State University.
- Michael E. Lopez-Alegria, Lt. Comdr., USN. Born May 30, 1958. B.S. in Systems Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.
- Scott E. Parazynski. Born July 28, 1961. B.S. in Biology from Stanford University and M.D. from Stanford University.
- Kent V. Rominger, Lt. Comdr., USN. Born August 7, 1956. B.S. in Civil Engineering from Colorado State University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.
- Winston E. Scott, Comdr., USN. Born August 6, 1950. B.A. in Music from Florida State University and M.S. in Aeronautical Engineering from the U.S. Naval Academy.
- Steven L. Smith. Born December 30, 1958. B.S. in Electrical Engineering from Stanford University, M.S. in Electrical Engineering from Stanford University, and M.B.A. from Stanford University.
- Joseph R. Tanner. Born January 21, 1950. B.S. in Mechanical Engineering from the University of Illinois.

Andrew S.W. Thomas. Born December 18, 1951. B.E. in Mechanical Engineering from the University of Adelaide (Australia) and Ph.D. in Mechanical Engineering from the University of Adelaide (Australia).

Mary E. Weber. Born August 24, 1962. B.S. in Chemical Engineering from Purdue University and Ph.D. in Chemistry from the University of California-Berkeley.

The following persons served on the rating panel and astronaut candidate selection board in 1991: Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Robert D. Cabana; Franklin R. Chang-Diaz, Ph.D.; Richard O. Covey; Bonnie J. Dunbar, Ph.D.; Robert L. Gibson; Linda M. Godwin, Ph.D.; Jeffrey A. Hoffman, Ph.D.; Carolyn L. Huntoon, Ph.D.; Roger L. Kroes, Ph.D.; David C. Leestma; Paul Lowman, Ph.D.; Donald R. McMonagle; Donald R. Puddy; Duane L. Ross; Rhea Seddon, M.D.; William M. Shepherd; Loren J. Shriver; Kathryn D. Sullivan, Ph.D.; Kathryn C. Thornton, Ph.D.; James D. Wetherbee; and John W. Young. Dr. Kroes was from NASA Marshall Space Flight Center (MSFC) and Dr. Lowman was from NASA GSFC. The others were from NASA JSC.

Group 15

The 1995 astronaut candidate class consisted of 10 pilot candidates, including two female pilots, and nine mission specialists. The 19 astronaut candidates were selected through a highly competitive process that evaluated their education, experience, and ability to work as members of a team. This was the first astronaut class to receive training on both the Space Shuttle and the International Space Station programs. The 1995 astronaut candidates included:

Scott D. Altman, Lt. Comdr., USN. Born August 15, 1959. B.S. in Aeronautical and Astronautical Engineering from the University of Illinois and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Michael P. Anderson, Maj., USAF. Born December 25, 1959. B.S. in Physics and Astronomy from the University of Washington and M.S. in Physics from Creighton University.

Jeffrey S. Ashby, Comdr., USN. Born June 16, 1954. B.S. in Mechanical Engineering from the University of Idaho and M.S. in Aviation Systems from the University of Tennessee.

Michael J. Bloomfield, Maj., USAF. Born March 16, 1959. B.S. in Engineering Mechanics from the U.S. Air Force Academy and M.S. in Engineering Management from Old Dominion University.

Kalpana Chawla. Born July 1, 1961. B.S. in Aeronautical Engineering from Punjab Engineering College in India, M.S. in Aerospace Engineering from the University of Texas, and Ph.D. in Aerospace Engineering from the University of Colorado.

Robert Curbeam, Jr., Lt. Comdr., USN. Born March 5, 1962. B.S. in Aerospace Engineering from the U.S. Naval Academy, M.S. in Aeronautical Engineering

from the U.S. Naval Postgraduate School, and Degree of Aeronautical and Astronautical Engineer from the U.S. Naval Postgraduate School.

Joe F. Edwards, Jr., Lt. Comdr., USN. Born February 3, 1958. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aviation from the University of Tennessee at Knoxville.

Dominic L. Gorie, Comdr., USN. Born May 2, 1957. B.S. in Ocean Engineering from the U.S. Naval Academy and M.S. in Aviation Systems from the University of Tennessee at Knoxville.

Kathryn P. Hire. Born August 26, 1959. B.S. in Engineering Management from the U.S. Naval Academy and M.S. in Space Technology from the Florida Institute of Technology.

Rick D. Husband, Maj., USAF. Born July 12, 1957. B.S. in Mechanical Engineering from Texas Tech University and M.S. in Mechanical Engineering from California State University.

Janet L. Kavandi. Born July 17, 1959. B.S. in Chemistry from Missouri Southern State College, M.S. in Chemistry from the University of Missouri-Rolla, and Ph.D. in Analytical Chemistry from the University of Washington.

Steven W. Lindsey, Maj., USAF. Born August 24, 1960. B.S. in Engineering Sciences from the U.S. Air Force Academy and M.S. in Aerospace Engineering from the Air Force Institute of Technology.

Edward T. Lu. Born July 1, 1963. B.S. in Electrical Engineering from Cornell University and Ph.D. in Applied Physics from Stanford University.

Pamela A. Melroy, Maj., USAF. Born September 17, 1961. B.S. in Physics and Astronomy from Wellesley College and M.S. in Earth and Planetary Sciences from the Massachusetts Institute of Technology.

Carlos I. Noriega, Maj., USMC. Born October 8, 1959. B.S. in Computer Science from the University of Southern California, M.S. in Computer Science from the U.S. Naval Postgraduate School, and M.S. in Space Systems Operations from the U.S. Naval Postgraduate School.

James F. Reilly. Born March 18, 1954. B.S. in Geosciences from the University of Texas, M.S. in Geosciences from the University of Texas, and Ph.D. in Geosciences from the University of Texas.

Stephen K. Robinson. Born October 26, 1955. B.S. in Mechanical and Aeronautical Engineering from the University of California, M.S. in Mechanical Engineering from Stanford University and Ph.D. in Mechanical Engineering from Stanford University.

Susan L. Still, Lt., USN. Born October 24, 1961. B.S. in Aeronautical Engineering from Embry-Riddle University and M.S. in Aerospace Engineering from Georgia Institute of Technology.

Frederick W. Sturckow, Capt., USMC. Born August 11, 1961. B.S. in Mechanical Engineering from California Polytechnic State University.

The 1994 rating panel and astronaut candidate selection board members were Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Kenneth D. Cameron; Kevin P. Chilton; Michael R. Clifford; Brian Duffy;

Michael Foale, Ph.D.; Robert L. Gibson; Estella H. Gillette; Linda M. Godwin, Ph.D.; Frederick D. Gregory; James F. Harrington; Bernard A. Harris, M.D.; Steven A. Hawley, Ph.D.; Gregory W. Hayes; Carolyn L. Huntoon, Ph.D.; Tamara E. Jernigan, Ph.D.; Roger L. Kroes, Ph.D.; Mark C. Lee; David C. Leestma; Paul D. Lowman, Ph.D.; David H. Mobley; John F. Muratore; Steven R. Nagel; Ellen Ochoa, Ph.D.; Stephen S. Oswald; Duane L. Ross; Jerry L. Ross; Pierre J. Thuot; James S. Voss; James D. Wetherbee; and John W. Young. Mr. Harrington was from the NASA KSC, Dr. Kroes was from NASA MSFC, and Dr. Lowman was from NASA GSFC. The others were from NASA JSC.

Group 16

In 1996, NASA selected 35 astronaut candidates in support of the Space Shuttle and Space Station programs. This was the largest astronaut candidate class since the first group of Shuttle astronauts was selected in 1978. The 10 pilots and 25 mission specialists included three African-American females and a pair of identical twins. On 12 August 1996, the candidates began a curriculum including extensive Space Shuttle and Space Station training. Upon successful completion of their training, they were qualified as astronauts and began supporting long-duration missions on the International Space Station. The 1996 candidates included:

David M. Brown, Comdr., USN. Born April 16, 1956. B.S. in Biology from the College of William and Mary and M.D. from Eastern Virginia Medical School.

Daniel C. Burbank, Lt. Comdr., USCG. Born July 27, 1961. B.S. in Electrical Engineering from the U.S. Coast Guard Academy and M.S. in Aeronautical Science from Embry-Riddle Aeronautical University.

Yvonne D. Cagle. Born April 24, 1959. B.A. in Biochemistry from San Francisco State University and M.D. from the University of Washington.

Fernando Caldeiro. Born June 12, 1958. B.S. in Mechanical Engineering from the University of Arizona and M.S. in Engineering Management from the University of Central Florida.

Charles J. Camarda. Born May 8, 1952. B.S. in Aerospace Engineering from Polytechnic Institute of New York, M.S. in Engineering Science from George Washington University, and Ph.D. in Aerospace Engineering from Virginia Polytechnic Institute.

Duane G. Carey, Maj., USAF. Born April 30, 1957. B.S. in Aerospace Engineering and Mechanics from the University of Minnesota-Minneapolis and M.S. in Aerospace Engineering from the University of Minnesota-Minneapolis.

Laurel B. Clark, Lt. Comdr., USN. Born March 10, 1961. B.S. in Zoology from the University of Wisconsin-Madison and M.D. from the University of Wisconsin-Madison.

Edward M. Fincke, Capt., USAF. Born March 14, 1967. B.S. in Aeronautics and Astronautics, and Earth, Atmospheric, and Planetary Sciences from

Massachusetts Institute of Technology, and M.S. in Aeronautics and Astronautics from Stanford University.

Patrick G. Forrester, Lt. Col., U.S. Army. Born March 31, 1957. B.S. in Applied Sciences and Engineering from the U.S. Military Academy and M.S. in Mechanical and Aerospace Engineering from the University of Virginia.

Stephen N. Frick, Lt. Comdr., USN. Born September 30, 1964. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

John B. Herrington, Lt. Comdr., USN. Born September 14, 1958. B.S. in Applied Mathematics from the University of Colorado and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Joan E. Higginbotham. Born August 3, 1964. B.S. in Electrical Engineering from Southern Illinois, M.S. in Management from Florida Institute of Technology, and M.S. in Space Systems from Florida Institute of Technology.

Charles O. Hobaugh, Capt., USMC. Born November 5, 1961. B.S. in Aerospace Engineering from the U.S. Naval Academy.

James M. Kelly, Capt., USAF. Born May 14, 1964. B.S. in Astronautical Engineering from the U.S. Air Force Academy.

Mark E. Kelly, Lt., USN. Born February 21, 1964. B.S. in Marine Engineering and Nautical Science from the U.S. Merchant Marine Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Scott J. Kelly, Lt., USN. Born February 21, 1964. B.S. in Electrical Engineering from the State University of New York Maritime College.

Paul S. Lockhart, Maj., USAF. Born April 28, 1956. B.A. in Mathematics from Texas Tech University and M.S. in Aerospace Engineering from the University of Texas.

Christopher J. Loria, Maj., USMC. Born July 9, 1960. B.S. in General Engineering from the U.S. Naval Academy.

Sandra H. Magnus. Born October 30, 1964. B.S. in Physics from the University of Missouri-Rolla, M.S. in Electrical Engineering from the University of Missouri-Rolla, and Ph.D. in Materials Science and Engineering from Georgia Institute of Technology.

Michael J. Massimino. Born August 19, 1962. B.S. in Industrial Engineering from Columbia University, M.S. in Mechanical Engineering and Technology and Policy from Massachusetts Institute of Technology, and Ph.D. in Mechanical Engineering from Massachusetts Institute of Technology.

Richard A. Mastracchio. Born February 11, 1960. B.S. in Electrical Engineering and Computer Science from the University of Connecticut, M.S. in Electrical Engineering from Rensselaer Polytechnic Institute, and M.S. in Physical Sciences from the University of Houston-Clear Lake.

William C. McCool, Lt. Comdr., USN. Born September 23, 1961. B.S. in Applied Science from the U.S. Naval Academy, M.S. in Computer Science from the University of Maryland, and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Lee M. Morin, Comdr., USN. Born September 9, 1952. B.S. in Mathematics and Electrical Science from the University of New Hampshire, M.S. in Biochemistry from New York University, M.D. from New York University, Ph.D. in Microbiology from New York University, and M.P.H. from the University of Alabama at Birmingham.

Lisa M. Nowak, Lt. Comdr., USN. Born May 10, 1963. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Donald R. Pettit. Born April 20, 1955. B.S. in Chemical Engineering from Oregon State University and Ph.D. in Chemical Engineering from the University of Arizona.

John L. Phillips. Born April 15, 1951. B.S. in Mathematics and Russian from the U.S. Naval Academy, M.S. in Aeronautical Systems from the University of West Florida, M.S. in Geophysics and Space Physics from the University of California, and Ph.D. in Geophysics and Space Physics from the University of California.

Mark L. Polansky. Born June 2, 1956. B.S. in Aeronautical and Astronautical Engineering from Purdue University and M.S. in Aeronautics and Astronautics from Purdue University.

Paul W. Richards. Born May 20, 1964. B.S. in Mechanical Engineering from Drexel University and M.S. in Mechanical Engineering from the University of Maryland.

Piers J. Sellers. Born April 11, 1955. B.S. in Ecological Science from the University of Edinburgh (Scotland) and Ph.D. in Biometeorology from Leeds University (United Kingdom).

Heidemarie M. Stefanyshyn-Piper, Lt. Comdr., USN. Born February 7, 1963. B.S. in Mechanical Engineering from Massachusetts Institute of Technology and M.S. in Mechanical Engineering from Massachusetts Institute of Technology.

Daniel M. Tani. Born February 1, 1961. B.S. in Mechanical Engineering from Massachusetts Institute of Technology and M.S. in Mechanical Engineering from Massachusetts Institute of Technology.

Rex J. Walheim, Capt., USAF. Born October 10, 1962. B.S. in Mechanical Engineering from the University of California-Berkeley and M.S. in Industrial Engineering from the University of Houston.

Peggy A. Whitson. Born February 9, 1960. B.S. in Biology and Chemistry from Iowa Wesleyan College and Ph.D. in Biochemistry from Rice University.

Jeffrey N. Williams, Maj., U.S. Army. Born January 18, 1958. B.S. in Applied Sciences and Engineering from U.S. Military Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Stephanie D. Wilson. Born September 27, 1966. B.S. in Engineering Science from Harvard University and M.S. in Aerospace Engineering from the University of Texas.

The 1995 astronaut candidate rating panel and selection board included the following individuals: Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.;

Ellen S. Baker, M.D.; Robert D. Cabana; Brian Duffy; Michael Foale, Ph.D.; Estella H. Gillette; Linda M. Godwin, Ph.D.; Steven A. Hawley, Ph.D.; Gregory W. Hayes; Susan J. Helms; Robert K. Holkan; Donald R. McMonagle; David H. Mobley; John F. Muratore; Bascom W. Murrah III; Duane L. Ross; John A. Rummel, Ph.D.; James D. Wetherbee; and John W. Young. Mr. Mobley was from NASA Headquarters, and Mr. Murrah was from NASA KSC. The others were from NASA JSC.

Group 17

In 1998, NASA selected 25 astronaut candidates to support the Space Station and Space Shuttle programs. The group of 8 pilots and 17 mission specialists consisted of 21 males and 4 females, including NASA's first Educator Mission Specialist. The astronaut class reported for training at the Johnson Space Center on August 15, 1998. The candidates were:

Clayton C. Anderson. Born February 23, 1959. B.S. in Physics from Hastings College and M.S. in Aerospace Engineering from Iowa State University.

Lee J. Archambault, Maj., USAF. Born August 25, 1960. B.S. in Aerospace and Astronautical Engineering from the University of Illinois-Urbana and M.S. in Aerospace and Astronautical Engineering from the University of Illinois-Urbana.

Tracy E. Caldwell. Born August 14, 1969. B.S. in Chemistry from California State University-Fullerton and Ph.D. in Chemistry from the University of California-Davis.

Gregory E. Chamitoff. Born August 6, 1962. B.S. in Electrical Engineering from California Polytechnic State University, M.S. in Aerospace Engineering from California Institute of Technology, and Ph.D. in Aeronautics and Astronautics from Massachusetts Institute of Technology.

Timothy J. Creamer, Maj., U.S. Army. Born November 15, 1959. B.S. in Chemistry from Loyola College and M.S. in Physics from Massachusetts Institute of Technology.

Christopher J. Ferguson, Lt. Comdr., USN. Born September 1, 1961. B.S. in Mechanical Engineering from Drexel University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Michael J. Foreman, Comdr., USN. Born March 29, 1957. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Michael E. Fossum. Born December 19, 1957. B.S. in Mechanical Engineering from Texas A&M University, M.S. in Systems Engineering from the Air Force Institute of Technology, and M.S. in Physical Science from the University of Houston-Clear Lake.

Kenneth T. Ham, Lt. Comdr., USN. Born December 12, 1964. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Patricia C. Hilliard. Born March 12, 1963. B.S. in Biology from Indiana University of Pennsylvania and M.D. from the Medical College of Pennsylvania.

Gregory C. Johnson. Born July 30, 1954. B.S. in Aerospace Engineering from the University of Washington.

Gregory H. Johnson, Maj., USAF. Born May 12, 1962. B.S. in Aeronautical Engineering from the U.S. Air Force Academy and M.S. in Civil Engineering from Columbia University.

Stanley G. Love. Born June 8, 1965. B.S. in Physics from Harvey Mudd College, M.S. in Astronomy from the University of Washington, and Ph.D. in Astronomy from the University of Washington.

Leland D. Melvin. Born February 15, 1964. B.S. in Chemistry from the University of Richmond and M.S. in Materials Science from the University of Virginia.

Barbara R. Morgan. Born November 28, 1951. B.S. in Biology from Stanford University.

William A. Oefelein, Lt., USN. Born March 29, 1965. B.S. in Electrical and Electronics Engineering from Oregon State University.

John D. Olivas. Born May 25, 1966. B.S. in Mechanical Engineering from the University of Texas-El Paso, M.S. in Mechanical Engineering from the University of Houston and Ph.D. in Mechanical Engineering and Materials from Rice University.

Nicholas J. M. Patrick. Born March 22, 1964. B.A.E. in Engineering from the University of Cambridge, England, M.A. in Engineering from the University of Cambridge (England), M.S. in Mechanical Engineering from Massachusetts Institute of Technology, and Ph.D. in Mechanical Engineering from Massachusetts Institute of Technology.

Alan G. Poindexter, Lt. Comdr., USN. Born November 5, 1961. B.A. in Aerospace Engineering from Georgia Institute of Technology and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School.

Garrett E. Reisman. Born February 10, 1968. B.S. in Economics from the University of Pennsylvania, B.S. in Mechanical Engineering from the University of Pennsylvania, M.S. in Mechanical Engineering from California Institute of Technology, and Ph.D. in Mechanical Engineering from California Institute of Technology.

Steven R. Swanson. Born December 3, 1960. B.S. in Engineering Physics from the University of Colorado-Boulder, M.A.S. in Computer Systems from Florida Atlantic University, and Ph.D. in Computer Science from Texas A&M University.

Douglas H. Wheelock, Maj., U.S. Army. Born May 5, 1960. B.S. in Applied Science from the U.S. Military Academy and M.S. in Aerospace Engineering from Georgia Institute of Technology.

Sunita L. Williams, Lt. Comdr., USN. Born September 19, 1965. B.S. in Physical Science from the U.S. Naval Academy and M.S. in Engineering Management from Florida Institute of Technology.

Neil W. Woodward III, Lt., USN. Born July 26, 1962. B.S. in Physics from Massachusetts Institute of Technology and M.A. in Physics from the University of Texas-Austin.

George D. Zamka, Maj., USMC. Born June 29, 1962. B.S. in Mathematics from the U.S. Naval Academy.

The members of the 1998 rating panel and astronaut candidate selection committee were Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Jeffrey W. Bantle; Robert D. Cabana; Kenneth D. Cockrell; Brian Duffy; Estella H. Gillette; Linda M. Godwin; Ph.D.; James D. Halsell; Steven A. Hawley, Ph.D.; Gregory W. Hayes; Susan J. Helms; James A. Hickmon; Robert K. Holkan; Ellen Ochoa, Ph.D.; Charles J. Precourt; Duane L. Ross; John A. Rummel; Ph.D.; Loren J. Shriver; James D. Wetherbee; and John W. Young. Mr. Shriver was from NASA KSC. The others were from NASA JSC.

Group 18

NASA selected 17 candidates for the astronaut class of 2000. The group consisted of 7 pilots and 10 mission specialists, including the first candidate selected directly from the Navy's submarine community. The following astronaut candidates reported to the Johnson Space Center in August 2000 to begin extensive training in support of the Space Shuttle and Space Station programs:

Dominic A. Antonelli, Lt., USN. Born August 23, 1967 in Detroit, Michigan. B.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology and M.S. in Aeronautics and Astronautics from the University of Washington.

Michael R. Barrett. Born April 16, 1959. B.S. in Zoology from the University of Washington and M.D. from Northwestern University.

Robert Behnken, Capt., USAF. Born July 28, 1970. B.S. in Mechanical Engineering and Physics from Washington University, M.S. in Mechanical Engineering from California Institute of Technology, and Ph.D. in Mechanical Engineering from California Institute of Technology.

Eric A. Boe, Maj., USAF. Born October 1, 1964. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.S. in Electrical Engineering from Georgia Institute of Technology.

Stephen G. Bowen, Lt. Comdr., USN. Born February 13, 1964. B.S. in Electrical Engineering from the U.S. Naval Academy and Degree in Ocean Engineering from Massachusetts Institute of Technology.

B. Alvin Drew, Maj., USAF. Born November 5, 1962. B.S. in Astronautical Engineering and Physics from the U.S. Air Force Academy, and M.S. in Aerospace Science from Embry-Riddle Aeronautical University.

Andrew J. Feustel. Born August 25, 1965. B.S. in Solid Earth Sciences from Purdue University, M.S. in Geophysics from Purdue University, and Ph.D. in Geological Sciences from Queen's University (Canada).

Kevin A. Ford, Lt. Col., USAF. Born July 7, 1960. B.S. in Aerospace Engineering from the University of Notre Dame, M.S. in International Relations from Troy State University, M.S. in Aerospace Engineering from the University of Florida, and Ph.D. in Astronautical Engineering from the Air Force Institute of Technology.

Ronald J. Garan, Jr., Maj., USAF. Born October 30, 1961. B.S. in Business Economics from SUNY College at Oneonta, M.S. in Aeronautical Science from Embry-Riddle Aeronautical University, and M.S. in Aerospace Engineering from the University of Florida.

Michael T. Good, Maj., USAF. Born October 13, 1962. B.S. in Aerospace Engineering from the University of Notre Dame and M.S. in Aerospace Engineering from the University of Notre Dame.

Douglas G. Hurley, Maj., USMC. Born October 21, 1966. B.S. in Civil Engineering from Tulane University.

Timothy L. Kopra, Maj., U.S. Army. Born April 9, 1963. B.S. in Computer Science from the U.S. Military Academy and M.S. in Aerospace Engineering from Georgia Institute of Technology.

K. Megan McArthur. Born August 30, 1971. B.S. in Aerospace Engineering from the University of California-Los Angeles.

Karen L. Nyberg. Born October 7, 1969. B.S. in Mechanical Engineering from the University of North Dakota, M.S. in Mechanical Engineering from the University of Texas-Austin, and Ph.D. in Mechanical Engineering from the University of Texas-Austin.

Nicole P. Stott. Born November 19, 1962. B.S. in Aeronautical Engineering from Embry-Riddle Aeronautical University and M.S. in Engineering Management from the University of Central Florida.

Terry W. Virts, Jr., Capt., USAF. Born December 1, 1967. B.S. in Mathematics from the U.S. Air Force Academy, and M.A.S. in Aeronautics from Embry-Riddle Aeronautical University.

Barry E. Wilmore, Lt. Comdr., USN. Born December 29, 1962. B.S. in Electrical Engineering from Tennessee Technological University, M.S. in Electrical Engineering from Tennessee Technological University, and M.S. in Aviation Systems from the University of Tennessee-Knoxville.

The following individuals served on the 2000 rating panel and astronaut candidate selection board: Michael P. Anderson; Ellen S. Baker, M.D.; Jeffrey W. Bantle; Robert D. Cabana; Franklin R. Chang-Diaz, Ph.D.; Kalpana Chawla, Ph.D.; Robert L. Curbeam, Jr.; Nancy J. Currie; Estella H. Gillette; Linda M. Godwin, Ph.D.; Steven A. Hawley, Ph.D.; Tamara E. Jernigan, Ph.D.; Ellen Ochoa, Ph.D.; Scott Parazynski, M.D.; William W. Parsons; Charles J. Precourt; James F. Reilly, Ph.D.; Kent V. Rominger; Duane L. Ross; John A. Rummel, Ph.D.; Loren J. Shriver; James D. Wetherbee; David R. Williams, M.D.; and John W. Young. Mr. Shriver was from NASA KSC. The others were from NASA JSC.

ASTRONOMY—INFRARED

Introduction

This article describes the astrophysical questions that can be addressed at infrared wavelengths, the advantages of pursuing infrared astronomy from space, the enabling technologies, and the missions that have been flown and are planned to exploit the unique potential of this wavelength range. The infrared band covers three decades—from $\sim 1\text{ }\mu\text{m}$ to $\sim 1000\text{ }\mu\text{m}$ —that encompass a very wide range of instrumental techniques and scientific issues. We have confined our discussion to rocket- and satellite-borne missions aimed primarily at astrophysical targets and have omitted the infrared instruments that have been carried on planetary probes. We draw the short-wavelength limit of our detailed discussion at $2.5\text{ }\mu\text{m}$ but note that the Near Infrared Camera and Multi-Object Spectrograph (NICMOS) instrument on the Hubble Space Telescope (HST) have operated very successfully in the 1 to $2.5\text{-}\mu\text{m}$ band; these wavelengths are also among those studied by the Diffuse Infrared Background Experiment (DIRBE) on the Cosmic Background Explorer (COBE). Wavelengths longer than $\sim 200\text{ }\mu\text{m}$ have been probed extensively from space only by the highly successful COBE spacecraft. We discuss COBE observations of the nearby Universe but cannot do justice to its extraordinary spatial and spectral measurements of the cosmologically critical cosmic microwave background radiation (CMBR).

The organization of the article is as follows. An introductory section describes the astrophysical uniqueness of the infrared and the tremendous benefits to be gained by carrying infrared instrumentation above the atmosphere. The next section discusses three key technical areas of particular importance for infrared astronomy—detectors, cryogenics, and optics—and the way they have been adapted to the space environment. Next, comes a review of previous and near-term missions for infrared astronomy from space, emphasizing the evolution of both science and technology since the first rocket experiments of the 1960s. The final mission we discuss in detail is the Space Infrared Telescope Facility (SIRTF), scheduled for launch in 2003 (1). SIRTF's advanced technology and great scientific potential will mark the end of the first phase of exploration of the Universe in the infrared band. But SIRTF is also a beginning, because it sets the stage for the missions of the next decade. We conclude with a summary of the technological challenges and scientific opportunities of these upcoming programs.

Uniqueness of Infrared

Infrared observations provide the following unique perspectives on the Universe: **The Cold Universe.** There is an inverse relationship between the temperature of an object and the peak wavelength λ of its intrinsic or blackbody radiation: $T(\lambda) = 3700/\lambda$. Here T is measured in degrees kelvin (K) above absolute zero, and λ in microns (μm). Objects with $T < T(\lambda)$ radiate very little at wavelengths less than λ . Observations at infrared wavelengths from 1–1000 μm

are thus uniquely sensitive to astronomical objects whose temperatures are from ~ 3000 K to ~ 3 K. These include the coolest stars, planets and interplanetary dust, circumstellar and interstellar matter, and, at the longest wavelengths, the Universe itself.

The Dusty Universe. Interstellar dust—microscopic particles composed of ices, minerals, and common organic and inorganic materials—is a ubiquitous constituent of astrophysical environments. The properties of this material are such that a cloud that is totally opaque in the visible or ultraviolet can be virtually transparent in the infrared; thus infrared wavelengths can probe regions—such as the core of our galaxy—which are inaccessible at shorter wavelengths. Additionally, the dust particles are heated by the shorter wavelength radiation they absorb and reradiate the absorbed power at infrared wavelengths. The majority of the radiant energy from dense, dusty regions such as star-forming clouds—and in some cases from entire galaxies—lies at infrared wavelengths because of this efficient downconversion process.

The Distant Universe. In the expanding Universe, the more distant an object is, the greater the velocity at which it recedes from us. This cosmic expansion shifts the starlight from distant galaxies into the infrared; the more distant the object, the farther out into the infrared. This expansion is characterized by the redshift parameter z : $1 + z = (\text{observed wavelength}/\text{emitted wavelength})$. The most distant known objects have $z > 6$, so that radiation from the middle of the visual band is shifted out beyond $3\text{ }\mu\text{m}$. Because $1 + z$ is also equal to the factor by which the Universe has expanded between the times of emission and absorption of the radiation, objects at $z = 5$ are seen as they were at an epoch when the Universe was only one-sixth of its present size.

The Chemical Universe. The infrared band contains the spectral signatures of a variety of atoms, molecules, ions, and solid substances—some of which will be found in any astrophysical environment. Examples range from cool ices in the interstellar medium to highly excited ions in active galactic nuclei. Infrared spectroscopy can isolate these features, determine their absolute and relative strengths, and provide an important and often unique probe of the chemical and physical conditions in these systems.

The Advantages of Space

The space environment presents powerful advantages for conducting infrared astronomical observations, which motivate the technological developments discussed below. First, in space, one is free of the absorption by Earth's atmosphere, which—even from the best mountaintop observatories—is totally opaque at wavelengths from ~ 30 to $\sim 300\text{ }\mu\text{m}$ (2). Outside of this region, there are other bands of high and moderate opacity, and atmospheric absorption remains appreciable at aircraft and balloon altitudes. Only from space do we have access to the entire infrared band. A second, equally fundamental benefit is that a space observatory is free of the blackbody radiation of Earth's atmosphere, and the space telescope can be cooled to low temperature to minimize its own blackbody radiation without fear of atmospheric condensation. Infrared observations from Earth are limited by very bright foreground radiation from the atmosphere and

the ambient temperature telescope; in space using a sufficiently cold telescope, the limiting background—set by the faint glow of the interplanetary zodiacal dust cloud—is some six orders of magnitude fainter. This is about the same factor by which the night sky at new moon is fainter than the daytime sky at high noon; note that optical astronomy is practiced at night, not during the day. The impact of this million-fold background reduction, in space, is impossible to overestimate because it produces a thousandfold increase in sensitivity, or a millionfold increase in the speed of observations. Thus the first major cryogenic infrared space observatory, the Infrared Astronomical Satellite (IRAS), revolutionized our knowledge of the infrared sky, even though it observed each point for less than about 20 seconds during its 10-month survey of the sky (3).

Complementary Approaches

Infrared astronomy is pursued very successfully from ground-, aircraft-, and balloon-borne platforms, and these sites present opportunities and capabilities complementary to the very high sensitivity and spectral access of space. The current state of the art for ground-based infrared astronomy is a series of 8- to 10-m diameter telescopes in Hawaii and Chile that provide ongoing scientific opportunities, much higher spatial resolution than achievable from space at present, and a greater variety of focal plane instrumentation—including complex spectroscopic instruments—than typically available in space observatories. Airborne observatories—exemplified by the imminent ~ 3 -m-class Stratospheric Observatory for Infrared Astronomy (SOFIA)—provide capabilities similar to those of large ground-based telescopes in most of the wavelength bands that are inaccessible from the surface of Earth. Balloon-borne instruments have been successful for specialized measurements, most notably survey observations and studies of the CMBR, and will have an important niche in the upcoming era of long-duration balloon flights.

Detectors and Detector Arrays

Modern detectors fall into two classes, bolometers and photoconductors. Bolometers are devices that change resistance when heated by absorbed radiation; they respond to radiation across a wide wavelength band, as long as they effectively absorb across this entire band. Bolometer technology has advanced dramatically in the past few years due to the application of modern semiconductor processing techniques. Photoconductors are solid-state devices in which incident photons can excite electrons from a bound state—a valence band or an impurity level—into a conduction band to produce a current in response to an applied voltage. Because the valence or impurity levels and the conduction bands are separated by a well-defined energy gap, the energy or wavelength range within which photoconductors respond to radiation is restricted. To cover a broad infrared wavelength range, a combination of different photoconductors generally needs to be employed. The current materials of choice are InSb and HgCdTe photodiodes for wavelengths shorter than $\sim 10\ \mu\text{m}$, extrinsic (doped) silicon photodetectors (Si:xx) for wavelengths from $5\text{--}40\ \mu\text{m}$, and extrinsic Germanium

(Ge:xx) for $\sim 40\text{--}200\ \mu\text{m}$. In this nomenclature “xx” denotes the specific dopant. The preferred dopants for silicon detectors are As, B, Ga, and Sb; Ga, Be, and Sb have been used as dopants for germanium. Bolometers are the detectors of choice for wavelengths longer than $200\ \mu\text{m}$ and for some applications at shorter wavelengths as well. Infrared detectors for space astronomy are discussed in detail in two recent books (4,5).

All detectors are inherently noisy. They register the incidence of arriving photons, generally referred to as “signal,” and also any number of other types of events classed as “noise.” Notable among the noise sources are thermally excited conduction electrons, or “dark current” in photoconductors, and thermal fluctuations in bolometers. Both sources of noise can be reduced by cooling the detectors to temperatures so low that thermal effects become negligible. In real-life applications, both types of detectors can be degraded by the electronics required to operate them and read them out, although modern circuit design techniques and on-chip integration generally allow minimizing these effects. In space, noise can also be generated by high-energy cosmic rays that traverse the detectors. Effective shielding against such particles becomes a high priority; in addition, special fabrication techniques can be used to reduce the susceptibility of the detectors to this ionizing radiation, as has been done with extrinsic silicon photoconductors of the type to be used on SIRTf.

A recent major advance in infrared detectors is large arrays of many active elements, or pixels, bonded to a multiplexer that is used to sample and read out the pixels. The impact of this technology on space infrared astronomy—which is similar to the CCDs used in the visible band—will be very dramatic. Used with photoconductors in the low-background space environment, the technology permits on-chip integration, so that the signal can be accumulated on the detector array and read out only when it is large enough to overcome electronic noise. Clever schemes involving multiple, nondestructive readouts of the array have been devised to suppress electronic noise further. Detector arrays are equally applicable to imaging and to spectroscopic instruments—and to photoconductor and bolometer technology, and they will certainly be used very extensively, if not exclusively, for space infrared astronomy in the future. There will continue to be a push for larger format arrays, and the next generation of infrared space experiments should use arrays of at least 1024×1024 pixels, a substantial advance over the 256×256 pixel arrays to be used on SIRTf.

The ultimate performance goal for detectors for infrared astronomy is that they permit “background-limited” observations, that is, the intrinsic detector and electronic noise should be less than the noise due to the statistical fluctuations in the rate of arrival of photons from ambient and astrophysical backgrounds. Modern infrared detectors achieve this readily in ground-based applications where the warm telescope and emissive atmosphere produce very high backgrounds. For space applications using cryogenic telescopes, the infrared background is that due to the zodiacal dust within the solar system, which is at least a million times fainter than the ground-based foreground sky. Achieving background-limited performance in this environment is quite challenging, even with the benefits of on-chip integration; for example, observations in the 3 to $5\ \mu\text{m}$ window require that dark current and electronic noise contribute less (often much less) than the equivalent of one electron/second/pixel (6). Detector

technologists and astronomers working together have responded to these challenges and improved the performance of infrared detectors by many orders of magnitude in the past two decades. The improvement has come from reducing the noise and also by improving the “quantum efficiency”—the fraction of incident photons that is absorbed by the detector. As a result, the arrays to be used on SIRTf will achieve background-limited performance for both photometry and low-resolution spectroscopy at all wavelengths.

Cryogenics

Space infrared telescopes invariably require efficient cooling or cryogenic systems; the telescope and the surrounding structure are cooled to reduce their background radiation, and the detectors are cooled to reduce their intrinsic noise and increase their sensitivity. In many applications, these effects together require cooling below 10 K. In many of the rocket and satellite instruments built to date, the entire telescope has been cooled to temperatures as low as 2 K, where no part of the apparatus emits as much radiation as the 2.73 K CMBR. This has been done by placing the entire telescope structure in direct physical or thermal contact with a pumped-liquid-helium bath, and the vacuum pump is the natural vacuum in space. The IRAS and Infrared Space Observatory (ISO) systems used this architecture, as shown in Fig. 1 (left). Liquid helium is required to achieve temperatures below ~ 5 K, but other stored cryogens that provide more cooling power per unit mass are used in applications where higher temperatures are acceptable. In practice, this is equivalent to reducing the long-wavelength limit of the instrument. Other cryogens that have been used—and the approximate temperature that they provide—are solid hydrogen (8 K), liquid neon (30 K), solid nitrogen (50 K), and liquid nitrogen (75 K).

A primary design problem for the cryogenic engineer is to minimize the heat load on cooled surfaces of the apparatus. A first step is to shield these surfaces from the principal heat source, which is solar radiation, and to use suitable combinations of low- and high-emissivity materials to reduce heat transfer within the satellite. A next step is to blanket the container that holds the cryogen with dozens of layers of aluminized mylar loosely packed within a vacuum jacket to isolate the entire system from its ambient-temperature surroundings before launch. Such a vacuum-packed cryogenic system is referred to as a dewar, named for the nineteenth-century Scottish scientist J. Dewar. A well-designed cryogenic system also uses the cold effluent gas generated as the cryogen evaporates or sublimates to cool the surrounding structures and further reduce the heat load on the cryogen.

A second design challenge is the construction of apparatus sufficiently sturdy to survive launch and also to maintain optical alignment between the cooled telescope and the guide telescopes or gyroscopic components that typically operate at ambient temperature within the spacecraft bus. The mechanical rigidity required tends to go hand in hand with high thermal conductivity, which the design must avoid; this requires using low-thermal-conductivity materials that have high strength, such as epoxy-glass composites.

Considerable attention has also focused on minimizing heat loads on the cryogen by passively radiating intercepted heat into cold space; this is referred to

Figure 1. This figure compares the cold launch architecture used for the ISO and IRAS observatories (left) with the warm launch architecture to be used for SIRTf (right). Each is shown in cutaway view. Certain components, such as the spacecraft (SC), the solar panel (SP), and the startracker (ST) are common to both systems. In addition, the telescope (T) and instrument package (I) are identical in size for the two. Each also includes a cryostat (C), containing the liquid helium cryogen in a separate helium tank, which is shown shaded. In the cold launch system, the telescope is located within the cryostat and cooled by direct contact with the cryogen tank. In the warm launch system, the cryostat and cryogen tank can be much smaller, and the telescope is cooled by conduction and by the cold boil-off helium gas. This architecture works in the solar orbit because the cylindrical thermal shields that surround the telescope cool radiatively to 40 K or below, so there is very little parasitic heat diffusing inward toward the telescope. The cryostat must withstand atmospheric pressure, and it is much larger and more massive for the cold launch than for the warm launch system. In the former, it surrounds the entire telescope and supports a heavy vacuum cover (VC). In the warm launch system, the telescope is launched at ambient temperature and pressure, protected only by a lightweight dust cover (DC). The sawed-off conical sunshade at the top of the cryostat is required in an Earth-orbiting system by the Sun–Earth-orbit geometry. A much smaller sunshade is needed in the solar orbit system because Earth is not a concern.

as “radiative cooling” (7). The SIRTf telescope, described later, exploits the favorable thermal environment of its heliocentric orbit by using a hybrid cryogenic system in which the instruments and detectors are cryogenically cooled, whereas the telescope is launched warm and is cooled by a combination of radiation, conduction, and effluent cryogen (Fig. 1 right). This approach has many advantages over that used in earlier missions such as IRAS and ISO, in which the entire telescope was placed within the cryostat. It leads to a lower mass cryogenic system for a fixed telescope size and decouples the size of the telescope from that of the cryostat. Thus this hybrid approach is certain to be adopted for large infrared telescopes in the future.

In a more extreme application of radiative cooling, it may be possible to cool the entire telescope to a temperature acceptable for many purposes without

using cryogenics. Just how low a temperature can be reached in practice is still not clear, but many designers now assume that equilibrium temperatures as low as 30 K could be within reach at 1 astronomical unit (the radius of Earth's orbit) from the sun. Lower temperatures might be achieved by a telescope operating in the outer solar system. At such low temperatures, a well-designed telescope that has exceptionally low-emissivity mirrors might radiate at such low levels in the wavelength range shorter than 100 μm that the primary and secondary mirrors require no active cooling at all. Active cooling would be required primarily for the detector arrays and their immediate housings. The reduced cooling requirements of such a system might be satisfactorily met by an acceptable, though still substantial, charge of cryogen, or by closed-cycle refrigerators required only to pump heat at low rates.

A stored cryogenic system always has a limited lifetime: unless replenished (an approach which has not been adopted for any astronomical mission), the cryogen eventually is fully depleted, the system warms up, and the mission comes to an end. To increase mission life spans, a variety of recyclable cryocoolers—both mechanical and electrochemical—have been under intense study (8). In principle, they could extend lifetimes indefinitely. In practice, a nagging long-term problem has been the limited reliability of closed-cycle, low-temperature refrigerators designed to operate in the vacuum of space. In the laboratory, such systems have often failed catastrophically after only a few months. No refrigerator of this type has ever operated in the laboratory continuously for a 10-year span. Yet this is the expected mission lifetime of many infrared astronomical space facilities now on the drawing boards. In 1998, NASA successfully tested a particular type of mechanical cooler on a Shuttle mission—a reverse Brayton-cycle cryocooler that can cool detectors to temperatures as low as 60–70 K. This test showed that operation under weightless conditions was not a problem for this type of cooler, but long-term reliability is still an open question, though the same coolers have a good record in the laboratory and run reliably for many months to a few years. Reliable closed-cycle cryocoolers are certain to affect critically the design and life spans of future infrared astronomical missions in space. The reverse Brayton-cycle cryocooler described before has been retrofitted to the NICMOS instrument on HST to extend its useful lifetime beyond the almost 2 years achieved with the initial charge of solid nitrogen.

Some types of highly sensitive infrared detectors now being planned for future missions operate effectively only at temperatures in the millikelvin range. Additional cooling beyond that achievable with liquid ^4He must be provided for them. In the laboratory, a variety of techniques has already been developed to reach such low temperatures; often, they require a succession of stages that might employ combinations of thermoelectric, liquid ^3He , $^3\text{He}/^4\text{He}$ dilution, adiabatic demagnetization, or other refrigerators. For long-duration astronomical space missions, reliable refrigerators will be required to provide these low temperatures continuously or cyclically. Again, these devices are often used in tandem; on the ESA/NASA Planck mission to study the CMBR, a hydrogen sorption refrigeration provides an 18-K heat station for a mechanical cooler which, in turn, provides a 4.5 K stage for a dilution refrigerator that cools the bolometer detectors to ~ 100 mK (9).

Light Collectors

With few exceptions, light collectors for the infrared are all-reflecting telescopes whose optical components may be aluminized, or gold-coated, depending on the wavelength range. Conventional telescopes image a portion of the sky onto a focal plane to provide accurate maps. Occasionally, however, the astronomer is interested in diffuse radiation that is not localized but arrives from all over the sky. For such observations, a carefully designed horn, an all-reflecting funnel, is generally employed to gather radiation from a large but well-defined field of view in the sky onto the smallest possible detector. These two types of light collectors were used, respectively, on the ISO/IRAS and COBE spacecraft.

For space applications, there is a premium on lightweight optics because the mass of the entire satellite scales with the mass of the optical system it must support, and, in turn, a more massive satellite requires a larger and more expensive launch vehicle. For an infrared mission, there is the added complication of the increased thermal conductivity of the beefier structure required to support the more massive optical system. Both IRAS and SIRTf, as discussed later, used all-beryllium optical systems because of the favorable strength-to-mass ratio of this material. The 85-cm diameter SIRTf primary, for example, has a mass of 15 kg and an areal density of 26 kg/m^2 . By comparison, the Hubble Space Telescope primary mirror has an areal density of 180 kg/m^2 . As telescope apertures beyond $\sim 4 \text{ m}$ diameter are considered for future missions, another launch vehicle limitation, set by the physical size of the payload shroud, is encountered. Thus planning for the 8-m diameter Next Generation Space Telescope (NGST) is based on ultralightweight panels of glass, beryllium, or composite materials, whose areal density is no greater than 15 kg/m^2 . It would deploy after launch to achieve the desired aperture (6).

Filters

Filters isolate wavelength ranges of particular interest to the astronomer. For imaging and photometry, a well-defined, broad wavelength range needs to be isolated. Carefully designed transmission filters are usually used for this purpose. For spectroscopy, different types of spectrometers that select numerous narrow-wavelength intervals are inserted between the light collector and the detector or detector arrays. The most common types of spectrometers for infrared are prism or grating “dispersive systems” that separate out radiation directionally, according to wavelength, and interferometers. Fabry–Perot interferometers select one narrow-wavelength range at a time; Michelson and other two-beam, multiplex interferometers transmit many wavelengths simultaneously but have to be swept through a range of settings to encode unambiguously and register the flux detected at each wavelength. Later, we describe spectrometers by their spectral resolving power R , defined as $\lambda/\delta\lambda$, where λ is the operating wavelength and $\delta\lambda$ is the finest discernible spectral detail. The unique requirements placed on filters and spectrometers for space applications are largely environmental and have to do with surviving launch or the ionizing radiation in space, or achieving low mass or volume, rather than with the device’s functionality or performance.

Early Rocket Instrumentation

In the mid-1960s, a collaborative effort between Cornell University and the Naval Research Laboratory led to the design of liquid-nitrogen-cooled and eventually liquid-helium-cooled, rocket-borne infrared telescopes. Early Cornell designs incorporated a parabolic primary mirror with an 18-cm aperture and focal ratio length ratio $f/0.9$. The entire telescope, except for the entrance aperture, was surrounded by the liquid. Four different types of detectors were flown on many of these flights to sample the spectral range from $5\text{ }\mu\text{m}$ to 1.6 mm (10). Using this apparatus, the total flux in a field of view roughly 1° in diameter was first successfully measured for the galactic center and four other regions in the central portions of the Milky Way, at 5, 13, 20, and $100\text{ }\mu\text{m}$. A first spectral measure of the radiation emitted by the solar system's zodiacal dust was also obtained (11).

Some years later, results from a survey conducted in a series of rocket flights were published by the U.S. Air Force Cambridge Research Laboratories (now the Air Force Geophysical Laboratories). The group initially flew liquid-neon-cooled telescopes that had 10-cm apertures and detectors sensitive to radiation at $12\text{--}14\text{ }\mu\text{m}$. Each of six detectors in a linear array surveyed a $10' \times 10'$ field of view. Later, the group began all-sky surveys using satellite-borne instrumentation and also began observations across wider spectral ranges. Early results of one of these surveys at 4.2, 11.0, 19.8, and $27\text{ }\mu\text{m}$ were cataloged and published by Price and Walker (12).

Although rockets have not been extensively used for infrared astronomy in recent years, large-format infrared detector arrays may enable significant science in the limited duration of a rocket flight. For example, a 16.5-cm rocket-borne telescope instrumented with a 256×256 InSb array and cooled by supercritical helium has been flown to search for a faint halo of low-mass stars enveloping a nearby edge-on spiral galaxy (13).

The Infrared Astronomical Satellite

The first true infrared survey of the sky from space was carried out by the Infrared Astronomical Satellite (IRAS), jointly sponsored by the United States, the Netherlands, and Great Britain (3). Approximately two-thirds of the 300-day mission that lasted from January to November 1983 was devoted to an unbiased survey of the sky that succeeded in charting 98% of the celestial sphere in four broad wavelength bands. IRAS was launched into a polar orbit at the day–night terminator which precessed about 1° per day. In this “Sun-synchronous” orbit the Earth/Sun/spacecraft geometry varied only slowly, so that the survey could be executed by a simple scanning strategy. Observations were carried out with an all-beryllium 57-cm aperture, $f/9.6$ Richey–Chrétien telescope whose focal plane was cooled to 3 K and featured a total of ~ 60 Si:As, Si:Sb, and Ge:Ga discrete photoconductors; each had a separate JFET amplifier readout. The detectors covered, respectively, the 12-, 25-, 60-, and $100\text{-}\mu\text{m}$ bands, using Ge:Ga appropriately filtered to cover the last two. A low-resolution spectrometer covered the wavelength range from $7.5\text{--}23\text{ }\mu\text{m}$.

A measure of the mission's success was the cataloging of some 250,000 celestial sources; the vast majority had never before been detected in the infrared. No area of modern astrophysics was untouched by IRAS. A few of the many scientific highlights include

1. The discovery of galaxies that emit up to fifty times more energy at far-infrared wavelengths than in the optical domain and also emit from 100 to 1000 times as much total power as our own galaxy, the Milky Way. The existence of such highly luminous infrared galaxies came as a huge surprise.
2. The discovery of disks composed of fine dust grains that orbit around a number of stars that, in many ways, were reminiscent of our own Sun. This dust, it was conjectured, is the remnant of an originally far more massive circumstellar cloud of gas and dust from which a system of planets had already formed and initiated further astronomical searches for signs of planets around these stars. A sharply defined, though far fainter, set of dust rings was also found orbiting our own Sun, as were enduring trails of dust left by the passage of solar system comets.
3. The successful measurement of spectra for planetary nebulae and a variety of other sources at wavelengths previously inaccessible due to telluric absorption. IRAS also identified patchy infrared emission from the diffuse interstellar medium, referred to as "infrared cirrus" because of its similarity to the thin, streaky clouds in Earth's atmosphere. Infrared cirrus is important as a tracer of matter within our galaxy and as a potential source of interference in observations of distant galaxies.

The Cosmic Background Explorer, COBE

COBE, built by NASA and launched into a polar orbit identical to that of IRAS in 1989, was dedicated to the study of the microwave and infrared background radiation in space (14). It carried three instruments; two of them, the Diffuse Microwave Radiometer (DMR) and the Far Infrared Absolute Spectrophotometer (FIRAS) were used to study the CMBR—the isotropic blackbody radiation whose temperature is ~ 2.73 K and is believed to be a relic of the Big Bang in which the Universe was born. The third experiment, the Diffuse Infrared Background Experiment (DIRBE), measured the background at infrared wavelengths from 1–200 μm . DIRBE and FIRAS were cooled by liquid helium and mapped the entire sky repeatedly during the ~ 10 -month cryogenic lifetime of COBE. The critical components of DMR were cooled passively to ~ 140 K; this instrument operated for about 4 years.

The CMBR carries important cosmological information, and DMR and FIRAS were extremely successful, respectively, in measuring the spatial structure in that radiative field and in establishing its blackbody nature at a very high degree of precision. These important cosmological experiments will not be discussed further here. Of course, both FIRAS and DMR also measured the foreground radiation from our own galaxy. FIRAS was a polarizing Michelson interferometer instrumented with helium-cooled bolometers as detectors. It

obtained spectra of the galactic emission from $\sim 100\text{ }\mu\text{m}$ to $\sim 3\text{ mm}$ using a 7° field of view. Of particular interest was its detection of emission from oxygen, carbon, nitrogen, and carbon monoxide from gas in the Galaxy (15).

DIRBE made measurements in ~ 15 wavelength bands, using a variety of discrete photodiodes and photoconductors from $1\text{--}100\text{ }\mu\text{m}$ and helium-cooled bolometers at 140 and $240\text{ }\mu\text{m}$. All measurements were referenced to an internal cold, black reference surface so that the absolute sky brightness was determined.

The principal scientific results from DIRBE include (16)

1. An improved determination of the distribution of the infrared radiation from the zodiacal dust cloud within the solar system, which has led to improved models of the dust cloud and its infrared emission. DIRBE also confirmed IRAS' discovery of a modest enhancement of emission in Earth-trailing direction, which is attributed to temporary gravitational trapping by Earth of zodiacal dust particles that are spiraling inward towards the Sun.
2. Measurements of the large-scale distribution of infrared radiation from the Galaxy, including both the far infrared radiation from $25\text{--}200\text{ }\mu\text{m}$ that samples the distribution of heated dust, and the near-infrared radiation from $1\text{--}25\text{ }\mu\text{m}$ that is indicative of the large-scale distribution of stars in the Galaxy.
3. Detection of an isotropic background of infrared radiation at 140 and $240\text{ }\mu\text{m}$ that arises from outside the Galaxy and may be attributable to the integrated effects of star-forming galaxies at redshifts $z \sim 1$ to 2 .

The Infrared Space Observatory (ISO)

The Infrared Space Observatory, built and launched by the European Space Agency (ESA), was the first comprehensive infrared astronomical space observatory. NASA and the Japanese Space Agency (ISAS), provided important technical, operational, and scientific support. ISO mapped celestial sources and analyzed them through spectroscopy, photometry, and linear polarization studies (17).

On the night of 16–17 November 1995, an Ariane 4 rocket launched ISO into a highly elliptical, 24-hour, circumterrestrial orbit, where the observatory operated with great success until its helium ran out and instruments began warming up in April 1998. The spacecraft in orbit was 5.3 m long, 2.3 m wide, and its mass was approximately 2500 kg . At launch, it carried a superfluid helium charge of 2300 liters, which maintained the Ritchey–Chrétien telescope, the scientific instruments, and the optical baffles at temperatures of $2\text{--}8\text{ K}$. The diameter of the telescope's fused silica primary mirror was 60 cm . A three-axis-stabilization system provided an absolute pointing accuracy of a few seconds of arc and stability of a fraction of an arc second in both jitter and long-term drift. The telescope was diffraction-limited down to wavelengths of roughly $5\text{ }\mu\text{m}$. Four instruments formed the core of the scientific payload:

1. A camera containing two 32×32 pixel arrays: InSb for the wavelength range $2.5\text{--}5.5\text{ }\mu\text{m}$, and Si:Ga for the range $4\text{--}18\text{ }\mu\text{m}$. Each array could be

operated with a selection of filters for broadband spectrophotometry or continuously variable filters (CVF) for low-resolution ($R \sim 40$) imaging spectroscopy and could view sources through three linear polarizers oriented relative to each other at angles of 60° .

2. A photometer covered the entire wavelength range from 2.5–240 μm . It employed Si:Ga detectors that gave peak response at 15 μm , Si:B detectors that gave peak response at 25 μm , unstressed Ge:Ga detectors that gave peak response at 100 μm , and stressed Ge:Ga detectors that gave peak response at 180 μm . Stressed detectors are mounted in a miniature clamp or vise that applies high mechanical pressure to the crystal, thereby extending their wavelength response. At 100 and 200 μm , the instrument housed, respectively, 3×3 and 2×2 arrays of unstressed and stressed Ge:Ga to facilitate mapping. Multiple apertures, multiple filters, and polarizers were used for photometric and photopolarimetric measurements in each range. Scanning and mapping operations were carried out at all wavelengths. Two grating spectrophotometers, each with a 64-element linear Si:Ga detector array, provided spectra with resolving power $R \sim 100$ at 2.5–5 and 6–12 μm .
3. A short-wavelength spectrometer included both grating and Fabry–Perot (FP) instruments. Grating spectra were available for the entire wavelength range from 2.38 to 45.2 μm , with resolving power $R \sim 1000$ –2000. The FP mode covered the 11.4- to 44.5- μm range and gave resolving power of a factor of 20 higher. For the grating mode, the detectors were InSb at 2.38–4.08 μm , Si:Ga at 4.08–29 μm , and Ge:Be at 29–45.2 μm . For the FP mode, Si:Sb was used out to 26 μm , and Ge:Be from 26–44.5 μm .
4. A long-wavelength spectrometer provided coverage from 43–196.9 μm . A grating provided resolving power $R \sim 150$ –200. A FP mode permitted observations at $R \sim 6800$ –9700. The 10 detectors, arranged in a linear array on a curved surface, were Ge:Be at 43–50 μm , unstressed Ge:Ga at 50–100 μm , and stressed Ge:Ga beyond 110 μm .

Among the scientific highlights of ISO were

1. The detection of water vapor throughout the interstellar medium of the Galaxy. Before ISO, the infrared emission from interstellar water vapor could not be detected because telluric water vapor absorbs at precisely the emission wavelengths. Water vapor, however, can be one of the primary coolants of interstellar clouds, and the extent of this cooling needed to be understood to assess the extent to which it facilitates protostellar collapse.
2. Detection of polycyclic aromatic hydrocarbons in the spectra of galaxies. These large molecules were well known in our galaxy, but ISO had the sensitivity needed to show that their emission dominates the 5- to 12- μm emission from nearby spiral galaxies as well. The emission from these molecules is due to radiative fluorescence: a molecule is excited by optical or ultraviolet radiation, quickly rereadiates the energy of a single absorbed photon, in the infrared and returns to the ground state.

3. Inventories of extragalactic source-counts at wavelengths ranging from 4–175 μm . These are of particular value in understanding the origins of the extragalactic diffuse infrared radiation detected by the COBE mission. Many of the randomly observed galaxies appear to be ultraluminous, indicating that they contain substantial regions of massive star formation or that they harbor an active galactic nucleus that possibly surrounds a massive central black hole.

The Space Infrared Telescope Facility (SIRTF)

NASA is developing SIRTF for launch in 2003; it has a projected cryogenic lifetime greater than 5 years (1). SIRTF will be an observatory for infrared astronomy from space and will complete NASA's family of Great Observatories (the other members are the Hubble Space Telescope, the Compton Gamma Ray Observatory, and the Chandra X-ray Observatory).

SIRTF culminates the four decades of technology development and scientific progress described above. SIRTF will be the first space mission to use exclusively the imaging and spectroscopic power of large format infrared detector arrays. SIRTF's all-beryllium telescope that incorporates an 85-cm diameter primary mirror and is diffraction-limited down to 6.5 μm , defines the state of the art for ultralightweight cryogenic optics. The SIRTF telescope and cryogenic system will be carried on a fairly standard spacecraft bus that provides pointing control, power, data storage, and communication. The pointing system is built around an external autonomous star tracker that controls and reports the spacecraft orientation at more than 2'' accuracy and has a reaction wheel/gyro control system. Visible light sensors in the cold focal plane can sense stars simultaneously using the external star tracker to track the relative orientation of the telescope and star tracker lines of sight. This pointing system architecture was used on ISO as well. The SIRTF spacecraft also incorporates a nitrogen gas system that is used to unload the reaction wheels if they accumulate too much angular momentum; the magnetic torquer bars used for this function in Earth-orbiting spacecraft would not work on SIRTF because it is far outside Earth's magnetosphere.

Unlike the missions previously described, all of which operated in Earth orbit, SIRTF will be placed into an Earth-trailing heliocentric orbit, drifting slowly away to reach a distance of ~ 0.5 AU from Earth after 5 years. In this orbit, SIRTF is free of the heat load from Earth and provides good access to the sky for target selection and scheduling. SIRTF will launch with the telescope warm and the instruments at helium temperature. In space, the telescope and its surrounding thermal shields cool radiatively to ~ 40 K, and the effluent helium from the cryogenic tank cools the telescope down to its operating temperature of ~ 5.5 K (see Fig. 1b). The thermal shields remain at 40 K and below throughout the mission, so that the parasitic heat conducted into the telescope is very small. As a result, the heat load that dissipates the SIRTF cryogen and determines the lifetime of the mission comes largely from the focal plane instruments.

This hybrid, radiative, cryogenic cooling system is facilitated because SIRTF can maintain an attitude in its solar orbit in which the solar panel is always

oriented toward the Sun and shades the thermal shields that control the telescope temperature. These structures, in turn, are optimized to minimize the heat transferred from the solar panel and to radiate to space any heat that is transferred. This approach would not work in near-Earth orbit because the heat load from Earth would occasionally be incident on the thermal shields and turn the radiator into an absorber.

This optimized cryogenic system, together with the low-power dissipation of its instruments and the elimination of parasitic heat loads, makes SIRTf a much more efficient system cryogenically than any of its predecessors. SIRTf carries 350 liters of helium at launch, and a lifetime of $5 +$ years is predicted, based on an average instrument power dissipation of ~ 5 mW. By comparison, ISO was launched with ~ 2300 liters of helium and achieved a lifetime of ~ 2.5 years with an average instrument power dissipation of ~ 10 mW.

SIRTf will carry three array-based focal plane instruments:

1. A near-infrared camera that provides imaging simultaneously in four bands at 3.6, 4.5, 5.8, and $8\text{ }\mu\text{m}$. Both of the 3.6- and $5.8\text{-}\mu\text{m}$ channels image the same field of view in the sky; this is made possible by a dichroic filter that transmits $5.8\text{ }\mu\text{m}$ and reflects $3.6\text{ }\mu\text{m}$. An adjacent field of view is imaged at 4.6 and $8\text{ }\mu\text{m}$ in a similar fashion. Each band uses a 256×256 pixel array hybridized to a 256×256 MOSFET multiplexer. The detector material is InSb in the 3.6- and $4.5\text{-}\mu\text{m}$ bands and Si:As in the 5.8- and $8\text{-}\mu\text{m}$ bands.
2. A spectrometer that provides low resolving power ($R \sim 60\text{--}120$) spectroscopy from $5\text{--}40\text{ }\mu\text{m}$ and higher resolution spectroscopy ($R \sim 600$) from $10\text{--}38\text{ }\mu\text{m}$. The spectrometer consists of four physically distinct modules; each contains a 128×128 array (Si:Ga for the shorter wavelengths, Si:Sb for the longer wavelengths) illuminated by an optical train of mirrors and gratings. The use of detector arrays allows these modules to be very compact and efficient and obviates the need for moving parts. The higher resolution modules use two diffraction gratings so that, an entire octave of the spectrum can be cross-dispersed across the entire array and measured simultaneously. In the lower resolution modules, a long entrance slit is used to permit obtaining spectra simultaneously at many spatial points. A portion of the array in one of these modules is also used for the precision target acquisition required to place a source on a narrow spectrograph slit, thereby alleviating the absolute pointing requirements placed on the spacecraft.
3. An imager/photometer that provides imaging and low-resolution spectrophotometry at wavelengths between 25 and $160\text{ }\mu\text{m}$. This instrument uses a 128×128 Si:Ga array at $25\text{ }\mu\text{m}$ but incorporates two Ge:Ga arrays for longer wavelength measurements. The 32×32 Ge:Ga array used by SIRTf at $70\text{ }\mu\text{m}$ is composed of eight 4×32 submodules; each in turn consists of four 1×32 linear arrays, coupled to a 1×32 amplifier/multiplexer. The 2×20 array used at $160\text{ }\mu\text{m}$ is similarly built up of four 2×5 pixel modules with the added complication that the module construction allows for the mechanical stress needed to extend the long-wavelength response of Ge:Ga from 120 to beyond $160\text{ }\mu\text{m}$. These arrays represent substantial

advances in the state of the art and point the way toward still larger arrays for future applications. Note that although these arrays have fewer pixels than those described before, they are to be used at longer wavelengths where the diffraction-limited image size is larger compared to the field of view. Thus they provide comparable sampling of the telescope's focal plane; in fact, all three arrays are designed to sample the image fully to allow numerical postprocessing of the data to enhance the spatial resolution.

The scientific return of SIRTf cannot be forecast because its capabilities represent such a great advance beyond what has been possible in the past and also because the bulk of the observing time on SIRTf will be dedicated to programs to be proposed and carried out by the general scientific community. However, based on the science return from the other missions described before, we anticipate that SIRTf will lead to great advances in our understanding of such problems as

1. the formation and early evolution of galaxies, stars, and planets;
2. the physical processes that power the objects of highest luminosity in the Universe;
3. the chemical composition of interstellar and circumstellar matter;
4. the nature of the coolest, lowest luminosity stars and star-like objects in the solar neighborhood; and
5. the properties and interrelationships of comets, asteroids, interplanetary dust, and other small bodies in the solar system.

In addition, SIRTf's large arrays, very high sensitivity, and long lifetime give this mission great potential for discovering new phenomena.

Other Infrared Missions Already Flown

Other significant infrared space astronomy missions are described briefly here:

1. The Spacelab II Infrared Telescope—1985. A 15-cm diameter helium-cooled telescope was flown on Spacelab-2 and made infrared measurements between 2 and 120 μm . It provided data about the structure of the Galaxy (18) and about the infrared background environment on the Space Shuttle.
2. The Midcourse Space Experiment (MSX)—1995. MSX carried a 35-cm aperture off-axis telescope and five linear Si:As arrays that mapped the sky in a push-broom fashion in bands from 4–22 μm . Although it was primarily designed to scan Earth's limb, it carried out a number of astrophysical experiments and produced excellent images of the entire galactic plane at ~ 18 arcsec resolution (19).
3. The Infrared Telescope In Space (IRTS)—1995. IRTS was an ISAS program with significant NASA participation. IRTS had a 15-cm diameter liquid-helium-cooled telescope and four varied focal plane instruments covering wavelengths from 3–800 μm . It was carried on a Japanese satellite

called the Space Flyer Unit and surveyed $\sim 6\%$ of the sky in a 5-week lifetime (20).

4. The Near Infrared Camera and Multi-Object Spectrograph (NICMOS)—1996. NICMOS is a replacement focal plane instrument, which was installed on HST. It was instrumented with three 256×256 HgCdTe arrays that carried a range of filters that covered the 1- to $2.5\text{-}\mu\text{m}$ spectral band and was optimized for high spatial resolution imaging. NICMOS was cooled by solid nitrogen and achieved a lifetime of slightly less than 2 years. This was somewhat less than expected because of a partial failure of the cryogenic system in orbit (21).
5. The Submillimeter Wave Astronomy Satellite (SWAS)—1998. SWAS was the first space mission to carry radio-type (heterodyne) receivers for spectroscopic exploration. SWAS has a 55×71 cm near-optical quality off-axis primary mirror and two heterodyne radiometers with Schottky barrier diode mixers and a single acousto-optical spectrometer. SWAS is surveying the galactic plane in the emission of atomic carbon, molecular oxygen, water vapor, and carbon monoxide in five transitions between 538 and $615\text{ }\mu\text{m}$ (22).

Future Missions

A number of missions are planned or proposed for the next two decades to go beyond even the great scientific and technical accomplishments described before. These include

1. The Infrared Imaging Surveyor (IRIS) is a Japanese mission that will employ a 70-cm telescope cooled to 6 K, using a hybrid cryogenic system that incorporates both liquid helium and mechanical coolers to achieve a lifetime in excess of 1 year. Its primary mission is to conduct an all-sky survey at wavelengths of $50\text{--}200\text{ }\mu\text{m}$ at an angular resolution of $30\text{--}50$ arc seconds. The detectors to be used for this purpose are stressed and unstressed Ge:Ga. IRIS is likely to be launched in the first half of the decade 2000–2010 (23).
2. The Far Infrared Space Telescope (FIRST) is a mission sponsored by the European Space Agency with substantial participation by NASA. Its primary mission is to provide detailed spectroscopy and imaging for the $80\text{--}670\text{-}\mu\text{m}$ spectral range. It features a 3.5-m passively cooled, primary mirror that illuminates three different liquid-helium-cooled instruments. FIRST is to be launched by an Ariane 5 rocket into a Lagrangian point L2 orbit in the second half of the decade 2000–2010 (24). FIRST will share its launch vehicle with the Planck mission to study the CMBR mentioned earlier. FIRST has been renamed Herschel by ESA.
3. The Next Generation Space Telescope (NGST) is an international mission led by NASA, that will use a radiatively cooled, ultralightweight 8-m diameter telescope that will deploy following launch (6). A suite of focal plane instruments using very large detector arrays will observe at wavelengths

$\sim 0.6\text{ }\mu\text{m}$ to beyond $10\text{ }\mu\text{m}$. NGST will greatly extend the scientific results of both HST and SIRTf in this wavelength region. NGST will be launched by an Atlas rocket into a Lagrangian point L2 orbit toward the end of the decade 2000–2010 and will have a scientific lifetime greater than 5 years.

4. Interferometers in Space (25). All of the missions described before were built around a single telescope. To achieve much higher resolution than the $\sim 0.1\text{--}1\text{ arcsec}$ achievable with an $\sim 8\text{-m}$ telescope, it will be necessary to use the techniques of interferometry, in which infrared radiation collected by two widely spaced telescopes can be brought together to achieve angular resolution comparable to that which would be provided by a single telescope whose aperture is equal to the separation of the two telescopes. Ultimately, this technique will be employed in NASA's Terrestrial Planet Finder, scheduled to launch in the 2010–2015 time frame to image Earth-like planets around nearby stars.

ACKNOWLEDGMENTS

Portions of this work were carried out at the Jet Propulsion Laboratory, California Institute of Technology, operated under a contract with the National Aeronautics and Space Administration.

B

BIOLOGICAL RESPONSES AND ADAPTATION TO SPACEFLIGHT: LIVING IN SPACE—AN INTERNATIONAL ENTERPRISE

Introduction

Attempting to predict human responses to space travel, physicians and researchers of the 1950s speculated that microgravity and spaceflight itself would present significant challenges—if not barriers—to the human body (1,6). They hypothesized that the combined stresses of launch acceleration, weightlessness, radiation, and heavy deceleration upon reentry would be incapacitating. At the very least, they predicted that the bodily systems sensitive to gravity-based cues would function improperly or not at all. Given this grim forecast, the initial focus was to demonstrate that life, away from Earth, could survive space travel and subsequent return to Earth's gravity. Faced with this challenge, both the United States and Soviet Union turned first to ground simulations, such as immobilization studies, and then to the study of animal test subjects launched on board high-altitude balloons, suborbital, and orbital rockets. What followed is a series of biological satellites that carried a variety of living specimens, from isolated cell cultures to whole instrumented organisms. The Soviet Union relied primarily on canines to provide such data, whereas the United States chose primates for such experimentation.

There is not much doubt that in the beginning of the U.S. space exploration effort, the primary motivation was very real competition with the Soviets. What is remarkable is that in 1969, at the very height of this competition, when the

Americans first landed on the Moon, a long-lasting collaborative program in space biology was initiated by the United States and the Soviet Union. In that year, NASA flew the U.S. built "Biosatellite". This was a complex satellite that was placed in near-earth orbit with an appropriately instrumented chimpanzee as the payload. "Biosatellite" was flown and was successfully recovered after a week in orbit. Numerous measurements were made, but ultimately NASA rated the mission as only "partially successful," because of the death of the primate early in the postflight period, due to complications from loss of fluids and potentially an infection, thus loss of valuable data.

The "Biosatellite" mission was managed by the NASA-Ames Research Center because Ames was NASA's lead center in space biology. With the Apollo program in full gear, NASA decided to cancel all planned biological flight programs, except for a small experiment involving the behavior of a frog's otolith in zero gravity. The response from the leadership at Ames was to seek permission from NASA Headquarters to initiate collaboration with the Soviets in this area. Drs. Harold P. Klein and Joseph C. Sharp succeeded in making the case, and they received permission to go ahead. Eventually, several distinguished Soviet scientists were invited to visit Ames. This group included Professor Alexander Oparin, who was a distinguished expert in exobiology, and Academician Oleg Gazenko, an important leader in the Soviet space organization.

Eventually, an agreement was reached that would call for U.S. scientists to develop biological payloads to be flown on Soviet "Vostok" spacecraft. Dr. Sharp was the coordinator on the U.S. side, and Dr. Eugene Ilyin, Dr. Gazenko's deputy for biology, was the Soviet leader of the program. The first payload was flown in 1975. Since then, there has been an average of one flight every 2 years, and some significant scientific results were obtained early in the program (2,4). The early success of this program led to a sustained cooperative effort that survived several U.S. – Soviet confrontations during the Cold War. The Soviet invasion of Afghanistan in late 1979 caused President Carter to terminate many relationships that had been established as the Cold War wound down. For example, U.S. participation in the Moscow Olympic Games in 1980 was canceled. However, early in 1980, an American biological payload was flown aboard a Soviet satellite. Appeals from the scientists involved in this work prevailed to keep things going.

The success of the U.S. – Soviet collaboration, which also included exchange of biomedical data from piloted missions, was followed by the much higher profile 1975 Apollo. Soyuz Test Project Joint U.S. – Soviet flight and docking of the respective countries, spacecraft in low Earth orbit. This program was the result of a diplomatic effort during the Nixon – Ford Administrations. To promote a "détente" in the Cold War, it was felt that a joint U.S. – Soviet space mission would be helpful. The joint U.S. – Soviet crew performed a number of scientific experiments, but it was clear that the primary justification was symbolic. In that sense, the linkup of the U.S. Apollo and the Soviet Soyuz spacecrafts, which led to the famous "handshake in space," was a successful effort that aided the process of "détente" (3).

Serious thinking about possible scientific U.S. – Soviet collaboration of people in space was triggered by the successful first flight of the new Space Shuttle "Columbia" in April 1981. The Soviets had deployed the "Salyut 7" space station in 1982, and the existence of these capabilities once again led to the development

of some specific proposals for collaborative efforts. In 1982 and 1983, Air Force Lieutenant General James A. Abrahamson, who was serving as NASA's Associate Administrator for Space Flight at the time, proposed a "people exchange" between "Columbia" and "Salyut 7." The idea would be to have "Columbia" fly close to the "Salyut 7" station. An Astronaut from "Columbia" would perform an extravehicular activity (EVA), do a "space walk," and enter "Salyut 7." This would be followed by a Soviet Cosmonaut leaving "Salyut 7" and joining the crew of "Columbia." A preliminary proposal was developed but was not implemented for various technical and political reasons that existed at the time.

The end of the Cold War in 1991 led to an expansion of U.S. – Russian collaborative activities in space. A series of meetings between the U.S. Vice President, Albert V. Gore, and Russian Prime Minister Victor Chernomyrdin resulted in agreements that involved the collaborative use of the Russian "Mir" Space Station, as the Russian participation in and contribution to the International Space Station Program. James Beggs and Dr. Hans Mark, the NASA Administrator and Deputy Administrator, secured Administration and Congressional support to initiate the latter facility in 1984. From the very beginning, the U.S.-led space station program was intended as an international effort. The European, Canadian, and Japanese Space Agencies had strong roles in the beginning, and in 1993, Russia was brought into the program. The Russian contribution was to build various segments of the Space Station and to use Russian "Proton" launch vehicles to resupply the Space Station. The Russians also agreed to provide the Soyuz TM spacecraft as an initial crew rescue vehicle. The NASA Administrator Daniel S. Goldin initiated the International Space Station redesign effort to accommodate all of the international partners, improve research capacity, and provide long-duration spaceflight training for U.S. astronauts and ground personnel. It was also a rehearsal for international partners of living and working together in space. In addition, NASA resources were used for more than 300 Russian space scientists for competitively selected research projects and collaboration with their U.S. counterparts. This effort provided much needed resources to the Russian space science community at the time of economic transition in the post-Soviet era. The Research program on the MIR Space Station was developed by Drs. Arnauld Nicogossian and Carolyn Huntoon for NASA. Dr. Nicogossian was responsible for overseeing the implementation of the research program on "MIR" and the funding of the Russian space science community.

These efforts began in 1995 with a rendezvous in space between the Space Shuttle "Discovery" and the "Mir" Space Station. An astronaut-cosmonaut exchange was executed later in 1995 in a docking of Space Shuttle "Atlantis" and "Mir" that finally fulfilled what General Abrahamson had proposed more than a decade earlier. The difference between what was done in 1995 and what had been proposed is that no EVA was necessary to do the 1995 mission. An adapter had been constructed to make it possible for the U.S. Space Shuttle to dock directly with the "Mir" Space Station. The first Shuttle – Mir mission was followed by a number of docking missions involving both American astronauts and Russian cosmonauts. In this way, several Americans experienced truly long-duration spaceflights for the first time.

With the advent of the International Space Station, U.S. – Russian collaboration quickened. It is now quite routine to have “mixed” U.S. – Russian crews working for long periods of time on the International Space Station. Thus, in the span of four decades, sustaining life in space has evolved considerably from the first flights intended to prove that humans could endure microgravity. Since the first forays into space by Gagarin, Shepard, Grissom, Titov, and Glenn, the United States has explored the Moon, the Soviet Union/Russia has maintained a series of space stations in orbit for more than 25 years, and American astronauts have shepherded the orbital Shuttle through more than 100 missions and hundreds of sophisticated biomedical experiments. One of those missions carried Senator John Glenn, on his second flight 36 years after the Mercury 6 orbital flight, intended to underscore another NASA – NIH cooperation in the study of aging. An intrinsic, even critical, component of this evolution has been to define and overcome the biomedical challenges of human space flight and also to understand the role of gravity in critical life processes. After all, life originated and evolved under the constant pull of Earth’s gravity, using this force from cradle to grave in ways that are still poorly understood. Only recently, pulling together ground and flight data obtained from integrated and interdisciplinary biological and clinical experiments, scientists have begun to unravel the effects of gravity on living systems. This understanding was made possible by the collaboration of scientists around the world and the participation of the National Institutes of Health. The ability of gravity to up- or down-regulate certain genes involved in musculoskeletal metabolism and the capacity of the nervous system to adapt its function rapidly as a result of changing gravitational forces are just two of the most fascinating discoveries reported recently (4).

What follows is an attempt to present a concise overview of life in space, physiological responses to this new environment, and associated health implications for future space travelers. Consideration must be given to the hostile, and yet dynamic environment of space; to the craft that protects the crew members from the harsh environment, allowing them to navigate in space; and to life itself as it adjusts to this novel environment. Today we know that some adaptive changes, such as immune and hormonal responses, are primarily the response to the stresses of confinement, isolation, and spacecraft design, not necessarily to the unique effects of the space environment.

The Spaceflight Environment

The first astronauts and cosmonauts were required to function—eat, drink, communicate, and move—for extended periods of time in a novel and complex environment. Early biomedical studies demonstrated that the combined factors of spaceflight did exact a toll on the physical performance and health of crew members. Furthermore, early crew members and aerospace engineers realized that spaceflight was really the sum of several complex factors, only one of which is microgravity. The success of each mission is driven by a number of parameters—crew performance, crew health, the internal spacecraft environment, system performance, and the external environment—whose sum represents a challenge to safety and, most importantly, human survival.

External. In orbit, a spacecraft moves around Earth in a constant state of free fall that produces microgravity. Because all organisms on Earth have evolved and developed in the presence of gravity, the absence of this force imparts adaptive changes that are initiated immediately upon exposure. Some of these continue throughout the course of the mission. The net results of these changes are altered physiological function and structure that can offset health and performance in space and postflight.

Although the most conspicuous characteristic of the space flight environment is reduced gravity, a number of other factors contribute to its biomedical effects on humans. Primarily, space is a hostile environment to life. It is distinguished by profound fluctuations in temperature ranging from 220 K in the stratosphere to 1000 K in the thermosphere (5), the lack of a breathable atmosphere due to a near-perfect vacuum, and a number of constant and intermittent radiative events. In addition, the spacecraft is usually subjected to micrometeoroid bombardment and recently, to a large amount of human-made debris. All of these external and internal environmental events require constant monitoring to protect crew health and mission safety (6,7).

The radiative environment is comprised of several sources of ionizing radiation, a general term that encompasses particles that can alter molecular electrons upon contact: solar energetic particles emitted during solar flares, particles trapped in Earth's magnetic field, and galactic cosmic radiation (8). Although each of these sources consists of various types of space radiative particles, the most significant barriers to mitigating radiative exposure are

1. an incomplete understanding of the detrimental effects caused by ionizing radiation, and
2. an inability to predict and model radiative events fully in time to protect a space-faring crew or biologically based life support system (9).

Presently, crew and spacecraft interior are monitored by a series of passive and active dosimeters, and ground-based monitoring can warn of impending solar flares so that the mission can be abbreviated. The Soviet Union and NASA performed a number of experiments, using biosatellites, the Space Shuttle, the Mir Space Station, and now the International Space Station (ISS), to understand the effects of protons, neutrons, electrons, and heavy cosmic ions on the function of living organisms. Now, it is postulated that one of the effects of continuous exposure to galactic – cosmic radiation can result in cellular genomic instability, manifested as generational cancer and/or malformations. Comparison of the measurements made during the Skylab mission in 1971–73 to those obtained from the NASA-MIR (ISS Phase I) experiments showed that the South Atlantic Anomaly, and the associated radiation, has moved westward and north, reflecting a displacement in Earth's electromagnetic fields (4,9). NASA, together with the ISS partners, is now beginning to standardize radiative measurements and data analysis. Since 1998, NASA and the National Institutes of Health developed a research program to study the long-term genetic implications of exposures to constant low-level radiation. One of the most unexpected findings from the NASA – Russian cooperation was the realization that the spacecraft's aluminum

shell results in fragmentation and transformation of incoming energetic rays (bremsstrahlung) that contribute up to 30% of the total space radiative exposures (10).

Internal. Not all biomedical changes or medical events observed in spaceflight result from altered gravity or the influences of the external environment. The human-rated spacecraft must protect the crew from the hostile external environment and provide the resources necessary to support human life and work (see U.S. Manned Spaceflight: Mercury to the Shuttle). The design and performance of such spacecraft has evolved considerably from the first space capsules to the “shirt-sleeve” environment of the International Space Station. Common to all spacecraft environments, however, is the requirement for appropriate air, water, temperature, and pressure and consideration for the human factor in design and performances, that is, the environment must be precisely monitored and maintained using a minimum of resources including power, mass, and crew time (11).

Although the spacecraft itself must be rigorously designed to shield crew members from both constant and intermittent ionizing radiation, cumulative exposure levels within the spacecraft must be constantly monitored and assessed. Currently, both active and passive dosimeters of different sensitivities are used to track the exposure of each individual and selected regions in the spacecraft. As missions of increasing duration are emphasized, however, monitoring requirements will become more stringent, and highly accurate modeling and prediction will become a central means of protecting crew members. Because missions beyond earth’s orbit cannot be rescheduled or aborted to avoid predicted radiative events, exploratory missions will require a heavily shielded shelter, preferably constructed with a nonmetallic and high hydrogen content material within the spacecraft, or some other solution for protecting space-faring crews from high radiative exposures.

The spacecraft environment itself provides additional challenges to crew health and safety. A majority of these constraints results from the combined physical environment of spaceflight. Crew members are expected to live in confinement far distant from friends and family are subjected to extreme scrutiny and pressure to complete their work in a timely and consistent manner (12). This stress and isolation is compounded by the fact that a sunrise or sunset occurs every 90 minutes in low Earth orbit. Although initially disconcerting to crew members, altered dark–light cycles have a significant physiological effect on the quality and quantity of sleep and ultimately, performance. The sum of these challenges, both mental and physical, can exact a considerable toll on crew members unless they have appropriate support from ground personnel, sufficient personal time and space, and flexible work/rest schedules.

Numerous analog environments, including extended bed rest and Antarctic wintering-over expeditions, have been explored to understand the cumulative effects on human performance and psychosocial health. Human experimentation in space is a tedious and difficult task: differences among missions, variability in environmental parameters, small sample size, and mission constraints have made the design and execution of controlled experiments quite challenging (6). The Soviet Union/Russia operated its spacecraft at near 760 torr and normal atmospheric gas composition and pressure, whereas the United States adopted a

one-gas (100% oxygen) one-third atmospheric (250 torr) pressure. The intent was to simplify the life support system and minimize decompression sickness during space walks. This approach was used for early human missions and was intended to save time in the race to the Moon. At the conclusion of the Apollo missions, NASA engineers were faced with a prospect of oxygen toxicity during the long-duration Skylab missions. NASA and U.S. Air Force life scientists solved this problem by adding 20% nitrogen to Skylab's atmosphere. In the meantime, the tragic death of the three Soviet cosmonauts returning from the first Space Station, Salyut 1, created concerns in NASA regarding the safety of long-duration biomedical research on Skylab. Following a cooperative agreement signed in 1971, Soviet life scientists shared the medical findings from the Salyut 1 mission with their NASA counterparts, demonstrating that rapid decompression, due to a hatch seal failure, resulted in crew death. This mutual collaboration ensured confidence and the success of Skylab missions, and it also generated an unprecedented and very successful scientific and professional medical relationship between the physicians and scientists of the two countries. This relationship persists to this day, despite many political and management changes in both countries. The major engineering and biomedical challenge to both countries was presented during the planning and execution of the Apollo-Soyuz Test Project, docking two spacecraft that had markedly dissimilar atmospheres, posing a potential fire hazard to the Soyuz Spacecraft, and the risk of bends to the crews. A special transfer airlock module was developed for this purpose. This module was carried by the Apollo spacecraft and docked with the Soyuz; during the joint phase, the atmospheric pressure in the Soyuz was reduced by 155 torr, and the oxygen concentration was slightly increased. During a 3-day period, the crews visited each other's spacecraft three times; no bends occurred despite repeated recompressions and decompressions in the airlock.

The Space Shuttle presented a real challenge for space walks and the risk of bends. NASA adopted a standard atmosphere composition and pressure, in a decision made in response to the demands from the international scientific community, but the space suit pressure and gas composition changed little. NASA's budgetary constraints precluded the opportunity of using advanced space suits designed by the Ames Research Center. This concern for bends continues to persist in the ISS era.

Over the years, life scientists learned that an answer to the challenges posed by the engineering design, mission constraints, and uncertainties of research in space is to use multiple species, in addition to humans, to document similarities in responses to experimental variables among species. This requires integrating many different biological specimens into major life science experiments, especially during the Shuttle/Spacelab era. The necessity to execute integrated international experiments to increase the scientific return was demonstrated by the U.S. and Soviet/Russian life science cooperation (4,10).

To date, more than 350 individual biological experiments were flown in space. NASA launched 20 suborbital and 4 orbital missions, and Soviet Union/Russia launched more than 22 spacecraft (Biosattelite) dedicated primarily to fundamental biology. The last 11 Biosatellites included international participation, with major contributions from the NASA Ames Research Center. A total of 35 different species were flown by NASA, Russia, Europe, Japan, Ukraine,

and Canada. The results of these investigations are presented in the following sections.

Biomedical Challenges

The organism uses a complex set of biological tools to sense, process, and respond to the ever-changing environment, be it the normal habitat on Earth or the close quarters of spacecraft. Full understanding of the relationships between these various tools is yet to be achieved. Table 1 presents concisely the sum of our current knowledge in this area.

Because of the complexity and individual nature of human adaptation to spaceflight, changes are often considered on a systemic basis. Although this approach is useful for understanding system-specific functional alterations, it does not fully characterize the effects of living and working in the spaceflight environment. As a result, more recent studies have focused on whether crew members maintain appropriate levels of functional performance, the ability to perform key activities such as intra- and extravehicular activity (IVA, EVA) or emergency egress during or following long-duration spaceflight. Aerobic capacity, a measure of the amount of oxygen consumed during a single bout of maximal exercise, reflects the integrated performance of the cardiovascular, nervous, and musculoskeletal systems. As illustrated in Fig. 1, aerobic capacity is diminished by spaceflight but does show a relatively rapid return toward preflight levels upon return to Earth (6,13).

Cardiovascular Deconditioning. The cardiovascular system has evolved in the presence of gravity as an intricate network of vasculature that contains blood and is powered by the heart. This vasculature is composed of both muscular arterial vessels that supply oxygenated blood to tissue and nonmuscular venous vessels that return blood to the heart. Baroreceptors and stretch-sensitive receptors monitor the critical parameter of blood pressure in vessels throughout the body and adapt to postural changes. On Earth, simple motions such as sitting, standing, or reclining result in significant and rapid responses to changes in gravitational force imposed on the body.

Spaceflight presents a challenge to the cardiovascular system that is generally stabilized by the fifth week of flight. In even longer Soviet space flights (3 months to 1 year or more), a slight increase in heart rate has been noted, particularly toward the end of the mission (7,14). Nevertheless, cardiovascular deconditioning, by Earth's standards, appears to be a self-limiting phenomenon on that does not worsen with flight duration (unless other medical conditions, such as dehydration or infection prevail) and does improve upon return to Earth. In space, cardiovascular responses represent an appropriate adjustment to a new environment, in which the gravitational load placed on the heart is considerably less than on Earth. Fluid pooling no longer occurs in the lower extremities but is instead localized to the upper body. Physically, this shift is revealed by facial edema, sinus congestion, decreased calf girth, and leg volume ("bird legs"). This shift is perceived as excess fluid, which in turn affects a series of immediate but long-lasting changes. An immediate decrease in plasma volume occurs, in addition to a more gradual loss of approximately 10% of red blood cell

Table 1. A Summary of the Physiological Changes Associated with Human Spaceflight

Physiological measure	Change associated with short spaceflights (<3 weeks) ^a	Change associated with long spaceflights (>3 weeks) ^a
Cardiovascular System		
Resting heart rate	<i>Peaks during launch and entry; ↓ in-flight; ↑ postflight</i>	<i>In-flight normal or slight ↑; ↓ orthostatic tolerance postflight</i>
Resting blood pressure	↔	Diastolic blood pressure ↔ or ↓
Total peripheral resistance	↓; ↔ at landing despite ↓ stroke volume and ↑ heart rate	Tendency toward ↓
Stroke volume	↓ postflight	↓ postflight
Exercise capacity	↔ or ↓ ≤ 12% after flight; increased HR for same O ₂ consumption; efficiency ↔	Submaximal exercise capacity ↔
Body Fluids		
Total body water	3% ↓ by flight day 4 or 5	↑ (first in-flight sample) followed by slow ↓
Plasma volume	↓ in-flight and postflight	↓ approximately 15% during first 2–3 weeks; recovery begins after 60 days and is independent of mission duration
Hemoglobin	↔ or slightly ↑ after flight	
Red blood cell (RBC) mass	↓ after flight (approximately 9%); sustained at least 2 weeks and associated with decreased erythropoietin level	
Plasma lipids	↓ cholesterol and triglycerides in-flight	
Plasma glucose	↓ during and immediately after flight	↓ first 2 months, then leveled off
Serum/plasma electrolytes	↑ K and Ca in-flight; ↓ Na in-flight; ↓ K and Mg postflight	↓ Na, Cl, and osmolality; slight ↑ K and PO ₄
Urine electrolytes	<i>Postflight ↑ in Ca, creatinine, PO₄ and osmolality; ↓ in Na, K, Cl, and Mg; decreased citrate</i>	↑ osmolality, Na, K, Cl, Mg, Ca, and PO ₄ ; ↓ uric acid excretion; decreased citrate
Insulin		↓
Urine volume	Postflight ↓	↓ early in flight

Sensory Systems		
Gustation and olfaction		
Vision	Subjective and varied experience; no impairments noted Intraocular tension ↑ in-flight and ↓ at landing; postflight ↓ in visual field, visual motor task performance and contrast discrimination; ↔ in-flight contrast discrimination or distant and near visual acuity; dark-adapted crews reported light flashes with eyes open or closed; retinal blood vessels constricted postflight 40–70% astronauts/cosmonauts exhibit in-flight neurovestibular effects, including immediate reflexive motor responses and space motion sickness; motion sickness symptoms appear early in flight and subside or disappear in 2–7 days. <i>Postflight ataxia and disrupted postural control</i>	Same as shorter missions Light flashes reported by dark-adapted subjects; frequency related to latitude In-flight vestibular disturbances are the same as those for shorter missions; cosmonauts have reported occasional reappearance of illusions during long-duration missions. <i>Ataxia postflight and significant alteration in postural control mechanism</i>
Musculoskeletal System		
Height	Slight ↑ (~1.3 cm/0.5 in) during first week in flight, and 1 day recovery to baseline Postflight weight ↓ average 3.4%; about two-thirds is due to water loss and the remainder due to lean body mass and fat ↓ 15% on flight day 2	↑ during first 2 weeks in flight by a maximum of 3–6 cm (1.2–2.4 in); stabilizes thereafter In-flight weight losses average 3–4% during the first 5 days and are probably due to loss of fluids; thereafter, weight ↑ or ↓ for the remainder of the mission and is related to metabolism
Extracellular fluid volume	↓ postflight	Center of mass shifts headward
Total body volume	↓ during and after flight, with 1–2 weeks recovery to baseline	
Muscle strength	Postflight EMGs from gastrocnemius suggest ↑ susceptibility to fatigue and ↓ muscular efficiency; EMGs from arm muscle ↔	
EMG analysis		
Bone density		<i>Os calcis density ↓ postflight; radius and ulna show variable changes, depending upon method, ↓ bone density in lumbar vertebrae, pelvis and femoral trochanters</i>
Calcium balance	↑ negative Ca balance in flight	<i>Excretion of Ca ↑ during first month of flight; fecal Ca excretion ↓ until day 10 then ↑ continually throughout mission; Ca balance becomes ↑ negative as the mission progresses</i>

^a ↔ unchanged; ↓ decrease; ↑ increase; N/A: not measured.

Figure 1. Aerobic capacity of crew members before launch (L – 10 days) and after flight (Return, Day 0 and Return, Day 3) as measured by maximum O₂ uptake in liters per minute during an exercise stress test. Control subjects did not perform any exercise, whereas CM subjects exercised using an onboard cycle ergometer up to 48 hours before landing (13).

mass (15). This condition is primarily attributed to a decrease in circulating blood volume. Systematic investigations have proven difficult because of individual differences in diet, sleep patterns, exercise, medications, and fluid intake associated with various space missions. Recent studies have focused on secretion of hormones (such as norepinephrine), baroreceptor changes with time, and the role of the central nervous system in regulating of the cardiovascular system (16).

Microgravity-induced cardiovascular adaptation becomes a medical problem only after crew members are subjected to accelerative forces during reentry or upon return to the constant 1-g stress on Earth. As early as the American Gemini program, cardiovascular deconditioning was documented in 100% of crew members. One component of this deconditioning is orthostatic intolerance, the inability to function effectively against gravitational stress, such that simple actions like sitting and standing may result in episodes of weakness, dizziness, or fainting. A standard measure of orthostatic intolerance is the stand test, in which recently returned crew members are asked to stand upright for several minutes after a period of reclining; by monitoring blood pressure and heart rates during this functional challenge, researchers can associate significantly altered arterial pressures with adaptation to space flight and the gravitational forces of landing. As shown in Fig. 2, approximately 20% of crew members showed altered levels of systolic and diastolic pressure following flight. Depending on the duration of the space flight and the amount of exercise performed in flight, the return of cardiovascular function to preflight values may take as long as 2 weeks. Routinely used countermeasures include aerobic exercise, fluid and electrolyte

Figure 2. Systolic and diastolic pressure responses of crew members to entry, landing, and egress shows altered reactions to the standard orthostatic challenge, the stand test. Blood pressure was measured preflight while seated and standing. The middle section of this graph represents blood pressure values in-orbit (an average of 130/76 mm Hg), during reentry, and until touchdown and egress from the orbiter seat. Values while seated in the orbiter are much higher than preflight values (16).

replenishment (especially before return to Earth), and exposure to simulated gravity via the lower body negative pressure device (6,7,17,18).

Neurosensory Disturbances. The central nervous system (CNS) controls both perception of and interaction with the environment. The sensory system, including the visual, vestibular, and proprioceptive organs, responds to environmental stimuli and supplies a constant flow of input to the CNS. In conjunction with a visual image of surroundings, the vestibular and proprioceptive systems supply additional information relating to orientation, balance, and limb location. The CNS processes this information and then directs the musculoskeletal system's movement and interaction with the environment. Each step in this intricate process is contingent upon a constant inflow of information about the surrounding environment. In microgravity, however, the CNS must adapt to a loss of sensory and proprioceptive input, and it also must also respond to reduced muscular capacity, including functional and structural changes in muscle tissue. Adaptation to unexpected or even absent sensory information is neither an instantaneous nor a constant process; thus identifying the mechanisms responsible and the appropriate countermeasures is somewhat of a challenge. Neurosensory adaptations have traditionally been difficult to measure but indirectly are evidenced through in-flight and postflight changes in crew performance.

Clinically, the most important vestibular disturbance associated with spaceflight is space motion sickness (SMS). As Titov noted, most crew members do experience a sensation of bodily inversion, which soon passes but can recur due to rapid movement (19). More susceptible individuals, however, develop a full host of SMS symptoms (20). Russian and U.S. demographics suggest that SMS affects 40–70% of astronauts and cosmonauts, depending on the classification of

symptoms. SMS occurs early in the mission, typically within the first 3 days. Symptoms range from minimal discomfort to nausea and vomiting, accompanied in rare cases by pallor and sweating. Head and body movements tend to worsen the discomfort. When the symptoms are severe, crew performance can be affected and mission efficiency severely compromised. During the Apollo IX mission, for example, certain crew activities were delayed by 24 hours due to space motion sickness.

The medical basis for space motion sickness is not fully understood, partly because the phenomenon can be studied effectively only during spaceflight. Guedry et al. (21) summarized studies of motion sickness in flight and on the ground, in which the most plausible explanation for neurosensory changes is the "sensory conflict" hypothesis. According to this concept, the usual sensory inputs to the vestibular receptors of the inner ear are no longer present in microgravity, causing altered processing of sensory information and ultimately resulting in altered motor responses. A series of elegant biological experiments conducted aboard the dedicated Spacelab Life Sciences Missions 1 and 2 and the NASA-NIH Neurolab Mission, dedicated to the Decade of the Brain, demonstrated the plasticity of the CNS in response to altered gravitational forces. The CNS does develop new coping strategies in novel environments, which facilitates orientation and navigation. Of interest is the fact that individuals who use internal cues for orientation fare better in the SMS manifestation and adaptation process than those use external cues. Repeated exposures to the space environment reduce the severity of SMS and the length of time required to adapt. Anecdotal data suggests that women are less susceptible to SMS. Finally, Earth-based simulators cannot identify individuals susceptible to SMS. Absorption of orally ingested medications is altered in space, and drugs are not effective in preventing or treating SMS. Injectable PhenerganTM has been successfully used to treat SMS in-flight and has minimal side effects (6).

Both the Russian and American human spaceflight programs recognize the complex interactions within and between the sensory-motor, nervous, cardiovascular, and muscular systems (10). A significant finding from postflight research is the ataxia present during ambulation in the majority of flown individuals. Current countermeasures against this ataxia involve resistive exercise combined with compressions along the longitudinal axis of the body.

Musculoskeletal Alterations. An integrated response from the skeletal, muscular, connective tissue, and nervous systems permits movement in a 1-g environment. This response is predicated on the fact that certain directional forces must be overcome to complete ordinary tasks, such as lifting an object or walking down stairs. In the microgravity environment, however, these directional forces are altered; the result is a cascade of functional and structural changes in the physiological systems that control locomotor tasks. Collectively, these changes yield reductions in strength, power, and endurance that ultimately influence crew-members' ability to perform routine motor activities (Table 2). The changes are ordinarily indicated in flight by a progressive decrease in total body mass, leg volume, and muscular strength. As weight-bearing muscles and bones adapt to the microgravity environment, several symptoms are manifested. Disturbances in postural and motor coordination, locomotion function, and equilibrium can be seen, and alterations in proprioceptor activity and spinal reflex

Table 2. Mean Strength Performance of Skeletal Muscle on Landing versus Preflight (n = 17) during Concentric and Eccentric (Extension) Motions of Selected Muscle Groups (13) Pre>Landing (p<0.05)

Muscle group	Test mode	
	Concentric	Eccentric
Back	- 23 (\pm 4)*	- 14 (\pm 4)*
Abdomen	- 10 (\pm 2)*	- 8 (\pm 2)*
Quadriceps	- 12 (\pm 3)*	- 7 (\pm 3)
Hamstrings	- 6 (\pm 3)	- 1 (\pm 0)
Tibialis Anterior	- 8 (\pm 4)	- 1 (\pm 2)
Gastroc/Soleus	1 (\pm 3)	2 (\pm 4)
Deltoids	1 (\pm 5)	- 2 (\pm 2)
Pecs/Lats	0 (\pm 5)	- 6 (\pm 2)*
Biceps	6 (\pm 6)	1 (\pm 2)
Triceps	0 (\pm 2)	8 (\pm 6)

mechanisms occur. Although all of these changes appear to be dependent, at least to some extent, on flight duration, they have been reversible, and no adverse sequelae have been reported thus far.

A primary indicator of changes in bone and muscle is body mass: in-flight weight losses of 3–4% were seen in early, short-duration spaceflights. With the advent of longer missions, most weight loss took place during the first three to five flight days, and a much more gradual decline thereafter (22). The findings suggest that a significant part of the initial change in body mass is due to the loss of fluids, either through diuresis or decreased thirst and fluid intake (18), and that subsequent losses are due to metabolic imbalances and/or muscle atrophy. These changes appear to be self-limiting, the largest weight losses recorded (6 to 7 kg) are independent of mission duration. In more recent long-duration space missions, where adequate caloric intake and physical exercise have been maintained by some crew members, actual weight gains have been reported. Such weight gains probably reflect an overall increase in fatty tissue, which was more than sufficient to offset losses of muscle tissue (7,10). In any event, body mass lost in flight is rapidly regained in the postflight period.

Muscle Atrophy. Muscle atrophy results from structural and functional changes in muscles. These changes are most readily apparent in the postural or antigravity muscles, such as the gastrocnemius abdominal, back, and neck muscles. Skeletal muscles exhibit numerous alterations in strength and endurance properties, including force- and power-generating capacities, shortening and relaxing rates, neural activation patterns, protein expression, and metabolic utilization profiles. Concomitant with these muscular changes, connective tissues undergo similar atrophy and functional alteration. At the molecular level, both slow-twitch and fast-twitch muscle fibers are affected. The process of functional and structural change is progressive and can be controlled to some extent by increasing caloric intake, dietary adjustments, and intensive strength exercises.

Evidence of the deterioration of muscle during spaceflight comes from several sources. In-flight measurements of leg volume (Fig. 3) show an initial rapid

Figure 3. Percent decreases in volumes of various leg muscles, measured by magnetic resonance imaging, from three extended duration Orbiter Shuttle missions (13).

decrease that can be attributed to the headward fluid shift and is followed by gradual recovery. Postflight biostereometric measurements of Skylab astronauts demonstrated more general losses of volume from the abdomen downward, although losses in the abdomen and buttocks were attributed to the loss of fat (23). Postflight urinary analyses reveal in-flight increases in the excretion of a number of metabolites associated with muscle breakdown, such as nitrogen, potassium, creatine, and amino acids. Metabolic balance studies and electromyographic analyses of muscular activity further substantiate the deterioration of muscle function during spaceflight. Electromicroscopic analysis of human and rodent muscle biopsies showed decreased production of slow-twitch myosin fibers (endurance) and normal distribution of fast-twitch myosin fibers (dexterity). Additional investigations performed on rodents flown on Spacelab missions demonstrated the selective effects of gravity on the type of muscle myosine production (4).

Bone and Mineral Changes. Removing muscular forces and weight from bones, as occurs in bed rest or having a limb in a cast, causes a loss of bone mineralization, known as disuse osteoporosis. During space flight, crew members experience a form of musculoskeletal disuse in which levels of bone mineral are decreased. Early studies of bone mineral changes using X-ray densitometry suggest that large amounts of bone may be lost during relatively brief periods of spaceflight, and countermeasures to this loss are mandatory for long-duration missions (24). The 12 crew members who participated in the Gemini 4, 5, and 7 and Apollo 7 and 8 missions averaged 3.2% postflight losses of bone density from the calcaneus (heel bone) compared with preflight baseline values. Some losses were also observed from the radius and ulna after these early flights. Data from Soviet/Russian cosmonauts and U.S. astronauts who flew on the Mir station show a continued loss of 1% of bone mass per month, even using exercise as a countermeasure. Resistive exercise, hormone therapy, and drugs such as bisphosphonates are currently being evaluated as potential countermeasures to bone loss.

In sum, these changes to the locomotion system means that crew members are at risk for increased falls, bone fractures, and limited mobility—conditions, which at a minimum, could make emergency egress a challenge.

Immunologic Alterations. The immune system defends the body against any cell, substance, or organism not recognized as self. As such, it is affected by both environmental and physiological fluctuations that occur during spaceflight. Although results from some studies are contradictory, most generally recognize an increase in the immune cells responsible for the immune response, known as leukocytes. More specifically, changes in the leukocyte population, particularly in the relative percentage of T and B lymphocytes, are altered compared to preflight levels. Lymphocytes from astronauts on board Soyuz 6, 7, and 8, Skylab 2, 3, and 4, and Salyut 4 exhibited poor response to mitogenic factors (25), the substances that induce the immune response. Therefore, the cells, experience a reduced functional capacity in microgravity conditions.

The immune system, like other body systems, responds dynamically to varying conditions, which may explain why results from one study contradict those of others. Studies conducted as early as the Skylab program suggest that impaired immune function during spaceflight is closely linked to the endocrine system and is particularly affected by corticosteroids and catecholamines (25); generally, this implies that changes in other regulatory mechanisms could closely affect immune function. In addition, results from *in vitro* studies may not parallel results from *in vivo* studies, indicating that the physiological environment plays an integral role in maintaining immunologic integrity (26).

It has been shown in several studies that stress has a considerable influence on immunity. Astronauts experience psychological and physical stresses that may result in reactivating latent viruses during space flight, potentially increasing the risk of infection among the crew. A study done on the amount of Epstein-Barr shedding pre-, in- and postflight on the Shuttle and Mir crews, showed that the virus, normally latent in most humans, was higher in samples taken before launch (27). Although results from this study suggest that stress levels are higher before than during or after flight, reactivation of latent viruses, combined with depressed immune response in flight, poses a threat to both short- and long-term missions in the event of injury or infections.

Because immune function and activity are interdependent on other systems of the body, there are implications for exploring countermeasures to mitigate the changes and for studying how pharmacological substances interact with the immune system in microgravity (18). Similar changes in immune response were reported in wintering personnel in Antarctica and, it is thought, are due to confinement and isolation. Carefully planned studies will be required to shed further light on this important issue, which could affect the development of chronic and debilitating diseases.

Hematologic, Fluid, and Electrolyte Changes. The headward shift of fluids in weightlessness and the resulting decrease in circulating blood volume are responsible for many of the physiological changes that occur during adaptation to spaceflight conditions. As has been discussed, they directly affect the functioning of the cardiovascular system. They also have several effects on the composition of body fluids, especially blood (Table 1). The most significant hematologic changes involve a reduction in plasma volume, alterations in red blood cell (RBC) mass,

and changes in the distribution of RBC shapes. From the time of the early Gemini and Vostok missions, a postflight decrease in total RBC mass has been observed in nearly all U.S. and Soviet crew members. There is a gradual decrease, losses average about 9% of the total RBC pool during the first 30 to 60 days in flight, and values range from 2–21%. Cosmonauts who participated in missions of 18 days to 6 months have shown a postflight decrease in erythrocyte counts that returned to baseline values within 6 weeks (22).

The magnitude of the RBC loss does not appear to relate to the length of missions longer than 14 days. Changes in RBC are also accompanied by changes in the shapes of erythrocytes, although these alterations do not seem to affect crew health or function in flight and are rapidly reversed postflight. The weight of evidence now suggests that the loss of RBC mass is due, instead, to insufficient circulating erythropoietin in combination with neocytolysis, or a decreased survival rate of newly formed RBCs (7,15). The decrease in RBC mass is effectively masked by a simultaneous, rapid decline in plasma volume (4–16% from preflight values) such that the ratio of cells to plasma remains roughly normal (18).

The microgravity-induced fluid shift produces at least a transient increase in central blood volume (18). Research from ground-based bed-rest studies suggests that the stretch receptors in the left atrium interpret this as an increase in total circulating blood volume and trigger a compensatory loss of water, sodium, and potassium from renal tubules. This is the first event in a series of fluid and electrolyte shifts that occur during the adaptation to weightlessness. So far, early diuresis has been observed only in bed-rest studies. It is difficult to demonstrate during spaceflight because of the problems involved in accurately documenting urine volumes early in flight while water intake is usually reduced due to SMS. Additional findings include in-flight increases in the urinary output of sodium, potassium, and chloride, an in-flight decrease in antidiuretic hormone, and reduced postflight excretion of sodium. Fluid retention has also been a consistent finding in cosmonauts after Soyuz flights, but it was found that excretion of potassium and calcium increases. Alterations in electrolytes are believed responsible for cardiac arrhythmias on Apollo 15 and subsequent U.S. and Soviet missions (7).

Psychological Health. The spaceflight environment consists of many elements that, even if experienced separately, are both physically and mentally challenging. A confined living space, high public interest and visibility, isolation from family and friends, crowded or often unappealing spacecraft conditions, and requirement for strong group dynamics are but a few of the obstacles that cosmonauts and astronauts face. These factors are compounded by the physical fact that light/dark cycles are altered in orbit, which affects circadian rhythm and is evidenced by disrupted or insufficient sleep (28). The most prevalent psychological events reported by crew members include high levels of stress or tension, anxiety often demonstrated as annoyance at other crew members or ground support personnel, decreased levels of concentration, emotional instability including mood elevation or depression, and general fatigue.

As increasingly longer missions become feasible, psychological and behavioral support has become an element of both the American and Russian space medicine programs. Often, support takes the form of comparatively small changes

in operations or scheduling that minimize crew requirements and permit crew members some flexibility in arranging their work/rest cycles. For example, astronauts have reported considerable improvements in outlook and performance when communications with family members or friends are provided regularly. Careful planning for work/rest cycles, proper recreation, nutrition, and interpersonal and family communications are essential in maintaining psychological health during long-duration missions. The Soviet/Russian program has developed an elaborate system for its crews, which is now adapted to the ISS program (7).

Time Course of Adaptations

The human body is exquisitely sensitive to changes in its surroundings and reacts to such changes with equal precision. Modest changes in gravitational force, for example, as a sitting person stands or a sleeping person awakens induce a host of regulatory or adaptive mechanisms to ensure that blood consistently reaches all extremities. A more significant change to the gravitational environment—such as the microgravity of spaceflight—clearly challenges the body's homeostasis to a much greater extent (6).

The earliest orbital flights were conducted in small capsules and lasted only a few hours or days. Within these first human-rated spacecrafts, the limited capacity for movement and the short exposure to microgravity meant that crew members mainly reported rapid onset of adaptation (1). As mission duration increased well beyond several days into months and even years, crews are now faced with further adaptive events and new physiological challenges; adaptation to spaceflight is neither instantaneous nor consistent, but instead depends on individuals, mission duration, and operational activities (6). Despite these differences, all crew members who return from both short- and long-duration flights report two periods of adaptation that occur after the transition from one gravitational environment to another.

The first is experienced upon launch and entry into orbit. Some symptoms manifested early in the mission abate as adaptation is resolved. The sensory conflict produced by the visual and vestibular systems is one example that is limited to the first 3 to 8 days of a mission.

The return to Earth's gravity requires a second period of adaptation, which again presents a significant challenge to crew activity and safety. Orthostatic intolerance stems from the cardiovascular deconditioning and cephalic fluid shift that occurs in response to microgravity; many crew members report presyncopal or syncopal episodes, that is, dizziness or fainting, upon return to 1g. Neuromuscular and neurovestibular adaptations produce postflight disequilibrium (including marked vertigo in some cases) and gait disturbances; both clearly limit coordinated maneuvers and interfere with nominal or contingency egress (13,21). Cosmonauts from long-duration Russian missions of 8 months have required more than 4 weeks of rehabilitation to function normally (29). Physical performance also declines as a result of significant and sustained loss of bone and muscle mass, documented at 10–20% of preflight levels during extended-duration missions.

Bone and connective tissue changes, for example, begin as early as 1 week into a mission and can continue for more than a year. These changes are not typically apparent in flight, but are instead demonstrated upon return to Earth as locomotor problems, bone frailty, and increased risk of kidney stones (22).

Challenges for Exploration-Class Missions

As human spaceflight continues beyond low Earth orbit, health monitoring and health maintenance through appropriate countermeasures will become more discrete and seamless in the spacecraft of the future. Crewmembers may well monitor their own medical status, evaluate environmental health, assess risks, and then direct automatic correction or restoration of an anomaly. The opportunity for novel or previously unexplored countermeasure approaches, including artificial gravity, could well alter what are currently considered the most dire biomedical challenges of human spaceflight. The crew of the International Space Station and future spacefarers will be just as dependent as their forebears on a thorough understanding and mitigation of these challenges (30).

BIOMEDICAL SUPPORT OF PILOTED SPACEFLIGHT

Recent progress in the conquest of space and in piloted cosmonautics is the result of developments in space technology and hardware and, to a significant extent, has also depended on the solution of complex biomedical problems and other achievements in space biology and space medicine. During the period under discussion, the duration of space flight has increased to 14.5 months for men and 6 months for women. The long period during which the Mir orbital station was used (15 years) has generated unique experience in solving biomedical problems to ensure the safety and efficiency of increasingly long spaceflights.

Space medicine is basically a type of prophylactic medicine. Its duties include predicting all of the physiological consequences of exposure to spaceflight factors and preventing or curtailing likely disruptions in the functioning of various systems.

Support of piloted spaceflights involves a complex set of biomedical, technical, and organizational measures directed at creating the conditions required if normal human vital processes are to occur in space and using special means and methods to maintain cosmonaut health and performance at the level needed to ensure completing the standard flight program and for high crew efficiency if contingency or emergency situations occur.

Many years of research conducted by the Institute of Biomedical Problems jointly with a number of other organizations (see section on Space Life Sciences) has resulted in creating an efficient biomedical piloted spaceflight support system. This system includes

- cosmonaut medical selection and training;
- medical monitoring of cosmonaut status during spaceflight;
- providing medical care on board orbital stations;
- postflight cosmonaut rehabilitation;
- preventing the adverse effects of weightlessness; developing ways to prevent cardiovascular and musculoskeletal deconditioning, disruptions of fluid-electrolyte metabolism, and sensory disorders;
- providing cosmonauts with food and water during flight;
- life support for spacecraft;
- maintaining radiation safety;
- maintaining cosmonaut safety during EVAs;
- sanitary and hygienic support of cosmonauts;
- developing optimal work-rest schedules and systems for psychologically supporting crews.

The overall program of measures performed by personnel working in space medicine is very extensive and includes three phases: preflight, in-flight and postflight (see Table 1).

Table 1. Program of Work in Space Medicine

Preflight measures	In-flight measures	Postflight measures
Identification of latent diseases and insufficiencies in compensatory physiological mechanisms during space-flight selection and training; preflight preventive treatment, if necessary quarantine or observation and other antiepidemiological measures; preventive surgical interventions; measurement of individual sensitivity to drugs	Prophylactic, diagnostic, and therapeutic procedures onboard the spacecraft; performance of medical procedures directed at physiologically preparing cosmonauts for the powered stages of flight (insertion into orbit and touch- or splash-down); if necessary, arranging emergency return to Earth	Medical monitoring and, if necessary, provision of medical care to cosmonauts after landing; designing and implementing rehabilitation measures; medical observation and development of measures to aid rapid crew-member postflight adaptation to conditions on Earth; medical examination between flights and at retirement to identify remote consequences of space flight

Major Components of the Biomedical Support of Piloted Spaceflight

Medical Selection and Cosmonaut Training. Clinical physiological examinations of cosmonauts are undertaken to enable expert evaluation of their health in various phases of flight preparation and during the postflight period. The number of examinations and the intervals between them are specified by a special program (1). Before being accepted in the training group, candidates for crew membership undergo an inpatient examination, whose results are used to determine whether or not their health allows accepting them for the crew-flight-training program.

During the training phase, cosmonauts undergo dynamic monitoring, allowing specialists to

- detect latent incipient stages of disease;
- study personality characteristics and assess an individual's functional and potential physiological capacities;
- develop recommendations determining the sequence and time line for various types of training and also measures for increasing physiological tolerance to exposure to spaceflight factors (2).

During the training period, crews periodically undergo detailed clinical physiological examinations to

- identify the characteristics of each cosmonaut's physiological and psychological reactions to specific types of training;

- on the basis of health status and psychological traits, determine cosmonauts' fitness for spaceflights of varying duration.

The medical commission uses the results of this comprehensive examination to decide whether to qualify crews for spaceflight.

Medical Monitoring of Cosmonaut Status During Spaceflight. Medical monitoring is an important component of the set of measures used to ensure crew safety during spaceflight. Such monitoring makes it possible to identify, analyze, and evaluate functional physiological changes exhibited by a cosmonaut, to assess whether use of prophylactic measures is indicated, and to select the optimum schedules for using them. An unusual feature of in-flight medical monitoring is that the patients are healthy, physically fit individuals. In addition, unlike medical monitoring on the ground, in-flight monitoring is remote—because the subject and the medical personnel are separated by vast distances. Under these conditions, sources of information consist of data on the status of a cosmonaut's physiological systems, the microclimatic parameters in the spacecraft or suit, the contents of radio communications between the crew and the Flight Control Center, and also special radio communication by the cosmonauts concerning how they feel during the flight. Telemedicine sessions, observations of crew actions, and monitoring how well they are performing their programmatic tasks serve as additional sources of valuable information (3).

The goals of in-flight medical monitoring include ongoing real-time monitoring of cosmonaut health status; identifying functional changes in physiological systems, and also of pathologies arising in flight; predicting potential for further continuance of the flight; planning and managing medical tests and prophylactic measures that facilitate retention of performance capacity in-flight and postflight; as well as monitoring the cabin environment, radiation conditions on the flight path, and adherence to the work-rest schedule, all of which are described in the respective portions of this article (4). In addition to this operational monitoring, periodically, crew members are subjected to more in-depth medical examinations, including administration of provocative (loading) tests to assess levels of functional physiological reserve capacity. Furthermore, the medical monitoring system, if necessary, can be used to perform an immediate emergency medical examination and can be shifted to a mode of continuous recording of physiological parameters.

Means and Methods of Medical Care in Flight. The means and methods for providing medical care if cosmonauts develop illnesses or health disorders are considered of prime importance within the system for operational medical support of piloted flights.

The spaceflight medical support system is tasked with preventing disease, injury, and exposure to toxic substances and penetrating radiation, and also various different functional disorders evoked by exposure to spaceflight factors. The medical care system has the goal of providing timely diagnosis of health disorders and effective aid to any crew member who requires treatment during preflight training, in flight, or after return to Earth (5).

Although only healthy individuals are permitted to fly and all sorts of prophylactic measures are employed in flight to minimize the negative physiological effects of spaceflight factors, it is still not possible to preclude completely the

occurrence of disease or other conditions that require medical treatment. Any such case is analyzed to identify possible shortcomings in the measures prescribed by the medical flight support system, and then the appropriate recommendations are derived.

The stressful operator activity, the metabolic shifts that occur in weightlessness and the changes in the reactivity of physiological systems may decrease resistance to adverse factors and damaging effects. This may lead to the development of neurasthenic symptoms (decrease in work capacity, susceptibility to fatigue, irritability, sleep disturbances), various inflammatory diseases and allergic states, and metabolic disorders of organs and tissues. Nor are such diseases as acute appendicitis or inflammation of the gall bladder or pancreas precluded during space flight because their occurrence is extremely difficult to predict even under normal conditions on Earth. Finally, emergency situations on board a spacecraft may lead to injuries, barotrauma, or poisoning.

The list of states that requires using prophylactic and/or therapeutic measures during spaceflight must include "motion sickness," the neurasthenic syndrome, local inflammatory diseases, and minor traumas.

The isolated nature of their living conditions, the unique conditions of their environment, and the limited number of crew members compel the cosmonauts themselves to bear responsibility for diagnosing illness and providing medical care.

All cosmonauts are adequately trained to provide medical care. If necessary, crew members, using onboard documentation, the computer database, and the capabilities of the telemedicine system can employ the appropriate onboard medical kit or medical procedures. Of course, the presence of a physician in the crew significantly facilitates medical monitoring and medical care and enhances their efficacy.

A special mobile unit equipped with all of the necessary medical instruments, which can be deployed at the reentry vehicle landing site, has been developed for use if it is necessary to give cosmonauts medical care immediately after landing.

System to Prevent Adverse Effects of Weightlessness. The system for preventing the adverse physiological effects of weightlessness includes a set of medical and technical measures that supports long-term human residence and work in space, including fostering appropriate adaptation to flight conditions and readaptation after return to Earth while fully maintaining health and performance capacity.

Weightlessness, which induces a number of specific adaptive changes in various physiological systems, may lead to the development of functional changes and to some structural changes as well.

In essence, the prophylactic countermeasures used today (see Table 2) are directed at preventing or substantially attenuating these adaptive processes, primarily to safeguard and facilitate the process of readaptation upon return to normal gravity. The two main goals of the system of prophylactic measures are to make up for the deficit in motor activity and to compensate for the effects of fluid (blood and interstitial fluid) redistribution typical of weightlessness (6).

On long-term flights, cosmonauts follow a schedule of prophylactic measures that has been specially developed for that flight on the basis of duration,

Table 2. Counter Measures in Space Medicine

Class of methods	Mechanisms underlying effects	Procedures
Compensation for effects of blood redistribution in weightlessness	Induction of lower body blood pooling; stimulation of neuroreflex mechanisms regulating circulation in erect posture on Earth	Lower body negative pressure; occlusion cuffs
Physical exercise	Maintenance of conditioning in most important physiological systems; activation of venous pulsations, circulation facilitation from muscle contraction; activation of weight sensors and proprioceptors; maintenance of motor skills needed to maintain vertical posture and perform locomotion after return to Earth	Physical exercise; (constant) loading suits; electric stimulation of muscles
Enhancement of orthostatic and acceleration tolerance	Maintaining hydration Preventing blood pooling in the lower body	Fluid-electrolyte supplements Anti-g suits
Alimentary correction	Correction of nutrients ingested	Dietary supplements containing minerals, amino acids, and vitamins
Pharmaceutical correction	Targeted effects on certain physiological functions to correct or prevent pathological symptoms	Numerous groups of drugs
Nonspecific prophylaxis	Methods fostering increased general physiological resistance to adverse effects	Endurance training; psychosomatic regulation of functions; breathing of gas mixtures with diminished oxygen
Correction of adverse external factors	Decrease in excessive stress on physiological systems and functioning during spaceflight	Optimization of living environment, and work-rest schedule; means and methods of psychological support

flight phases, and the functional status of physiological systems. The following measures are included:

1. Constant wearing of the "penguin" constant loading suit during all waking hours in the intervals between physical exercise sessions, including during the performance of professional duties. This suit applies lengthwise axial loading to the musculoskeletal system (from the shoulder girdle to the foot) to simulate weight loading and reproduces some degree of deformation and stimulation of the resistance and muscle receptors.

2. Two hours daily of physical exercise on the inboard exercise machines (VB-3 bicycle ergometer and UKTF treadmill) to maintain conditioning in the most important systems and retain overall physiological work capacity, activate venous pulsation and the circulation facilitating effects of muscle contractions, stimulate mechanoreceptors, and also foster retention of skills needed for maintaining a vertical posture and for locomotion. Physical exercise generally involves the UKTF apparatus, which consists of a treadmill equipped with a system of straps, individually fitted loading suits, special shoes, and an elastic harness. The treadmill permits cosmonauts to walk, run, jump, do knee bends, and lift “weights,” thus reproducing constant static loading along the vertical axis of the body and the effect of maintaining upright posture in gravity.
3. Electric stimulation of muscles—high frequency (using the Tonus-3 stimulator) and low-frequency (using the Myostim)—preferably after physical exercise, to maintain muscle strength, and static and dynamic endurance.
4. Use (in accordance with a specially developed schedule) of the “Chibis” suit, which creates lower body negative pressure and thus in weightlessness, reproduces the hydrostatic blood pressure pattern characteristic of Earth. During the early period of adaptation to weightlessness (week 1 of flight), if they so desire, cosmonauts use “Bracelet” occlusion cuffs and the “Karkas” and “Kentavr” devices to decrease the severity of blood redistribution effects.
5. During the flight, fluid and salt supplements are ingested to facilitate fluid retention and prevent symptoms of dehydration, and thus, help to increase endurance to acceleration and orthostatic tolerance. During descent, special couches and anti-g suits that increase orthostatic tolerance and endurance of gravitational loading are used.
6. A balanced diet (containing salts, amino acids, and vitamin additives) is provided to combat possible deficits in the food.
7. Use of drugs to affect certain physiological functions to eliminate adverse symptoms or exert a corrective effect (preventing and/or treating “motion sickness,” maintaining of orthostatic tolerance, counteracting bone loss, and normalizing myocardial metabolism).
8. A set of psychological support measures to combat the adverse effects of spaceflight—isolation, a sealed, technogenic environment, excessive stress, and compulsory adherence to a nonoptimal work-rest schedule (7).

Preflight, to increase general physiological tolerance of adverse effects, nonspecific prophylactic measures are used, including endurance training, physical and special training, sleeping in head-down position, and breathing gas mixtures with diminished oxygen content.

Prophylactic measures directed at preventing or partially compensating for undesirable changes caused by weightlessness play an important role in maintaining cosmonaut performance level in flight and in ensuring their safe return to Earth.

Life Support on Board Spacecraft. A life support system (LSS) is a set of devices and systems, as well as supplies of food and other substances, required to maintain vital processes (metabolism) and human performance in pressurized spacecraft cabins. The LSS maintains the atmosphere in the closed cabin at a preset chemical composition and physical parameters (pressure, temperature, humidity, rate of movement), satisfies the crew's need for food and water, and disposes of the wastes of the crew and other biological subjects. In accordance with these functions, the LSS is divided into a number of subsystems (components): air regeneration, water supply, food supply, thermal regulation, and sanitary and hygienic support. This is the structure of the typical LSS in the narrow meaning of the term. On long-term spaceflights, measures to maintain crew health and performance capacity are significantly enhanced. For this reason, the LSS also encompasses all devices and objects that satisfy the day-to-day cultural and aesthetic needs of the crew, provide physical exercise (weightlessness and the limited size of the inhabited portions of the spacecraft lead to a deficit in physical activity), and also provide radiation shielding.

LSS parameters are determined by the need to satisfy human requirements for food, water, oxygen, and for waste disposal. When LSSs are designed, all relevant factors are considered (purpose, type of spacecraft, duration of functioning, size of crew, characteristics of flight path, mass-energy constraints, safety, reliability, cost, and performance characteristics). The LSSs developed for Russian spacecraft are highly reliable, display stable performance under the influence of spaceflight factors, even in emergency situations, and are distinguished by their minimal power use, mass and size, and good maintainability.

As a function of the way they replace consumables, LSS subsystems are classified as either nonregenerative (based on stored supplies of the needed substances or supplies brought by transport spacecraft) or regenerative (the substances needed to support human life are recovered from biological wastes of humans and other spacecraft inhabitants) or mixed.

The LSS for the first spaceflight was designed on the "nonregenerative" principle and provided the cosmonauts with a store of equipment and onboard supplies whose nature and amount was based on the caloric needs and the nutritive balance required by a healthy human on Earth. But, as flight duration increased and information accumulated on the dynamics of human metabolism under spaceflight conditions, there was a growing tendency to design and implement integrated regenerative systems, which utilized wastes and by-products of the functioning of various LSS components. Creating a completely closed LSS, simulating the processes of Earth's biosphere, based on methods of abiogenic synthesis, remains a difficult challenge to this day. Partially closed LSSs, which regenerated water and the most important components of the atmosphere and also disposed of solid wastes, were developed for the flights of Salyut and Mir.

The formation of the spacecraft cabin atmosphere during flight is directly associated with the problem of atmospheric pollution. Sources of pollution may include construction materials and technological processes, as well as human waste products. The study of the biological effect of spacecraft atmospheric pollution is one of the more important problems that requires physiological and hygienic research. The practical result of such research is establishing of threshold limit values (maximal permissible concentrations) for a wide range of

polluting (toxic) substances and developing of techniques for removing them from the spacecraft's atmosphere (8).

So-called biological life support systems (BLSS) are based on a qualitatively new principle of environmental formation. The functioning of a closed biological system is based on the principle of repeated use of a relatively small initial quantity of chemical elements as the closed cycle transforms the substances of the system itself. To support human life, a BLSS must transform human waste products into food, oxygen, and water, that is, regenerate them. That such a system can exist in principle is obvious because the elements used by an adult organism are eventually emitted into the environment in the same quantities. Thus, for example, oxygen that is consumed oxidizing organic substances in food is emitted as a component of water and carbon dioxide, along with the hydrogen and carbon of the oxidized nutrients (9).

Systems based on biogenic synthesis are closest to conditions on Earth and thus to the biological needs of human beings, and are capable of self-regulation at all levels of the system by mutual correction of processes.

The first practical results in this direction were obtained in experiments on board Space Station Mir, when three complete developmental cycles of wheat "from seed to seed" were completed in the station's Svet greenhouse.

Cosmonaut Nutrition and Water Supply In-flight. Sufficient and well-balanced nutrition of crews is one of the most important ways to maintain health and high psychophysiological energy and is the source of positive emotions in spaceflight. As flight duration and the degree of crew isolation increase, job pressure and responsibility are enhanced, and stress situations become more frequent, the importance of a diet adequate for cosmonauts' physiological needs increases as well.

Onboard cosmonaut nutrition systems on Salyut and Mir were highly developed technological systems, including, aside from the food itself, the appropriate "infrastructure" to ensure reliable storage and enable the crew members to prepare and eat their meals under spaceflight conditions. The nutritional systems components were functionally linked to the other life support subsystems, especially the water supply system, waste collection and disposal system, the power supply system, and the system maintaining microclimatic parameters (10).

Food rations (daily or for the whole flight) were appropriate to the cosmonauts' caloric needs and contained the optimal amounts of nutrients (proteins, fats, carbohydrates, vitamins, and minerals). This was particularly true of the essential nutrients (certain amino acids, unsaturated fatty acids, and vitamins), which are insufficiently synthesized by the human body or not synthesized at all.

The major task of the water supply system was to ensure that the cosmonauts received a regular supply of water in quantities appropriate to their physiological needs to prevent the development of a fluid deficit in flight. Water is the largest component of the human body by weight, and its daily consumption exceeds the total consumption of oxygen and nutrients. This means that every day the cosmonauts were given ad lib access to a significant quantity of water of acceptable taste and odor, free from toxic contaminants and, if necessary, enriched with minerals.

On relatively short flights (up to 30 days), water supply systems based on supplies of potable water brought from Earth were preferred. As flight duration

increased, it became necessary to have an entire water generation cycle take place on board the spacecraft. For this purpose, the space stations were provided with systems for regenerating water from low concentrated (concentrates of atmospheric moisture and process water) and highly concentrated (human urine and wash water) solutions for repeated use. The problem of in-flight water regeneration also encompasses problems of conditioning the taste and the chemical, as well as the bacteriological, properties of the regenerated water before it is used for drinking or reconstituting dehydrated food (11).

Sanitary and Hygienic Support of Cosmonauts. Sanitary and hygienic support of cosmonauts includes a wide range of problems relating to maintaining conditions in the spacecraft cabin where they live and work that are conducive to crew comfort and well-being. This includes developing hygienic standards and prophylactic measures for maintaining the spacecraft crew's health and performance capacity, providing cosmonauts with clothing and means of personal hygiene, waste disposal, maintaining cosmonaut microflora in an optimal state, and maintaining the spacecraft atmosphere and surfaces (12).

The significance of the personal hygiene component of the biomedical flight support system has grown as flight duration has increased. Various technological processes and measures were used to satisfy crew-members' sanitary and hygienic needs. Here, the significance of hygienic procedures was dictated by hygienic and physiological considerations and also mainly by psychological/aesthetic, epidemiological, and possibly toxicological concerns.

The criteria for selecting personal hygiene devices and techniques included inducing a sensation of bodily cleanliness after the procedure had been completed and also the feeling of "refreshment" and psychological comfort.

Personal hygiene measures included four basic types of procedures:

- complete cleansing of the body;
- washing of certain portions of the skin;
- oral hygiene;
- haircuts, shaving, and nail care.

Dry and wet (moistened with special washing and cleaning solutions) wipes and towels were used to cleanse the body. The wipes provided adequate skin cleaning and refreshment. In addition, they could be used to wipe down the surface of the spacecraft cabin.

Oral hygiene was considered an important personal hygienic measure. It involved regular cleaning of the teeth and rinsing of the mouth. Various types of toothbrush, toothpaste and powder, toothpicks, mouthwash, and rinses were used for this purpose.

Hygienic treatment of the hair consisted of periodic haircuts and shaving of the beard and mustache. The main problem in hair care during space flight is preventing fragments of hair or beard from getting into the cabin atmosphere.

The saying that the best clothing is that whose presence cannot be felt is highly applicable to cosmonaut clothing, which must be comfortable for working and relaxation and should not impede or limit motion. The cosmonaut wardrobe consists of underwear, a flight suit, which the cosmonaut wears inside the

spacecraft, and a thermal suit. The fabrics specially selected for cosmonaut underwear were light and elastic, did not impede heat convection and radiation or evaporation of moisture from the body surface, and at the same time were strong enough to be worn for long periods of time and to allow attaching sensors for recording biotelemetric information.

The flight suit was fully compatible with the underwear and thermal suit. Its design allowed freedom of motion and made using sanitary facilities convenient. It was easy to put on and take off. One of the main functions of the flight suit was to maintain the cosmonaut's thermal balance by preventing both excess heat loss and accumulation of excess heat. The thermal suit is designed to be used on landing in a deserted spot under adverse climatic conditions. In addition, it may be used if the spacecraft air conditioning system does not function properly. The thermal suit set included shoes, which had to be light, strong, and to have good thermal insulation properties. This was achieved by selecting the appropriate materials and design, which also account for the fact that the cosmonaut would have been adapted to weightlessness (13).

In closed pressurized cabins of limited size, the presence of even small concentrations of harmful substances in the atmosphere may have a serious effect on human health and performance capacity. The sanitary hygienic subsystem included studies of sensory parameters and chemical analytic tests of the air, which made it possible to identify the nature and rate of the offgassing of harmful substances from polymers and wastes. One of the main sources of atmospheric pollution in a pressurized environment is the human body, which releases a large quantity of metabolic products through the lungs, skin, kidneys, and intestinal tract. The amount of volatile chemicals emitted by a person varies within broad limits and depends on a number of factors: the nature and quality of the diet, metabolic status, and the nature and intensity of work performed.

Polymer materials are a second, no less important, source of atmospheric pollution in a pressurized cabin. Polymer synthesis involves using a number of auxiliary compounds that belong to a number of different classes and have an extremely broad spectrum of toxic effects.

The concept of "wastes" encompasses the set of products that form as a result of human vital activity and the operation of the equipment installed in the spacecraft cabin and not subsequently used. Regardless of chemical and bacterial composition or physical and other properties, wastes have one basic property in common. They are one of the sources that pollute living and working areas with undesirable or harmful substances and foster the development of microflora, some of whose species can cause illness in crew members or damage equipment (14). Correct structuring of waste containment and disposal is one of the major requisite conditions for maintaining normal vital processes and high performance capacity in spacecraft crew members.

However, the technical implementation of these operations under the unique conditions of spaceflight encounters a number of difficulties. The great majority of wastes are gaseous or liquid. Experience with space stations Salyut and Mir has shown that collection and transport of substances in this state present great technical difficulties in weightlessness.

Research on the problem of microbiological damage (biodegradation) to structural materials was initiated when Salyut-6 was in use and continued on all

subsequent Soviet and Russian orbital stations. It was established that spacecraft microclimatic parameters, i.e. the presence of specific chemical contaminants in humidity condensate and anthropogenic pollution (with human metabolic products) are the stimulating factors for growth of bacteria and mold on the materials of the cabin interior and equipment. More than a 100 species of microbes—bacteria and fungi—have been isolated from the surfaces of these materials during long-term spaceflights. Among these were species that present potential danger to human health, the so called pathogenic saprophytes, which can grow actively on artificial substrates, and also nonpathogenic bacteria and fungi that damage (destroy and degrade) various materials (metals and polymers) and thus cause failures and disrupt instrument and equipment operation.

Because, cosmonauts may show symptoms of dysbacteriosis or develop states of immunodeficiency from the effects of spaceflight factors and the processes of pathogen recirculation are intensified in a small pressurized cabin, the risk of spread of infection among crew members increases. All of this motivated the development of a microbial spacecraft safety system, which stipulated, in particular, that during preparations for flight, only structural materials that had been, in ground-based simulations, most resistant to microbial action were to be selected and that special disinfecting measures be undertaken. During spaceflight, the system called for treating spacecraft cabin surfaces, including the spaces behind instrument panels, with wipes moistened with special antibacterial and antifungal agents (fungistats). Experience with long-term flights on Salyut and Mir demonstrated that this system is highly effective.

Maintenance of Radiation Safety in Spaceflight. The radiation safety system is a set of means and measures directed at preventing and precluding the adverse effects of ionizing radiation (for example, during powerful solar flares or flights in Earth's radiation belt) on cosmonauts. These means and measures include physical screening of inhabited spacecraft modules, additional local screening of cosmonauts (radiation shelters), pharmacological and chemical protection of cosmonauts, inboard radiation monitoring devices, and the results of monitoring the radiation situation by the Solar Service (15).

Measures directed at ensuring crew safety include predicting the level of cosmonaut radiation exposure during the planned flight, developing initial recommendations for constructing piloted spacecraft, analyzing the radiation conditions in the flight path, radiation monitoring in the spacecraft cabin and station orbits, evaluating of levels of radiation exposure; developing recommendations to keep irradiation from exceeding the threshold limit dose, and providing cosmonauts with complete and current information.

The high biological interaction of various types of cosmic radiation makes them dangerous. For this reason, a research study was undertaken to determine acceptable levels of radiation exposure and to develop means and methods for prevention and for shielding cosmonauts from cosmic radiation.

By now, many techniques and devices have been developed to measure absorbed dose, dose equivalent, particle flow, linear energy transfer spectra, charge and energetic spectra and spectra of particle mass; each serves a strictly defined measurement function.

Radiation monitoring systems may be classified as active or passive. In active systems (including tissue equivalent ionization chambers, microdosimeters,

and particle spectrometers), instrument readings are recorded by crew members in orbit or are telemetered to Earth in realtime. In passive systems (including thermoluminescent dosimeters and dielectric track detectors), the readings are recorded and analyzed after the spaceflight has been completed.

Evaluation of radiation risk involves assessing the likelihood of specific adverse somatic effects (ASE) on human health as a result of exposure to ionizing radiation. The conception of risk from the effects of ionizing radiation assumes that the likelihood of developing ASE is directly proportionate to dose equivalent. In this case, the likelihood of ASE is the product of two contingent probabilities: the likelihood that a person will be exposed to a given dose equivalent and the likelihood that the dose equivalent will provoke ASE.

The risk to humans of cosmic radiation in flight may be minimized by a number of measures to decrease the likelihood of ASE to a justified (minimal reasonably acceptable) level, that is, according to the "ALARA" (as low as reasonably achievable) principle. The concept of a reasonably acceptable risk makes it possible to decrease it, comparing advantages and disadvantages, under the assumption that certain threshold limits on a momentary dose of irradiation are the upper limits of the safe level of exposure. It follows from this that a dose limit exists (the lowest level) that is absolutely unacceptable to exceed if there is to be any further exposure. Thus, it is not sufficient to decrease radiation exposure to a level below the dose limit; rather risk must be limited by reducing all radiation exposures to the minimally reasonably acceptable level.

In accordance with the standard dose limits adopted in Russia, the amount of irradiation to which a cosmonaut's hemopoietic organs have been exposed throughout the entire period of his career must not exceed 1 Sv (16). This dose limit has been established to limit the adverse remote effects of cosmic radiation. To avoid immediate radiation effects during flight, which may decrease in-flight performance capacity, dose standards for shorter periods have also been adopted. For example, the annual dose limit is 0.5 Sv, and the monthly dose limit is 0.25 Sv. On 1-year orbital flights, the total dose did not exceed 0.2–0.25 Sv, although there is some small probability that this value should be increased significantly to account for powerful solar proton events. Thus, the adopted dose limits and the radiation conditions characteristic of near-Earth orbit permit increasing space flight durations on these paths to up to 4–5 years.

In practice, radiation risk may be decreased by regulating the amount of time an individual spends in the cosmic radiation field and also by designating an area within the spacecraft that has a low radiation dose rate where the cosmonauts spend the majority of their time. Radiation risk may be decreased during the spacecraft design phase by selecting the best materials for radiation screening to prevent particles from penetrating the interior of the spacecraft cabin and also by minimizing induced radioactivity. The total whole body radiation dose as well as the dose to certain organs can be significantly decreased by local screening of these organs and areas of the body. Moreover, medical prevention and treatment methods are being developed (use of radioprotectors, prophylactic biomedical drugs, and postradiation therapy) that may enhance reparative processes in affected tissues. There is also a possibility that proactive genetic selection of cosmonauts could be used (selection of individuals who are

highly resistant to the effects of radiation or whose tissues can rapidly recover from radiation damage).

Psychological Support of Long-Term Flights. The increase in spaceflight duration and the complexity of flight missions have substantially increased the priority of the human factor in the “cosmonaut–spacecraft” system. Solution of problems relating to human psychological stability on long flights involves considering a large number of behavioral factors: psychological needs; subjective states; anxieties; interactions with colleagues on the crew and on the ground, for example, at the Flight Control Center; role-based relationships; work planning; criteria for success; and an external motivation system. The difficulty of maintaining psychological stability in a crew increases as flight duration begins to be measured in years.

One of the problems of space psychology is how to increase the psychological and professional reliability of cosmonauts. The solution of this problem will require improving the means and methods of selection, training and crew formation, and of evaluating cosmonauts’ psychological status. Prevention and correction of psychological disadaptation is extremely important here and must entail investigating the characteristics of group dynamics and the chronobiological aspects of adaptation, as well as optimizing cosmonaut professional performance (17).

Improvement of crew living and working conditions on board the spacecraft attenuates the psychogenic consequences of living in an artificial environment. During preflight training, a cosmonaut masters the necessary professional skills and knowledge and the skills involved in group dynamics. On this basis and also based on their own beliefs and expectations, cosmonauts construct their own individual representation of the upcoming spaceflight.

One particularly significant psychological problem that arises in connection with the increased heterogeneity of space crews in nationality, gender, profession, and other characteristics is the problem of optimizing the psychological climate in a heterogeneous crew, ensuring that effective independent group decisions are made, and that international space crews interact successfully with national flight control centers. In this context, the crew training phase, during which cosmonauts must develop mutual trust, a common system of values, and a strategy for managing and resolving problems as a team, takes on additional significance (18).

During the first 4–6 weeks of flight, cosmonauts come to terms with the living environment in the spacecraft. During this period, they must cope with new sensations, impressions, and characteristics of movement. In this situation, cosmonauts require additional time to prepare for and implement their professional tasks and to set up interactions with specialists in ground services. This may lead to time pressure and fear of not completing tasks on schedule, which creates conditions conducive to emotional stress and fatigue.

Next comes a phase of physiological and psychological stabilization; however, the crew members begin to feel an intense desire for new information as a result of the “sensory deprivation” they are experiencing. The novelty of spaceflight begins to lose its significance for them, as they get used to the unfamiliar living and working schedule and conditions. The effect of these factors can lead to

diminished psychological tonus, development of symptoms of debilitation, and disruption of the “sleep–waking” cycle.

In the period 15–30 days before landing, crew members enter another phase of psychological adaptation—emotional reorientation—as they begin to focus on imminent return to Earth.

The shift to long-term space flights, the way to which was paved by technological progress and the new capacities of space technology in the 1970s, required well-grounded safeguards that crew members would retain their health, high performance capacity, and the ability to work without “breakdown.”

As part of medical flight support, a great deal of attention is paid to monitoring the crews’ work–rest schedules. Information is collected about planned and actual cosmonaut schedules, these data are analyzed immediately, and scientifically justified suggestions and recommendations are generated for immediate adjustment of the schedule on one- and multiday time scales. The work–rest schedule is then revised, taking into account the crew’s status and progress in flight program implementation.

Maintenance of normal rhythms in physiological functions takes on critical significance on long-term flights. The planned work–rest schedules of Salyut and Mir cosmonauts were based on the familiar 24-hour schedule without displacing the “sleep–waking” cycle. However, in a number of instances, the need to perform such critical tasks as launch, docking, EVAs, and others compelled occasional shifts in the phases of the cycle.

Each shift of this kind represented stress and led to additional pressure on regulatory systems. In cases like this, special measures were taken to minimize the adverse consequences of these shifts and prevent desynchronization.

In addition to the duration of crew work shifts, each member’s interest in various types of task was studied, as was the relationship between their level of motivation and the quality of their work.

A number of effective quantitative methods were developed to aid in objective assessment of cosmonauts’ psychological status on long-term flight, and these have been used successfully in medical support of piloted flights, including flights of international crews.

Although the structuring of the crew’s lives on long-term space flights is limited by technical capacities, medical personnel and psychologists have labored intensively to improve conditions for living and working in space and to attenuate the psychogenic consequences experienced by crew members because of shortcomings in the artificial living environment.

The concept of “psychological support” was introduced to space medicine in connection with the support of space-station flights of increasing duration. Cosmonauts who have made long-term flights unanimously acknowledge that the standard system of psychological support is an important factor in maintaining a normal sense of well-being and performance capacity under such conditions. Generally, the aspect that has the most important role is the opportunity to have private conversations with their families and unstructured communications sessions with their relatives, friends, and various public figures.

The system of psychological flight support for cosmonauts is directed at optimizing the psychological status and performance capacity of healthy individuals, prevention of psychological and psychophysiological impairments, and

support of harmonious psychological interactions within the crew. Only through effective use of psychological and personal reserves of strength during a flight is it possible to avoid developing undesirable neurophysiological changes (diminished performance capacity, disruptions of sleep, debility, and conflict stress) that occur as a result of adverse psychological spaceflight factors: heightened risk, sensory deprivation, monotony, heightened responsibility for performance of flight operations, and the limited and imposed nature of social contacts.

Psychological support, which is generally not based on the use of drugs, makes it possible to compensate effectively for the deficit in social contacts (teleconferences with relatives and friends), the information deficit (news broadcasts and Internet access), and gives the cosmonauts the opportunity to feel the importance and interest those on the ground attach to the results of their work and their constant concern and attention to them as individuals (through packages containing their favorite books, films and music, and congratulations on dates of personal importance). Particular significance is attached to compensating for the loss of accustomed terrestrial stimulation—landscapes and sounds of nature—which are reproduced on special video and audio programs, produced with help from cosmonaut friends and family members. If necessary, cosmonauts can talk to psychologists on a confidential channel. Constant work with the families of crew members makes it possible to optimize the psychological climate surrounding each cosmonaut, to prepare family members for communicating with the space station, and to facilitate subsequent postflight psychological rehabilitation.

Space medicine and space psychology have developed objective methods for daily psychological monitoring of cosmonaut psychophysiological status and performance capacity, as well as of the psychological climate of the crew as a whole. Diagnoses are made by analyzing radio conversations with the crew as experts make ratings on specially developed scales. Significant diagnostic information regarding performance capacity is provided by the onboard psychodiagnostic system. In addition, each cosmonaut's pattern of psychological and emotional reactions to various situations, including extreme ones, has been charted preflight. The diagnostic information obtained is used to plan problem-oriented psychological support measures; predict changes in psychological status and work capacity in subsequent phases of the flight; and provide recommendations to flight directors on the advisability of a cosmonaut performing key operations—night work, docking, and EVA.

Methods of prevention and correction include the following:

- special preflight training;
- measures to optimize professional performance;
- formulation of positive feedback that acknowledges the success of tasks performed;
- measures to counteract the “asthenic syndrome” (dysthymia) and eliminate nonspecific anxiety components, including the use of drugs.

Support of Cosmonaut Safety During EVAs. EVAs are an important and effective operation performed during space flight. During the period Soviet

and Russian spacecraft were used between 1965 and 2000, a total of 96 EVAs were performed by 51 different cosmonauts (including one woman). Cosmonauts performed an enormous amount of work during these operations; they conducted unique scientific experiments, transported and mounted large structures on the space station exterior, performed various repair and debugging tasks, tested self-contained manned maneuvering units, and inspected depressurized modules. The maximum duration of an EVA from opening to closing of the access hatch was 7 hours 14 minutes by A. Solvyev and N. Balandin in 1990 (19).

The EVA medical support system includes monitoring during training, EVA implementation, and post-EVA. At present, there are no specific medical requirements for crew members who conduct EVAs. They undergo obligatory training on a technical trainer, learn about the EVA suit and study a number of operations that crew members will have to perform.

Four basic technical trainers are used: a setup enabling training in the absence of weight loading (hydrolaboratory), a full mock-up of the spacecraft, high-altitude barochambers, and a simulator of space suit system failure modes. The hydrolaboratory is typically used in constructing and testing various spacecraft components, apparatus, and crew equipment, and also for developing work techniques for the crew and determining what work operations can be performed during EVA within the limit loading values. Moreover, it provides wonderful opportunities for conducting preflight cosmonaut training. Here, cosmonauts become familiar with the schedule of planned operations and master skills of locomotion under conditions maximally simulating those of weightlessness. Before each submersion in the water, crew members undergo a brief medical examination and while they are submerged, they are subject to constant physiological monitoring.

Physiological criteria for EVA on long-term spaceflights include evaluating the possible effects of microgravity on crew performance efficacy. This means that every change in a physiological system, including changes in proprioception, strength and muscle mass, cardiopulmonary deconditioning, bone demineralization, and effects on vestibular functioning and gas exchange, may have some relation to the crew's readiness to perform an EVA effectively. For this reason, as part of EVA preparation, 2 weeks before the EVA, crew members undergo a comprehensive medical examination, including provocative tests on the bicycle ergometer.

During an EVA, the ground services, in addition to recording technical space suit parameters, monitor physiological parameters (EKG, pneumogram, body temperature, and caloric expenditure).

During and after an EVA, cosmonauts may develop various problems that require the attention of experts in space medicine. These may include

- general and local (midsized and small muscles of the arms) fatigue;
- pressure sores and blisters on the hands;
- emotional stress;
- shifts in thermal status (chilling, overheating);
- symptoms of high-altitude decompression sickness.

To prevent altitude decompression sickness brought on by the shift from the low working pressure inside the space suit (330 mmHg) to the normal atmospheric pressure within the spacecraft, immediately before the start of the EVA, crew members prebreathe pure oxygen at a pressure within the space suit of 533 mmHg for denitrogenation (20).

Postflight Medical Rehabilitation. Despite cosmonauts' use of measures provided by the prophylactic system, exposure to adverse spaceflight causes them to exhibit certain changes in the cardiovascular system's tolerance of the orthostatic position and in the characteristics of bone and muscle tissue, metabolic shifts, and vestibular and sensory impairment (see *Biological Responses and Adaptation to Spaceflight: Living in Space—An International Enterprise*), which require them to undergo medical rehabilitation postflight.

A system of rehabilitative and therapeutic measures has been adopted using data generated by clinical medicine, previous orbital flights, and ground-based simulation studies to help cosmonauts adapt to conditions on Earth, effectively restore their altered physiological functions and performance capacity, and ensure their professional longevity.

The specific rehabilitation program is based on

- the flight program (its duration and crew workload);
- characteristics of the crew-members' adaptation to spaceflight conditions;
- severity of fatigue (debilitation) during the flight;
- postflight changes in a cosmonaut's feeling of well-being and health status;
- individual characteristics of crew members and their preferences.

Structurally, the rehabilitation period consists of the following phases:

- meeting the crew at the landing site and evacuating it to a specialized rehabilitative and therapeutic base;
- readaptation at the rehabilitative-therapeutic base;
- recovery at a sanatorium or health spa.

The goal of the first phase is to provide a safe, nonstressful transition to conditions of normal gravity. This is achieved by limiting orthostatic, physical, and vestibular stress and through use of postflight prophylactic suits.

The most critical stage of readaptation, which takes place at a specialized rehabilitation and therapeutic base, lasts an average of 2–3 weeks. The major goal of this period is restoration of previous functional physiological status. During this phase, motor activity is gradually increased, and different techniques of rehabilitation (calisthenics, massage, and workouts in the pool and on exercise machines) are sequentially introduced. Loading is increased by increasing the rates of walking, running, or swimming, decreasing the duration and number of rest periods, and increasing the number of exercises and their difficulty.

Creating a favorable psychological climate and positive emotional factors are considered highly important. In addition, selecting and sequencing rehabilitation methods are based on the results of comprehensive batteries of postflight clinical and physiological tests.

The sanatorium/health spa phase of rehabilitation lasts for the next 20–30 days. Factors considered in site selection include climatic conditions at the time of year, level of equipment at the sanatorium, and the preferences of the crew members. During this stage, extensive use is made of climatic factors, physical therapy, and mud baths, the methods of therapeutic exercise and physical training, and long-distance running along a natural course. The rehabilitation and therapeutic methods employed are directed at completely restoring health status and functional physiological reserves. An individualized approach is used for prescribing procedures, accounting for health status and the temporal course of recovery and also of the capacities and desires of the crew members. Postflight psychological rehabilitation (the final phase of psychological support) is considered a very important part of this process. Such rehabilitation is directed at restoring social contacts, which have been partially lost (including family ties), as well as psychophysiological reserves that have been depleted under the extreme conditions of spaceflight (21).

Future Prospects for Developing the Biomedical Flight Support System

From a medical point of view, the use of the International Space Station (ISS) will be characterized by

- an increase in crew size and in the heterogeneity (including nationality) of the payload specialists involved;
- heightened work intensity, use of multiple shifts, an increase in the number of EVAs, and increased complexity of the EVA programs;
- permanent capacity to evacuate sick and injured from the ISS using specialized rescue spacecraft.

These characteristics will determine the set of specific medical, engineering psychological, and ergonomic tasks that must be performed, including

- developing criteria for a differential approach to selection and flight qualification for individuals who vary in initial health status, age, and gender;
- establishing criteria for permissible and optimal duration, the number of repeated flights, and the interval between them for various groups of cosmonauts;
- developing a system for medical support of rescue work;
- developing a system of measures for medical support of space crews whose members do not fully meet standards (for example, space tourists); this requires an individualized approach to regulating schedules of work, rest, meals, physical training and to conducting medical monitoring and therapeutic and preventive treatments;
- developing measures to support the safety of group EVAs for conducting planned work and rescue operations;

- developing a scientific basis for specifications of the ergonomic characteristics of the ISS, the structure and particular methods of medical support, and the functions of the crew physician.

Current attainments in this area are a good foundation for further progress in solving biomedical problems presented by future piloted space projects, including the Mars mission.

The isolation of the crew on a flight to Mars will require significantly more reliable safeguards both for the spacecraft systems and for the medical flight support system. The impossibility of emergency return of the crew to Earth or replacement of a sick crew member make it absolutely essential that a highly qualified physician-cosmonaut take part in the mission. An automated system for collecting, transmitting, and analyzing biomedical information and data banks and databases is already being created for the medical support of such autonomous spaceflights.

Another of the most important conditions to support a Mars mission is successful solution of a set of psychological problems, including psychological readiness to accept risk and to perform tasks at the limit of psychological and physical capacities and to resolve nonstandard contingency situations while living in isolation from Earth. An obligatory condition for inclusion in the crew must be a candidate's previous experience with long-term flights, because an interplanetary flight will mobilize all of the individual resources of the crew.

We will have to develop a more biologically complete and ecologically based artificial living environment fully appropriate to long-term human needs. We must create an analog of Earth's biosphere on board the Mars spacecraft, whose active components will be human beings, animals, plants, and microbes. Once this is accomplished, existing LSSs will be replaced by a regenerative LSS with a high coefficient of cycle closure. Laboratories on Earth have already produced encouraging results.

Another important problem is protection from galactic and solar cosmic radiation, which increase significantly outside the bounds of the radiation belts. On long-term interplanetary voyages, we will have to contend with the risk of mutagenic processes and also with threats to the lives and health of our cosmonauts. Approaches to ensuring radiation safety under these conditions may include selecting certain periods of solar activity for flights, creating a radiation shelter on board the spacecraft, and possibly, using pharmacological protective agents.

The risk of a Mars expedition is significantly higher than that associated with human presence in near-Earth orbit and thus interplanetary missions must be preceded by intensive in-depth research in the area of space physiology, psychology, radiobiology, life support systems, and the development of reliable means for protecting and maintaining the health of cosmonauts. For this purpose, along with the obligatory use of existing ground-based experimental bases and devices, we will need to make maximally effective use of the potential of existing and planned space stations and unpiloted biosatellites, which will allow us to create a strong foundation of global cosmonautics to conquer the planets of the solar system (22).

CARDIOVASCULAR SYSTEM IN SPACE

The microgravity environment of space is well tolerated by the cardiovascular system over during periods ranging from weeks to several months. In many ways, the heart, peripheral vasculature, and central cardiovascular control system are exposed to fewer challenges in microgravity than on Earth. Consider the simple act of standing upright in the normal gravity field of Earth. Assumption of an upright posture on Earth causes a redistribution of blood volume to the lower parts of the body, resulting in an increase in blood pressure in dependent blood vessels and a decrease in arterial blood pressure above the level of the heart. The cardiovascular system must quickly compensate for these changes by altering the heart rate, the force of contraction of the heart, and the resistance of the blood vessels to maintain enough blood flow to the brain to prevent loss of consciousness. Under weightless conditions, however, there are no postural changes in blood volume and pressure, which greatly reduces the demands placed on the cardiovascular system to maintain homeostasis. Furthermore, moving about in microgravity requires far less energy than required in gravity, which places less demand on the cardiovascular system.

During the long term, however, many physiological systems become dysfunctional when they are not required to perform at a normal level. For example, the muscles and bones of a leg immobilized in a cast for a month or two become atrophied and weak. Similarly, the relatively unchallenging environment of microgravity ultimately results in dysfunctional changes in the heart, the vasculature, and the central cardiovascular control system that may have harmful consequences during spaceflight and upon reexposure of the human organism to a gravitational field.

For example, many astronauts cannot maintain normal blood pressure and feel dizzy or faint when standing upright immediately following spaceflight, a

condition called *orthostatic intolerance*. This may impair their ability to get out of a spacecraft quickly should an emergency arise, or to perform meaningful work upon arrival in a gravitational field, for example, after a trip to Mars. There are also reports of rhythmic disturbances of the heart (*cardiac arrhythmias*) during spaceflight and of loss of muscle mass of the heart (*cardiac atrophy*). The latter two conditions, though less well documented than orthostatic intolerance, represent potentially life-threatening alterations in cardiovascular function. Before examining these problems in more detail, however, we will present a brief review of normal cardiovascular physiology.

Cardiovascular Physiology

The heart is composed of four chambers, the left and right atria and the right and left ventricles. The atria serve as booster pumps to aid in filling the ventricles during their filling cycle—ventricular diastole. The ventricles are the main pumping chambers of the heart. Blood is ejected from the ventricles during their contraction cycle—ventricular systole. The right ventricle pumps blood to the lungs through the pulmonary circulation. The left ventricle pumps blood through the systemic circulation. The systemic circulation is a branching network of vessels. The arteries bring blood to the various tissue beds. Oxygen and nutrients are delivered to the tissues, and carbon dioxide and waste products are removed through the smallest vessels, the capillaries. Capillary blood flows into the venous system starting with the smallest vessels in the venous system, the venules. The smaller veins merge into progressively larger veins ending up in the vena cava which returns blood back to the heart.

From a functional point of view, the large arteries serve as compliant capacitance vessels, ensuring that blood pressure does not fall to zero during ventricular diastole during which no blood is being ejected from the ventricles. The bulk of the resistance to flow in the systemic circulation resides in the microcirculation, consisting of arterioles, capillaries, and venules. The control of resistance to flow resides in the arterioles which, unlike capillaries and venules, have a muscular wall whose tone can be controlled by local factors (autacoids), by circulating hormones, and by the sympathetic nervous system. The large veins are extremely compliant and serve as a large blood reservoir. These veins have muscular walls whose tone can be increased by sympathetic nervous system stimulation. Constricting the large veins functionally is equivalent to shifting blood from the reservoir into the remainder of the circulation. This is an important function because filling of the right ventricle is determined to a large extent by the pressure in the vena cava—the central venous pressure—which may also be called *preload*. A drop in central venous pressure can lead to a precipitous drop in the filling of the right ventricle which in turn leads to a drop in cardiac output—the total rate of blood flow out of the heart into the systemic circulation. The large veins also provide small resistance to blood flow.

The cardiovascular system is exquisitely controlled by multiple feedback and control loops. Intrinsic control of the cardiovascular system is achieved by local factors (autacoids) that, for example, control the muscular tone in arterioles to match local blood flow to local tissue demand. Extrinsic control of the

cardiovascular system is achieved by the autonomic nervous system and circulating hormones. The autonomic nervous system is composed of two main branches—the parasympathetic nervous system and the sympathetic nervous system. The main function of the parasympathetic nervous system is to slow the heart rate. The sympathetic nervous system has two classes of receptors, alpha and beta. Stimulation of alpha receptors increases venous and arterial tone. Stimulation of beta receptors increases the heart rate and the contracting force of the heart (inotropy) and decreases arteriolar tone.

Cardiovascular Alterations Associated with Spaceflight

The constellation of cardiovascular deconditioning effects associated with spaceflight include decreased orthostatic tolerance (1–8) and exercise capacity (9,10) upon return to a gravitational field, decreased cardiac muscle mass (11), and the occurrence of a variety of arrhythmias in some individuals (12–14). Maintaining exercise capacity and orthostatic tolerance at preflight levels requires the integrity of both cardiac pump function and the multiple neurohumoral control mechanisms that mediate the hemodynamic response to exercise and orthostatic challenge. Orthostatic intolerance is a high priority problem because it may interfere with the crew's ability to function during reentry and postflight; therefore, we will start our discussion with this problem. In later sections, we will discuss cardiac arrhythmias and cardiac atrophy.

Alterations in Cardiovascular Parameters That May Contribute to the Development of Orthostatic Intolerance. Exposure to microgravity undoubtedly removes the blood pressure gradients from head to feet that are associated with upright posture on Earth (15). Thus, there is an equalization in blood pressures throughout the body. Mean arterial pressure at the feet is reduced from about 200 to about 100 mmHg and is increased within the head from about 70 to about 100 mmHg. Dependent blood vessels are exposed to lower than 1G normal blood pressure, whereas the vessels between the heart and head are exposed to higher than 1G normal blood pressure.

During spaceflight, body fluid shifts from the lower extremities to the thorax, and overall fluid volume is reduced. It is believed that the mechanism of orthostatic hypotension following spaceflight involves pooling of blood in the legs resulting in reduced preload to the heart, a decrease in cardiac output, and low blood pressure (*hypotension*). About 20% of astronauts after short (weeks) missions and 83% of astronauts after long missions (months) cannot support standing arterial blood pressure for 10 minutes (8). Physiological mechanisms that contribute to orthostatic hypotension include alterations in peripheral vascular resistance, venous compliance, intrinsic vascular reactivity, reduced intravascular volume, altered heart rate arterial baroreflex, and altered cardiac systolic and diastolic function.

Altered Vascular Resistance

Changes in Total Peripheral Resistance (TPR). Fourteen crew members from the Space Life Sciences (SLS)-1 and -2 Space Shuttle flights were studied within 4 hours of landing after flights of 9 or 14 days (3). Hemodynamic measurements were compared between finishers and nonfinishers of a 10-minute

stand test. Only nine of the 14 subjects (64%) finished the stand test. There were equally significant postflight increases in upright heart rates and decreases in stroke volumes in both finishers and nonfinishers. The amount of venous pooling was similar in both groups. The critical difference between finishers and nonfinishers in this series was inadequate vasoconstrictor response in nonfinishers (29.4 ± 2.3 units in finishers vs. 19.9 ± 1.4 units in nonfinishers, $p < 0.05$). Although the vasoconstrictor response increased compared to preflight levels in both subgroups, only the finishers had vasomotor responses enhanced enough to maintain adequate arterial blood pressure. These investigators concluded that microgravity-induced hypovolemia is a likely prerequisite for developing postflight orthostatic intolerance, but the outcome in a given individual may depend to a great extent on the magnitude of the systemic vasoconstrictor response.

Although the mechanisms that underlie inadequate postflight response remain to be identified, two principal alternatives are (1) adaptation to microgravity has caused a degradation of neurohumoral cardiovascular control mechanisms that are essential at 1G, or (2) the dynamic range of the mechanisms that produce appropriate orthostatic vasoconstriction is an inborn characteristic of the individual. A limited range that is adequate for an ordinary 1G condition becomes inadequate in the hypovolemic state early after return from space. A degradation of the neurohumoral vasoconstrictor mechanisms may occur at one or more levels, that is, afferent input, central integration, efferent output, and/or end organ responsiveness. Currently available information provides no conclusive answers (16).

In a study of 24 astronauts before and after missions of 4 to 5 days using two-dimensional echocardiography, the standing TPR index (TPRI) was significantly greater ($p < 0.03$) in the standing compared with the supine position on all test days except landing day. Similarly, the TPRI orthostatic response decreased on landing day ($p < 0.03$). Thus, there was an apparent reduction in the ability to augment peripheral vascular tone when assuming the standing position (4).

In a study of 40 astronauts before and after spaceflights that lasted up to 16 days, it was found that those who could not complete a 10-minute stand test on landing day had significantly lower (23 ± 3 units vs. 34 ± 3 units; $p = 0.02$) standing TPR (7).

Changes in Levels of Catecholamines. Forty astronauts were studied before and after spaceflights of up to 16 days. Of the original 40, seven were excluded because they had consumed promethazine, dextroamphetamine, or caffeine shortly before landing, and four were excluded because blood samples were ruined. On landing day, eight of the remaining 29 astronauts (28%), could not complete a 10-minute stand test due to presyncopal symptoms (dizziness or faintness). It was found that those who did not complete the stand test had significantly reduced peripheral vascular resistance and blood pressure when standing. These same subjects, it was noted, had significantly lower peripheral vascular resistance and supine and standing diastolic and systolic blood pressure before spaceflight. In addition, the nonfinishers had significantly smaller increases in plasma norepinephrine levels when standing than those who finished the stand test (105 ± 41 vs. 340 ± 62 pg/ml; $p = 0.05$). These results were taken as evidence for hypoadrenergic responsiveness, possibly centrally mediated, as a contributing factor in postflight orthostatic intolerance (7).

A 2-week head-down bed-rest study (a ground-based model of weightlessness) of eight healthy volunteers demonstrated a decrease in norepinephrine excretion of 35% on day 14 of bed rest from that on the control day. Though excretion rates of norepinephrine decreased, plasma levels were only variably and not significantly decreased. This was likely to be related to concurrent hypovolemia and is still consistent with a subnormal norepinephrine spillover in this setting. Excretion rates of epinephrine, dopamine, and dihydroxyphenylacetic acid were unchanged, suggesting that head-down bed rest produces sustained inhibition of sympathoneural release, turnover, and synthesis of norepinephrine without affecting adrenomedullary secretion or renal dopamine production. This sympathoinhibition in the face of decreased blood volume may help to explain orthostatic intolerance in returning astronauts (17).

The discordance between the response of plasma dopamine and plasma norepinephrine documented above may further exacerbate the deleterious effects of the sympathoinhibition. Renal tubular cells can synthesize dopamine from dopa (18), and in normal circumstances, the diuretic, natriuretic, and renal vasodilatory effects of locally produced dopamine are balanced by the effects of renal sympathetic nerve activity and the resultant release of norepinephrine, which promotes renal absorption of sodium and water and reduces dopamine-induced vasodilation (19). It is interesting to note that an extreme example of discordance between plasma dopamine and plasma norepinephrine is found in patients who are deficient in the enzyme dopamine beta-hydroxylase (20). In these patients, excessive production of dopamine, coupled with an inability to convert dopamine to norepinephrine, leads to a volume-depleted state with extraordinarily severe orthostatic hypotension, which is enhanced by the absence of the vasoconstricting properties of norepinephrine.

Other studies have shown a dissociation between an increase in circulating catecholamines and peripheral vasoconstrictor responses, from which it was concluded that there is a blunted vasoconstrictor response to sympathetic stimulation (5,21) following exposure to microgravity. This may be due to downregulation of adrenergic receptors in response to increased levels of plasma norepinephrine in microgravity. During the D2-Spacelab mission, plasma norepinephrine in four astronauts was approximately twice the value of that in the supine position on the ground, suggesting that the level of sympathetic nervous activity during microgravity is more similar to the upright ground-based position than to the supine (22).

Changes in Local Mediators. Endothelial functional changes resulting from exposure to microgravity have yet to be extensively studied. As outlined before, some studies document a blunted vasoconstrictor response to sympathoadrenal activation after spaceflight (5,21), whereas others have shown sympathoinhibition (7,17). In either case, it is likely that local endothelial vasodilatory function mediated by endothelium-derived relaxing factor, or nitric oxide, is altered following exposure to microgravity.

Altered Venous Compliance

Central Venous Pressure (CVP). There is some evidence that central venous pressure is decreased during spaceflight. CVP was measured in one subject aboard Space Life Sciences-1 and in two subjects aboard Space Life Sciences-2. Mean CVP in the seated position prelaunch was 8.4 cm water, and with legs

elevated, prelaunch in the Shuttle was 15.0 cm water and fell to 2.5 cm water after 10 minutes in microgravity. In these same subjects, however, the left ventricular end-diastolic dimension, as measured by echocardiography, increased within 48 hours in microgravity (23). Given this increase in cardiac filling, it seems likely that a decrease in intrathoracic pressure of greater magnitude than the decrease in CVP may occur in weightlessness, leading to an effective increase in right atrial transmural pressure. Simultaneous measurements of CVP and intraesophageal pressure, recently made in weightless parabolic flight, confirm this hypothesis (24). The SLS-1 and -2 data confirm previous observations in space (25).

Increased Peripheral Pooling of Blood. Data from Skylab-3 and -4 suggest that leg blood flow and compliance increase during the early hours of spaceflight (26), and ground-based studies simulating microgravity have documented an increase in leg vessel compliance (27–29).

Reduced Intravascular Volume

Decreased Red Blood Cell Mass (RBCM). Six astronauts on SLS-1 and -2 were studied. Plasma volume (PV) decreased by 17% within the first day of spaceflight. RBCM decreased as a result of the destruction of red blood cells (RBCs) either newly released or about to be released from the bone marrow, whereas older RBCs survived normally. Upon return to Earth, PV increased, causing a decreased RBC count and increased erythropoietin levels. The proposed mechanism for these changes is that entry into microgravity causes acute plethora secondary to a decreased vascular space, leading to increased hemoglobin, that leads to decreased erythropoietin levels. RBCM decreases to an appropriate level for the microgravity-induced decreased PV via destruction of recently formed RBCs. Acute hypovolemia upon return to Earth stimulates an increase in plasma volume, leading to anemia that stimulates an increase in serum erythropoietin and corrects the anemia (30).

Decreased Plasma Volume (PV). Adaptation to actual and simulated microgravity is associated with decreased total blood volume (2,31). It was initially postulated that diuresis accounts for fluid volume losses during spaceflight; however, diuresis during spaceflight has rarely been documented (32). Body fluid balance was studied on three recent spaceflights (N of subjects = 7) with special emphasis on oral intake and renal excretion of fluid and sodium (33). In no case was increased diuresis and natriuresis observed; rather, both oral fluid and sodium intake, as well as renal fluid and sodium output, appear reduced compared with the preflight condition. These results are consistent with findings during the Skylab program, in which fluid intake and renal fluid loss also appeared reduced or unchanged, at least during the first flight days (34). They are also consistent with the results of SLS-1 and -2 subjects in whom plasma volume, extracellular fluid volume, urine excretion, and fluid intake all decreased, and the glomerular filtration rate (GFR) was elevated (32). It was felt that the reason for the discrepancy between reduced or unaltered renal excretion and reduced body water was most likely due to insufficient caloric intake and subsequent decreased water binding capacity (1 g glycogen binds 3–4 g water; 1 g protein binds 8 g water). In addition, the decreased plasma volume coupled with upper body edema points toward an increased extravasation of fluid as a result of the headward fluid shift (33). Leach et al. postulate that increased permeability of

capillary membranes may be the most important mechanism causing spaceflight-induced PV reduction, which is probably maintained by increased GFR and other mechanisms (32).

Hormonal Changes. Following an isotonic saline infusion in microgravity, renal sodium and fluid output were lower than expected from results of simulation experiments; venous plasma norepinephrine and renin were higher. Because plasma arginine vasopressin (AVP) was low, high levels of this peptide were not responsible for decreased renal fluid output during flight (22,35).

SLS-1 and -2 subjects had increased AVP (also referred to as antidiuretic hormone, or ADH) on flight day 1 and on landing day; AVP levels normalized on other days. The elevations on launch and landing days, it was felt, were stress related. Plasma and urinary cortisol levels were elevated, although not statistically significant, throughout the flights, and again, it was felt that stress plays a role in this elevation. Plasma renin activity (PRA) and aldosterone decreased in the first few hours after launch, but PRA was elevated 1 week later. During flight atrial natriuretic peptide concentrations were consistently lower than preflight mean values, (32).

Altered Cardiac Function

Changes in Heart Rate (HR) and the HR Baroreflex. Using a neck collar to produce computer-controlled beat to beat changes in carotid artery transmural pressures in subjects before and after 8 days in orbit in SLS-1 and D2 flights demonstrated a significantly attenuated change in the cardiac cycle length interval for a given change in carotid transmural pressure (36). Similar results were found after head-down bed rest (37). The conclusion of these studies was that spaceflight reduces baseline levels of vagal-cardiac outflow and vagally mediated responses to changes of arterial baroreceptor input. These results were recently corroborated by studies of the spectral power of heart rate and blood pressure in Mir cosmonauts during and after 9 months of spaceflight (38). It has been argued, however (15), that baroreflex assessments based on R-R interval changes alone may be inadequate because they ignore the contribution of stroke volume to cardiac output. For example, HR increases more during in-flight lower body negative pressure (LBNP) than during preflight LBNP, and standing HR is elevated postflight to compensate for the stroke volume deficit imposed by microgravity-induced hypovolemia. These observations alone imply adequate functioning of the cardiac baroreflex arm.

A study of 24 astronauts following missions from 4 to 5 days found that, on landing day, supine HR increased by 23% ($p < 0.0005$) and standing HR increased by 35% ($p < 0.0001$), compared with preflight values. Preflight HR began to level off 2 or 3 minutes following the initial increase when standing, but postflight, it continued to increase for the duration of the 5-minute stand test. This was taken as evidence of postflight orthostatic dysfunction (4,6).

Changes in Ventricular Filling and Cardiac Contractility. After Apollo flights, standard anterior-posterior chest roentgenograms taken pre- and postflight showed that heart size decreased following spaceflight (39). These results have been confirmed in a study of 24 astronauts after missions of 4 to 5 days evaluated by two-dimensional echocardiography. Supine left ventricular end diastolic volume index (EDVI) diminished by 11% ($p < 0.04$) on landing day, compared with preflight. Supine left ventricular stroke volume index (SVI)

diminished by 17% ($p < 0.006$) on landing day, compared with preflight. Both recovered to preflight levels within 48 hours. Standing EDVI was less than that of supine EDVI, but SVI did not change significantly with position. The ejection fraction and the velocity of circumferential fiber shortening did not change significantly, suggesting no effect on myocardial contractility (4).

More recent early in-flight echocardiographic measurements in three subjects from SLS-1 and -2 showed an increase in cardiac filling, the mean increase in the left ventricular (LV) diastolic diameter was from 4.6 cm to 4.97 cm (23). Analyzing the data by a technique that produces a three-dimensional reconstruction of the LV showed a time course of adaptation where the initial increase in LV size was followed within 48 hours by a significant decrease in size relative to preflight supine dimensions (16). Contractile state—as defined by the LV ejection fraction, end systolic volume, and velocity of circumferential fiber shortening—did not change during the mission. Stroke volume measurements after 2 days in space approximated the 1 G supine data, and measurements after 5 days or later approached, but did not reach, preflight upright levels. This suggests that cardiovascular conditions in microgravity after adaptation may represent an intermediate hemodynamic state that accurately reflects the normal 24-hour human postural pattern, that is, one 8 hour part supine and two parts upright (16,23).

A recent bed-rest study suggests that changes in LV pressure–volume characteristics may develop during a 2-week period of bed rest in normal subjects and produce a stiffer ventricle that has reduced end-diastolic volume, compared to the normal physiological range of filling pressures (9).

Alterations in Cardiac Muscle Mass. Magnetic resonance imaging of four members of the German D-2 German Spacelab mission showed a significant loss of myocardial mass after a 10-day mission (11). Levine et al. (40) found that normal subjects subjected to 2 weeks of microgravity simulated by bed rest showed a significant reduction in ventricular mass also, as measured by magnetic resonance imaging. However, the mechanisms by which reduction in cardiac mass occurs, the functional sequelae of the changes in cardiac mass, and whether or not these changes are reversible after space flight all remain to be investigated.

Alterations in Cardiac Electrical Function. Another aspect of the cardiovascular deconditioning process involves potential alterations of cardiac conduction processes associated with spaceflight. Cardiovascular deconditioning has been investigated quite extensively, but there have been relatively fewer systematic investigations into the effects of spaceflight on cardiac electrical function. However, a variety of heart rhythm disturbances have been observed in astronauts during and after spaceflight. Occasional premature ventricular contractions were seen in Gemini and Apollo missions (13,41). Reports indicate that all crew members in the Skylab series had some form of rhythmic disturbance (14,41) and one individual experienced a five-beat run of ventricular tachycardia. The incidence of arrhythmias was higher during flight than during preflight testing and higher than would be expected in a random sampling of a healthy population. Cardiac arrhythmias have also been seen during Shuttle flights (41) and on Mir. Analysis of nine 24-hour ECG recordings (Holter monitoring) obtained during long-term spaceflight on Mir revealed one 14-beat run of ventricular tachycardia (12). Two Mir missions have undergone major changes in crew composition and/or responsibilities due to cardiac dysrhythmias (42). Fur-

thermore, a research primate recently died suddenly shortly after returning to Earth from extended space flight; cardiac dysrhythmic mechanisms were suspected as a possible cause (43).

Thus, there seems to be significant anecdotal evidence suggesting that spaceflight is associated with an increased susceptibility to potentially life-threatening ventricular arrhythmias. Furthermore, it is likely that ventricular arrhythmias during spaceflight will be of increasing concern in the future as older individuals are involved in spaceflight and as the durations of missions lengthen. At a joint National Aeronautics and Space Administration/National Space Biomedical Research Institute workshop in January 1998, cardiac arrhythmias were identified as the leading cardiovascular risk to a human Mars exploration mission (44). Older individuals have a greater statistical likelihood of having underlying structural heart disease, in particular, coronary artery disease and thus, will be at greater risk for heart rhythm disturbances. If spaceflight does increase susceptibility to ventricular arrhythmias, such arrhythmias could pose a significant threat to crew safety and mission success. However, the available data are too anecdotal to permit one to conclude whether spaceflight does increase susceptibility to ventricular arrhythmias. Therefore, it is important to conduct systematic investigations to determine whether exposure to microgravity alters cardiac electrical stability.

Recently a new technique—the measurement of microvolt level T wave alternans (TWA)—has been developed. In a series of clinical studies in varied patient populations, this technique compared favorably to other noninvasive risk stratifiers and invasive electrophysiological testing as a predictor of sudden cardiac death, ventricular tachycardia, and ventricular fibrillation (45–47). In a recent National Space Biomedical Research Institute project, healthy volunteers participated in a 16-day head-down, tilt, bed-rest study (a ground-based analog of weightlessness) and had TWA measured before and after the bed-rest period during bicycle exercise stress. In three subjects, bed rest induced sustained TWA, although they had an onset heart rate above the 110 beat per minute (bpm) cutoff below which TWA is clinically associated with increased arrhythmic risk. In these subjects, sustained TWA disappeared 2 to 3 days after bed rest. In one subject who had sustained TWA and an onset heart rate above 110 bpm before bed rest, bed rest abolished sustained TWA, which reappeared 3 days after bed rest. These findings provide the first evidence that simulated weightlessness has a measurable effect on myocardial repolarization processes, which suggests that spaceflight may alter susceptibility to life-threatening ventricular arrhythmias (48).

The potential lethal arrhythmic risk for astronauts is sustained ventricular tachycardia or ventricular fibrillation. Nonsustained ventricular tachycardia could cause syncope. Given the data suggesting that cardiac arrhythmias might pose a problem for long-term spaceflight and given that the consequence of ventricular arrhythmias may be astronaut death, this will be an important area of further study.

Countermeasures

Fully effective countermeasures against the problem of orthostatic intolerance have yet to be developed. Currently, the US space program regularly employs

anti-g suits for reentry to limit acutely the amount of blood pooling in the lower extremity and oral intake of saline before reentry in an attempt to restore intravascular volume closer to preflight levels. Oral saline loading appears to be effective in preserving standing arterial blood pressure after short flights of up to 5 days (49); however, it has not been as effective after longer flights. This finding is consistent with other evidence that changes in autonomic control of cardiovascular function, and perhaps myocardial contractile function, rather than simply inadequate intravascular volume, is responsible for orthostatic intolerance following spaceflight.

One technique that appeared promising in the past was the use of lower body negative pressure (LBNP) during flight to simulate exposure periodically to gravity gradients. The LBNP device is a cylinder into which the subject's lower body is placed, and it has a rubber cuff that goes around the waist. A partial vacuum created in the cylinder causes blood to pool in the legs, similar to standing in Earth's gravity. Although exposure to LBNP during flight was moderately protective against orthostatic intolerance upon return to Earth, it was unpopular with astronauts, who reported that exposure to LBNP during flight caused them to reexperience many of the unpleasant sensations they had experienced upon initial exposure to weightlessness (50), such as nasal stuffiness and facial fullness. This is consistent with the idea that the cardiovascular system makes appropriate adaptations to weightlessness and that trying to simulate gravitational conditions periodically during flight may interfere with these appropriate inflight adaptations.

A new pharmacological countermeasure, midodrine, was recently tested and found protective against orthostatic intolerance following microgravitational simulation for 16 days (51). There is evidence that both venous return and peripheral vascular resistance are reduced after spaceflight. Though not the only contributors, both of these factors most certainly increase the incidence of post-spaceflight orthostatic hypotension and presyncope. Several studies have demonstrated a reduction in cardiac stroke volume upon return from space (3,4,7), and others have shown reduced resistance responses to standing, particularly in those astronauts who have the most difficulty maintaining arterial blood pressure while standing (3,7). Midodrine is an agonist at α -adrenergic receptors located on the smooth muscle in both veins and arterioles, and thus reduces venous pooling and increases peripheral vascular resistance (52–54) by reducing the diameters of arterioles and veins. The success of this trial after bed rest (51) suggests that midodrine also may be an effective treatment for orthostatic hypotension following spaceflight. Trials of midodrine following spaceflight are now being conducted.

Conclusion

The cardiovascular system performs fairly well during spaceflight. The primary adverse effects of spaceflight on the cardiovascular system are orthostatic intolerance, cardiac arrhythmias, and cardiac atrophy. Spaceflight also impairs exercise intolerance, but current in-flight exercise programs seem to be an adequate countermeasure. Preexisting silent cardiovascular disease (such as

coronary artery disease) may also become manifest during long-duration spaceflight, particularly in older astronauts.

In terms of the primary adverse effects, postflight orthostatic intolerance is a current operational problem that occurs at high frequency, particularly after long-duration spaceflight. Orthostatic intolerance is generally not life-threatening. The task here is to develop and test effective countermeasures.

It is not known whether or not spaceflight increases the risk of life-threatening cardiac arrhythmias. However, if it does, the consequences could be the death of an astronaut. The task here is to establish whether or not spaceflight increases susceptibility of the heart to life-threatening arrhythmias and if so, to develop effective countermeasures.

Finally, it appears that short-duration spaceflight may modestly decrease cardiac mass. It is not known whether the degree of cardiac atrophy increases with the duration of spaceflight, what are the mechanisms involved, what are the functional sequelae, and whether this effect is reversible after spaceflight. The task here is to answer these questions and if indicated, develop effective countermeasures.

CHANDRA X-RAY OBSERVATORY

Introduction

The Chandra X-ray Observatory (originally called the Advanced X-ray Astrophysics Facility—AXAF) is the X-ray component of NASA's "Great Observatory" Program. Chandra is a NASA facility that provides scientific data to the international astronomical community in response to scientific proposals for using it. The Observatory is the product of the efforts of many organizations in the United States and Europe. The Great Observatories also include the Hubble Space Telescope for space-based observations of astronomical objects primarily in the visible portion of the electromagnetic spectrum, the now defunct Compton Gamma-Ray Observatory that was designed to observe gamma-ray emission from astronomical objects, and the soon-to-be-launched Space Infrared Telescope Facility (SIRTF). The Chandra X-ray Observatory (hereafter CXO) is sensitive to X rays in the energy range from below 0.1 to above 10.0 keV, corresponding to wavelengths from 12 to 0.12 nanometers. The relationships among the various

Figure 1. The electromagnetic spectrum as a function of temperature and wavelength. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

parts of the electromagnetic spectrum, sorted by characteristic temperature and the corresponding wavelength, are illustrated in Fig. 1.

In 1895, the German physicist, Wilhelm Roentgen, discovered what he thought was a new form of radiation. He called it X radiation to summarize its properties. The radiation could pass through many materials that easily absorb visible light and could free electrons from atoms. We now know that X rays are nothing more than light (electromagnetic radiation) but at high quantum energies.

Light has been given many names: radio waves, microwaves, infrared, visible, ultraviolet, X-rays, and gamma radiation are all different forms. Radio waves are composed of low-energy particles of light (photons). Optical photons—the only photons perceived by the human eye—are a million times more energetic than the typical radio photon, whereas the energies of X-ray photons range from hundreds to thousands of times higher than those of optical photons. Very low temperature systems (hundreds of degrees below 0°C) produce low-energy radio and microwave photons, whereas cool bodies like our own (about 30°C) produce infrared radiation. Very high temperatures (millions of degrees Celsius) are one way of producing X-rays.

X-ray astronomy is an extremely important field because it has been found that all categories of astronomical objects (or a subset thereof), from comets to quasars, emit X-rays. Thus learning how and why these objects produce X-rays are fundamental to our understanding of the way astronomical systems work. This, together with the large amounts of energy required to produce X-rays, makes their study interesting and exciting. A second reason that the field is so important is that the vast bulk of the matter in the Universe that we can directly observe through the electromagnetic radiation that it emits is in the very hot (temperatures of millions of degrees) X-ray emitting gas that fills the space between galaxies in clusters of galaxies (Fig. 2), the largest collections of matter in the Universe. The CXO is the prime method of gaining new information about the X-ray emission seen in the Universe.

The field of X-ray astronomy began with the discovery in 1948 that the Sun is a source of X rays. The experiment performed by scientists at the Naval Research Laboratories used photographic film mounted in a V-2 sounding rocket. Earth's atmosphere absorbs X rays, and so experiments must be performed above it. The first X-rays from a source other than the Sun were detected in 1962 by R. Giacconi and B. Rossi using a Geiger counter in a sounding rocket. For this,

Figure 2. The Chandra X-ray image of Hydra A, a galaxy cluster 840 million light years from Earth, shows strands (blue/pink) of 35–40 million degree Celsius gas embedded in a large cloud of equally hot gas (blue) that is several million light years across. A bright white wedge of hot multimillion degree Celsius gas is seen pushing into the heart of the cluster. (Courtesy of: NASA/Chandra X-ray Center/Smithsonian Astrophysical Observatory.) This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

and subsequent pioneering efforts including fostering the development of the Chandra X-ray Observatory, Giacconi was awarded half of the Nobel prize for physics in 2002.

Most of the early X-ray astronomy experiments used gas-filled X-ray detectors, either Geiger or proportional counters. Locating the X-ray sources in the sky used mechanical collimation to restrict the field of view to at best about 0.5° (the apparent size of the Sun and the Moon). This crude accuracy made identification of the X-ray sources with objects seen in either the visible or the radio difficult. One notable exception in this early era was an experiment by H. Friedman and colleagues at the Naval Research Laboratories that used lunar

Figure 3. Subrahmanyan Chandrasekhar. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

occultation to show that the nebula associated with the X-ray pulsar in the Crab Nebula was extended.

X-ray astronomy began to make huge strides due to the development of focusing X-ray optics that could concentrate large amounts of X rays into small areas and form an image. The first X-ray astronomy satellite fully devoted to extrasolar X-ray imaging was NASA's second High Energy Astronomy Observatory, it was referred to as the Einstein Observatory in the scientific community, and it was launched in 1979. The prototype of the Chandra X-ray Observatory, the Einstein observatory had the first large-area grazing incidence X-ray optics and featured an angular resolution of about 10 seconds of arc, although only a small fraction of the X rays reflected by the telescope was within this central core due to scattering caused by the roughness of the reflecting surfaces.

The next major advance in X-ray focusing was the German/USA/UK mission Rosat (1990–1998; see, e.g., Truemper, 1983). It was equipped with an imaging X-ray telescope of about 4 seconds of arc angular resolution and three interchangeable imaging X-ray detectors, and it made numerous contributions.

The CXO was named in honor of the late Indian-American Nobel laureate, Subrahmanyan Chandrasekhar (Fig. 3), nicknamed “Chandra” which means “moon” or “luminous” in Sanskrit. He was one of the foremost astrophysicists of the twentieth century and, in 1983, was awarded the Nobel prize for his studies of the physical processes important to the structure and evolution of stars.

The Observatory and Its Instrumentation

An artist's drawing of the CXO is shown in Fig. 4. The CXO has three major parts, as shown in Fig. 5: (1) the X-ray telescope or High-Resolution Mirror Assembly

Figure 4. Artists rendering of the CXO. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

(HRMA), whose mirrors focus X rays from celestial objects; (2) the science instruments—the advanced CCD imaging camera (ACIS) and the high-resolution camera (HRC) that record the X rays and two sets of objective transmission gratings (OTG) discussed below; and (3) the spacecraft, which provides functions such as power and telemetry necessary for the telescope and the instruments to work.

Figure 5. Line drawing of the major components of the CXO. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

The building and operation of this 1.5-billion-dollar facility has been a marvel of modern technology and ingenuity. Overall program management and technical and scientific oversight are provided by NASA's Marshall Space Flight Center. The Marshall Center was ably assisted by the Smithsonian Astrophysical Observatory (SAO). The prime contractor was the company, TRW, Inc., which was responsible for the spacecraft construction and integrating of all subsystems into the Observatory. Major subcontractors and their principal functions were Raytheon Optical Systems—telescope grinding and polishing; Optical Coating Laboratories, Inc.—telescope coating; Eastman Kodak Corporation—telescope assembly and alignment; Ball Aerospace and Technology Corp.—science instrument accommodation module and aspect system.

The spacecraft systems for the CXO are fairly standard; they have modest (32,000 bits/second) data rates and moderate pointing accuracy and stability. These latter two were feasible by employing an onboard, visible-light-sensitive, aspect camera which is used on the ground after the data are taken to correct the position of the X rays detected to sky coordinates. This is possible because the X-ray cameras on CXO record the position of each X-ray detected.

Because Earth's atmosphere absorbs X rays, the CXO was placed high above it. This meant that the ultraprecise mirrors and detectors, together with the sophisticated electronics that conveys the information back to Earth, had to withstand the rigors of a rocket launch and operate in the hostile environment of space.

Figure 6. CXO launch sequence and orbit. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Chandra's unusual orbit, shown in Fig. 6, was achieved after initial deployment by the Space Shuttle Columbia, Eileen Collins (Fig. 7) commanding. This particular Shuttle launch was especially noteworthy because Commander Collins was the first female commander. Initial deployment was followed by a boost into a high Earth orbit by an inertial upper stage built by the Boeing Corporation. Final placement into the orbit used a built-in propulsion system. The orbit, which has the shape of an ellipse, takes the spacecraft more than a third of the way to the moon before returning to its closest approach to Earth, 10,000 kilometers (6,214 miles). The time to complete an orbit is about 65 hours. The spacecraft spends about 75% of its orbit above the belts of charged particles that surround Earth. Uninterrupted observations as long as 55 hours are possible.

Because of their high quantum energy, X rays do not easily reflect from mirrors. However, reflection can take place when the angle of incidence is shallow. This property can be exploited to build optical systems that can bring X rays to a common focus. A particular design, that used for the CXO, is illustrated in Fig. 8. The design, referred to as a Wolter type 1, uses a paraboloid of revolution followed by a hyperboloid of revolution—two reflections are necessary to bring objects away from the axis of symmetry into focus. Nesting several of these

Figure 7. Commander Eileen Collins. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 8. Illustration of a cross section of two nested, Wolter I, X-ray optics. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

pairs of paraboloids and hyperboloids increases efficiency for collecting X rays. The CXO has four such systems whose diameters range from 0.65 m (2.13 ft) to 1.2 m (3.94 ft). Each optical element is 0.84 m (2.75 ft) long. The elements are constructed of Zerodur, a glassy ceramic, and together weigh more than 2000 pounds.

Figure 9. Chandra's image of what had been a puzzling X-ray source in the globular star cluster M15 shows that it is not a single system but two sources that are so close together (2.7 seconds of arc) that they were undistinguished by previous X-ray telescopes (courtesy of NASA/White and Angelini, 2001). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

The most unique attributes of the CXO X-ray optics, those that makes this observatory so powerful, are the angular resolution (the ability to distinguish two separate objects very close to each other) and the high efficiency by which photons are collected within the narrow spot that defines its ability to resolve different objects. This high efficiency results from the smoothness of the X ray reflecting surfaces so that the X-rays are not scattered from the intended path. The angular resolution is better than 0.5 seconds of arc, that is, the letters of an X-ray-emitting STOP sign can be distinguished at a distance of 12 miles! The surface roughness is measured in angstroms. If the state of Colorado were as smooth as Chandra's mirrors, Pike's Peak would be less than 1 inch tall. The angular resolution of Chandra is significantly better than any previous, current, or even currently planned X-ray observatory. Figures 9 and 10 and illustrate the utility of the superb angular resolution and low scattering.

The science instruments aboard the Observatory and the organizations that led their development are the advanced CCD imaging spectrometer (ACIS)—Penn State University and the Massachusetts Institute of Technology (MIT); the high-resolution camera (HRC)—Smithsonian Astrophysical Observatory (SAO); the high-energy transmission grating (HETG)—MIT; and the low-energy transmission grating (LETG)—Space Research Institute of the Netherlands and the Max Planck Institute for Extraterrestrial Physics in Garching, Germany.

Either (but not both simultaneously) of the two transmission gratings can be commanded in place directly behind the telescope. When in position, X rays are

Figure 10. Chandra image of the supernova remnant Cassiopeia-A based on about three-quarters of an hour of data. The point source at the center, previously undetected, simply leaps out of the Chandra image (courtesy of NASA/Chandra X-ray Center). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

diverted (dispersed) according to their energy, along one dimension, from their normal path. The X-ray image now represents, to a high degree of accuracy, the energy of the incident photons. Determining the energy is called spectroscopy.

The ACIS detectors record X-ray images and can, to a certain degree, also determine the energy of the incident X-ray but not as well as the gratings. The spectroscopic advantage of the ACIS detectors is that they are far more efficient for detecting X rays when the gratings are not in place. There are two ACIS detectors; either can be placed at the focus of the telescope by command. The ACIS-I is made of a 2×2 array of front-illuminated (FI), 2.5-cm-square, X-ray sensitive, charge-coupled devices (CCDs) analogous to those found in visible-light-sensitive digital cameras. ACIS-I provides high-resolution spectrometric imaging across a 17-arcmin-square field of view. ACIS-S, a 6×1 array of 4 FI CCDs and two back-illuminated CCDs, is mounted along the dispersion direction of the transmission gratings and serves both as the primary read-out detector for the HETG, and, using one of the back-illuminated CCDs that can be placed at the aim point of the telescope, also provides high-resolution spectrometric imaging extending to lower energies, but across a smaller (8-arcmin-square) field than the ACIS-I.

As in the ACIS, there are two HRC detectors that may be moved into place to record X-ray images. Both are microchannel-plate detectors that consist of millions of tiny tubes of cesium-iodide-coated glass. These detectors record the position of the X rays, but unlike the ACIS, can barely distinguish energies. The HRC-I array is a 10-cm square plate that has a field of view of 31 arcmin square. Comprising three rectangular segments (3×10 cm each) and mounted end-to-end along the dispersion direction, the HRC-S serves as the primary read-out detector for the LETG. A important advantage of the HRC for certain scientific experiments is its ability to determine the time when the X-ray event was detected to high a much higher precision (microseconds) than achievable with the ACIS (milliseconds).

Scientific Results

X rays are produced by highly energetic processes—thermal processes in plasmas at temperatures of millions of degrees—or non thermal processes, such as synchrotron emission (realized when charge particles are accelerated by magnetic fields) or scattering of visible light or radio waves from very hot electrons. Consequently, X-ray sources are frequently exotic: supernova explosions and remnants, whose explosion shocks the ambient interstellar medium or a pulsar, a rotating neutron star, powers the emission; disks of accreting nearby material or jets around stellar-mass neutron stars or black holes; accretion disks or jets around massive black holes in the nucleus of galaxies; hot gas in galaxies and in clusters of galaxies that traces the gravitational field and can be used to determine the mass. These are all examples of sites of, and methods for, producing X rays. Here we give several examples of observations by the CXO that illustrate its capability for investigating these processes and objects.

Chandra's capability for high-resolution imaging enables studies of the structure of extended X-ray sources, including supernova remnants (see Fig. 10),

Figure 11. This Chandra image, 24 arc seconds on a side, shows details in the powerful jet shooting from the quasar 3C273, providing an X-ray view into the area between 3C273's core and the beginning of the jet (courtesy NASA/Chandra X-ray Center/Smithsonian Astrophysical Observatory/Marshall et al., 2001). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

astrophysical jets (Fig. 11), and hot gas in galaxies and clusters of galaxies (Fig. 2). The capability for spectrometric imaging allows studies of structure in X-ray intensity and also in temperature and chemical composition. Through observations by Chandra, scientists have begun to address several of the most exciting topics in contemporary astrophysics.

Comets and Planets. Besides the Sun, which is too bright to be observed safely by the Observatory, other known X-ray sources in our solar system include Earth, the Moon, Venus, Jupiter and some of its moons, and comets. The X-rays from the Moon, Venus and, to a certain extent, Earth are due to the fluorescence of solar X rays that strike the atmosphere. The discovery image of X-ray emission from Venus (Fig. 12) by Chandra shows a half crescent due to the relative orientation of the Sun, Earth, and Venus. Solar X-rays are absorbed in the Venusian atmosphere above the surface of the planet that knock electrons out of the inner parts of atoms and excite the atoms to a higher energy level. The atoms almost immediately return to their lower energy state and emit a characteristic or “fluorescent” X-ray. Similarly, ultraviolet light produces the visible light of fluorescent lamps. The origin of the X-ray emission from Jupiter (Fig. 13) is more complex and not completely understood. Important ingredients are the presence of a magnetic field and rotation of the planet. Studies using Chandra should help provide a better understanding of the physical processes involved.

Normal Stars. The CXO has optical instrumentation aboard that provides an “aspect solution,” which shows where the observatory was pointing during an

Figure 12. Chandra image, the first X-ray image ever of Venus, shows a half crescent due to the relative orientation of the Sun, Earth, and the planet—the Sun is to the right. X-rays from Venus are produced by fluorescent radiation from oxygen and other atoms in the atmosphere about 130 kilometers above the surface (courtesy of NASA/Max Planck Institute for Extraterrestrial Physics/Dennerl et al., 2002). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 13. Chandra image of X-ray emission from Jupiter. The red colors indicate the highest intensity. The bulk of the emission takes place near the magnetic poles (courtesy of NASA/Marshall Space Flight Center/Gladstone et al., 2002). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 14. The CXO image of the Orion star cluster. The region shown in this image is about 10 light years across. The bright stars in the center are part of the Trapezium, an association of very young stars whose ages are less than a million years (courtesy of NASA/Pennsylvania State University). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

observation to an accuracy of about 1 second of arc. However, it is usual for Chandra observations to detect the X-ray emission from several stars that have much more accurate cataloged positions based on their optical emission. Using the stellar positions as a local reference, the remaining X-ray sources in the field can be positioned far more precisely to about 0.2 to 0.4 seconds of arc. One example of using such positions is the determination of the positions of the more than 1000 X-ray sources in the Orion Nebula star cluster (Fig. 14). It is interesting that this single Chandra image contains more X-ray sources than had been detected in the first 15 years of X-ray astronomy. The Orion Trapezium, a region only 3 light years across at the core of the Orion Nebula star cluster, contains very young stars and therefore offers astronomers a view into a region where stars are born. The cluster is composed of stars whose a median age is only around 300,000 years, and, at a distance of 1400 light years, is one of the nearest star-forming regions. The CXO was used to identify X-ray emission from individual stars and found that almost all of these young stars were much hotter than expected.

The Center of Our Galaxy. Precise positioning was critical for the unique identification of the X-ray emission from the object known as Sagittarius A*, the source at the extremely crowded center of our own Milky Way galaxy (Fig. 15). This source is a moderately small black hole of about 3 million solar masses, and is very faint compared to other galactic nuclei. X rays are emitted just beyond

Figure 15. The ACIS-I image of the galactic center. This image shows the central region of our Milky Way Galaxy as seen by the CXO. The bright, point-like source at the center of the image was produced by a huge X-ray flare that occurred in the vicinity of the black hole at the center of our galaxy (courtesy of NASA/Massachusetts Institute of Technology/Baganoff et al., 2001). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

the horizon within which no light can escape, and thus the black hole may be “seen.” A bright flare was detected by the CXO on 27 October 2000, whose X-ray intensity increased by more than a factor of 10 for about 3 hours and then rapidly dipped on a timescale of 10 minutes. The rapid variation in X-ray intensity indicates that the flare was due to material as close to the black hole as Earth is to the Sun. This is compelling evidence that matter falling toward the central black hole is fueling energetic activity at the center of our galaxy.

Supernova Remnants. Another example of Chandra’s ability to provide high-contrast images is exemplified by the now classic image of the remains of the remnant formed by the implosion of a star, a supernova, called the Crab Nebula and its compact core, a rotating neutron star that pulses. The image (Fig. 16) shows the intricate structure produced by the pulsar interacting with the local environment. This image is not static; observations by the CXO spaced out over time have shown the dynamic motions that take place as a result of the interaction of the pulsar at the center of the remnant and the local environment.

Globular Clusters. One of the most striking examples of the power of Chandra X-ray imaging is in the spectacular Chandra images of globular clusters. Figure 17 is an ACIS-I image of the globular cluster 47 Tucanae. The left panel is composed of red/green/blue images derived from X rays recorded in different energy bands and shows the central portion of the cluster. The

Figure 16. Chandra image of the Crab pulsar and nebula made using the LETGS and the HRC-S. The nearly horizontal line in the figure is a cross-dispersed spectrum of the pulsar produced by the LETG fine support bars. The nearly vertical line is the LETG-dispersed spectrum from the pulsar (courtesy of NASA/Marshall Space Flight Center/Weisskopf et al., 2000). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 17. Chandra image of 47 Tucanae. The left image covers the central $2' \times 2.5'$. The further enlargement of the central region to the right is $35'' \times 35''$. The different colors represent the dominant X-ray energy range: low-energy X-ray emission (red), intermediate-energy X-ray emission (green), and high-energy X-ray emission (blue). The white sources are bright in each of these ranges. The faint red sources are mostly millisecond pulsars, whereas the bright white sources are mostly binaries containing white dwarfs that produce X-rays by pulling matter from normal stars (courtesy of NASA/CfA (Center for Astrophysics)/Grindlay et al., 2001). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

enlargement at the right is the central core. Some 108 sources, excluding the central core, are detected. This number is more than ten times that found by previous X-ray satellites.

These Chandra images of 47 Tucanae provided the first complete census of the brighter X-ray producing stars in the core of the globular cluster. As the oldest stellar systems in galaxies, globular clusters are laboratories for stellar evolution. Nearly all objects in the Chandra images are “binary systems,” in which a normal, Sun-like star orbits a collapsed star, either a white dwarf or neutron star from which X-rays are emitted. The data also reveal the presence of many “millisecond pulsars,” neutron stars that rotate extremely rapidly between 100 to nearly 1000 times a second.

The image, associated spectra, and measured time variability reveal more about the binary content and stellar, as well as dynamic, evolution of a globular cluster than achieved by all previous X-ray observations of globular clusters combined.

Normal Galaxies. In addition to mapping the structure of extended sources and the diffuse (extended) emission due to the presence of hot gas in galaxies, the high angular resolution of the CXO permits studies of ensembles of discrete sources, which would otherwise be impossible owing to the large number of sources crowded together in a small region of the sky (source confusion). A beautiful example comes from observations of the center of the Andromeda galaxy (M31) shown in Fig. 18. The image shows what used to be considered the emission associated with the black hole at the center that is now resolved into five distinct sources. A most interesting consequence is that the emission from the region surrounding the central black hole is unexpectedly faint relative to the mass, as in the Milky Way.

M81 (NGC 3031) is a spiral galaxy at a distance of approximately 3.6 Mpc. The galaxy was observed by using the ACIS-S instrument on Chandra (Fig. 19). Previously, the galaxy had been observed using both the Einstein and Rosat X-ray observatories, and about 30 sources had been detected. This Chandra observation detected 97 X-ray sources, 41 in the bulge of the galaxy and 56 sources in the disk. Twenty-one of these latter sources were close to, or in, the spiral arms. The sheer number of X-ray sources detected by Chandra in a typical nearby galaxy makes studies of the global properties of X-ray source populations possible.

In many galaxies, observations using Chandra have detected one or more sources which are so bright that if truly associated with the galaxy and if the emission is not highly beamed, then the object must have a mass substantially greater than that of a neutron star and is thus likely to be a black hole whose mass is more than 25 times the mass of the Sun. Such “ultraluminous” sources appear to be quite common in nearby galaxies, and there are too many of examples of such objects to give much credence to the idea that they are all more local than one might think. If they are local (closer), then they are not nearly so powerful as they appear and would not be considered “ultraluminous.” Because of the ubiquity, the concept of an intermediate-mass black hole is gaining some acceptance. Lower mass black holes are born in explosions of massive stars (supernova); very high mass (hundreds of thousands of solar masses or larger) black-holes are born in (form in) the nuclei of galaxies. Precisely how an “intermediate-mass” black hole is created is not completely understood.

Figure 18. Central region of M31 observed with the ACIS-I. The circle is 5 arcseconds in radius and illustrates the previous location of the X-ray nucleus. The old X-ray nucleus is resolved into five individual sources, and the source labeled CXO J004244.2 + 411609 is within 0.15 arcseconds of the black hole at the center of the galaxy (courtesy NASA/Smithsonian Astrophysical Observatory/Chandra X-ray Center/Garcia et al., 2002). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Quasars. Quasars look like normal stars through an optical telescope. Not until the 1950s, when radio astronomy was first developed, did astronomers discover that these objects were well outside our own galaxy and were therefore emitting massive amounts of radio energy. These objects are called “quasars,” short for “quasi-stellar radio sources.” Quasars are among the most distant, energetic objects ever observed. Individual quasars are brighter than hundreds of galaxies put together, yet many are smaller than the size of our own solar system. Radio astronomers use a system of numbers to name objects in the sky. 3C273 was named in the 3rd Cambridge catalog as the 273rd radio source identified. 3C273, along with 3C48, were the first quasars to be identified as such. These objects had bizarre optical spectra unlike any ever studied before. In 1963, astronomers Maarten Schmidt (3C273) and Jesse Greenstein and Thomas Matthews (3C48) noticed that these spectra made sense only if the objects were simply moving away from us, thus causing the apparent wavelengths to shift to the longer (redder) wavelengths (hence redshift)—in the case of 3C273 at about one-tenth the speed of light. Quasars are now considered a subset of active galaxies (called active galactic nuclei or AGN) powered by the presence of a massive black holes at their centers.

Figure 19. Chandra observations of M81. Left: X-ray image with contours. Right: X-ray contours on optical image (courtesy of NASA/Marshall Space Flight Center/Tennant et al., 2001). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

More detailed and modern studies of quasars show that there are high-powered jets associated with these objects and often the material in the jets moves at velocities very close to the speed of light. Exactly how this happens is a topic of major astrophysical interest. Furthermore, instead of seeing a smooth stream of material driven from the core of the quasar, most optical, radio, and X-ray observations have revealed inconsistent, “lumpy” clouds of gas. The Chandra image (Fig. 11) of 3C273, however, shows, for the first time, a continuous X-ray flow emanating from the core. One would like to learn how and why matter is so violently ejected from near the quasar’s core. The energy emitted probably comes from gas that falls toward the supermassive black hole at the center of the quasar but is channeled by strong electromagnetic fields. The black hole itself cannot be observed directly, but scientists hope to discern properties of the black hole by studying the jet.

Clusters of Galaxies. Chandra observations of clusters of galaxies frequently show us structures that have characteristic angular scales of a few arcseconds. Before Chandra, it was thought that the X-ray emission from galaxy clusters arose from a fairly simple system. The Hydra A radio galaxy (3C 218), shown in Fig. 2, was observed early in the Chandra mission. This very early image shows large areas of low X-ray brightness, indicating the presence of regions of low density or cavities in the hot gas. Similar, but even more dramatic cavities were found in the Perseus cluster shown in Fig. 20.

The X-ray Background—the Chandra Deep Surveys

The first sounding rocket flight in 1962 that detected the brightest X-ray source in the sky, other than the Sun, also detected a general background of X radiation (Giacconi et al., 1962). Since this first experiment, the detailed nature of the

Figure 20. Chandra image of the X-ray core of the Perseus cluster of galaxies (courtesy of NASA/Institute of Astronomy/Fabian et al., 2000). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

background radiation had been a puzzle. The lack of any distortion of the energy spectrum of the much cooler cosmic microwave background could be used to eliminate the possibility that the X-ray background glow was truly diffuse (Mather et al., 1990). Thus, the glow must have consisted of sources so faint as to be unresolved by the telescopes of the time. The question remained—what faint sources were contributing to this background glow? Observations by previous X-ray satellites such as ROSAT were a major step in resolving a significant fraction (about 75%) of the glow at low energies into discrete objects (Hasinger et al., 1998) and found that the sources reside mainly in active galaxies at redshifts from 0.1 to 3.5. The Japanese ASCA satellite observations extended the search for sources in the 2–10 keV band and resolved about 30% of the background glow (Ueda et al., 1998).

Chandra is ideally suited to search for faint sources. Two very deep exposures, one of one million, the other of two million seconds have been accomplished to date. These exposures are referred to as the Chandra Deep Fields. A portion of the image of one, the Chandra Deep Field North, is shown in Fig. 21. About 350 sources were detected in each of the one-million-second surveys. The most distant source detected (so far) is a quasar at a redshift of 5.2. The majority of the X-ray sources beyond a redshift of 0.5 are active galaxies that have massive black holes at their centers. The Chandra deep surveys extend the study of the background to signals levels more than an order of magnitude below that which could be previously achieved and have confirmed that most of this background is due to a variety of different types of discrete sources. At very low

Figure 21. Chandra “true -color” ACIS image of the Chandra Deep Field North. This image has been constructed from the 0.5–2.0 keV band (red) and 2.0–8.0 (blue) images. Part of the Chandra Deep Field North has also been surveyed in visible light using the Hubble Space Telescope, and this region is shown in outline (courtesy of NASA/Pennsylvania State University/Hornschemeier et al., 2001). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

energies, there is somewhat diffuse component that results from warm-hot intervening matter (referred to as WHIM), concentrated regions of matter that formed in the early stages of the Universe when the first galaxies and galactic clusters formed.

The spectrum of the X-ray background had also been considered puzzling because it was found that the majority of the bright AGN have an energy spectrum different from that of the background itself. One of the purposes of the Chandra Deep Surveys has been to explore the spectra of the sources, because the faint sources must modify the spectrum from the average of the bright AGN sample. The faint source spectrum was estimated by adding the spectra of individual sources detected in the surveys. This has now been accomplished and the paradox resolved (see, e.g., Rosati et al., 2002).

Sources of Gamma-Ray Bursts. Cosmic gamma-ray bursts (GRBs) were discovered in the late 1960s by satellites designed to detect gamma rays produced by atomic bomb tests on Earth. The bursts appear as a brilliant flash of gamma rays that lasts seconds to minutes. The bursts are often, but not always, followed by afterglows observable at X-ray (always), optical, and radio

Figure 22. Chandra image of the X-ray afterglow from gamma-ray burst GRB010222 (courtesy of NASA/Center for Nuclear Research/Garmire et al.). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

wavelengths (sometimes). Using one of the experiments on the Compton Gamma-Ray Observatory, astronomers took an important step in understanding the sources of these bursts by determining that the objects that produce them are not in our own galaxy. This discovery implied that the sources of these bursts are extremely energetic. The source of this tremendous energy is unknown. Models currently in vogue involve a fireball of energy where matter moves at nearly the speed of light. The source of this rapidly moving matter is unknown; theories include the merging of neutron stars, or black holes, or the collapse of an extremely massive star.

The CXO is being used to help to solve the mystery of gamma-ray bursts by studying X-ray afterglow (Fig. 22). An example of this is the Chandra observation of the gamma-ray burst that took place on 22 February 2001. The Chandra data supported the model in which a very massive star has exploded, a “hypernova.”

High-Resolution Spectroscopy. Owing to their unprecedented clarity, Chandra images are visually striking and provide new insights into the nature of X-ray sources. Equally important are Chandra’s unique contributions to high-resolution dispersive spectroscopy. High-resolution X-ray spectroscopy is the essential tool for diagnosing conditions in hot plasmas. It provides information for determining the temperature, density, elemental abundance, and ionization stage of X-ray emitting plasma. The excellent spectral resolution of the Chandra gratings isolates individual spectral lines (i.e., features at specific energies), which would overlap at lower resolution. The spectral resolution also enables the

determination of flow and turbulent velocities, by measuring Doppler shifts, shifts in the apparent energy, and the widths of the lines produced by these motions. Spectroscopy using the CXO gratings achieves its best energy resolution for nonextended (point) sources. Thus, observations that use the Chandra grating have concentrated on, but are not limited to, X-ray emission from the hot regions surrounding stars (stellar coronae), X-ray sources in binary systems, and active galactic nuclei.

Web Site

The official CXO site on the World Wide Web is <http://www.chandra.harvard.edu>. This site has numerous Chandra images, as well as information about the Observatory and X-ray astronomy.

CIVIL LAND OBSERVATION SATELLITES

Introduction

The first, and still the most dramatic, example of seeing where we live from the vantage point of space was the image of a pale blue and white globe hanging all alone in an infinite expanse of darkness taken through the window of Apollo 8 on its way to the Moon in December 1968. Three and a half years later on 23 July 1972, NASA launched ERTS-1, later renamed Landsat-1. This was the first civil imaging satellite that had enough resolution, 80 meters, to image human-scale activities; that is everything bigger than a football field. Its more capable successors now provide anyone, anywhere, the ability to see images of motorcycle size objects any place on the globe at almost any time. As of November 2002, there are 23 satellites in orbit whose resolutions range from 30 meters down to 0.6 meter. They are being operated by the United States, France, India, Korea, Canada, China/Brazil, the European Space Agency, and three private corporations, two U.S. and one Israeli. The number of satellites and the number of their national and private sponsors show that civil land observation satellites have arrived at the point where they are now another permanent payoff of the space age. It will take much longer than the Weather, Communication and Global Positioning System (GPS) satellites for their full economic and social effects to be felt, but they are already forcing national and international discussions on the effects on nations, corporations, and individuals of the worldwide transparency that these satellites will inevitably bring (1).

The Big Picture

Figure 1 provides the orbital history of every satellite whose sensors can provide Earth images, both optical and radar, and whose resolutions are equal to and better than Landsat 1's 80 meters. It shows quite clearly that there have been three distinct periods in the history of civil land imaging satellites. For 13 years,

Figure 1. Orbital history of all optical and radar land imaging satellites that have Landsat or better resolution. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

the United States' five optical and one radar satellites were the only such systems in orbit that provided civil data. The second period started with the launches of Russia's Resurs-01-1 in late 1985 and of France's SPOT 1 early in 1986 and extends up to the first launch attempts by American commercial systems in 1997. During this period, there were 20 foreign launches and one failed U.S. attempt. The third period begins in 1997 when high-resolution commercial systems entered, includes NASA's return to Landsat and research launches, and continues to the present day. The following discussion will provide some of the details of these periods to illuminate why they occurred as they did and will provide some sense of where the development and use of civil land imaging satellites might take us in the future. First, however, there are a few facts about satellite and sensor technology that will be helpful in understanding their development.

The Technology

This article discusses the special set of Earth orbiting satellites designed to acquire detailed images of the global land surface. It is the high-resolution subset of the larger family of Earth sensing satellites that image the land and oceans on a kilometer scale and measure the characteristics of the atmosphere to record the weather and to explore the complex interrelationships among the atmosphere, the oceans, and the land surface that cause the weather and our climate. The following describes the satellite, sensor, and data technologies involved.

Satellites. Essentially all current and planned imaging satellites operate in sun-synchronous polar orbits and cover Earth about 14 times a day, as illustrated in Fig. 2. Sun-synchronous means that the satellite crosses the equator at the same time on every orbit. This characteristic means that all images have the same Sun angle and, therefore, shadow characteristics thus eliminating one interpretation variable. (The Sun angle changes as the seasons change.) The crossing times vary between 9 and 10:30 A.M. The current satellite orbits range between 460 and 904 kilometers; the lower range is chosen by balancing the need for a high enough orbit to ensure a long satellite lifetime and a lower orbit for higher resolution. The higher limit is a balance between the desire for the broad coverage area provided by high orbits and the higher resolution provided by lowering the orbit.

Sensors. Except for one Russian intelligence film based satellite (Spin-2) used for a commercial mission, all commercial optical sensors have been and are electronic imagers; they focus the light from the ground onto the telescope's focal plane, either by sweeping it across a small line of sensors in a system called a whisk-broom scanner or by using the satellite's movement along its orbit to sweep the image across a much larger set of sensors. This latter design, called a push-broom scanner, is the dominant sensor used today with one prominent exception: Landsat 7 has retained the whisk-broom design first flown on Landsat 1.

However, from the viewpoint of the uses to which the data are to be put, the choice of scanner type is not as critical as the four basic imaging characteristics of the total satellite system, that is, spatial resolution (how small an object can be perceived), scene size (how large an area is captured in each image), temporal

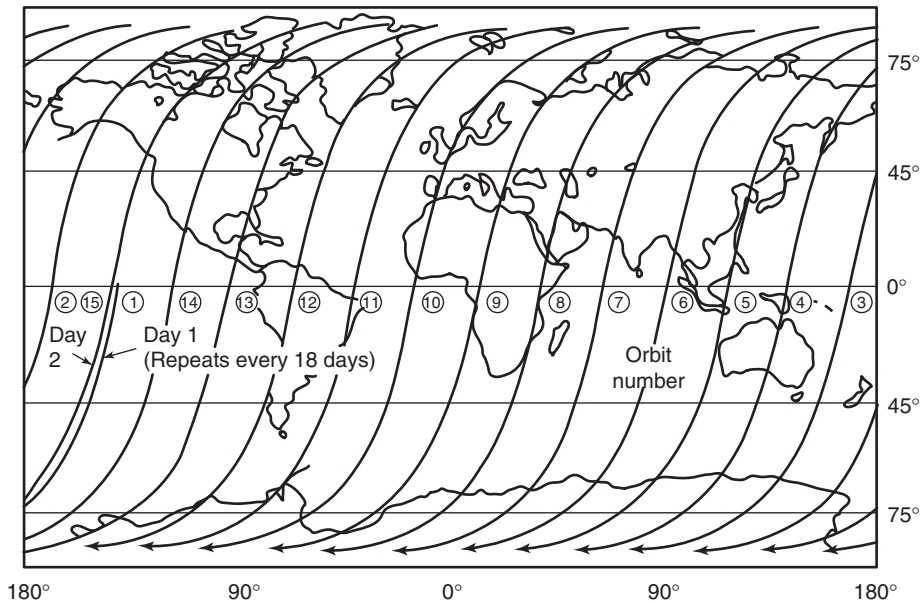

Figure 2. Typical Landsat daily ground trace.

resolution (how quickly a scene can be imaged again), and spectral resolution (the number and location of the spectrum bands measured). Each will be discussed in turn.

Spatial Resolution. The size of the imaged feature on the ground that the satellite can resolve is largely a function of the sensor's telescope design and the satellite's orbital altitude. Resolution is the most important of the three system characteristics for most users because it defines the scale and, therefore, the type of applications the system can serve. Scale is particularly important in making maps. Figure 3 provides a comparison of images of the U.S. Capitol taken at the resolutions of current satellites.

Scene Size. The width on the ground imaged by the sensor/satellite system is called its swath and serves as a surrogate for scene size since the along track image can be taken continuously and scenes are created for data management reasons by arbitrarily cutting the strips into lengths about equal to their swath width. Large scene sizes are essential for the repeat imaging of the regional and global areas that is required to study the changes in our land cover and land uses. In general, the higher the resolution, the smaller the swath.

Temporal Resolution. For fixed nadir-pointing satellites like Landsat that can only image the land beneath their orbit, the time to return to image a given area is almost entirely a function of its swath width. The TIROS weather satellite and its 1000-meter resolution AVHRR imager has a ground swath of 2500 kilometers and images the entire globe daily. Landsat has a 185-kilometer swath and repeats its global cycle every 16 days.

For satellites that can point their sensor to either side of the ground track, the return visit time is a function of both the basic orbit repeat time and the

range of the off angle pointing. SPOT uses a mirror to point the sensor and can provide a variety of scene location patterns (see Figure 4) as well as increase its 22 day nadir image repeat time to 3 or 4 days. The smaller higher resolution satellites point their sensor by tilting the spacecraft to achieve 2 to 3 day repeat cycles. However, because these systems have very small swath widths, between 8 and 16 kilometers, they would take 6 months or more to image the globe. Please

Figure 5. Imaging modes available from Radarsat.

keep in mind that the world's average 50% cloud cover means that in practice getting repeat cloud-free images could take from 2 to 3 times longer than the days quoted above.

The location, pattern, and size of radar images are controlled by electronically programming the radar's antennae and can easily be varied in a number of ways. This flexibility is illustrated in Fig. 5.

Spectral Measurement. The number and the placement of the spectral bands that are sensed are critical to the ability to classify surface features automatically, be they vegetable, mineral, or man-made. This feature of multispectral sensors has extended the use of images beyond their original mapping and object identification functions. The repeated classification of the continuing changes in forests, rangeland, and farmland at the state, country, and global scales, so important to understanding our environment, could not be accomplished by the eyes of photo interpreters alone. Figure 6 presents the number and location of the spectral bands for the major satellite classes. Figure 7 provides examples of the way Landsat band data can be combined in three band combinations to bring out various features in the scene.

The Road to Landsat

As noted before, the practical beginning of civil land imaging satellites was the 1972 launch of Landsat 1. But the process that preceded and finally resulted in that launch was long, complex, and acrimonious. It is important because its history illustrates many issues that are still not fully resolved to this day.

Humankind has probably recognized the military advantage of occupying the high ground since people first descended from the trees. As early as 1783, it was obvious to Benjamin Franklin, when, as Ambassador to France, he observed the first Montgolfier balloons in flight over Paris and predicted their use in "conveying Intelligence" about "an Enemy's Army" (2). After the Wright brothers

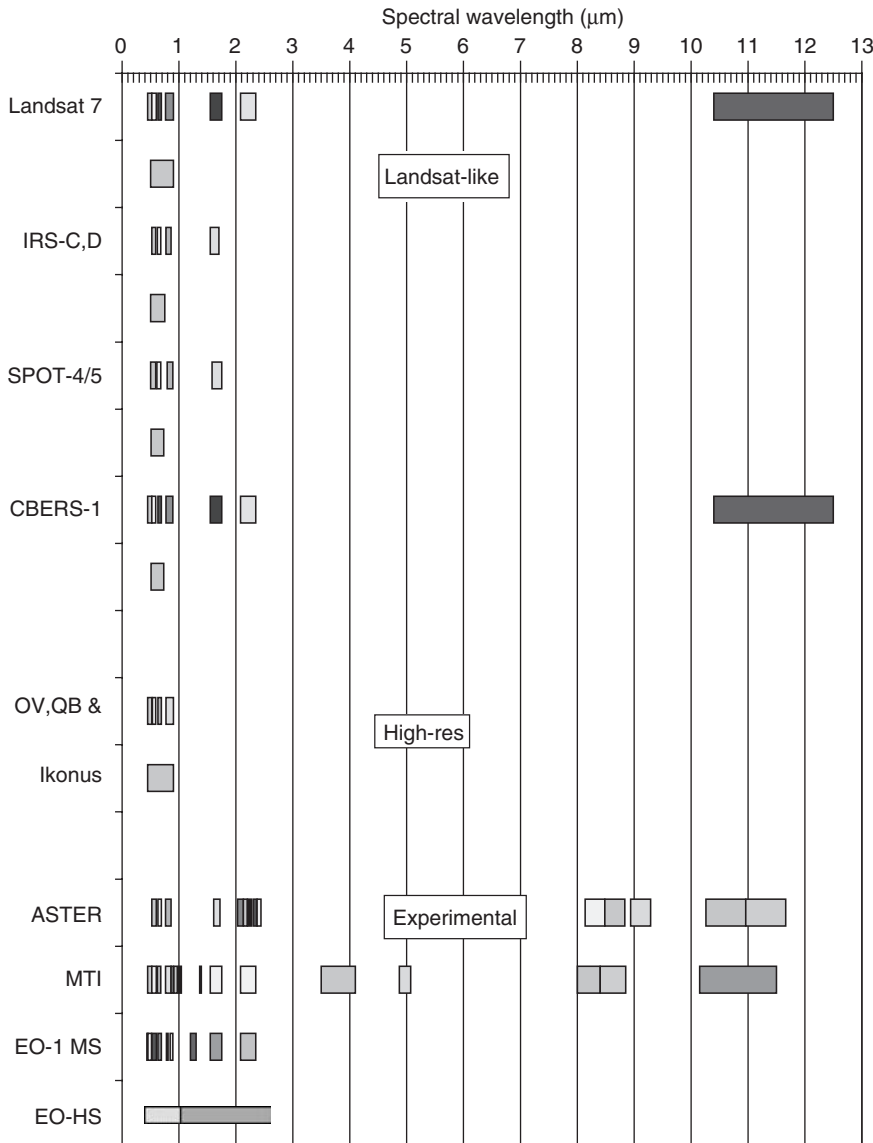

Figure 6. Number and location of the spectral bands for several satellites. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

demonstrated flight, the incredibly rapid development of the airplane in World War 1 was due almost entirely to the importance of its unique reconnaissance capability. (The development of fighter aircraft, dogfights, and aces resulted when each side tried to deny the enemy the use of air reconnaissance.) Bombers dominated aircraft use in the Second World War, but reconnaissance was still a major air function, and infrared imaging was developed out of the need to identify camouflage. The cold war caused the United States to develop the fastest and highest flying aircraft in the world for the sole purpose of photoreconnaissance.

Although the Soviet launch of Sputnik in October 1957 shocked the American public, the only surprise to the science and military communities was that the Soviets did it first. In 1955, both the Soviets and the United States had announced plans to orbit an Earth satellite to support the 1957/58 International Geophysical Year (IGY). The American announcement mentioned the beginning of the ill-fated Vanguard Program that President Eisenhower, in his press release congratulating the Soviets scientists on Sputnik I, pointedly noted was separate from our military launch vehicle programs. President Eisenhower's private response to Sputnik was to increase the funding for an Air Force program first organized in 1953 that, after 12 failed attempts, resulted in the successful launch and recovery of the film carrying capsule of Discoverer XIV on 30 August 1959. The images were not as clear as the U-2 aircraft photos but covered Soviet areas never seen by spy planes. The purpose of the program was kept top secret until 1995 when President Clinton declassified it under its proper name of Corona. (See the article on the Military Use of Space in the Encyclopedia for more details.)

The Russians soon flew their own spy satellites, and in a kind of bilateral "don't ask, don't tell" spirit, the Russians finally, but tacitly, accepted Eisenhower's "Open Skies" policy. This policy actually followed the aircraft reconnaissance

focused Open Skies policy and is more accurately called the “satellite data non-discriminatory dissemination policy.” It supports the freedom of all satellites to image the surface of any and all countries by assuring access on an equitable basis by the imaged country to all images of its territory. (See discussion in the “Getting Data to Users” section.)

There were, of course, prophets. In 1946, well before Sputnik, the United States Army Air Corps requested that RAND Corporation consider how objects might be inserted into orbit (3). The study resulted in a report, Preliminary Design of an Experimental World-Circling Spaceship (4). The proposed midget moon, or “satellite,” would provide “... an observation aircraft [sic] which cannot be brought down by an enemy who has not mastered similar techniques.” The public sector had its own prophet. In 1951, 6 years before Sputnik 1, Arthur Clarke, a science fiction writer, proposed that a satellite could be inserted into orbit over the North and South Poles while Earth revolved beneath it, and that this satellite would permit humans to view the planet in its entirety (5). (Clarke is also credited with being the first to propose using satellites for communications.)

The civil satellite potential was not neglected. In April 1960, the National Aeronautics and Space Administration (NASA) and the Department of Defense (DOD) launched the Television and Infrared Observational Satellite (TIROS-I) into a polar orbit, inaugurating the first experimental weather satellite. This system generated the first television-like pictures of the entire globe in a systematic and repetitive manner. This ongoing series of TIROS satellites became operational in 1966 as the TIROS Operational Satellites (TOS) and in 1970, the National Oceanic and Atmospheric Administration (NOAA) renamed them the Polar Orbiting Environmental Satellites (POES). (For a full account, see the Weather Satellites in this *Encyclopedia*.)

In spite of the deep secrecy of the Discoverer Program, the military early recognized the need to involve the scientific community in developing techniques for using satellite data. In February 1962, at the Navy-sponsored *First Symposium on Remote Sensing of the Environment*, Dana Parker, one of the organizers, focused his inaugural address on the fundamentals of the electromagnetic spectrum, a subject that suggested that multispectral data could provide information that went beyond the “eyeball” analysis of photographic data on which all reconnaissance analysis was based. His talk heralded the multispectral interpretive approaches responsible for the selection of the Multi Spectral Scanner (MSS) flown on Landsat 1 and the current capability to analyze continental and global scale Earth cover changes (5).

The person who was probably the most influential in realizing and promoting the value of multispectral sensing was Robert N. Colwell, a professor of forestry at the University of California at Berkley. In the 1950s, Colwell and others showed that agricultural crops, trees, and even different soils possess a telltale electromagnetic signature that could be measured from any height and used to identify the object. He and his American colleagues were not alone in such thoughts. A Soviet scientist named E. L. Krinov had measured the spectral signatures of some 370 natural and man-made objects in the 1940s, and he, too, had aerial mapping in mind. In a prescient article in *American Scientist* in 1961, Colwell wrote, “Just as our musical appreciation is increased greatly when more than 1 or 2 octaves are exploited, so also is our appreciation of the physical

universe through multiband spectral reconnaissance, which already can exploit more than forty 'octaves'." He and his colleagues at Michigan and Purdue were instrumental in the selection of the MSS launched on Landsat 1 (2). Colwell's students were pivotal in making the rapid development of multispectral sensing possible.

Getting Landsat Started

The concept of a dedicated, unmanned land-observing satellite emerged in the mid-1960s. It was stimulated by the early interest of the ONR, and aided by NASA's studies and aircraft sensor experiments starting in 1963 in its Office of Manned Space Flight's Earth-Orbital Apollo Extension System under P. C. Badgley. These efforts bore direct fruit in Earth-sensing experiments on Skylab in the mid-1970s, but were more important to the Landsat decision because Badgley also funded the U.S. Geological Survey (USGS) and the U.S. Department of Agriculture (USDA) to define practical uses for space-derived images (6). By 1996, Badgley, then working in NASA's Office of Space Science and Applications, and Leonard Jaffe, in charge of its Application programs, were well aware of the desire of the USGS and USDA for the speedy development of an Earth resources satellite, but NASA upper management showed little inclination to address the desires of the potential user agencies. What attention they were giving to Earth application needs was centered on planning to use the Apollo spacecraft as a manned Earth observation system. (This should not be surprising. At this same time, the U.S. Air Force, in spite of the already very active unmanned observation program, was in the first stages of the Manned Orbiting Laboratory (MOL) program which would use the Gemini spacecraft to support a space station filled with both optical and radar sensors. MacNamara canceled it probably because of its rising costs, but also because there was no clear argument that the presence of a crew in orbit would add value to the reconnaissance data. He was also aware that the loss of a manned spy satellite due to enemy action would require a much more dangerous response on our part than the elimination of a simple satellite.)

While NASA's manned program developed and tested some of the relevant technology and the startling photographs from Gemini and later Apollo gave scientists insight into how valuable satellite imagery could be (7), the real credit for the Landsat satellite must go to the USGS and in particular to its then director, Dr. William T. Pecora. Disturbed by the continuing lack of progress by NASA, Pecora set up a press conference on 21 September 1966 at which his boss, Interior Secretary Stewart Udall, announced the Interior's plans for an Earth Resources Observation Satellite program (EROS) to be run in cooperation with NASA. James Webb, the NASA Administrator, made aware of the press conference on the previous day, arranged an immediate meeting with President Johnson, who reaffirmed that the development of space technology was NASA's responsibility. Secretary Udall was informed by NASA on the day after the press release that NASA had been assigned "lead agency" responsibility for civil experimental space applications. The USGS announcement had stressed its development of an operational system, but NASA managed to maintain that any

satellite system, even if it carried sensors considered ready for operational use, was experimental (6). This has been governmental and NASA policy to this day, though it has several times required some imaginative interpretation of “experimental.”

Although unsuccessful with its own “operational” satellite system, the Department of the Interior (DOI) continued to press NASA for a satellite. The overall goal of the proposed EROS program was to acquire remotely sensed data from satellites in the simplest possible way, deliver these data to the user in an uncomplicated form, and ensure their easy use (8). NASA did not believe that the problem was technically that simple and was especially negative about the schedule that the USGS was proposing. DOI seemed to have lost the battle, but the result was that NASA accelerated its planning for a small unmanned satellite.

However, it was not to be that easy. NASA was initially frustrated by the Bureau of the Budget (BOB) that rejected NASA’s FY 1968 budget. In the fall of 1967, NASA and the DOI budget request for FY 1969 funding for the project was again turned down. It took a direct appeal by NASA Administrator James Webb to President Johnson to have the request restored and a rescheduling of the elements in that budget by Congress to allow NASA to start on the initial contractor studies for the satellite. DOI’s budget request was still refused, which caused a delay in its plans to initiate a data processing and distribution facility. This delay would cause problems in getting Landsat 1 data to user communities for several years after the launch.

Though NASA finally was given its FY1970 budget request as well, the BOB was still fighting hard to stop the program; one internal BOB memo written in June 1968, while the FY 1970 request was being developed, suggested that the Landsat satellite proposal should be eliminated and replaced with an Earth resources aircraft program (6). Because the EROS satellite was being developed to prove that satellites images could be beneficial to a wide range of governmental and public activities, the BOB had required NASA to make a cost-benefit analysis of its potential value. The argument that aircraft could do the same jobs better and at less cost was an issue that plagued Landsat then and later as it presented its plans for the follow-on Landsats. Amron H. Katz, in an article in *Astronautics and Aeronautics*, made this argument most forcibly in June 1969, and he was still arguing the superiority of aircraft through 1976, long after the launch of Landsat 1 (6). At this time, Katz’s argument is in the process of being tested in the marketplace by the recently launched commercial satellites whose 0.6 to 1-meter resolutions can compete directly with many (but not all) of the imaging tasks performed by aircraft-based sensors.

Interior changed the “S” in its Earth Resources Observation Satellite (EROS) program from Satellite to System and placed it under the direction of the USGS. The EROS mission was to archive and distribute remotely-sensed data and to support remote sensing research and applications development within the DOI. To carry out the EROS responsibilities, the USGS built the EROS Data Center in Sioux Falls, South Dakota, in 1972. This location was chosen after a competition with a location in Mississippi. Both were being considered because their central locations would enable a receiving antenna to record satellite passes over both the East and West Coasts. The receiving antenna was finally installed

at the EROS Data Center (EDC) in 1998, the delay being due to the commercialization of the program since the contractor chose Norman Oklahoma as the location for its receiving station.

The Multispectral Scanner Years, 1972 to 1984

Table 1 provides the complete history of the Landsat system, its sensor complements, and operational periods.

Landsat 1 carried two sensors, the return beam vidicon (RBV) and the MSS. The RBV was a television camera designed for cartographic applications and was the sensor of choice of the USGS and originally NASA. The MSS was designed to identify natural features using spectral analysis and came to NASA in an unsolicited bid from a group at Hughes Aircraft headed by Virginia Norwood. The Hughes scanner triggered quite a debate. “Mapmakers like myself were very suspicious of the multispectral scanner, which we could not believe would have geometric integrity,” admitted the USGS’s Alden Calvocoresses. “We were wrong on that one.” “People were so emotionally opposed to a mechanical device,” Norwood recalls. The argument which went on for more than a year, was resolved by flying both. However, the six-band sensor originally proposed by Hughes had to be reduced to a four-band system because of weight restrictions. In retrospect, the decision was to prove a crucial one. Soon after the launch, the TV cameras became afflicted with an unexplained electrical problem and had to be shut down within the month. The scanner, designed to work for 1 year, was still functioning, moving mirror and all, when the satellite was turned off 6 years later. Figure 8’s schematic of the MSS shows how the mirror scans across the track while the satellite motion provides the other dimension. Figure 9 shows the whole satellite with the locations of the MSS and RBV noted.

The launch of Landsat 1 in the summer of 1972 settled the issue. The quality of the images, including their geometric fidelity provided by the multispectral scanner (MSS), was a surprise to many in the community and was quickly followed by the recognition that its data scale, resolution, and four color bands provided new, unique, and very useful ways to see and understand our geography.

Table 1. History of the Landsat Satellites

Satellite	Launched	Status as of July 2002	Sensors
Landsat 1	7/23/72	Ended ops 1/06/78	MSS & RBV
Landsat 2	1/22/75	Ended ops 2/25/82	MSS & RBV
Landsat 3	3/05/78	Ended ops 3/31/83	MSS & RBV ^a
Landsat 4	7/16/82	Standby	MSS & TM
Landsat 5	3/01/84	Operational	MSS & TM
Landsat 6	10/05/93	Launch failure	ETM
Landsat 7	5/15/99	Operational	ETM +

^aLandsat 3 was kept “experimental” by adding a thermal band to the MSS and by replacing the three 80-meter RBVs with two 40-meter panchromatic cameras. The thermal band failed, and the added resolution of the RBVs did not provide sufficient improvement to increase their low use relative to the MSS.

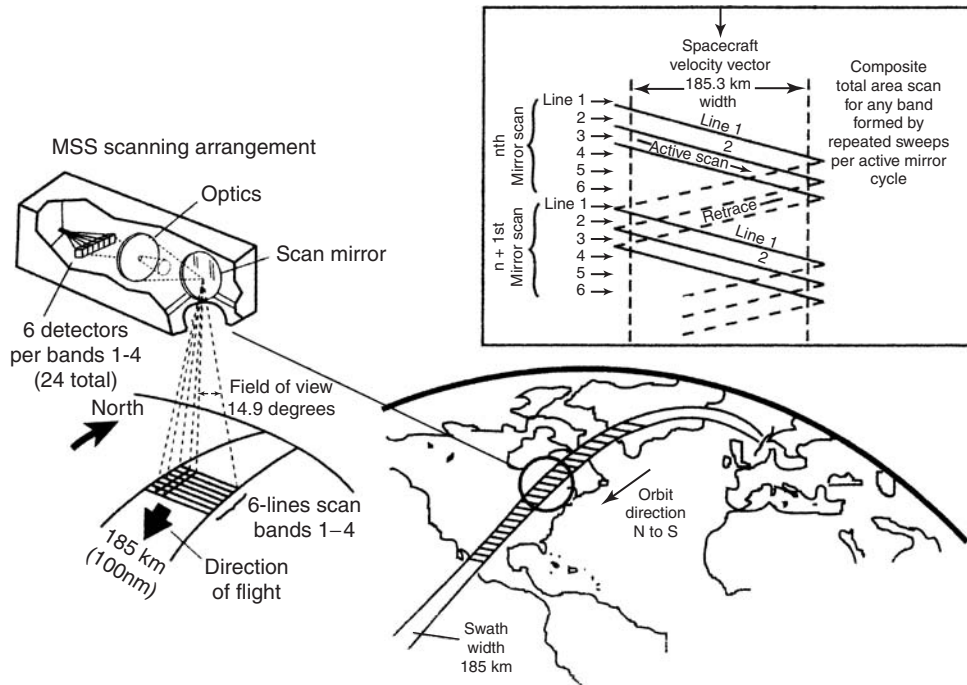

Figure 8. Scanning geometry of the multispectral scanner (from Landsat 4 Data Users Handbook, 1984, USGS).

The satellite data were received on Earth in digital form. However, nearly all of the initial MSS products were provided as color and black and white prints and negatives because the user community had little experience with or training in analyzing data in its digital form. In addition, their computer facilities were only marginally up to the job of processing the amount of data involved, and the interpretive algorithms were still in an early developmental stage. There was a cost difference that certainly had some effect in the later years; film costs varied between 8 and 15% of the cost of digital tapes. Film dominated the product sales in dollars until 1984, but even then 35,000 film scenes were delivered compared to 5,000 digital scenes. Digital sales increased rapidly after that until, in 1993, EOSAT eliminated its photographic product line because it was not economically viable (9). Finally, 21 years after Landsat 1, the digital applications made possible by the MSS, had worked their way into the marketplace. Today, all of the 24,000 annual sales are in the digital format.

The quality of the photographic images was more than sufficient to inspire a rush to explore their uses for many applications. For the first time, mapmakers had images that covered 100 miles on a side with near orthophotographic geometry. (The edge of the scene was imaged at only $7\frac{1}{2}^\circ$ from the vertical. Figure 10 shows just how impressive this capability is. It is one Landsat scene covering $185\text{ km} \times 170\text{ km}$, virtually 100 miles on the side, showing the Chesapeake and surrounding land, including Baltimore and Washington, D.C. Aircraft montages for that same area would involve hundreds of

Figure 9. Platform configuration, Landsats 1, 2, 3.

individual images, each of which would have had to be corrected to match their 30 or 40° edge angles with their neighbors.) Geologists were able to recognize innumerable new fault lines revealed by the consistency of the lighting and shadow angle across the whole scene. There was even a minor coffee-table book rush to present the public with pictures of both familiar and far away places made strange and beautiful by the many colors generated by manipulating the four color bands.

The first sizable use by industry was by the major mineral and oil exploration companies. They were targeted early in the program by JSC's Earth Resources program office and, after some initial skepticism, formed Landsat analysis groups that used Landsat images to update maps and to identify surface features that warranted further exploration. It was equally important for them to be able to obtain images anyplace on the globe without their rivals knowing about it. (Early in the program, EDC established the policy of keeping the data

Figure 10. 100 mile square Landsat image of Chesapeake Bay and environs. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

buyers' identities private.) The industry put together an advocacy group, the GEOSAT Committee, that served as its representative in the many Landsat debates that were to be a feature of the Landsat program over the years. Robert Porter, who resigned his position as Director of the NASA Earth Resources Program in 1970 to found his own company, Earth Satellite Corporation, to apply Landsat analysis to commercial needs, estimated that at least \$1 billion worth of oil had been found using Landsat data (6).

The boost this application gave to those in NASA who defended the Landsat program would be short-lived; the exploration companies generally needed only one look. Landsat covers the whole globe 24 times a year, every year, and its "killer application" must be one that needs that kind of repetitive coverage. The management of things that grow, trees, grass, and food, seemed to fit that bill and were, of course, the intended target of the multispectral analysis for which the MSS was designed.

Transferring Landsat Technology

NASA's Office of Space Applications (OSA) was split from the Office of Space Science and Applications (OSSA) in 1971 and retained the Landsat program that had been transferred to OSSA from the Office of Manned Space Flight in 1966. OSA also developed the first communication satellite, the first weather sensors and satellites, both polar and geosynchronous and the first and still the only U.S. civil radar satellite, Seasat (See Radar section). However, it recognized from the start that its function went beyond the development of satellites and included the development of the required ground systems and data analysis technologies that

would enable users to apply the satellite data to their problems. OSA's success in these basically technical problems can be rated excellent for the satellites and sensors and after a very slow start, good for the ground systems and analysis algorithms. But it soon was forced into the social and political engineering role of technology transfer. OSA's results in this function are still being debated. The best study of this activity and its results for the period up to 1990 is Pamela Mack's *'Viewing the Earth: The Social Construction of the Landsat Satellite System'* (6), which has been the source of many of the facts in this article. As will be noted later in this article, the social and political issues concerning Landsat and its successors became even more complex after 1990.

NASA's initial approach to the technology transfer issue was to fund studies in universities and user agencies. The university studies were most often concerned with developing and testing analytical techniques to exploit the manipulation of the signals from the four bands to identify crops and to measure their yield and health. The user agencies were concerned about defining operational and land management functions that could be done better, and more economically using Landsat images, or new but needed applications that could not be done at all without Landsat. NASA requested proposals even before Landsat 1's first launch. Expecting 40 or so principal investigators, it was inundated by more than 500 proposals. Wanting to encourage the broadest use possible, it set up peer review panels in several disciplines (chiefly geology, hydrology, and geography). The panels chose more than 300 investigators (6).

The large number of investigators made NASA carefully consider what the data distribution policy should be. Because there was the possibility of using an image to find value on someone else's property, NASA decided to release all data to the public immediately to avoid charges of unfair discrimination. Data distribution policy is a crucial issue still facing the civil program, involving as it does the complex relationship between the commercial interests that require exclusive distribution to earn their profits and the government's desire to provide data to scientists and government agencies at prices commensurate with "public good" support.

The results of these and following studies were presented in a series of symposia hosted by GSFC starting in March 1973. The presenters were asked to report on "user identified significant results" in agriculture/forestry, environment, geology, land use/land cover, and water. Each of the *Proceedings* approached 2000 pages. The studies produced valuable scientific results from the time of the first launch, but they also revealed that some of the capabilities promised by the magic of multispectral analysis fell a bit short when faced by the heterogeneity of the real world and the radiometric and resolution limitations of the MSS. Though many crops could be identified, the accuracy of the identification varied widely by crop type, growth status, atmospheric conditions, and field size. There was much to learn, but the reports demonstrated the value of multispectral analysis for a wide variety of surface analyses. These analyses were also able to identify the limitations on analysis imposed by the limited resolution and number of spectral bands of the MSS, thus giving support to the need to develop a better scanner. The development of the new scanner, the Thematic Mapper, is described below.

The Large Area Crop Identification Experiment (LACIE)

The NASA technology transfer effort did not rely only on the numerous individual studies that NASA continued to fund throughout this first period. In the 1970 and 1971 growing seasons, the Johnson Space Center (JSC), the USDA, and Purdue University used aircraft equipped with a variety of sensors, including a multispectral scanner that simulated the MSS, to fly over 210 test areas in seven Corn Belt states. The program detected the corn blight early enough to check it by pesticides and, as a result, led to the operational use of low flying aircraft to solve the farmers' problem (6). It did not provide Landsat with a direct application, but it did provide valuable experience in dealing with the problems of crop identification and health detection in the real world, which were important in developing NASA's Large Area Crop Inventory Experiment.

In July 1973, Congress asked NASA why it had failed to do more to predict the failed Russian wheat crop of 1972. Congress was concerned because American farmers lost potential profit by being unaware of the condition of the Russian crop. NASA saw an opportunity to reply with a plan when Robert MacDonald, who had led the corn blight team at Purdue and was then the Landsat Chief Scientist at JSC, suggested the large-scale agricultural experiment that later became LACIE. LACIE was certainly large scale; it monitored the entire Russian wheat crop and the U.S. Great Plains for three years, involved a contractor force of more than 200 Lockheed analysts, and cost between \$10 and \$15 million a year. In 1997, its third year, it met its goal of 90% accuracy, successfully predicting the poor Russian wheat harvests in that year. But as a technology transfer mechanism, it failed. USDA, in response to the direction of the OMB (see below) formed the ArgriStar program in close cooperation with NASA, but chose to focus it on improving and testing the techniques of crop identification rather than continuing the country production estimates of the LACIE program. Over the many years since, it has developed new and different uses of Landsat data and has been the largest civil agency Landsat data purchaser.

The End of NASA Application Activities

LACIE's last year was 1997, as it was for most of OSA's Landsat technology transfer programs. The Office of Management and Budget (OMB, the new name for the BOB) informed NASA that it would no longer support NASA activities that benefited other agencies on the theory that if they were really beneficial to those agencies' functions, the agencies should budget for them. NASA was being told to return to its experimental and scientific mission. This was part of the commercialization of the Landsat drive discussed in the next section. By the end of 1978, OSA had virtually ceased all application efforts, replaced its application managers with science managers, and embarked on studies to define the scientific requirements for Earth observation satellites. This effort resulted in the creation of the Office of Earth Sciences and the development of the Earth Observation Systems (EOS) program designed specifically to support the interagency Global Change program. Landsat was eventually to be considered part of this program, but it received little

management attention, which resulted in little science or application research funding during Landsat's commercial phase. NASA did, however, continue its development of the Thematic Mapper throughout this period, as befitted its technology development role (11).

The Thematic Mapper

As noted before, during the 1972 to 1978 period, NASA developed a new and improved multispectral sensor, named the Thematic Mapper (the TM) to emphasize that it was designed to measure and map the basic features or themes of the earth's surface automatically, that is, forests, plains, rivers, lakes, cities, farms, etc. Originally the sensor designers at GSFC reacted to the success of the MSS by proposing two alternate improvements, a 10-meter high-resolution pointable imager (HRPI) and a 30-meter resolution TM. HRPI was to be a small sensor using a new technology, multilinear array sensors, the scanner technology adopted by the French for their SPOT system in 1978 and for virtually all (except Landsats 6 and 7) land imaging sensors since then. HRPI could be programmed from the ground to point to targets along or to the sides of the flight path. This pointability provided 2 to 3 day repeat looks at a given target. It also made it possible to generate stereo images. However, high resolution came at the price of a small field of view, 10 kilometers. The decision between the two was a fairly easy one for NASA because the scientists liked the large area coverage of the MSS and DOD made it plain that 10 meters exceeded their threshold for civil system resolution. It is interesting to speculate on the path remote sensing would have taken if HRPI had been chosen. HRPI had the pointability and higher resolution that have been the capabilities that finally emboldened the private sector to fund commercial systems in the mid-1990s.

The TM was selected because its 185-kilometer wide, 16-day global repeat coverage replicated that of the MSS, a very important requirement of the science community and user agencies. The user agencies and the scientific community were called upon to determine the exact spectral bands for the TM. The consultation process culminated in a 3-day conference at Purdue under the direction of Dr. David Landgrebe, the director of their remote sensing group. Three teams, each composed of sensor designers, data analysis experts, and data users, debated the merits of all possible band combinations. There was surprising consensus among the three teams, and the selection of six bands was essentially unanimous (12). Much later in the sensor development process, the geological community led by Alex Goetz, feeling they had been slighted in the band selection process because of NASA's focus on agricultural users, requested that a band he had shown was sensitive to minerals, be added. Fortunately, the addition was found technically feasible, and a seventh band was added. The increased capabilities of the TM came with significant weight and size increases over the MSS. The TM weighed 258 kg versus the MSS' 64 kg and it measured $1.1 \times 0.7 \times 2.5$ meters compared to the MSS' $0.5 \times 0.6 \times 1.3$ meters. Figure 11 presents a picture and cutaway of the TM.

The user community also was able to convince the OMB that any satellite carrying an experimental sensor should also carry the MSS to allow testing the

Figure 11. Landsat-7 ETM+ (note dimensions are $1.8 \times 7 \times 2$ meters). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

new sensor relative to the established and understood characteristics of the MSS. While this was a scientifically reasonable position, the user agencies were also worried that they would have budget problems upgrading their computer systems to meet the greatly increased data volume generated by the TM. Thus, Landsats 4 and 5 came into being. Figure 12 presents a drawing of Landsats 4 and 5.

Figure 12. Landsat 4 and 5 observatory configuration.

Commercialization 1984–1992

When the TM on Landsat 4 was launched in 1982, NASA could declare Landsat a technical success. Landsat was also an international success as the look-alike programs of France, India, Russia, and Japan were soon to demonstrate. However, as is the fabled fate of prophets in their own land, NASA failed to convince any other agency or any commercial entity to develop its own system. The user agencies, which were vociferous in telling NASA what they needed to make the program better and, above all, their need for it to be operational, were very cautious in their testimony to Congress on the value of Landsat, lest they be asked to use part of their budget to build the next system.

The basic issues had been there from the start: should there be a civil operational Landsat and which agency should fund and manage it? The large benefit–cost ratios derived from the BOB-requested economic cost studies and used by NASA to justify the continuation of the program, inadvertently added a third issue: should the system be commercialized? In June 1978, the Office of Science and Technology Policy published the results of a study of policy options for civilian remote-sensing satellites. The study concluded that the President should make a commitment to an operational Earth resources satellite system and suggested that NASA have responsibility for that system (6). User agencies and the states disagreed that NASA be the manager. In November 1979, President Carter issued Presidential Directive 54, which gave NOAA temporary responsibility for operational Earth satellites and called for the National Oceanic and Atmospheric Administration (NOAA) to develop a plan for turning over Earth resources satellites to private industry. The decision to have an operational remote sensing system and to have it managed by NOAA along with its management of weather satellites was roundly applauded. However, the suggestion that it should later be turned over to private industry sparked a strong controversy that has continued to this day. A 1980 report by a task force of state representatives explained that “the establishment and operation of a land remote sensing satellite system is viewed as a public service in the same context as census, cartographic, geological and meteorological data which are supplied by the Federal government” (Recommendations of the National Governor’s Association April 30th 1980). As required by the directive, NASA turned over the operations of Landsat 4 in 1982 after assuring that it was functioning as designed.

Carter’s steps toward gradual privatization were quickly trumped by Reagan whose administration moved rapidly to transfer the Landsat program to the private sector. Reagan attempted to include the weather satellites in this process but strong objections from Congress and a scandal concerning questionable lobbying and contact between COMSAT (which lobbied strongly because the privatization mechanism was based on its successful commercialization of communication satellites) and the Department of Commerce resulted in PL 98-52 which prohibited the transfer of weather satellites to the private sector. Reagan signed the final law, Public Law 98-365, the Land Remote-Sensing Commercialization Act of 1984.

In January 1984, NOAA solicited bids to operate the existing Landsats, retrieve and develop a market for their images and, aided by government

subsidies, to build and operate future systems. Both of the two final bidders, EOSAT a partnership between Hughes, the MSS contractor, and RCA the satellite contractor, and Kodak, required government subsidies of about \$500 million spread out over a 6 to 10-year period. This was a reasonable amount based on several NOAA-funded studies that agreed it would take at least 10 years before the sales of Landsat images could support the development of a satellite. OMB did not want to supply federal funds. Reagan's chief of staff split the difference, and the contract was limited to \$250 million of government funding. Kodak withdrew, and EOSAT was selected. However, the cost cap kept contract negotiations going until both parties agreed to a final amount of \$350 million, and the contract was signed in September 1985.

With that signing, the Landsat community breathed a sigh of relief because it seemed that Landsat was finally on a course toward the long desired goal of operational status. This was short-lived, however, as the impact of the EOSAT 200% price increases and their restrictive licensing requirements became felt. This was especially critical for the academic community and the state users who were used to buying the data at almost the cost of reproduction. The result was that during the commercial period, studies to develop and test new uses of multispectral analysis using Landsat scenes almost came to halt. Most of the major advances in spectral analysis of satellite imagery in this period were made using the free 1-kilometer resolution data from the advanced very high resolution radiometer (AVHRR) on the NOAA weather satellites.

The Reagan administration continued its campaign to reduce spending on Landsat even after the contract was signed; this made it virtually impossible for EOSAT to continue its marketing efforts and to plan for the follow-on satellite. In 1986, the French government launched SPOT1, designed specifically as a commercial data gathering system. EOSAT was faced with selling 30-meter data against SPOT's 10-meter panchromatic and 20-meter color data. In 1991, Landsat's sales were \$32 million and SPOT sales topped \$40 million. Note that neither number approached a level that would support a fully commercially financed system.

The first positive boost to the program occurred early in 1989 after NOAA directed EOSAT to turn off Landsats 4 and 5 due to lack of program funds. The newly elected Bush Administration was deluged with hundreds of letters from academic researchers, foreign governments, private companies, and concerned congresspersons demanding the necessary funding. Vice President Quayle, head of the newly formed National Space Council (NRC), canvassed the major user agencies and put together an ad hoc funding plan that kept the satellites in orbit. Unfortunately, there was still division in the administration, and the ad hoc process had to be invoked for the next 2 years. Landsat did start to gain backing in the government due to three factors: Bush's Global Environmental Change initiative, the utility of Landsat and SPOT data during the Gulf War; and the technological impact of computer capabilities, especially Geographic Information Systems (GIS) and the satellite-based Global Positioning System (GPS). The first had impact because Landsat was the only consistent set of global data extending back to 1972, and the second because it caused the powerful military and intelligence communities to state openly the importance of Landsat for their missions. (By late 1980, the DOD was the single largest user of Landsat data in the

world.) The third factor finally allowed science and application users to take full advantage of the digital data on affordable computers. The forces for change were set in motion.

Landsat Returns to the Government in 1992

Landsat commercialization was a failure. That is not just an opinion; Congress so declared it in the findings of the Land Remote Sensing Policy Act of 1992. Passed in October of that year, it was the result of a congressional process that was started by Representative George Brown and Senator Larry Pressler. Brown, Chair of the House Science and Technology Committee, was a dedicated environmentalist, and from that viewpoint, he declared that Landsat should be returned to the government to be treated as the weather satellites, as a public good (13). He introduced a bill in the house for the purposes of “Amending the Land Remote Sensing Commercialization Act of 1984...” and Pressler offered a similar bill in the Senate.

The Land Remote Sensing Policy Act of 1992 was a farsighted and fruitful act. It created the commercial licensing process that culminated in the current leadership of the United State in the high-resolution commercial market. It recognized the importance to this country’s scientific, resource management, security and economic sectors of continuing the then 20-year recording of the global land surface by the midresolution Landsat series and established “continuity” as the criterion for Landsat follow-on systems. That somewhat loosely defined criterion resulted in Landsat 7 and is the basis of the current plans for its successor, the Landsat Data Continuity Mission (LDCM). The law also mandated that the data be provided to everyone for the “cost of fulfilling user requests,” responding to Chairman Brown’s desire to make Landsat data a public good. It gave the DOI the responsibility for creating and maintaining an archive of land image data, a responsibility that the DOI assigned to the USGS. Subsequently, the USGS entered into an interagency agreement with NASA to operate Landsat 7 and its data collection, archiving, and distribution functions. The law recognized those desiring commercialization by giving the DOC, appropriately consulting with the DOD, CIA, and the NRC, the task of licensing private companies to fly Earth-sensing satellites.

The administration was not idle while Congress debated. In March 1992, NASA and DOD released the management plan that Bush had requested. The plan called for the development of Landsat 7 to replace the EOSAT-built Landsat 6 at the end of its expected life and to continue the “continuity” of the Landsat data series. The plan assigned the responsibility of the space segment for Landsat 7 to the DOD and the ground segment to NASA and provided a budget of \$470 million for DOD and \$410 million for NASA. After so many years of cross-purposes, it seemed that the Bush administration and Congress agreed at last on the role of civil remote sensing satellites.

The real breakthrough for the commercial satellite companies occurred as the result of a joint meeting of the House committees on Science and Intelligence in 1994. One company, Earth Watch (now Digital Globe), quickly obtained a license for a 3-meter resolution satellite. (Unfortunately, it failed soon after

launch in 1997.) However, at the time of hearing, Lockheed had been waiting 6 months for an answer to its request for a 1-meter system. Congress wanted to know why. The testimony of all of the agencies was that the availability of 1-meter images to the world might pose a serious threat to our security and required more study. Congress suggested that they reevaluate their concerns in the light of the 2-meter satellite scene of the Mall that had been purchased on the commercial market from Russia. Two weeks later, President Clinton issued Presidential Decision Directive (PDD) 23 that authorized commercial satellite high-resolution imagery and set specific regulatory guidelines. It left the definition of high resolution to the decision of the agencies involved, but its intent was clear to all, and Lockheed had its 1-meter license. At the present time, two companies have licenses for systems of 0.6-meter resolution and one is already operational.

Though the DOD overplayed its hand a bit, it did have legitimate concerns about the availability of such data in time of war. The license contains a “shutter control” clause for just that situation. However, shutter control’s legality is being questioned on the basis that it is prior constraint and not allowed by the Constitution. During the Afghanistan engagement, the National Imaging and Mapping Agency (NIMA) finessed the prior constraint issue by contracting with SpaceImage for exclusive use of all the data taken over Afghanistan during the critical months of the operation. Most of the data were made available to all 2 months later.

Landsat Returns to NASA

Hardly a year passed before the Landsat program was evaluated for a third time, principally because NASA felt that its budget would not cover building the extra capabilities in the ground data system that would be required by DOD’s addition of a high-resolution (5 meters) multispectral stereo imager (HRMSI). The National Science and Technology Council (NSTC) meeting in response to the launch failure of Landsat 6 and aware of DOD’s reluctance to continue a program without a HRMSI sensor, recommended developing Landsat 7 with only an improved TM instrument and establishing a new management structure, so that DOD could withdraw from the program. This resulted in Presidential Decision Directive/NSTC-3, dated 5 May 1994, reconfirming the Administration’s support for the program but giving NASA, NOAA, and the USGS joint management responsibility (White House, 1994). The Landsat Program Team (the LPM) was created by the three agencies. It proceeded to negotiate with EOSAT for new Landsat 4 and 5 product prices for the U.S. government and its affiliated users and began the process of defining and developing Landsat 7.

A project office was established at GSFC. It defined a new sensor, the ETM+ (extended TM+), that replicated the TM bands but also included several improvements made possible by advances in technology since the earlier Landsats. The improvements included adding a 15-meter panchromatic channel, sharpening the thermal band to 60 meters, and increasing sensor sensitivity and calibration accuracy. It also defined a data acquisition goal. The system was to be

able to acquire the entire landmass of the globe on the average of four times a year. Thus, for the first time in Landsat history, the satellite was to be programmed to do what its supporters had long envisioned: acquire a scientifically useful annual archive of the seasonal and annual changes that take place on all of Earth's land surface.

Landsat 7 was launched on 15 April 1999. Its data have met all expectations. Landsat 7 is the first and still the only midresolution system programmed to acquire and archive all of Earth's land surfaces once per season. The data acquisitions are being collected under the guidance of a program developed by Dr. Sam Goward's team at the University of Maryland. The program maximizes the probability of observing critical seasonal changes and reduces the number of cloud-filled scenes acquired from the system's capability of 250 scenes per day. This is not a trivial task because clouds cover 50% of the globe, on average, and some of the most biologically active areas are covered 80% or more of the time. (For the past 2 years, scientists have been able to gather data at twice the frequency of the 16-day Landsat repeat orbit because Landsat 5 is still functional in its eighteenth year of operations.)

Equally important, especially to the global environmental change science community, as required by the 1992 law, all of the data are archived at EDC and are sold to everyone at the cost of fulfilling user requests, currently about \$600 per scene for the standard product. A survey of EDC image sales for the first 10 months of Landsat 7 operations showed that sales averaged 2400 a month. An analysis of the 1000 separate purchasers revealed that when account is taken of the many commercial and academic buyers who purchase data for use on government programs, the government is the ultimate purchaser of more than 80% of the data sold. This supports the observation in the 1992 Law that Landsat data are effectively a public good.

The Landsat Data Continuity Mission (LDCM)

Goddard created a Landsat Data Continuity Mission (LDCM) team with the USGS in 2000 (NOAA had left the Landsat Program Team earlier because it did not get its Landsat budget) to formulate plans for a follow-on mission to Landsat 7. In response to Congressional mandates that NASA not develop any satellite until it could demonstrate that it could not buy similar data commercially, GSFC first developed a rigorous set of data specifications that would meet the requirement for data continuity: 30-meter multispectral resolution, 15-meter panchromatic, 185-kilometer swath, data quality equal to or better than Landsat 7, and delivery of an average of 250 scenes a day for 5 years. After several iterations with the science and application community, the resulting data specifications were made the basis of an RFP to industry for a 6-month study to provide several trade-off studies to NASA, including the cost of keeping the thermal data requirement. The contractors were also requested to provide the design of a total satellite, sensor, and ground system to the level of detail required for a traditional Program Design Review. Two contractors were chosen. Both bids were for systems designed to supply a commercial market that required much higher capability than NASA was requesting, but whose data could be degraded to meet

the government's requirement exactly. It is just possible that a formula has been found that will meet the requirements of both sides of the commercialization–public good debate. NASA will get a product that meets its scientists' goals without having to remain in the satellite operations business, Landsat type data will be provided to all at the cost of reproduction, and industry will get the help it needs to develop new products that will broaden and add to its nascent high-resolution business.

Getting Data to Users

The Landsat history described so far left out a major element in the Landsat program; the ground system hardware and software that received, processed, stored, and distributed the data to users. The history of the development and operation of the ground-based systems is as full of trials, tribulations, decisions, and revisions as there are in the space segment's story. The facts in the following summary have been taken (sometimes literally) from an excellent article by W. C. Drager et al. (9).

To Pecora (8), the success of Landsat depended on making the data available to users in a timely and efficient manner. NASA recognized that it was its responsibility to develop the hardware and software to process the data from its new instruments. The technical problems turned out to be more difficult than expected, and data processing systems were slow in reaching the ability to handle the amount of data that was being downloaded from the spacecraft and ordered by users. Also, NASA did not think that its job was to be operationally responsible for the processing, storage, and distribution of the data products. Thus prior to the launch of Landsat 1, NASA signed an agreement with the USGS to process, archive, and disseminate Landsat data at the USGS EROS Data Center (EDC). That agreement, together with similar agreements with NOAA during its Landsat tenure, was codified by The Land Policy Act of 1992 that directed DOI/USGS to maintain a national archive of land remote sensing data and, as noted before, to make it available to all users at the cost of fulfilling user requests. That remains the situation currently.

As the United States established the Landsat program, it made extraordinary efforts in the United Nations and elsewhere to gain worldwide acceptance of nondiscriminatory dissemination of remotely-sensed data from space. The United Nations adapted this position in 1986 as "The Principles Relating to Remote Sensing of the Earth from Space" (10). This concept (often called the "open skies" policy, although that name is more correctly applied to an Eisenhower initiative to exchange the rights to do aircraft remote sensing with Russia and other nations) was responsible for many early activities aimed at getting Landsat data into the hands of data-poor third-world countries. Soon after the launch of Landsat 1, U.S. development assistant agencies, including USAID and the International Development Bank (IADB), began offering sizable Landsat data grants and funding for personnel to third-world countries. In 1974, for example, USAID awarded \$260,000 worth of Landsat data and training grants to 10 developing countries in South America and Africa. By 1981, that program had grown to approximately \$40 million and included projects in

Figure 13. Landsat revenue history.

35 countries that ranged from forest surveys in Costa Rica to geological mapping in Monaco (11).

NASA and the USGS initiated another major "open skies" initiative, the establishment of Landsat data receiving stations in foreign countries. NASA agreed to downlink Landsat data directly to such stations every time the satellite passed within its range. In addition to disseminating the data to the widest possible user audience, the establishment of foreign ground stations had two other very practical reasons: they served as a very valuable backup for the failure of the onboard tape recorders that were the weakest link in the data system, and they provided a significant source of revenue to NOAA that offset its operational expenses. The early annual fee of \$250,000 rose to \$600,000 by 1998 (11). Figure 13 presents Landsat's revenue history that shows the large part that station fees played. Each station has the right to sell all of the data it receives and the responsibility to archive that data for possible use by scientists; this responsibility has not been followed to the extent that the Landsat scientists would like. However, the foreign stations have been very active in distributing Landsat data. From 1979 through 1995, more than \$234 million worth of data has been distributed worldwide; at least \$103 million of that was through foreign ground stations (9).

Starting with Canada in 1972, 17 countries have built Landsat receiving stations over the years. The names and locations of 16 stations are presented in Fig. 14. (Argentina, Spain & Taiwan created stations after the period shown on the chart.) In the midlatitudes, each station covers an area the size of the United States, and at the higher latitudes, a great deal more. The result is that the ground stations cover virtually all of the global land cover except a large portion of northern Asia, principally Russia and China, and central Africa. These stations, all of which are government run or supported, have become their country's focal

Figure 14. An example of Landsat receiving stations and areas of coverage.

point for remote sensing. In recent years, many have established agreements with SPOT, Radarsat, and commercial high-resolution satellite operators.

There is no question that the Landsat program's early and continued aggressiveness in promoting and supporting foreign ground stations has been the major element in developing the worldwide application of satellite data and of creating the many national infrastructures that are critical in exploiting the satellites' unique global capabilities for both global science and the creation of a global market for commercial systems. This activity also became important to the Landsat program itself; the support of the international ground stations aided in the many debates on whether Landsat should be continued.

The International Period

The "United States only" period ended rather abruptly in late 1985 as the foreign activities generated by the early Landsats culminated in the launch of multispectral satellites by Russia, France, Japan, and India, all within the following 2 years. Though it took a little longer, Seasat's radar images also impacted the international activities starting with the launch of Russia's COSMOS-1870 in 1987, followed a year later by the Japanese and ESA launches.

This "international" period of very aggressive foreign development and launch of civil land-imaging satellites extended through 1996. During this second period, France, India, Japan, and Russia launched 14 optical systems. The United States' only launch, Landsat 6, did not make orbit. It was only the incredible extension of the orbital operations of Landsats 4 and 5 beyond their

5-year design lives that kept the U.S. land imaging program alive. The radar situation was even more biased as the foreign countries aggressively pursued radar imaging and launched seven radar satellites in this period.

Satellite Types. Before discussing the individual programs, it will be useful to note the data of Table 2. This table divides the current land imaging satellites into four classes; Landsat-like, frequent global coverage, high-resolution, small area coverage, multi & hyperspectral experimental, and radar. The columns provide the ground resolutions of the panchromatic and multispectral bands, the location of the color bands, and the image swath. The similar values of these parameters in each class illustrate the practical results of the trade-offs that must be made among the three principal observation variables, spatial resolution, spectral resolution and band coverage, and temporal resolution or swath width when designing a satellite/sensor system. The table also lists the wide field of view sensors carried by the Indian, French, China/Brazil, and U.S. satellites that provide daily or near daily coverage everywhere at low resolutions, usually 1 kilometer or a bit less. These sensors are similar to the imaging sensors carried on weather and ocean color satellites that are not covered in this article. (See Weather Satellites by Singer and Rao in this *Encyclopedia*.)

The broad swaths of the Landsat class satellites enable them to cover the entire globe many times each year: Landsat and CBERS 23 times; SPOT, when using both sensors, 15; and IRS 18 times a year. The number of times that optical systems can be expected to obtain cloud-free images is one-half to one-third of those figures. The public sector is responsible for mapping and managing large (state to country to global) land areas, so it should not be surprising that all of the satellites in this category are government funded. The high-resolution systems have about one-tenth the swath of the broad area systems, and as a result, they cover the total land cover about twice per year. However, they can point off-track and thus can return to any given site within 1 to 3 days.

The majority of the satellite and sensor data in following sections were taken from Ref. 14. It is not much of an exaggeration to say that this chapter could not have been written were it not for the extraordinary work of H. J. Kramer. Mr. Kramer's 1500 pages recording the engineering and operational characteristics of every sensor and satellite launched into Earth orbit from Sputnik to 2000 will be considered the essential reference volume of Earth and atmospheric observation programs for years to come.

France. The SPOT (Satellite Pour l'Observation de la Terre) series was created by the government's Centre National D'Etudes Spatiales (CNES) and is operated by the SPOT Image Corporation. SPOT Image sells the SPOT images and data products worldwide through a commercial network of distributors and 23 ground receiving stations. The corporation's main shareholders are the government's Centre National D'Etudes Spatiales (CNES—38.5%) and ASTRIUM, the prime contractor for the SPOT satellites (35.6%) (15).

SPOT was designed for the commercial application market from the beginning. Its 10-meter Pan band was pointed to user mapping needs, and its ability to look from side to side made it possible to see any particular site seven times during its 26-day global coverage cycle (compared to Landsat's once in 16 days, see Figure 4). This capability was developed to meet a commonly expressed user requirement to see a site often and at specific times. Four satellites are currently

in operation that give customers the opportunity to see their sites every day. SPOT 1, 2, and 3 had only three color bands. This limited SPOT's value for some types of multispectral analysis of special use in crop monitoring. However, the addition of a fourth band on SPOT 4 and 5 has somewhat mitigated Landsat's advantage in such multispectral applications.

Spot 1 was launched in 1986, 2 years after Landsat was commercialized; the two commercial entities competed fiercely. In 1991, Landsat's sales were \$32 M and SPOT sales were more than \$40 M. Neither figure is close to making the program self-sustaining. Since 1999, SPOT sales have faced serious competition from Landsat 7 because the 1992 law requires selling Landsat data at the "Cost of Filling User Requests" (COFUR) which is presently \$600 a scene, compared to SPOT's roughly \$2000 for a much smaller image. Landsat 7's 15-meter Pan band also cut away much of SPOT's 10-meter advantage. Based on the launch of SPOT 5 (4 May 2002), Spot Image is hoping that its 60-kilometer swath, 2.5 and 5.0-meter resolution images will fill a large mapping niche that neither the new 1-meter, 10-kilometer swath commercial satellites or Landsat 7 can fill. Perhaps even more salable is its currently unique ability to produce continuous stereo strips for the production of high accuracy three-dimensional maps. Spots 4 and 5 also carry the vegetation sensor that the European Union and several of its member countries developed to meet their agriculture monitoring requirements. This sensor provides a daily 1-kilometer global coverage similar to, but with much better spectral data than, the advanced very high resolution radiometer (AVHRR) on POES used by NOAA to produce daily and 10-day vegetation maps of the globe. However, the AVHRR data are provided at the cost of reproduction, as are the data from NASA's moderate-resolution imaging spectroradiometer (MODIS) sensor that has even better spectral data than the vegetation sensor. Thus, the U.S. policy is again in the position of negatively affecting France's commercialization objective.

SPOT plays an important role in the European Community (EC). The Commission of the European Communities is using SPOT to set up an environmental database covering the entire EC. SPOT data are now an integral part of the EC's operational agricultural statistics system used to manage its common agricultural policies.

India. The Indian Space Research Organization (ISRO) manages the Indian Remote Sensing Satellite (IRS) system. The intent of the program is to support India's National Natural Resources Management System (NNRMS). NNRMS supports the national economy in the areas of agriculture, water resources, forestry, and ecology, and the availability of the new high-resolution satellites makes studies of urban sprawl, infrastructure planning, and large-scale mapping possible. The basic use of the IRS data is to support such national infrastructure efforts, but ANTRIX Corp. Ltd., ISRO's marketing arm, sells the data commercially and has franchised sales of its data through the Space Imaging Corp. in the United States (1).

As can be noted in Table 2, IRS-1C and D have four color bands, 23-meter resolution, and a 142-kilometer swath that make it comparable with Landsat in many ways. However, IRS-1C's 5-meter panchromatic capability was the best resolution commercially available on a regular basis until the launch of SPOT 5. (Note that the Russians sold some of their archived intelligence satellite data

scanned to 2 meters resolution in this period). Having launched its Technology Experiment Satellite (TES) in October 2001, India is now the only government orbiting a nonmilitary, 1-meter class mission. Its current plans include launching one more. Its high-resolution systems do not carry a multispectral sensor apparently because color is not required for mapping and tracking civil and military activity/construction. India also plans to match SPOT 5's 2.5-meter relatively broad swath capability with its P-5 satellite.

Japan. Japan's early interest in keeping up with the United States and other space-faring nations began with launcher development and communications satellites. As noted in Ref. 1, "The success of Landsat led to Japanese interest in remote sensing... (and their)... remote sensing strategy therefore followed the so-called "Landsat model"—developing remote sensing satellites for scientific and research purposes." From 1987 to 1996, Japan launched four satellites that had land imaging sensors of better than 50 meters resolution.

The first two, Marine Observation Satellites 1 and 2, launched on 19 Feb. 1987 and 7 Feb. 1990, respectively, focused on ocean and atmospheric data but also carried two land imaging sensors that had 50-meter resolution and 100-kilometer swaths. When combined with a 15-kilometer overlap, their total swath matched Landsat's 185 kilometers exactly. The sensor's 15-kilometer overlap, also provided stereo images. The next satellite, Japan Earth Resources Satellite (JERS-1), launched on 11 Feb. 1992, was devoted totally to Earth resources. It carried both optical and radar sensors; each had 18-meter resolution and a 75-kilometer swath. Its successor, the Advanced Earth Observing Satellite (ADEOS), launched on 17 Aug. 1996, was like the MOS satellites, a combination land, ocean, and atmospheric measurement system. The land sensor, the Advanced Visible and Near-Infrared Radiometer (AVNIR), added a Pan band that had 8-meter resolution and the additional capability of tilting from side to side for faster site-return opportunities. The Japanese have consistently opted for large satellites that have many sensors (Table 2 lists only the land imaging sensors; each had several others). That is often the preferred scientific approach because it provides the opportunity for comparing multiple observations of the same site. The unfortunate early demise of ADEOS has caused a large gap in the Japanese satellite program. They have, however, ambitious plans to continue in the land imaging field and are currently building their Advanced Land Observing Satellite (ALOS) for launch in 2004. ALOS will carry both optical and radar sensors. Its two optical sensors contain advanced features that are required to meet the mission's goals of mapping at 1:25,000 scale without the use of ground control points and with 3.5-meter vertical accuracy for contour plotting. The panchromatic remote-sensing instrument for stereo mapping (PRISM) provides continuous three image stereo (fore, nadir, and aft) and has 2.5-meter resolution and a swath of 35 kilometers. The nadir view has a swath of 70 kilometers. The advanced visible and near-infrared radiometer-2 (AVNIR-2) has four spectral bands at 10-meter resolution and a 70-kilometer swath and has the ability to swing off-track for quick return viewing. Its other major goal of 24-hour response for covering disasters requires both pointing and an all-weather capability of the radar system. It will be an impressive test of the value of a multisensor suite on a single satellite.

Japan has also supplied a major new land imaging sensor, the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) that is currently flying on NASA's Earth Observation Science (EOS) Terra Satellite. See discussion later.

Russia. Russia was the first to use CCD push-broom technology in space for the 18 June 1980 launch of the experimental Meteor-Piroda-5 satellite carrying the MSUE-E (multispectral scanning unit electronic) that had three spectral bands, a spectral resolution of 28 meters, and a swath of 28 kilometers. This successful test was followed up by incorporating several versions of this sensor into a series of land remote sensing satellites similar in function to Landsat, called the Resurs-O1 series. Operated by SRC Planeta, a large conglomerate of scientific and industrial centers, the four satellites provided moderate (45-meter) resolution multispectral images. Resurs -01 #1 was launched on 3 Sept. 1999, #2 on 20 May 1988, #3 on 4 Sept. 1994, and #4 on 7 July 1998. None is currently operational (14). Unlike France, India, and the United States, Russia did not commercialize these data.

However, Russia was the first to offer high-resolution imagery on the commercial market. The Soviet trade association Soyuzkarta offered 5-meter imagery in 1987, and in 1992, two Russian firms began to sell selected images whose resolutions were as low as 2 meters (16). As noted previously, the 2-meter commercial sales were important in pushing the Clinton administration into a commercial licensing policy that has granted licenses for 1- and 0.6-meter commercial resolution systems. The Russian data were digitized from film data taken by their military satellites. The Soviet and the Russian agencies concluded many sales distribution agreements with U.S. and European market organizations (17), but none has been commercially successful. The most aggressive of these programs was SPIN-2 (for Space Information, 2 meter resolution). In July of 1995 Sovinformspутnik signed a contract with a group of American companies, Aerial Images, Central Trading Systems and Lambda Tech International, for a bulk supply of 2-meter imagery of the southeastern part of the U.S. The contract envisioned American customers paying for the launch and operation of a Kometa film carrying satellite. The first attempt on 5/14/96 was lost due to failure of the Soyuz-U rocket. The second launch and flight from 2/17/98 to 5/2/98 was a success. However the commercial sales, in spite of a companion agreement with Microsoft for the development of a system for selling imagery on the Internet, failed to materialize, putting an end to future launches. However, data from a wide range of sensors, including two synthetic aperture radars, are still being offered (17) and are potentially useful to those seeking to chart land surface changes during the last 20 years.

In addition to making images from its military satellites available, Russia has many plans for future satellites (17), but all are apparently on hold at present due to the lack of available resources. However, it can be expected that their considerable experience in optical and radar technology and their ongoing launch and spacecraft activities will someday bring them back into the commercial imaging market.

China. China's first venture into land satellite sensing was carried out in cooperation with Brazil. The China/Brazil (CBERS) satellite carries two multispectral sensors, the HRCC (high-resolution CCD camera) and the IRMSS

(infrared multispectral scanner). The HRCC is a push-broom sensor that has five 20-meter resolution bands and the ability to image off-axis to provide repeat viewing in 3 days. The IRMSS is a whisk-broom scanner like the TM and has the same bands: 76-meter resolution in the reflective bands and 156-meter resolution for the thermal. Both sensors have a 120-kilometer swath. The IRMSS also is like the TM and the ETM in that it has an onboard calibration system that includes both an internal calibrator and a solar calibrator that provide 3% band to band and channel to channel calibration precision and absolute calibration accuracy of less than 10%; these figures compare favorably with the TM. The satellite also carries a wide field imager that has 250-meter resolution and an 885-kilometer swath. The two countries have apparently made no attempt to make the data available in the marketplace. The first CBERS was launched on 10/14/99 and the second is scheduled for 8/10/03. The two countries have also announced plans for CBERS 4 and 5 that will add a 5 meter panchromatic sensor to the multispectral capability of CBERS 1 and 2. China has also launched two satellites of its own, Ziyuan ZY-2A and 2B launched on 9/1/00 and 10/27/02 respectively. Both have panchromatic sensors, the first reportedly of 9 meters resolution and the second 3 meters.

Korea. Korea launched its first satellite on 10 Aug. 1992 as part of its program to gain space technology capability and has supported an increasingly aggressive program since then. KITSAT-3 (Korean Institute of Technology Satellite 3) launched on 26 May 1999 was Korea's first medium-resolution land imaging satellite. Its Multispectral Earth Imaging System (MEIS) sensor has three 15-meter resolution bands and a 50-kilometer swath. The KITSAT series was followed by the KOMPSAT (Korea Multi-Purpose Satellite) series. KOMPSAT-1, launched on 20 Dec. 1999, carries an electro-optical camera (EOC) that has a 6.6-meter Pan band and a 17-kilometer swath. It is designed to obtain cartographic maps of Korea at 1:25,000 scale. It also carries an ocean color sensor. KOMPSAT 2 is being developed for launch in 2004 to provide surveillance of large-scale disasters. The plan is for it to carry a 1-meter Pan and a 4-meter, four-band multispectral sensor (14).

The Current Period

The third period, 1997 to the present, is dominated by the entrance of commercial high-resolution systems, but includes the return of U.S. activity in the form of an R&D program and the launch of the long-awaited Landsat 7. In addition, as discussed before, Korea, China, and Brazil, the latter two in a cooperative program, joined the civil land imaging satellite community in this period.

Commercial Satellites

As can be seen in Table 2, high-resolution systems image objects that range in size from 1.8 to 0.6 meters (6 to 2 feet). These resolutions are about the same as the original classified systems of the early 1960s. The private sector dominates in this capability range. Three of the four high-resolution mission satellites launched successfully to date have been commercial systems.

U.S. commercial systems are the direct result of the 1992 Land Remote Sensing Policy Act and the subsequent 1994 Clinton administration policy that led to licensing commercial resolutions as high as 0.6 meters. The commercial sector, after ineffectually pursuing a market in Landsat and SPOT images is hoping that satellite imagery of 1 meter or less resolution can be profitably marketed at prices that will capture some of the very large aircraft remote sensing market and create entirely new markets based on the satellite's ability to gather scenes anywhere, anytime, for anyone, clouds willing. The commercial companies are also well aware that their 0.6 to 1.0-meter resolutions are sharp enough to provide very useful information to the military and are pursuing both national and international defense markets.

These high resolutions have been achieved by restricting the width of their images to between eight and 16 kilometers and for those with color bands, limiting the spectral coverage to the VNIR bands. The narrow swath does restrict their utility for the broad area monitoring tasks of the Landsat type systems, but the satellites' ability to point off-track provides the capability to image any specific target at 1 to 2-day intervals. This agile pointing enables the acquisition of stereo images and thus the production of three-dimensional images.

Three American companies, Space Imaging (SI), Digital Globe (DG) (formerly Earth Watch), and OrbView and one Israeli company, ImageSat International (ISI), are currently offering high-resolution images commercially. They have had their share of launch failures. Prior to the successful launches, Digital Globe lost its first two satellites at or shortly after launch; OrbView, SI, and ISI, their first. Launch insurance has enabled them to survive to date. All recognize that their business cannot survive with single satellites, and the three U.S. companies are each planning follow-up satellites. ISI has published a very aggressive plan for six more launches by 2006 of a new and improved system that essentially copies Digital Globe's half-meter panchromatic and four-band multispectral capabilities. The timing of all of these future systems is somewhat uncertain because it depends on each company's ability to obtain the necessary funding from their slowly growing sales or from the currently troubled financial marketplace.

The technical success of the commercial systems has proven that the private sector can meet the technological challenges in providing sophisticated data products. As each company struggles to turn its technical success into a financial success, it is faced with a variety of challenges. The very technologies that have made spacecraft imaged data possible, digital sensors and GPS (the satellite Global Positioning System), have also increased the capabilities of their aircraft-based competition. The satellite's ability to get images of any and all countries is their prime advantage over their aircraft-based competitors. That feature is of interest to many multinational companies and to some nongovernmental organizations (NGOs). It is of great interest to governments for military and political reasons. The U.S. companies are pursuing agreements with foreign countries, but they face the perception that the "shutter control" clause in their government license would subject the availability of data to the whims of U.S. foreign policy. Several foreign governments have already announced plans for their own high-resolution satellites (see The Future section). In the United States, the administration is well aware of military utility of high-resolution data and has instructed NIMA (the

National Image and Mapping Agency) to use commercial systems to expand its capabilities and to reduce the requirements on its classified systems.

There may be another market niche. As noted previously, the Congressionally mandated commercial data buy for the Landsat Data Continuity Mission has prompted two companies, Digital Globe and Resource 21, to compete to provide NASA with Landsat data as a by-product of their own projected satellite data service, weekly crop health reports to farmers. These reports will enable farmers to take early remedial actions on the less productive areas, the so-called "precision farming" approach made possible in part by another satellite service, GPS. These systems will have the coverage and spectral capabilities of Landsat but at higher resolutions, 7.5 or 10 meters and more frequent coverage, 4 or 8 days.

At this time, it must be concluded that the commercial land imaging satellite programs are still in their start-up stage and that their future is still uncertain. The interested reader is advised to seek out their web pages to keep up with their progress.

Multi- and Hyperspectral Tests

These systems, 3 funded by the U.S. government and one by ESA, are space tests of advanced sensors. As shown in Fig. 6, the sensors include more and narrower bands to provide increased sensitivity for analysis. Aircraft tests have demonstrated that measurements of the radiance of essentially all of the spectrum using the so-called hyperspectral sensor provides increased ability to identify a wide range of geologic material and crops as well as to discern crop health and potential yield. Two of the new sensors have added increased thermal coverage that has also been demonstrated to improve crop classification and health status.

ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer), a Japanese sensor flown on NASA's Terra mission, has twice the number of Landsat's 7's spectral bands. It is actually a set of three telescopes flown together. The VNIR system includes a backward pointing telescope that is combined with its nadir telescope to provide 15-meter resolution, continuous stereo data. The six shortwave IR (SWIR) bands and the five thermal IR (TIR) bands, all at 15-meters resolution, are opening new analytical capabilities.

The MTI (Multispectral Thermal Imager) was developed by the DOE's Office of Nuclear Non-Proliferation to test the ability of multiband thermal data to measure the heat output of nuclear plant-cooling and thereby its power level. In addition to its four standard VIS 5-meter bands, it includes a unique series of 20-meter bands, three NIR, three SWIR, two MWIR, and three TIR. The DOE 3-year program includes imaging industrial, government, and natural sites. Unfortunately, its data have not yet received the attention of the broader research community they deserve.

EO-1: This NASA spacecraft is designed to test advanced technologies of potential use in the next Earth resources satellite. It carries two 30-meter resolution sensors: the Advanced Land Imager (ALI) with six VNIR bands, three SWIR bands, and one 10-meter resolution pan band; and a hyperspectral imager, Hyperion, which has 220 bands covering the VNIR and SWIR range. It has been placed in orbit near Landsat 7 to obtain comparative data sets. An extensive scientific and

application analysis program is in process as this is written. It has proven so useful that EO-1 operations are being continued beyond their planned duration by selling data to several government agencies. The ALI push-broom approach resulted in a sensor that is one-quarter the weight and one-seventh the volume of the ETM+ but provides three more bands and a 10-meter pan band (18).

PROBA: PROBA is a technology demonstration satellite designed to demonstrate many advanced satellite technologies in a manner similar to EO-1. It carries CHRIS, an experimental hyperspectral imager that can be programmed to produce either 19 VNIR bands with 18 meter resolution or 63 bands with 36 meter resolution. It also carries an 8 meter resolution panchromatic sensor.

Radar

Radar images through clouds and at night; this can be very important in those parts of the world like the tropics and Europe that are cloud-covered a high percentage of the time. Their sensitivity to a target's size, shape, and material characteristics and to its moisture content provides an entirely different information set than an optical system's measurement of reflected and emitted radiation. Radar sensors come in a variety of types based on their signal frequency and signal and reception polarization. To date, all satellite radar systems have been single frequency, which, like panchromatic optical data, are very valuable for mapping type functions but are not very good at classification functions.

Radar has not yet been used in civil Earth observation satellites to the extent that the optical sensors have. As the discussion on future systems below notes, this may change in the next decade. Figure 1 shows the orbit history of the civil radar satellites to date. Seasat was a multisensor satellite developed by NASA in cooperation with the Navy. Its SAR sensor is regarded as the first imaging SAR system used in Earth orbit (14). Launched 27 June 1978, it failed abruptly 106 days after. In spite of its short life, it was a great success. The quality of its data was responsible for ESA's 1981 decision to favor development of a radar system. ESA was stimulated by radar's ability to image through Europe's frequent cloud cover (19). As can be seen in the figure, ESA has maintained the continuity of its radar program to the present. In the United States, radar data were apparently judged so potentially valuable for military use that civil radar satellites were discouraged, and there have been no U.S. civil radar satellites to date. The current Defense Department position limits civil systems to five-meter resolution, a restriction that caused Canada to cancel their contract with an American firm and turn to Italy to build its planned 3-meter system.

At present, the uses of single-frequency systems are many and impressive. A short list would include oil spill detection, ice movement monitoring, mapping (one of Canada's prime applications), monitoring forests and agricultural land in the tropics, geological mapping aided by its oblique viewing angle and vegetation penetration capabilities, and disaster evaluation, especially cloud-covered floods. Using data from two overflights, radar satellites can provide interferometric maps of surface elevation changes of the order of a few centimeters.

Current and planned radar satellites come in two styles. ERS-2, Envisat, and ALOS-1 carry many other observation sensors along with their SAR. Canada's current and planned Radarsats are dedicated to their SAR mission.

A discussion of radar satellites would not be complete without mentioning the NASA-sponsored Shuttle-based radar sensor program. Although restricted from creating free-flying radar satellites, NASA's Jet Propulsion Laboratory (JPL) was able to advance the technology in a series of five Shuttle missions carrying radar sensors. SIR A, flown in 1981, and SIR B, flown in 1984, carried L-band sensors. The third and fourth Shuttle missions, SIR C/X-SAR, flown twice in 1994 in cooperation with Germany and Italy, consisted of separate but connected L, C, and X-band SARs. The long and complex analysis program of that data has shown that multifrequency radar analysis can serve many of the applications that multispectral analysis has made possible for optical systems, which, in effect, could lead radar into closer competition with the now dominant optical world. The fifth Shuttle mission produced what may be space-based radar's most useful accomplishment to date. The 10-day Shuttle Radar Topographic Mission (SRTM) was sponsored by NASA and NIMA and launched on 11 February 2000. It carried two SIR-C/X SARs separated by a 200-ft boom attached to the Shuttle's bay. The data from the resulting continuous stereo view produced a topographic map of the land surface on which 95% of Earth's population lives and which is 80% of the total global land surface. Surface elevation of all ground points 30 meters apart will be provided to scientific investigators, and elevations 90 meters apart will be open to the public.

The Future

Predicting satellite launch dates, even by those who are paying for them, is a risky business. Since 1995, the author has tracked the progress of more than 30 land imaging satellites. The delays between the first announced launch and the actual launch date averaged a bit more than 2 years, and nine of the 30 had an average of a 4-year delay. Keep this history in mind while reading the following discussion.

Even without firm knowledge of the status of many of the satellites being proposed, one thing is certain, that civil land imaging satellites will be spread over the globe. This is dramatically illustrated by Fig. 15. As its caption aptly states, "Global competition is heating up." There are 16 foreign countries that have plans for land imaging satellites. The 1-meter and better satellites, currently mostly the province of the U.S. commercial sector, will be seeing a significant part of this global competition in the form of government systems in France, Italy, Korea, and India, as well as the multisatellite plans of Israel-based ISI.

The most mature of these plans have been noted in the previous sections, but as this is being written, both governments and private corporations are discussing/announcing ever more ambitious plans. Rapid/Eye of Germany continues to promote its plans for a commercial four-satellite, 6-meter system to provide a crop monitoring service similar to that being proposed by the LDCM contractors. The French and Italians are discussing the development of a five-satellite, 1-meter satellite system to be launched by 2005/2006 made up of the French Pleiades two-satellite optical system and the Italian Cosmos-Skyimed three-satellite radar program (14). The German

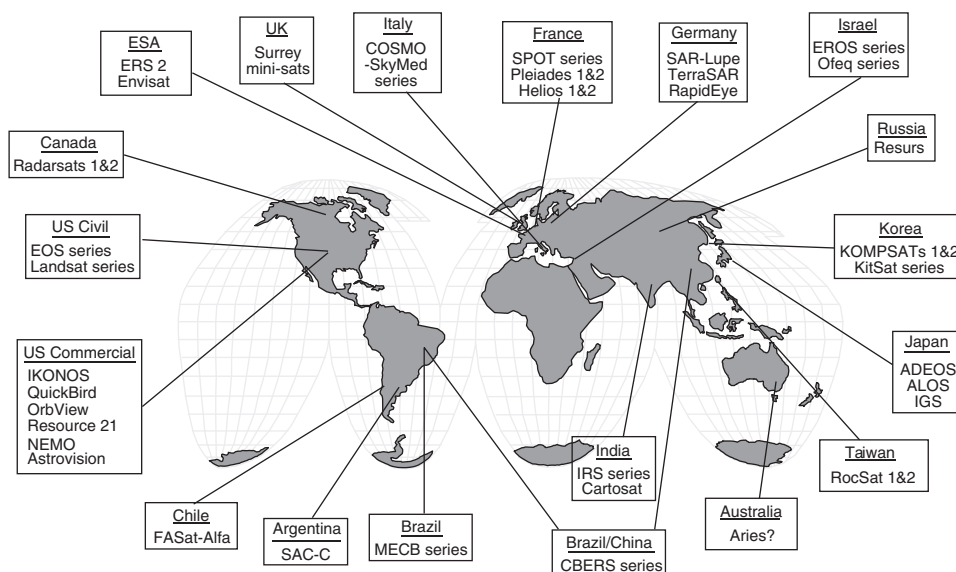

Figure 15. Global competition is heating up. Reproduced by the kind permission of John Baker and the Rand Corporation.

government announced TerraSarX and TerraSarL, a 1-meter radar satellite program planned for launch in 2006. These somewhat competing programs are the subjects of much debate in the European Union planning process. However, should most of these plans carry through to launch, there could be 19 1-meter or better systems in orbit by the end of 2006, including three to five radar systems.

A new approach to combining daily coverage and medium resolution land observation capability by creating a constellation of small low cost microsatellites (as much as 1/5th the cost of current commercial systems) is being developed by the British company, Surrey Satellite Technology Ltd. (SSTL) (20). An early example is already in orbit. UoSAT-12, developed and funded by SSTL, carried payloads from Singapore and ESA into a 64° inclination orbit on a Russian launcher on 12 May 1999. Its payload included one 10-meter resolution panchromatic sensor that had a 10-kilometer swath, one 975-meter resolution sensor that had a 1000-kilometer swath, and two 32.5-meter resolution multi-spectral sensors that had 33-kilometer swaths. SSTL is currently building a five-satellite Disaster Monitoring Constellation (DMC) that will be capable of providing 32-meter resolution, three-band color images of any location once per day (14). The first mission sponsored by Algeria was launched from Russia on November 28, 2002, and four more are scheduled in 2003 (21). The other sponsors are Nigeria, UK, Thailand, and Turkey. China and Vietnam are planning similar systems for launch in 2004 that carry a 4 meter panchromatic sensor. It is clear from the number of nations involved, that remote sensing of one's land from space brings out a strong desire to have one's own satellite for reasons that appear to be a mixture of security, practical applications, and simple national pride.

Summary

Of all efforts to date to use our ability to operate satellites in space for the betterment of life on Earth, the U.S. Landsat program certainly ranks among the most successful. It invented and implemented a whole new technology, a truly new and powerful way of looking at Earth through the analysis of its reflective and emitted radiation, a method that for the first time has made it possible and practical to monitor the entire surface of Earth on a regular basis at resolutions capable of observing and assessing human-scale activities. At the same time, the Landsat program and other government programs actively spread the data and the technologies involved throughout the whole world, with specific emphasis on third-world countries. The technical achievements are significant, but it may be that this worldwide sharing will be its enduring monument.

All of this was accomplished despite the difficulties the program encountered from before its birth to the present, difficulties related to national security issues, agency roles, delays in data delivery, funding uncertainties, and a failed attempt to commercialize the federal program. Its 30 years of synoptic global data remain the only systematic collection of consistent global land images. The current U.S. policies of having Landsat image the entire global land surface four times a year and of providing data to all for the cost of reproduction has yet to be emulated by any of the foreign satellite systems.

The rest of the world started their civil land imaging programs 15 years later, and they have launched more than twice the number of missions. France and India equaled or bettered the launch pace of the early Landsat years, and both countries have strong plans to continue and improve their systems. Japan and Russia started just as vigorously, but halted after their late 1990 launches. Japan has seemingly firm plans to restart its program in 2004, and Russia's future plans remain uncertain. Although foreign optical satellite programs have been very impressive and in some ways more innovative than the U.S. program, their image acquisition programs have focused on getting data for sale in the marketplace rather than on creating a synoptic archive of global images for scientific use.

The radar history is entirely different. The U.S. short-lived Seasat radar mission provided sufficient data for Russia, Japan, ESA, and Canada to create radar satellite programs that, Russia excepted, have been maintained to the present. To date, all of the civil land imaging radar satellites have been foreign, and current planning statements indicate that this situation will continue into the foreseeable future. This is due to a combination of reasons, including Europe's persistent cloud cover, Canada's strong interest in mapping the changing ice fields of their North, and the reluctance of the U.S. defense establishment to allow civil radar systems.

Until the late 90's all of the systems were funded by their respective governments. As a result of the U.S. 1992 Land Remote Sensing Policy Act that permitted the development and operation of civil satellites with resolutions in the meter or less range, the pull of the marketplace entered the land imaging satellite game. This was a significant break with the tacit international policy of keeping high-resolution "spy quality" data as the exclusive province of

governments. This opening of high-resolution data to the civil sector was helped by Russia's commercial sale of 2-meter data, but was vigorously protested by France as well as by U.S. defense agencies. Congress' motivation was based on the belief that meter-level systems could compete with aircraft data for that multibillion dollar market and that sharing the cost of such satellites with a commercial market would dramatically reduce the government's data costs. At this time, it still is uncertain if purely commercial systems will find a sufficient market share to ensure their future.

In any case, the secrecy genie is out of the bottle. The availability of meter-scale data in the open marketplace has opened the door to data uses far beyond the scientific and large-scale land management functions of the Landsat resolution data. The door has been opened to global information transparency that can change the relationships between nation and nation and between citizens and their governments (1). The political, scientific, and commercial currents during the next 25 years of Earth-observing systems will be no easier to chart than were the first, but the systems they spawn will certainly advance the understanding and informed use of the planet's resources and aid in establishing the trust among nations, that will make global environmental management possible.

Further Reading

The history, description, technologies, data analysis and data distribution of the Landsat program up to 1997 are covered in detail in the journal *Photogrammetric Engineering & Remote Sensing* 63 (7): July 1997 that commemorated the twenty-fifth anniversary of Landsat. The authors are individuals closely involved with that aspect of Landsat activity they treat, and the papers listed must be considered as basic source material:

Lauer, D.T., S.A. Morain, and V.V. Salomonsons. The Landsat program: Its origins, evolution, and impacts.

Mika, A.M. Three decades of Landsat instruments.

Thome, K., B. Markham, J. Barker, P. Slater, and S. Biggar. Radiometric calibration of Landsat.

Landgrebe, D. The revolution of Landsat data analysis.

Drager, W.C., T.M. Holm, D.T. Lauer, and R.J. Thompson. The availability of Landsat data: Past, present, and future.

Ecological Indicators for the Nation. National Academy Press, 2000.

A useful examination of the policy issues:

Harris, R. *Earth Observation Data Policy*. Wiley, 1997.

A basic textbook on remote sensing and image interpretation:

Lillesand, T. M., and R. W. Kiefer. *Remote Sensing and Image Interpretation*, 3rd ed. Wiley, 1994.

A detailed guide to the theory and practice of multispectral imagery:

Multispectral Imagery Reference Guide. Logicon Geodynamics Inc. Spectral Imagery Training Center, 1997.

The Internet

The above suggested reading will be useful. However, the field is a rapidly evolving one and the reader is well advised to make use of the internet. The NASA and USGS home sites have directions to sites specifically devoted to Landsat and other satellite imagery. All of the commercial companies have their own sites, easily located by any search engine. The same is true of all of the countries involved in satellite sensing. Finally, news about the status of any particular satellite can often be found by typing its name into Google.

Introduction

The solar system formed 4.6 billion years ago from a cloud of dust and gas called a molecular cloud (1). The molecular cloud was composed predominantly of hydrogen and helium gases and a small amount of heavier atoms and molecules that had been formed during the lifetimes of previous generations of stars. In addition, refractory (heat resisting) dust grains were also present in the cloud. Something, perhaps a nearby supernova, caused increased density regions to form within this molecular cloud. If these cloudlets became massive enough, then they would gravitationally attract the nearby gas, causing the cloudlets to increase in mass and contract. Any residual motion or small rotation within the gas would cause these cloudlets to spin more rapidly as they contracted under gravity. These spinning cloudlets formed the center of the protosolar nebula. The cloud collapsed from the inside out. The rotation caused the nebula to flatten into a disk with most of the mass in the disk and in a bulge at the center. However, there was still some gas in a halo around the disk.

As the central bulge collapsed, it added more material from the surrounding disk and halo. Gravitationally, the center collapsed to a smaller sphere, and the pressure and temperature increased. When the pressure and temperature were sufficiently large (temperature of a few million degrees), the hydrogen atoms in the core of the sphere started to fuse into helium, and the cloud became a new

star. At this point, the star was still surrounded by a disk of material and a halo of gas. The high luminosity of the infant star propelled a “wind” of material flowing outward along its rotational axis, creating a bipolar flow. This blew away much of the material in the surrounding halo, stopping the infall onto the disk. It is within this disk that the planets themselves formed. We can estimate the minimum mass that this disk must have been to form the current planets by several methods: the percentage of rocky material in the gas (0.4% of the total) or the mass-loss rates of young stars ($3 \times 10^{-8} M_{\odot}$ /year for 3 million years or a total mass loss of $0.06 M_{\odot}$ where M_{\odot} is the current mass of the Sun). Thus, the disk from which the planets formed must have had a substantial fraction of the mass of the Sun and much of it was lost after the planets formed.

About this time, clumps of rock and ice started to grow in the disk. The clumps began to collide with one another and accrete (stick together), causing them to grow larger. Larger objects have greater gravitational attraction, so the biggest clumps grew bigger and “gobbled up” the surrounding material. The clumps grew until a critical size was reached, and then they collapsed into the cores of the planets. The largest core became our current-day Jupiter and was 20–30 times the mass of Earth after a few million years (it is currently 300 times the mass of Earth). Around the time the cores achieved such large masses, they began to have profound influences on the surrounding leftover material.

The timescales for these processes are short: the cloud collapse took around 10,000 years, the disk/wind clearing took around 100,000 years, and the initial building of planets was complete in around 10 million years (2).

As the Sun settled into the main part of its life as a normal star, the gravitational attraction from the protoplanets, along with the wind from the Sun, gradually removed the residual material from the disk. Some time after the molecular cloud started to collapse, our solar system consisted of the Sun, the major planets, and small quantities of leftover building blocks of planets, called planetesimals. The nature of these leftover planetesimals depended on where they were in the solar system relative to the Sun. Those nearer the Sun, in the region from Mercury through the asteroid belt (the so-called terrestrial planet zone), were predominantly rocky bodies. In the region from Jupiter onward (the so-called giant planet zone), the bodies were a combination of ices and rocky material. Note that “ice” in this context does not refer only to water ice, but includes ices of other more volatile materials such as carbon dioxide, ammonia, methane, and formaldehyde. The leftover planetesimals from this early period that still reside in our solar system (more on their fate later) are called comets. The comets of today are mostly unchanged from the time they were formed. *Thus, comets today preserve information on conditions when the solar system was formed and are of prime importance for providing constraints on conditions in the early solar nebula.*

Physical Properties

Comets present a striking appearance in the night sky. Their presence has been noted since ancient times; their name is Greek meaning “hairy ones.” Our modern understanding of their nature dates to the 1950s (3). Basically, a comet is a

“dirty snowball.” It is a small body; typical comets have nuclear dimensions of 1–20 km. This nucleus is composed of ices and dirt. As the comet approaches the Sun in its orbit, the nucleus is heated, causing the ices to sublime (sublimation is the process whereby materials go from the ice stage to the gas stage directly without ever becoming liquid). These gases form a coma around the nucleus as they flow outward from the nucleus into the vacuum of space. As the ices sublime and flow outward, they carry dust with them into the coma. The coma of a comet is not a bound atmosphere because the gravitational pull of the tiny nucleus is small. Instead, the coma gases are constantly being replenished via sublimation, and the gases in the outer coma are being lost into interplanetary space.

Once the coma has formed, it is extremely difficult to image the nucleus of the comet with ground-based or Earth-orbital telescopes because it is shrouded by the coma. Only two comets have had their nuclei fully resolved by imaging. Comet Halley was imaged by the Giotto and Vega spacecrafts in 1986. Using the high-quality Giotto images, we measured the nucleus as $8 \times 8 \times 16$ km, but it was actually quite an irregular shape. Comet Borrelly was imaged by the Deep Space 1 spacecraft with a size of $4 \times 4 \times 8$ km and, again, was quite irregular. Other comets have had nucleus sizes estimated by various other techniques. Unfortunately, the spacecraft did not travel close enough to Halley or Borrelly for the comet’s gravity to influence the spacecraft orbits, so we do not have any direct measurement of the density or mass of a comet. Various assumptions have led to the concept that the density is between 0.2 and 1.2 g cm^{-3} (water has a density of 1.0 g cm^{-3}).

As the comet continues in its orbit around the Sun, the Sun is exerting an outward force known as radiative pressure on the dust, pushing the small dust grains away from the Sun. Thus, the dust ends up lagging the comet in its orbit around the Sun. The combination of the radiative pressure of the Sun and the Keplerian motion of these particles as they continue in orbit around the Sun causes the dust to curve away from the comet on a track outside of the cometary orbit and form a tail known as a dust tail. However, not all comets develop dust tails.

Interplanetary space is not empty, and the comet interacts with its local environment. In addition to emitting radiation at most wavelengths, the Sun sheds ionized material in the form of the solar wind. The solar wind is a hot ($\sim 100,000$ K) plasma consisting of an electrically neutral mixture of ions (mostly electrons and protons) that originates in the solar corona, is accelerated into interplanetary space, and drags along the solar magnetic field. By Earth’s orbit, the bulk velocity of the solar wind reaches a maximum of $200\text{--}800 \text{ km sec}^{-1}$. Comets have no intrinsic magnetic fields or ionospheres, but they are continually releasing neutral gases through sublimation. Some of these gases become photoionized. Some tens of thousands of kilometers on the sunward side of the nucleus, a bow shock forms (a sharp boundary separating the ionized material of the comet, called the magnetosphere, from the solar wind material which is forced to flow around the comet) at the distance where the kinetic pressure of the solar wind particles equals the magnetic pressure of the ionized gases. As the solar wind magnetic field drapes around the comet, the solar wind exerts a tangential force on the boundary on the side away from the Sun, dragging the plasma into a long tail called the magnetotail. On opposite sides of the

magnetotail, the current travels in opposite directions. Inside the magnetotail, where the opposing currents meet, is a neutral region called the neutral current sheet. In addition, the solar wind reacts with the ionized coma gases, pushing the ionized gases outward. This forms what is known as the ion tail of a comet. The ion tail is straight and always points directly away from the Sun, which means that it sometimes leads the comet in its orbit. Not all comets display ion tails.

Figure 1 shows a picture of comet Hale–Bopp. This comet was discovered in 1995 by Alan Hale and Thomas Bopp (independently) and came closest to the Sun on 1 April 1997. This image was obtained with a CCD camera (an electronic detector) and special filters on the 0.76-m telescope of McDonald Observatory. The various parts of the comet are labeled in this picture.

The nucleus is quite small, but the dimensions of the rest of the comet are substantial. A typical cometary coma is more than 1 million km in radius, or substantially *bigger* than the Sun. However, as large as the coma is, it is quite insubstantial and has a density that qualifies it as a better vacuum than can be created in most laboratories (a pressure of $10^{-8} - 10^{-9}$ torr)! The tail of the comet can stretch to several hundred million km behind the comet, but the tail has densities even lower than the coma.

A comet does not shine from its own radiation. Instead, the light from the Sun is reflected from the dusty material, and the gas generally “glows” by a process known as fluorescence. (Fluorescence occurs when an atom or molecule reaches an excited state by absorbing a photon and then returns to a lower state by emitting a photon. Fluorescence is termed resonance fluorescence when the wavelength of the

Figure 1. An image of comet Hale–Bopp obtained by the 0.76-m telescope of McDonald Observatory. The image is approximately 40 arcmin on a side. The parts of the comet are labeled on the picture. This is an image obtained by a CCD camera.

exciting photon has the same energy as that of the downward transition and the atom or molecule goes back to the energy level from which it started).

Very far from the Sun, there is not enough heat to sublime the gases of the comet. Therefore, if a comet were viewed at large distances from the Sun, it would appear just as a small, rocky, icy body that has no coma. However, comae have been detected around cometary nuclei at distances past Saturn's orbit [e.g., (4)].

Cometary Orbits and Origins

A comet is generally discovered as a fuzzy object that is moving with respect to the background stars. About half of the comets are discovered by amateurs, who scan the skies looking specifically for comets, and the other half are discovered by professional astronomers who are obtaining images of the sky when they discover the comet. Discoveries of comets are relayed to the International Astronomical Union's (IAU) Central Bureau for Astronomical Telegrams for confirmation and assignment of a designation.

Each cometary discovery is given an official designation by the IAU that consists of the year of discovery followed by a letter identifying in which half month of the year the discovery is made (e.g., January 1–15 is A, January 16–31 is B, ... , December 16–31 is Y; the letter I is not used for half month designations) and by a consecutive number to indicate the order of discovery in that half month. Thus, the fourth comet discovered in the first half of March 1996 would have been designated 1996 E4. This gives each comet a unique name. In addition, comets are named for their discoverer(s); up to three names are assigned to the comet. Thus, the comet that is shown in Fig. 1 is officially comet 1995 O1 (Hale–Bopp) and was the first comet discovered in the second half of July 1995. It was discovered by Alan Hale and Thomas Bopp.

The position of the comet needs to be measured carefully with respect to a fixed reference frame of distant stars or quasars. These positions are then used to compute an orbit around the Sun, taking into account the gravitational influence of all of the planets. All known cometary orbits are elliptical; the eccentricity e of the orbit ranges from close to circular, in the case of comet Schwassmann–Wachmann 1, to parabolic. (Note that the orbits of the planets are very close to circular, except for Pluto.) If it takes the comet fewer than 200 years to orbit the Sun, a comet is termed to be in a periodic, or short-period, orbit. Strictly speaking, all comets are in periodic orbits, in the sense that they are gravitationally bound to the Sun, but some of the comets have periods that are so long compared with a human lifetime that they are designated as long-period or nonperiodic comets. The division at 200 years is purely arbitrary and historical.

The orbits of the major planets are all confined, more or less, to a single plane. If we define the plane of the ecliptic as the plane of Earth's orbit around the Sun, we find that, except for Pluto, all of the major planets are in orbits that are inclined by no more than 7° from the plane of the ecliptic. Even Pluto is inclined only 17° from the plane of the ecliptic. All of the planets also travel around the Sun in the same direction, which we call the prograde or direct sense. Prograde orbits confined near the plane of the ecliptic are consistent with our picture of the formation of the solar system from a disk of material surrounding the newly

forming Sun. For convenience in describing the location of objects in our solar system, astronomers use a distance known as an *Astronomical Unit* or AU, which is defined as the mean distance of Earth from the Sun. It is approximately 1.5×10^8 km. The heliocentric distance of an object is its distance from the Sun.

Cometary orbits have properties very different from the orbits of the planets. Taken in aggregate, there is no preferred inclination of cometary orbits to the plane of the ecliptic. Some comets have orbits that travel around the Sun in the direction opposite from the planets, or retrograde. An example of a comet that has a retrograde orbit is comet Halley.

For now, we will ignore the short-period comets and concentrate on the orbits of the comets that have long- or non-periodic orbits. The semimajor axis of an ellipse is designated a . The inverse $1/a$ of the semimajor axis is proportional to the orbital binding energy, which is the additional energy a comet would need to escape the gravitational attraction of the Sun completely. If $1/a < 0$, the comet is not bound to the Sun.

For long-period comets, we can compute a quantity $1/a_0$, the inverse semimajor axis of the *original* orbit, where the original orbit is the orbit of the comet integrated backward in time to the point before it entered the planetary system and referenced to the barycenter of the solar system. Figure 2 is a histogram of $1/a_0$ (data from Reference 5 with updates). Note the pronounced peak in the histogram around $a \sim 20,000$ AU. This peak was first noticed by Oort in 1950 (6) using a sample of only 19 cometary orbits. From such a histogram, Oort concluded that the solar system must be surrounded by a spherically symmetrical halo of comets, gravitationally bound to the Sun, and at distances greater than 10,000 AU. This halo of comets is currently called the Oort cloud. The position of its inner edge is quite uncertain, but the position of its outer edge is defined by the Sun's tidal truncation radius of 100,000–200,000 AU (7).

Oort realized that the typical change in energy that a comet receives when it passes through the planetary system (the part of the solar system within Pluto's orbit) is approximately $\pm 0.0005 \text{ AU}^{-1}$. Yet the peak in Fig. 2 is fairly narrow. It is unlikely that a comet that started out in the peak on its first passage into the planetary system would have a value of $1/a$ which would leave it in the peak on subsequent passages. Thus, we refer to comets where $a \geq 10,000$ AU as dynamically "new" comets because it is likely that they are on their first passage into the planetary system. Comets not in the peak in the histogram have most likely passed through the planetary system before. On a first passage into the inner solar system, gravitational perturbations from Jupiter would eject roughly half of the new comets and capture the other half to more tightly bound (smaller values of a), less eccentric orbits. Only 5% of new comets would be returned to Oort cloud distances (8).

Returning to the short-period comets, Fig. 3 plots the inclination i as a function of semimajor axis a for the 130 short-period comets that are currently cataloged. Note that the vast majority of these objects have semimajor axes between 3 and 4 AU. This group of objects tend to have their *aphelions* (farthest distance from the Sun) near Jupiter and have small encounter velocities with Jupiter. The orbits of this group of comets are highly influenced by Jupiter. These comets have come to be known as Jupiter-family comets (JFCs). Typically, there has been an arbitrary cutoff for JFCs at an orbital period of 20 years. This limit is

Figure 2. The number of comets as a function of inverse original semimajor axis. The data for this histogram are from Reference 5 with further updates from Marsden (personal communication). Note the sharp peak at $1/a_0$ slightly larger than 0. This is the evidence that there is a spherical reservoir of comets known as the Oort cloud.

shown as a dotted line in the plot. Comets whose orbital periods are between 20 and 200 years are referred to as Halley-type comets (HTCs), after their most famous member that has a 76-year orbital period.

In Fig. 3, note that all of the JFCs are in prograde orbits that have relatively low inclinations (a mean of $\sim 13^\circ$) and some of the HTCs are in retrograde orbits ($i > 90^\circ$; the HTCs have a mean inclination of $\sim 78^\circ$). These differences in properties suggest that the JFCs and HTCs may be dynamically different and perhaps have different origins.

Most of the JFCs are clustered at inclinations of less than 35° , suggesting that the three comets whose periods are less than 20 years but inclinations are greater than 40° may be different from the other JFCs. Carusi et al. (9) have offered an alternate, less arbitrary, definition for the division between JFCs and HTCs. They suggest that the boundary should be based on a parameter known as the Tisserand parameter T , which is defined as

$$T = a_J + 2\sqrt{(1 - e^2)a/a_J \cos(i)}, \quad (1)$$

Figure 3. The inclination as a function of the semimajor axis for the short-period comets. In this figure, the orbits for the 130 cataloged short-period comets are shown. The dotted line divides the plot into two segments based on the traditional separation between Jupiter-family and Halley-type comets of orbital period = 20 years. The open circles are those comets whose Tisserand parameter (see text) $T > 2$; the closed circles are comets where $T < 2$. Jupiter-family comets are confined to the plane of the ecliptic, preferentially, whereas Halley-type comets are not.

where a_J is the semimajor axis of Jupiter's orbit and a , e , and i refer to the semimajor axis, eccentricity, and inclination of the cometary orbit. In their scheme, the division between JFCs and HTC's would be $T = 2$. The Tisserand parameter is a measure of the relative velocity between Jupiter and a comet during a close approach, here $v_{\text{rel}} \propto \sqrt{3 - T}$. Objects where $T > 3$ cannot cross Jupiter's orbit and are confined to orbits either totally interior to (the case for Comet Encke) or totally exterior to (the case for Chiron) Jupiter's orbit. In Fig. 3, the value of the Tisserand parameter is coded as an open circle for comets where $T > 2$, or JFCs, and closed circles for $T < 2$, or HTC's. Inspection of this figure now shows that the JFCs in this definition all have low inclinations with a mean of 11.6° , whereas the HTC's seem to have no preferred inclination. Note that this definition is an improvement over the 20-year period definition because it takes into account Jupiter's gravitational influence on the comets. Thus, this definition, along with some modifications (10), is now being widely adopted to differentiate between different types of comets.

Note that the orbits of the HTC's are reminiscent of the long-period and nonperiodic comets in that there are no preferred inclinations for their orbits. Thus, both of these types of comets appear to come from a spherical reservoir of a form different from the disk envisioned for forming the planets. JFCs, on the other hand, have low inclination orbits. For this reason, they are sometimes referred to as ecliptic comets.

How do comets get from the outer solar system to the inner solar system? The most important force acting on Oort cloud comets is the gravitational effects of the disk of our galaxy (11,12). The gravitational tidal forces of the galactic disk will cause the Oort cloud to be a prolate spheroid whose long axis points toward the center of the Galaxy. This force acts like a torque on each comet and leaves

the semimajor axis virtually unchanged but causes the perihelion distance (closest approach distance to the Sun) to undergo a random walk. When the perihelion distance crosses into the planetary system, the planets (especially Jupiter) begin to have a major influence on the orbit.

Other external forces that influence cometary orbits are passing giant molecular clouds (GMCs) or stars passing through the Oort cloud. These are much less important than the Galactic gravitational field. Passing GMCs are rare events that have a mean interval of occurrence of 300 million years (8). However, when they do occur, they have a major effect on the part of the Oort cloud they pass.

During the lifetime of the solar system, about 5500 stars have passed within 100,000 AU of the Sun. A star of the same mass as our Sun tunneling through the Oort cloud with a velocity of 20 km sec^{-1} will eject all comets within about 450 AU of the star. Passing stars have probably ejected about 10% of the total population of the Oort cloud (8).

It is estimated that the mean dynamic lifetime of comets in the Oort cloud is only about 60% of the age of the solar system. Thus, the Oort cloud must somehow be replenished for Oort cloud comets to exist still. One possibility for replenishment is the capture of comets that originally formed around other stars and then were ejected into interstellar space. This process is very unlikely because the relative velocity of these comets with respect to our solar system makes them difficult to capture.

A more likely scenario for replenishing the Oort cloud is that an inner Oort cloud exists at a few thousand AU from the Sun whose cometary orbits are perturbed to move them from the inner Oort cloud to the outer Oort cloud (13). When these inner Oort cloud comets are at aphelion, Galactic and stellar perturbations would be sufficient to raise their perihelia from the inner to the outer Oort cloud. However, normal effects of the Galactic gravitational field would not affect them other than at aphelion, so that the orbits of inner Oort cloud comets would otherwise be stable for the entire lifetime of the solar system. There is no physical demarcation for the inner and outer Oort clouds, and the differences between these clouds is only a matter of definition. The inner Oort cloud is, in general, just the part of the Oort cloud that remains relatively inactive, whereas the outer Oort cloud is the principal source of comets that enter the inner solar system.

Let us return to the question of why the Oort cloud appears spherical although we theorize that comets are leftover debris from the formation of the planets in a disk of material surrounding the young Sun. Current dynamic simulations have shown that the comets did not form originally at the location of the present Oort cloud. Instead, the comets are leftovers from the region of the giant planets, Jupiter through Neptune (14). Small objects that remained in the region of the giant planets after the planets formed would come under the gravitational influence of these planets. As a planetesimal comes near a planet, the planet exerts a gravitational tug on the planetesimal. This excess force is strongest at the closest approach to the larger body, but because the two bodies are in different orbits that have different velocities around the Sun, the excess force is exerted only for a short time. This excess force changes the orbit of the planetesimal (because of conservation of momentum, it also changes the orbit of the larger planet, but by a very much smaller amount than the change in the

planetesimal's orbit because the mass of the planet is much larger than the mass of the planetesimal). Thus, the orbit of the planetesimal is changed in a random-walk fashion. When the planet that causes the change in orbit is very massive, such as Jupiter or Saturn, then the excess velocity imparted to the planetesimal is most often large enough to eject the planetesimal from the solar system on a hyperbolic orbit. Some small fraction of objects would have their orbits changed to orbits near Uranus and Neptune or out to the inner Oort cloud.

Uranus and Neptune are not massive enough to impart such a large increase in velocity. Instead, the influence of Uranus and Neptune would increase eccentricities, perihelia, and inclinations of the orbits. Ultimately, most of the objects that start in the solar nebular disk at the distance of the current Uranus and Neptune would end up in orbits whose semimajor axes are several thousand AU but their orbits would no longer have inclinations that were small with respect to the plane of the ecliptic. Instead, the perturbations of the orbits by Uranus and Neptune would randomize the inclinations, and the planetesimals would form a spherical cloud at the distance of the inner Oort cloud. From there, they would populate the outer Oort cloud.

Thus, we are able to start with a disk of material in the protoplanetary system and, through the influence of gravity, the major planets perturb the orbits into the spherical Oort cloud. Most of the Oort cloud comets were formed in the Uranus/Neptune region, whereas Jupiter and Saturn ejected most of the leftover debris that existed near their orbits.

Let us return to the short-period comets. In Fig. 3, it was shown that there are two dynamic classes of short-period comets, the JFCs and HTC. Using the Tisserand parameter definition for delineating these two groups, we noted that the average inclination of the JFCs was low (11.6°) and no orbits had inclinations greater than 35° . This is quite reminiscent of the original protosolar disk. The HTCs, however, show no preferred inclinations. In 1988, Duncan et al. (15) showed, by computer simulations, that it was impossible to reproduce the low-inclination, short-period comet orbits from perturbations of the spherical Oort cloud because comets that enter the planetary system from the Oort cloud would preserve their random inclinations. Duncan et al. showed that a cometary source that has a low orbital inclination distribution was far more consistent with the observed orbits. They posited that a belt of comets must exist outside Neptune's orbit that were the source of the short-period comets. They named this reservoir the Kuiper belt because it was first suggested by Kuiper in 1951 and Edgeworth in 1949 that the disk of the protosolar nebula would not be truncated at Neptune's orbit. (Some scientists think that the reservoir for short-period comets should be named the Edgeworth–Kuiper belt, but this is not universally accepted.) Further computer simulations have shown that a significant fraction of the orbits of objects in the Kuiper belt would be stable for the lifetime of the solar system. Perturbations of the giant planets would be sufficient occasionally to stir up the objects near the inner edge of the Kuiper belt and bring these objects into the inner solar system. However, the inclinations of the perturbed objects would not be changed enough to lose the signature of a disk.

In summary, from dynamic considerations, our understanding of the structure of the outer solar system is that it consists of two parts. Starting from

around the orbit of Neptune, there is a disk of objects, known as the Kuiper belt. This disk has a thickness of order $\pm 25^\circ$. This disk is a primordial disk of objects (it formed at the same time as the planetary system), and a significant fraction of the orbits of objects in this belt is stable for the lifetime of the solar system. Starting at a few thousand AU from the Sun, there is a separate reservoir of comets known as the Oort cloud. This reservoir is spherical in shape, not disk-like. The Oort cloud consists of two regions, the inner and outer Oort clouds. The inner cloud is relatively unperturbed and replenishes the outer Oort cloud, but the orbits of objects in the outer Oort cloud are stable only for about 60% of the lifetime of the solar system. Objects in the Oort cloud did not form in the cloud but instead formed in the Uranus/Neptune zone, and planetary perturbations changed their orbits to the Oort cloud. Thus, the Oort cloud is not a primordial reservoir of comets.

Objects that reside in the Oort cloud are much too faint to be detected by current techniques. Our only evidence for the Oort cloud, therefore, is the peak in the histogram of the inverse semimajor axis of long-period comets shown in Fig. 2. Our concept of the mass of material in the Oort cloud comes about from simulations and is quite uncertain (estimates range from a few to 50 Earth masses).

We have hard observational evidence for the existence of the Kuiper belt. The first Kuiper belt object was discovered in 1992 (16) and since that time, 241 objects whose orbits are in the Kuiper belt have been discovered (as of 21 February 2000—more are being discovered regularly). The objects that have been discovered are relatively large; diameters range from 50 to 500 km. Even so, they are up to 100,000 times fainter than can be seen with the naked eye and require very difficult, dedicated searches. However, these objects are clearly much larger than the comets that are seen in the inner solar system as active comets. One study (17) using the Hubble Space Telescope to image 100 times fainter than ground-based surveys reported the discovery of objects of more typical cometary dimensions. However, this study is controversial and has not yet been duplicated.

Figure 4 shows the inclinations of the orbits of the current catalog of Kuiper belt objects as a function of the semimajor axis. Included on this plot are several dashed vertical lines that mark the location of orbits that resonate with Neptune's orbit. The 2:3 mean motion resonance refers to an orbit in which the object orbits the Sun twice for every three times that Neptune orbits the Sun (that is, the object is in general exterior to Neptune's orbit). These resonances are very special dynamic places. If an object starts out in orbit nearest to Neptune in a 2:3 resonance, then every time it orbits the Sun twice, it will come back nearest to Neptune. Thus, Neptune will have an excellent opportunity to perturb the object repeatedly, and this orbit is unlikely to remain stable for very long. On the other hand, if an object is in a 2:3 resonance and starts off away from Neptune, it can *never* get near Neptune, and it is protected from Neptune's influence, even if the eccentricity of the orbit is such that the object crosses Neptune's orbit. Pluto's orbit is an example of an orbit that crosses Neptune's orbit, but Pluto is in a 2:3 resonance with Neptune and thus, is protected. Inspection of Fig. 4 shows that many of the Kuiper belt objects that have been discovered are in protected resonances, especially those whose orbits cross Neptune's. Nonresonant orbits inside Neptune's orbit have been cleared of objects.

Figure 4. The inclination as a function of the semimajor axis for the known Kuiper belt objects. In this figure, 228 Kuiper belt orbits are shown. Thirteen objects have semimajor axes >55 AU. Mean motion resonances of Neptune are denoted by vertical dashed lines.

From the properties of the discovered objects, we can attempt to estimate the number and mass of Kuiper belt objects. While doing this, we must keep certain difficulties in mind. We can discover only the larger, brighter objects in the inner part of the Kuiper belt. Thus, we have no knowledge of the density of small objects, nor of the density of objects in the outer part of the Kuiper belt. Indeed, we have no real knowledge of the distance to the outer edge of the Kuiper belt. When objects are discovered, we can measure their brightness. From this, we need to figure out their sizes and masses. The Kuiper belt objects do not shine on their own, but, instead, they reflect light from the Sun. We know how much light the Sun emits at all wavelengths, and we know how far the objects are from the Sun. However, to convert from brightness to size, we need to know what percentage of the incoming light is reflected from the surface of the object. This percentage is known as the albedo. The albedo of these objects is generally unknown, though we have an idea of the albedo of some active comets, especially Halley's comet. Typical active comets have albedos of 4%, that is, only 4% of the incident light is reflected. If comets are ice, why is the albedo so low? After all, ice is bright white! Think in terms of snow that has fallen and been plowed and has had dirt mixed into it. That snow will be dirty and gray and much less bright than freshly fallen snow. The same is true of comets. The dirt in the nucleus mixes with the ice and makes the ice much less reflective than if it were pure. If we assume that comets in the Kuiper belt also have 4% albedo, we can convert from brightness to size. These estimates of size are only as good as our estimate of the albedo. Pluto has an albedo of 40%, which may be due to frost deposition, but may tell us something about albedos in the same region as the Kuiper belt. If Kuiper belt objects had similar albedos, they would be much smaller than our current estimates. From the size, we can determine the volume. Then, if we know the density of the body, we can determine the mass. However, as discussed above, the density of comets is very uncertain. Taking all of these factors into account, we believe that the Kuiper belt has only a fraction of an Earth mass of material.

Composition

To date, several spacecraft have visited comets and have made measurements *in situ*, but we have yet to retrieve samples and return them for study in our laboratories. The vast majority of our knowledge of cometary composition comes, however, from remote observations obtained with ground-based or Earth-orbital telescopes. These data are gathered using spectroscopic and photometric techniques on a wide variety of comets. The spectrum of a comet is characterized predominantly by molecular emission coupled with an underlying continuum of sunlight reflecting from the dust.

As indicated earlier, the nucleus of a comet is a combination of ices and refractory (dusty) material. About 50% of the mass of the comet is ice and the rest is dust. As the comet approaches the sun and sublimates and gas flows away from the nucleus into the coma, gas phase chemical reactions take place. Some of the chemical reactions are between two molecules or between molecules and dust, but the vast majority of the reactions are photochemical reactions resulting from the interaction of solar radiation and gases in the coma. The gas species become changed quickly. We term the original gaseous species that are the same as the ices the parent species. Species that are produced by chemical reactions of all types are termed daughter species (though some are granddaughter, great-granddaughter, etc.). Optical spectra of comets have been studied for more than 100 years. Until recently, only daughter species were detected. In the past two decades we have detected directly parent species with observations in the IR and mm. Table 1 contains a list of species that have been observed in the spectra of comets. Obviously, some of the species listed here are radicals and cannot be parent species. Others are stable species that could be parent species or could be the result of chemical reactions.

Gas. Spectra of comets can be used for determining the bulk composition of coma gases. However, it requires sophisticated models to use observations of daughter species to determine the nature of parent species. The importance of understanding the nature of ices is to understand which species were formed in the interstellar medium, before incorporation into the protosolar nebula and which species are the result of chemical processing in the early protosolar nebula. The exact composition of the species, the ratio of one species to another, and the isotopic ratios yield information about the conditions in which the ices formed.

Table 1. Atoms and Molecules Detected in Comets

Type species	Species
Atoms	H, O, C, S, Na, K, Ca, V, Cr, Mn, Fe, Co, Ni, Cu
Diatomics	OH, CH, NH, CN, C ₂ , CO, CS, S ₂ , SO
Polyatomics	NH ₂ , C ₃ , H ₂ O, CO ₂ , HCN, HNC, H ₂ S, OCS, H ₂ CO, H ₂ CS, CH ₄ , C ₂ H ₂ , C ₂ H ₆ , NH ₃ , HNCO, HCOOH, HC ₃ N, CH ₃ OH, CH ₃ CN, NH ₂ CHO, CHOOCH ₃
Ions	C ⁺ , Ca ⁺ , OH ⁺ , CH ⁺ , CO ⁺ , N ₂ ⁺ , H ₂ O ⁺ , HCO ⁺ , H ₃ O ⁺ , CO ₂ ⁺
Solids	Organics, silicates

Our understanding of the chemical composition of comets has increased tremendously in the past few decades because of improvements in our ability to observe comets with an ever increasing array of highly sensitive instruments. Originally, cometary spectra were confined to the optical region of the spectrum, using photographic plates as the detector. These observations were limited in spectral coverage and in detail because the dynamic range of plates is too limited to record properly the range of abundances in comets.

In the 1980s, we added charge-coupled devices (CCDs) to our arsenal of optical detectors. These allowed including the near-infrared region of the spectrum, and they possessed the dynamic range necessary to study coma densities that range across many orders of magnitude.

In the 1980s, the International Ultraviolet Explorer (IUE) spacecraft was launched. This spacecraft made it routine to observe comets in the ultraviolet, where several important atomic and molecular transitions, such as hydrogen Lyman α and Lyman β , CS, CO, S₂, etc., are found. Systematic studies of comets in the UV by the IUE yielded important understanding of the relative abundances in comets. These observations have been continued with the Hubble Space Telescope (HST) since the demise of the IUE. The HST is much more sensitive than the IUE and can cover the optical and IR wavelengths, in addition to the UV. It also has much higher spatial resolution and yields important information about the distribution of gases within the coma.

Radio observations of comets were added in the 1970s but lacked the sensitivity to observe all except the OH radical. In the 1980s, came more sensitive radio detectors and the advent of millimeter-wave observations of comets. In addition, sensitive IR array detectors were developed, allowing IR observations of comets. The radio, millimeter, submillimeter, and IR bandpasses are extremely critical to our understanding of comets because it is only in these bandpasses that we can detect parent molecules directly.

All of these detector improvements, coupled with the appearance of the bright comets Hyakutake and Hale–Bopp in the mid-1990s, have allowed a manyfold increase in our understanding of the chemistry of comets.

Inspection of Table 1 shows that a wide range of species is detected, from very simple atoms and molecules to quite complex molecules. However, 80% of the ices are water ice. The presence of fully oxygenated species alongside fully reduced species (i.e., CO versus CH₄ and C₂H₂) indicates that the comets could not form in a thermochemically equilibrated region of the solar nebula.

HNC is a species that could yield clues to the amount of chemical processing in the protosolar nebula (HCN is hydrogen cyanide, whereas HNC is hydrogen isocyanide, a differently bonded combination of the three atoms). HNC is seen in the interstellar medium at a ratio $\text{HNC}/\text{HCN} \propto 1/T$ (where T is the temperature of the interstellar region). HNC could be a parent molecule and would be indicative of the formation temperature. If HNC were a parent, then the ratio HNC/HCN would be constant as the heliocentric distance of the comet changed. Irvine et al. (18) measured both HNC and HCN in comet Hale–Bopp as a function of heliocentric distance and found that the ratio was not constant with heliocentric distance. They concluded that this was clear indication of ion–molecule chemistry in the coma and that HNC was not a parent and could not yield information on deposition temperatures.

Formaldehyde (H_2CO) is ubiquitous in the interstellar medium, and its presence in comets would be expected if comets incorporated interstellar ices. However, it is also possible to produce formaldehyde through chemical processing in the protosolar nebula, so the fact that we detect formaldehyde in comets does not necessarily indicate that ices survived from the interstellar medium until they were incorporated in comets. The detailed abundance of formaldehyde can lend a clue to this question. However, we have evidence that the formaldehyde may be contained in inhomogeneous inclusions in the nucleus, so our present understanding of the quantity of H_2CO is insufficient to determine its origins.

Earth's atmosphere is more than 70% nitrogen. This nitrogen is important for life. How does the nitrogen abundance of comets compare with that of Earth? This is mostly an unanswered question because nitrogen-bearing species are very difficult to measure. The most likely nitrogen-bearing parent species in a comet are the dust, which does have some nitrogen, N_2 , NH_3 , and HCN . Of these, only HCN is easily detected, but it is expected to be a trace species. Wyckoff et al. (19) reviewed the various observations that bear on the question of the abundance of nitrogen in comets and concluded that the total nitrogen relative to other species is depleted from solar by about 6–10 times. Until more data become available, this is still an open question.

The frosts of noble gases are extremely volatile, so observations of noble gases would represent very sensitive thermometers of the formation temperatures and subsequent evolution of comets. Measurements of the noble gases would indicate the warmest temperatures the comet had ever reached. Unfortunately, noble gases are extremely difficult to detect, and none was identified in the *in situ* measurements of Halley's comet. So far, only weak upper limits have been obtained for any noble gases (20).

Much can be learned about the fractionation history of the solar nebula by looking at the isotopic ratios of the comets. (Isotopes of an element have the same number of protons but different numbers of neutrons in their nuclei, e.g., hydrogen and deuterium). The fractionation history is a function of temperature, density, and pressure. If we can determine the isotopic ratios as a function of *formational* distance from the Sun, we have accurate values for these parameters. In general, the isotopic ratios for comets bear much more resemblance to those of the Sun and meteorites than they do to the values in the interstellar medium.

The isotopic ratio D/H is of particular importance to our understanding of the evolution of the solar nebula and its bodies, and particularly to our understanding of Earth. The protosolar nebula started with a value of D/H which was representative of the interstellar medium at the time it was formed. Various processes cause the loss of deuterium and hydrogen from a planet's atmosphere. Less massive bodies lose more of their light elements as they evolve because their gravitational fields are smaller than the more massive bodies. Because hydrogen is lighter than deuterium, hydrogen is lost first. It is, thus, easy to deplete both of these elements but almost impossible to enrich them. Because H is lost faster than D, the ratio of D/H will tend to increase as a result of loss processes in a planet. Material at different heliocentric distances will also have different D/H values because of the temperature gradients in the solar nebula. Figure 5 shows measured values for D/H in various solar system bodies. These are difficult

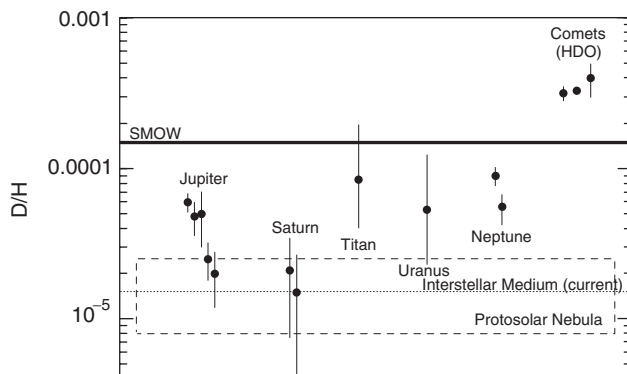

Figure 5. The D/H ratio of a number of solar system bodies. The data for the giant planets and Titan come from Table 3 of Lecluse et al. (34). The comet values are, from left to right, for Halley (35), Hyakutake (36) and Hale–Bopp (37). Also marked on the plot are values for D/H in the interstellar medium and a range of values for D/H from protosolar nebula models. A heavy line marks the D/H ratio for standard mean ocean water (SMOW), a measure from Earth’s oceans. For details of the individual numbers, see the sources cited.

measurements, so for some bodies there are multiple values, and they do not always agree. As one moves upward on this plot, one is measuring an enriched D/H value compared with the original protosolar value.

In Fig. 5, D/H values are plotted for three different comets. The agreement in their ratios is quite good, but a great deal more data are necessary before we can understand the degree of homogeneity in the comet formation region. Recall that comets formed in two distinctly different regions of the protosolar nebula. All three comets are Oort cloud comets, and the agreement suggests that the value of D/H measured may be typical of Oort cloud comets. It will be necessary to sample comets from both reservoirs to understand the conditions better. However, no Kuiper belt comets are bright enough to measure the D/H ratio with current equipment. As detectors and telescopes improve, this situation should change. Note, too, that the plotted values for cometary D/H are obtained from observing H_2O and HDO. For comet Hale–Bopp, the D/H ratio was also measured by observing HCN and DCN. The ratio obtained this way was about a factor of 7 higher than that measured using the water species. We will return to this later.

The D/H ratio of Earth is measured from oceanic water and is shown on the plot as a heavy line marked SMOW (standard mean ocean water). Note that it is heavily enriched compared to the protosolar nebula. Comets show a value about twice the value for SMOW. It has been suggested that the enrichment over protosolar measured for Earth results from comets having been the source of the water on Earth. Although it is sure that a number of comets have bombarded the earth, thus contributing to the water content of Earth, the fact that the D/H ratio of comets is twice as high as Earth’s means that comets could not have been the most significant source of water on Earth. If comets were a major contributor to the oceans, the D/H ratio for SMOW would be closer to the D/H ratio for comets. Thus, D/H ratios can point to comets as only a minor source of Earth’s oceans and limits the rate of bombardment by cometary bodies.

In addition to measurements of D/H in comets, isotopic ratios of $^{12}\text{C}/^{13}\text{C}$ (in the gas) for about half a dozen comets and $^{14}\text{N}/^{15}\text{N}$ (for Hale-Bopp) have been measured. These isotopic ratios are similar to the value measured in the Sun and are vastly different from interstellar values. Measurements of $^{12}\text{C}/^{13}\text{C}$ in dust particles collected by the various Halley flybys show that this ratio is highly variable in the dust.

We have gathered various pieces of evidence; some of them indicate that comets contain material from the interstellar medium, but others indicate that there was substantial chemical processing in the protosolar nebula. Can any of these pieces of evidence indicate the temperature at which the cometary ices were deposited? Several lines of evidence yield such deposition temperatures.

The ratio of $\text{H}_2\text{O}/\text{CO}$ is indicative of the deposition temperature. However, extreme caution must be taken when computing this ratio because of the relative volatility of the two species. If observations are made of a comet at 5AU, then any sublimation is being driven by the CO, not the H_2O . However, at 1AU, both species are sublimated, so a measure of $\text{H}_2\text{O}/\text{CO}$ gas at 1 AU will yield a value indicative of the ratio in the ices and thus gives information on sublimation temperatures. Laboratory experiments have been conducted by Bar-Nun and co-workers to determine the order in which the ices are deposited on grains and the subsequent ratio of sublimed gas. Comparison with observations of Halley, Hale-Bopp, and Hyakutake indicate that all three of these comets have deposition temperatures of ~ 50 K.

Recall that the D/H ratio, as measured by DCN, was a factor of 7 higher than the D/H ratio measured for HDO. The disparity between these ratios is also an indicator of the deposition temperature and implies a deposition temperature of 25–50 K. This is consistent with the $\text{H}_2\text{O}/\text{CO}$ temperature given before.

Dust. Before the spacecraft flybys of comet Halley in 1986, our picture of the dust component in comets was entirely shaped by indirect evidence. The color of the continuum and the structure of the dust tail gave indications of the sizes of the particles in the coma. In addition, it was considered likely that some dust particles collected in Earth's upper stratosphere originated from comets, although it was impossible to link any of the collected particles to a particular comet.

Our picture of the dust was that it was a component entirely separate from the gas. Our ideas changed dramatically with comet Halley and with subsequent IR observations of other comets. Three of the five spacecraft that visited comet Halley had instruments on them to measure the dust. Giotto, Vega 1, and Vega 2 all carried instruments to measure the composition of the cometary dust by having the dust hit a target surface and performing time-of-flight spectroscopy on the resultant components. These instruments were called PIA (particle impact analyzer) on Giotto and PUMA on the two Vega spacecraft. Based on these experiments, it was determined that the dust component of the coma had two different parts: an organic component rich in carbon, hydrogen, oxygen, and nitrogen (dubbed CHON particles) made up around 30% of the sample; Mg-rich silicate particles constituted another third of the particles; the remainder of the particles consisted of a mix of the two types of particles (21). The CHON particles, it was shown, are fragile and showed evidence of fragmentation during their outflow into the coma. The volatile nature of these grains allows them to be

converted into gaseous species as they flow outward. Thus, the CHON particles turned out to be an extended source of gas in the coma.

The PIA/PUMA instruments sampled only small grains in the range of 10^{-16} – 10^{-11} g. This would correspond to spherical grains 0.06–3 μm in diameter. However, grains this size represent only a small fraction of the total dust mass. Another instrument on the Giotto spacecraft, DIDSY (dust impact detection system), measured grains as large as 10^{-5} kg (22). In addition, during the close approach of the Giotto spacecraft to the comet, an impact of a single grain on the spacecraft sent the spacecraft wobbling and damaged the optics. Models of the necessary size of the impactor indicate that the grains were as large as $\sim 2 \times 10^{-2}$ kg.

The PIA/PUMA instruments measured the mass of the detected particles, their densities, and their compositions. They found that the CHON particles had a density of $\sim 1 \text{ g cm}^{-3}$ and the silicate particles had a density of $\sim 2.5 \text{ g cm}^{-3}$. This implies that the CHON-dominated grains are quite fluffy, whereas the silicate-dominated grains are more compact. However, the heavier grains of a particular type are as fluffy as the lighter grains. The bulk composition of the dust analyzed by PIA/PUMA shows that the dust in Halley's coma has an elemental composition which is similar to the solar system composition (of course, the dust is depleted in hydrogen from the solar value but that is because it is easily lost, as explained before). This implies that Halley's comet was not fractionated with respect to the protosolar nebula (21).

The analysis of the composition of individual grains shows a lack of chemical equilibrium among the grains. This was deduced from examining the ratios $\text{Fe}/(\text{Fe} + \text{Mg})$ and Fe/Si versus Mg/Si , two quantities that have been used for laboratory samples of dust to distinguish different types of particles. The analysis also found very few, if any, Ca-Al-rich grains in Halley's dust. One startling discovery was that the isotopic ratio $^{12}\text{C}/^{13}\text{C}$ was not the same at the grain level but varied from 1 to 5000 for individual grains (the normal solar system value is 89, and meteorites have ranges from 4–120). The low cometary dust values may be an instrumental artifact, but the high values appear to be real. The only explanation for such high $^{12}\text{C}/^{13}\text{C}$ ratios is that these particular grains were produced in a nucleosynthetic process, probably before the protosolar nebula was formed, and were incorporated into the comet unchanged.

Recently, the Infrared Space Observatory (ISO) observed the IR spectrum of comet Hale-Bopp in the spectral region from 7–45 μm . The spectrum obtained when the comet was at around 3 AU shows features that can be matched well by crystalline magnesium-rich olivine (fosterite, Mg_2SiO_4) (23). Other ISO spectra, obtained when the comet was closer to the Sun, might also contain features of pyroxene. In the interstellar medium, any observed silicates are only in their amorphous form, so the detection of *crystalline* fosterite is quite significant. At the temperatures and pressures of comet formation, silicates would form in their amorphous state, not in a crystalline form, so the detection of crystalline silicates in comets requires that these crystalline silicates formed elsewhere and were incorporated into comets when already in their crystalline form. ISO also detected, for the first time, crystalline silicates in evolved stars (so-called AGB stars and planetary nebulae), as well as in young stellar objects (24). This suggests that the crystalline silicates might have been formed before

the protosolar nebula was created and were incorporated into comets when they were formed.

Diversity. Detailed study of individual comets such as Halley or Hale-Bopp tells us much about one comet. However, to characterize the early protosolar nebula, we need to study a large sample of comets and determine if the compositions are similar. If all comets have the same composition, this indicates that the protosolar nebula in the region where the comets formed was homogeneous. If all of the comets are not the same, then there could be a primordial difference, implying that the protosolar nebula was lumpy, or there could be an evolutionary difference. Extensive ground-based telescopic surveys have been conducted to determine the degree of heterogeneity of cometary abundances. These studies were carried out by Cochran and co-workers at The University of Texas, McDonald Observatory; by Newburn and Spinrad at The University of California, Lick Observatory; and the largest survey was completed by A'Hearn, Millis and co-workers, primarily at Lowell Observatory.

A'Hearn et al. (25) compared observations of 85 comets and looked at relative gas abundances. They found that the vast majority of comets seems to have similar relative abundance (one species relative to another). However, they found that a group of comets exists that is depleted in carbon-chain molecules, such as C_2 and C_3 , but not in other carbon-bearing molecules, such as CN (comet Giacobini-Zinner is the prototype for this group of depleted comets). Although the carbon-chain-depleted comets represent a minority of their sample, all of the carbon-chain-depleted comets are Jupiter-family comets. Recall that JFCs formed *in situ* in the Kuiper belt, but other comets formed interior to the Kuiper belt and were ejected to the Oort cloud. Thus, if all of the carbon-chain-depleted comets are JFCs and none of the other comets is depleted, this points to differences in the conditions in the two zones of formation. It should be noted that not all JFCs show the carbon-chain-molecule depletion. This still leaves the question whether there are Oort cloud comet interlopers in the JFC sample, whether we are seeing compositional differences in the Kuiper belt region, or whether there are evolutionary differences in Kuiper belt comets.

Evolution of Cometary Nuclei

Comets represent the least altered components left over from the formation of the solar system, but they are probably not totally pristine. Though the Oort cloud is sparsely populated, collisions between Oort cloud comets can still occur occasionally. Several physical processes can also modify the outer layers of cometary nuclei while they reside in the Oort cloud.

The ices of the nucleus are subjected to various forms of radiation, including the radiative flux from passing stars, UV flux from forming stars while the protosolar nebula was still in a star-forming region, X-ray photons from the Galactic background and nearby exploding supernovae, and Galactic cosmic rays. These forms of radiation can profoundly alter the nature of the ices by altering the chemical bonds, radiation darkening and polymerizing ices (26,27). The radiation damage can increase the density and porosity of the ices and can turn simple ices into more complex ones. These processes can penetrate to

different depths within the nucleus; UV-induced changes occur in only the outermost layers (a few to hundreds of atoms or 1–10 nm deep), and X-ray induced changes as deep as 10–100 μm . The depth of the alteration for charged particle radiation would depend on the energy of the particles; low-energy solar protons hardly penetrate, and high-energy protons penetrate deeply. If cometary surfaces have low density, the radiation damaged crust might extend many meters deep (28). Depending on the depth of radiation penetration, the altered ices may survive one or more passages into the inner solar system before being lost to sublimation and subsequent coma outflow.

Collisions between comets are responsible both for increasing the size of objects through accretion and reducing some objects to dust via grinding. Calculations by Stern (29,30) show the frequency of collisions in each region. The Kuiper belt comets which have already been discovered are large and have volumes some 1000–10,000 times that of a Halley-sized comet. To build each object, it was necessary for many collisions to take place (30). Comet–comet collisions in the Oort cloud are less important than in the Kuiper belt and probably only 1 in 10,000 comets suffers a catastrophic collision in the age of the solar system (29). However, small debris in the region (some of which is the result of previous collisions) will collide with the comets, gardening, polluting, and roughening the surface.

When the comets pass into the inner solar system and are heated, sublimation of the gas will carry away much of the embedded dust. However, some of the dust grains are sufficiently large that they cannot escape even the weak gravitational field of the nucleus. These grains will fall back upon the surface. In time, unless some event catastrophically ejects the entire surface, these larger grains will form a mantle on the surface of the comet, insulating the ices and choking the ability of the ices to sublime (31). Indeed, this scenario of sealing the surface of the nucleus has been proposed as one ending for the life of the comet.

Cometary Impacts

Every single day, about 100 tons of interplanetary material hits the upper atmosphere of Earth, and some of that material reaches the surface. A large percentage of the smallest particles originates in comets as dust grains that are released when ices sublime. These small cometary particles represent no hazard to Earth. Many of them are fluffy aggregates that “float” in the upper stratosphere for long periods of time and are occasionally collected for study by specially equipped high-flying aircraft.

The present gentle rain of small particles on the upper atmosphere has not always been the pattern for impacts on Earth. In the early stages of the formation of the solar system, many planetesimals still remained, and the young solar system was a much more chaotic place. Before they were ejected from the solar system, the icy planetesimals’ orbits were perturbed so that they often impacted the planets in the inner solar system. We see this record on the surfaces of atmosphereless and geologically inactive bodies such as the Moon or Mercury. Soon after the planets were first formed, they were being bombarded by icy and

rocky planetesimals (comet and asteroid pieces) at a rate which was about 1000 times greater than the current rate; the bombardment rate fell dramatically to “only” 30 times the current rate around 3.5 billion years ago (32). While the planets were being so heavily bombarded, they were in constant upheaval. It was impossible for life to form. Around 3.8 billion years ago, a period we call the late heavy bombardment, conditions began to change for the better for life. The oldest currently known fossils that indicate life forms are about 3.5 billion years old. Thus, the heavy rate of cometary impacts must have frustrated the origins of life in the earliest days of the solar system.

Did comets also serve as a catalyst for life on Earth? Comets contain large quantities of water, a necessary ingredient for life, along with other more volatile materials. It has been proposed that these organics, along with water, may represent the important prebiotic building blocks necessary for life (33). The arrival of large quantities of cometary material in the early evolution of Earth may have made available necessary raw materials for the formation of amino acids. Thus, once the late heavy bombardment had ended, the materials which were delivered to Earth from the bombardment might have played a critical role in the origins of life on Earth.

Once life had begun, the future interactions of Earth and comets was not entirely beneficial or even benign. We know that, even in recent times, objects impact Earth, as evidenced by locales such as the Barringer meteor crater in Arizona, the Chicxulub crater in the Yucatan (the remains of the impact event which, it is thought, destroyed the dinosaurs at the time of the Cretaceous–Tertiary (K/T) boundary 65 million years ago), or the Tunguska impact zone where an impactor fell in 1908. Many of these impactors are *not* icy, cometary bodies, but are asteroidal in origin. Rocky materials are stronger than the fragile cometary nuclei and can more easily survive passage through the atmosphere to impact the ground. However, comet impacts are still possible. A recent spectacular example of a cometary impact was the Shoemaker–Levy 9 impacts (in 1994) on Jupiter. Though these impacts had no effect on Earth, they serve as a reminder of the magnitude of effects that are caused by impacts on planetary bodies. Indeed, cometary impacts can be more extreme relative to the mass of the impactor than asteroidal impacts because of the random orientations of the cometary orbits relative to the plane of the ecliptic. If an impact occurs with the impactor in a retrograde orbit, the relative velocity of the comet and the Earth can be very large, and the impact energy is proportional to the square of that relative velocity.

The best defense against impactors of any type is to know in advance that the body exists and is potentially hazardous. NASA is currently coordinating large search efforts for near-Earth objects to catalog as many objects as possible. This effort is likely to be relatively complete for bodies of asteroidal origins, but many cometary bodies will go undetected in these searches because the random inclinations of the cometary orbits make systematic searches difficult and expensive. Thus, we could be faced at any time with the threat of a cometary impact and the resultant damage. Our best hopes for planetary protection are to be as vigilant as possible and to enhance our understanding of the nature of cometary nuclei so that we understand the properties of potential impactors.

Missions To Comets

Much can be learned about the nature of comets via observations from the ground and Earth orbit. However, we can never see the nucleus of the comet in this way, and we must infer information about its nature by using models. To study the nuclei of comets, it is necessary to send spacecraft to them. These spacecraft missions can range from simple flybys, to rendezvous missions, to landings and sample returns. In this section, the completed and planned cometary missions of the U.S. and other nations are described.

Completed Missions

ICE. The first cometary mission did not start its life as a mission to a comet. The International Sun Earth Explorer (ISEE) 3 was a mission to study the interaction of the solar wind with Earth's magnetosphere. It was launched in 1978. After excursions into Earth's magnetotail and five swingbys of the Moon, the spacecraft was retargeted to flyby comet Giacobini-Zinner and its name was changed to the International Cometary Explorer (ICE). The flyby of comet Giacobini-Zinner occurred on 11 September 1985, making this mission the first to encounter a comet.

Because the mission was intended to study the plasma environment of Earth, no cameras were carried by the spacecraft. The goal of ICE was to study the interaction of a comet with the solar wind. The spacecraft was targeted to fly through the tails of Giacobini-Zinner to gather data on the changing magnetic field and plasma. The experiments on board ICE found a thin, dense, and cold plasma sheet. The magnetic field strength was low, and the spacecraft detected a change in polarity as it crossed the comet axis. The temperature of the plasma increased with increasing distance down the tail until about 20,000 km from the nucleus. Because the mission was not intended to sample a comet, very little compositional information was obtained.

Sakigake, Susei, Vega 1, Vega 2, and Giotto. Comet Halley is one of the most famous comets, and so it was not surprising that there was great interest in missions to this comet. An international armada of spacecraft visited this comet: the European Space Agency sent the Giotto mission; the USSR sent two spacecraft, Vega 1 and 2; and Japan sent two spacecraft, Sakigake and Susei. A detailed description of these missions and their first science results can be found in a special issue of *Nature* (Volume 321, May 1986).

The two Japanese spacecraft were officially part of the Planet-A project of the Institute of Space and Astronautical Science (ISAS); one spacecraft was an engineering test spacecraft dubbed MS-T5 (renamed Sakigake, Japanese for "forerunner", after launch), and the other the Planet-A main spacecraft (renamed Susei, Japanese for "comet", after launch). They were launched in January and August 1985, respectively. The two spacecraft were identical but carried different instrument complements: Sakigake carried a plasma-wave probe, whereas Susei carried an ultraviolet imager and charged particle analyzer. Concerns about the dust environment near the nucleus caused the probes to be targeted well sunward of the nucleus; Sakigake passed 7 million km away on 11 March 1986, and Susei 151,000 km away on 8 March 1986. The relative velocity of Susei and the comet was 73 km sec^{-1} .

The two Vega missions were combination missions, whose goals were studying Venus with balloons and landers on their way to a rendezvous with comet

Halley. They were launched 6 days apart in December 1984 and flew by Venus 4 days apart in June 1985. They flew by comet Halley on 6 March and 9 March 1986 at around 8,000 km on the sunward side of the nucleus. The two three-axis stabilized spacecraft were identical, including instrumentation. Each carried a complement of 15 scientific instruments to measure the plasma, the dust, the composition, and to obtain images of the comet. The encounter velocities were 79.2 and 76.8 km sec⁻¹.

The Giotto mission was launched by the European Space Agency (ESA) on 2 July 1985; it was the first ESA interplanetary mission. It achieved closest approach to the nucleus on 14 March 1986 at an encounter distance of 600 km and a flyby velocity of 68.4 km sec⁻¹. The spacecraft was spin-stabilized and carried a complement of 10 instruments, including a camera, mass spectrometers, dust detectors, and plasma instruments. The close encounter distance coupled with the fast flyby velocity were a calculated risk to the spacecraft but were driven by the desire to get close for the best imaging and for sampling by the various instruments. The biggest risk came if the spacecraft entered a dust jet (a dust jet is a region of the coma in which the flux of 1- to 10- μ m particles is enhanced by a factor of 3–10 over the ambient coma). Fourteen seconds before the closest approach, the spacecraft apparently was hit by a “large” dust grain, causing the spacecraft’s angular momentum vector to shift by 0.9° and to wobble. Because the spacecraft had no onboard data storage devices, this interrupted communications and data transfer, though some data were transmitted intermittently for the next 32 min. Some of the instruments were damaged at this time, but in general, the spacecraft remained healthy. Thus, ESA was able to retarget the spacecraft for a flyby of comet Grigg–Skjellerup on 10 July 1992, but some instruments, such as the cameras, were not functional.

The Giotto mission’s Halley multicolor camera achieved the milestone of the first excellent images of the nucleus of a comet, supplemented by images from the Vega cameras. The images showed a lumpy, elongated object; the dimensions were 8 × 8 × 16 km with several very active jets, and the rest of the surface was relatively quiescent; only 20–25% of the surface appears to be active. The nucleus had a very dark albedo of 2–4%, comparable to the darkest known bodies in the solar system. The comet does not rotate simply around a single axis but has a complex wobble-spin tumbling motion. The dust environment was quite severe, especially at the high encounter velocities. It was this armada of spacecraft that finally confirmed our general picture that 80% of cometary ice is H₂O ice.

Deep Space 1. This mission is the first of the NASA New Millennium missions intended primarily as demonstrators of cutting-edge technology never before flown. The Deep Space 1 mission was launched on 24 October 1998. It was primarily an engineering mission that had a science component planned to be executed if possible. This mission was intended to test 12 new technologies; the most important was ion propulsion, but included such technologies as autonomous navigation, low power electronics and new instruments. The nominal scientific mission was a flyby of asteroid 1992 KD (Braille) at 10-km altitude on 28 July 1999. The mission was extended to flyby comet 19P/Borrelly on 22 September 2001 at a closest distance of 2170 km from the nucleus. During the course of the flyby, 52 visible-wavelength images and 45 infrared spectra were obtained.

Deep Space 1 observed an irregularly-shaped cometary body with a long axis of 8 km and a 2:1 axis ratio (38). The surface had a low albedo of 3% and true albedo variations from 1–3%. Only about 10% of the surface appeared to show activity and no ices were detected on the surface. A jet appeared to emanate directly from the rotational pole.

Current Missions. Great interest continues in understanding comets and their constraints for models of the protosolar nebula. Thus, several missions are currently planned and launched or to be launched within the next decade. This section will describe all of these missions.

Stardust. This is the fourth mission in the NASA Discovery program of small focused planetary science missions, and it is the first robotic return of material from beyond the Moon's orbit. The Stardust spacecraft was launched on 7 February 1999 (Principal Investigator Dr. Donald Brownlee of the University of Washington). The Stardust mission will encounter comet Wild 2 in June 2004 at a relative encounter velocity of 6.1 km sec^{-1} and an encounter distance as close as 150 km. Wild 2 is expected to be much less active than comet Halley, and the much lower encounter velocity should protect the spacecraft. In addition, the encounter with Wild 2 will take place at a heliocentric distance of 1.86 AU, where comets are less active than the 0.9 AU heliocentric distance of Halley at encounter. Stardust will carry a camera for imaging and a dust particle analyzer (CIDA—a similar instrument to the PIA/PUMA instruments discussed earlier).

The most important goal for Stardust is to capture samples of interplanetary dust (collected in 2000) and cometary dust and return them to Earth for analysis. It will accomplish this goal by using a capture target built of *aerogel* attached to panels on the spacecraft. Aerogel is an ultra-low-density microporous substance which has been tested on previous shuttle missions. Once the flyby of the comet has been achieved, the aerogel target will be closed into a sealed sample return capsule (SRC), and the spacecraft will return to the vicinity of Earth. When the spacecraft approaches Earth, the SRC will be released from the spacecraft and will descend into the atmosphere on a parachute. It is planned that the sample will land in the Utah Test and Training Range, where the SRC will be recovered by helicopter or ground vehicle and transported to the planetary materials curatorial facility at the Johnson Space Center. The Earth return of the SRC is scheduled for 2006. More information can be found at <http://stardust.jpl.nasa.gov>.

CONTOUR. The comet nucleus tour (CONTOUR) is another NASA Discovery mission; its goal is studying the diversity of cometary nuclei (Principal Investigator Dr. Joseph Veverka of Cornell University). CONTOUR includes detailed investigation of two diverse short-period comets: Encke (November 2003) and Schwassmann–Wachmann 3 (June 2006). However, the mission profile is extremely flexible and can be modified to include the first-ever study of a “new” comet (such as Hale–Bopp) should one be discovered during the mission.

The spacecraft is scheduled for launch in July 2002 and will carry four instruments with it: a wide-field and a high-resolution camera, a dust analyzer (CIDA—a copy of the Stardust instrument), and a neutral and ion mass spectrometer. To maintain its extreme orbital flexibility, the CONTOUR spacecraft uses repeated Earth-return trajectories and multiple gravity-assist maneuvers. A unique feature of CONTOUR is that it will be placed into a spin-stabilized

“hibernation” mode, requiring no ground contact, during its cruise intervals between comet encounters and Earth swingby maneuvers. The spacecraft will be “awake” for 75 days around encounters and 50 days around each Earth maneuver. More information about CONTOUR can be found at <http://www.contour2002.org/>.

Rosetta. The Rosetta mission is the third *Cornerstone* mission of the European Space Agency (ESA). This mission is to be launched January 2003 from Kourou, French Guiana, aboard an Ariane-5 rocket. Rosetta is designed to rendezvous with comet P/Wirtanen in August 2011, orbit around the comet, making observations of the nucleus, and eventually, to land a package of instruments called the Rosetta Lander (or RoLand) on its surface in August 2012. The long cruise phase (eight years) is necessary to rendezvous with the comet far from the Sun and at a low enough encounter velocity.

Rosetta is larger than the previous three missions. It carries 12 instruments in addition to RoLand. The orbiter instruments include a camera, several spectrographs, a neutral and ion mass spectrometer, a dust analyzer similar to that on Stardust and CONTOUR, a dust detector, and a plasma instrument. RoLand carries a suite of eight additional instruments to evaluate samples of the comet *in situ*. No samples will be returned to Earth. RoLand will include an instrument to take a core sample from 200 mm under the nucleus’ surface.

One unique problem faced by the Rosetta mission is to land successfully on the surface when we do not currently have any information about the nature of the material on which RoLand will land. RoLand will land with a relative velocity of less than 1 m sec^{-1} and will fire an anchoring harpoon into the nucleus to secure the lander to the surface (recall that the gravity of a comet is weak because it has such low mass). Once tethered to the surface, RoLand will begin its measurements, transmitting the data to the orbiting spacecraft for relay to Earth. More information can be obtained about Rosetta at <http://sci.esa.int/rosetta/>.

Deep Impact. The final cometary mission is another in the Discovery program. Deep Impact is to be launched in January 2004 and will encounter comet Tempel 1 on 4 July 2005 (Principal Investigator Dr. Michael A’Hearn of the University of Maryland). Deep Impact’s goal is to sample the deep interior of a cometary nucleus. It would be quite impossible to do this by trying to drill a core sample, so the Deep Impact approach is quite different. Deep Impact will expose material deep in the interior by creating a crater of $> 100\text{-m}$ diameter and $> 20\text{-m}$ deep. This will be done by releasing an autonomously targeted mass of roughly $1/2$ metric ton (mostly composed of copper) one day before the impact. Cratering is a natural process in space. The difference between a naturally created crater and that created by the Deep Impact spacecraft is that we will know the size and mass of the impactor and exactly when it hit.

The impactor will be carried by the flyby spacecraft. After the release of the impactor, the flyby spacecraft will decelerate slightly so that its closest approach to the nucleus will occur after the impact at an interval roughly twice the predicted time to form the crater. The impactor will carry a camera to obtain high-resolution images of the surface of the impact site just before impact. The flyby spacecraft will carry two cameras and two spectrometers to observe all phases of the crater-forming process, the resultant crater, the debris plume, and the

changes induced in outgassing. The comet will be observed simultaneously from Earth to record data about the changing comet. For more information, see <http://www.ss.astro.umd.edu/deepimpact/>.

Summary

Comets are small icy/dusty bodies left over from the formation of the solar system and represent the least altered bodies from the epoch of formation. They formed in the outer parts of our planetary system; some still reside in their primordial reservoir known as the Kuiper belt; those formed in the Uranus-Neptune region were ejected to a spherical reservoir known as the Oort cloud; those formed near Jupiter and Saturn were ejected from our solar system entirely.

The nuclei of comets are small (typically a few km) bodies composed of ices and dust. Of the ices 80% is water ice. The dust is composed of organics and silicates. As the nucleus is heated, the ices sublime and flow outward from the nucleus. The dust/gas mixture forms a large coma and even larger tails.

We are on the verge of increasing our knowledge of comets tremendously with a series of spacecraft already launched and about to be launched. The next decade should revolutionize our understanding of comets and thus, the solar nebula.

COMMERCIAL APPLICATIONS OF COMMUNICATIONS SATELLITE TECHNOLOGY

Introduction

According to the Teal Group, satellite communications industry consultants, some 1,017 commercial satellites will be launched in the 10 years from 1999 to 2008. Of these, 102 satellites will be dedicated to conventional broadcasting of radio, television, and data: 82 to direct-to-home satellite broadcasting; 384 to broadband and multimedia transmissions; and 449 to mobile communications. Together, these satellites represent a total market value of US \$49.8 billion (1).

Commercial communication satellites constitute the fastest growing segment of the global satellite market, including satellites for the military civilian government, and scientific applications. This rapid growth is driven by the development of new and more cost-efficient satellite technologies and the demand for more telecommunications services worldwide.

Transmission of network, independent, and cable television programming to affiliates and cable headends will continue to be a dominant application of

commercial satellites. The U.S. company PanAmSat, based in Greenwich, Connecticut, for example, has 22 satellites orbiting Earth that perform this service, as well as satellite newsgathering (SNG) and transmitting live special events from around the world. The company, owns the world's largest commercial geostationary satellite system and is the world's largest provider of video and data broadcasting services via satellite. PanAmSat plans to expand its global fleet to at least 25 spacecraft by mid-2001. On 1 January, 2000—and on the days immediately preceding and following this date—PanAmSat delivered millenium celebrations to viewers throughout the world for more than 40 customers, including ABC, BBC, CNN, Fox, and NBC. In total, there were more than 1300 hours of live event coverage and some 300 satellite feeds. PanAmSat used a total of 12 U.S. domestic and international satellites plus 5 teleport facilities.

Since 1980, with the debut of international broadcaster Cable News Network (CNN), satellite newsgathering has been an increasingly large user of satellite time because of the world's growing appetite for live TV coverage of breaking news. During the past 20 years, satellite technology has become a primary tool of newsgathering for television news organizations throughout the world because fiber connectivity is often difficult or impossible to arrange on short notice and from remote locations. The excitement of real-time news from anywhere is something that television viewers throughout the world have come to expect, either through local stations or news organizations like CNN. CNN is the world's first 24-hour-a-day global news channel and is now seen in 184 million households in more than 210 countries. In recent years, CNN and other TV reporting from such venues as the Persian Gulf, Bosnia, and Chechnya have enables viewers worldwide to share live experiences and to form their own opinions based on what they hear and see via satellite. Competition among broadcasters continues to stimulate SNG. For example, the American television network ABC has about 80 SNG trucks deployed around the world.

Most SNG transmissions use the higher frequency Ku band rather than the C band, which is used for most broadcast and cable program distributions to system affiliates. There are several reasons for this. First, unlike C-band transmissions, Ku-band transmissions are largely unaffected by terrestrial microwave interference and large structures in metropolitan areas. Second, the cost of Ku-band satellite dishes for SNG broadcasting is only one-fourth of that for C-band dishes. And third, Ku-band dishes are at least three times smaller than traditional C-band dishes, making them easier to transport and set up quickly.

Another factor stimulating the growth of SNG is the technology of digital compression, one of the manipulations of data made possible by digitalization. Through digital compression, it is possible to use only a fraction of a satellite transponder for transmission. Thus, the lower costs associated with SNG have helped to expand the number of SNG broadcasts around the world.

In fact, digital technology does much more than merely allow for compression of television signals, although this is a major commercial capability. Digital television allows for CD-quality audio and cinematic-quality video, both of which generate files so dense with data that they cannot be transmitted across the airwaves without digital video and audio compression. Digital satellite technology is also making possible the transmission of high-definition television because an HDTV picture requires much more information than a conventional analog

television channel can provide. In the coming decade, as consumers buy new digital television sets to replace their aging analog models and as TV production houses acquire digital cameras and other digital technologies for their studios, many more programs will be produced in the HDTV format.

As full implementation of digital technology and the compression of TV channels occur, virtually each new satellite will be able to broadcast up to six times as many programs simultaneously, using the same amount of bandwidth, compared with the older analog technology. This is putting satellites on the same footing as cable in terms of their capability to deliver hundreds of channels into the home. In fact, satellite-to-home television companies like EchoStar Communications and DIRECTV are challenging cable's dominance and keeping cable subscriber costs down, where satellite services can easily compete. Furthermore, a measure passed by Congress in 1999 allowing satellite TV operators to provide local broadcast TV channels to their subscribers is expected to produce huge market gains for the satellite TV industry (2). It is projected that, by 2003, more North American TV households will receive digital TV signals via satellite than by cable (3). DIRECTV now delivers more than 225 digital satellite TV channels directly into the home.

Direct broadcast satellites (DBS) are a worldwide phenomenon. Today, throughout the world, more than 62 million ground receivers measuring as little as 18 inches (45 centimeters) in diameter look at more than 60 high-powered geostationary satellites that deliver direct-to-home (DTH) programming. Of these satellite dish antennas, 42.7 million are in 36 countries of Europe, North Africa, and the Middle East (4). The phenomenon of DBS was first solidly established in Europe in the early 1990s by such providers as British Sky Broadcasting (UK), SES Astra (Luxembourg), and Telenor (Norway). By the mid-1990s, the skies above Asia were also populated with direct-to-home broadcast satellites. For example, since 1990, AsiaSat of Hong Kong has launched two satellites that cover 66% of the world's population in 53 countries that span Asia, India, and the Middle East. In the United States, four companies pioneered DBS: EchoStar, Primestar, United States Satellite Broadcasting, and DIRECTV. Subsequently, DIRECTV absorbed both Primestar and USSB, and now is the largest US DTH television company. In the coming years, DBS growth overseas is expected to exceed U.S. growth; Europe will contribute 40% of all DBS subscribers by year-end 2008 (5). In the shorter term, between 2000 and 2003, the number of DBS subscribers will triple (6).

Interactive TV is another powerful commercial application made available by digital television technology. Viewers at home can participate in live programs and manipulate the broadcasts: they can choose camera angles, stop, reverse, or go back to viewing a program in real time. Companies such as WebTV, TiVo, Sun Microsystems, Intel, and America Online (AOL) are forging new relationships with broadcasters and satellite operators that will showcase their new interactive services. For example, at the Consumer Electronics Show in Las Vegas in January 2000, TiVo, which has partnered with Hughes Electronics Company's DIRECTV service, demonstrated TiVo's VCR-like software that can pause, rewind, and fast-forward live and recorded television.

Also, Hughes and AOL formed a strategic partnership to link the satellite operator with a leading content provider. In 1999, AOL invested US \$1.5 billion

in Hughes to get its interactive multimedia AOL-TV product onto the DIRECTV platform and launch its AOL-Plus high-speed Internet service via DirecPC, a high data rate service from Hughes. AOL-TV will allow users to surf the Web, "chat" online, and E-mail back and forth as they watch TV. Finally, a deal struck in June 2000 between Microsoft and DIRECTV gives Microsoft's interactive WebTV product a place on the DIRECTV platform. The two companies will offer a new VCR-like service that marries a computer hard drive and a digital TV so that viewers can record up to 30 hours of TV programming for later playback. The service, called Ultimate TV, is similar to that offered by TiVo. In addition to digital video recording, it also offers Internet access and interactive TV.

Meanwhile, Sun Microsystems has demonstrated an interactive music program from the BBC that enables viewers to vote for their favorite bands and change camera angles while watching a weekly pop music show. And Intel and WebTV possess enhanced TV technologies that can overlay statistics onto sports broadcasts, add detailed product information to commercials, and let viewers play along with game shows. Commercial interactive and enhanced TV services will generate nearly US \$1 billion in revenues and reach more than five million households by 2002 (7). According to Forrester Research, within 5 years, interactive TV-based Web browsing will generate US \$11 billion in advertising and billions more in commerce (8).

The digitalization of the television signal, along with the fast growth of DBS, has encourage the worldwide radio industry to launch new, satellite-delivered domestic, regional, and international radio networks that provide CD-quality sound. Two of the new services Sirius and XM Radio, are scheduled to debut hundreds of channels of enhanced audio entertainment and information programming to fixed and mobile consumers from year-end 2000 to early 2001. A third service, WorldSpace, is already operational. Its goal is to provide high-quality, multilingual digital audio programming to the emerging and underserved markets of the world. The first WorldSpace satellite to become operational (in June 2000), AsiaStar, broadcasts more than 50 channels of programming to 4-inch satellite dish antennas. Two additional commercial satellites for Africa and Latin and South America will complete the WorldStar offering.

Data transmission is big business. A team of World Trade Organization (WTO) economists has estimated that, by year-end 2000, there will be more than 300 million Internet users worldwide and that electronic commerce will amount to a US \$ 300 billion a year industry. Beyond this, 80% of all business-to-business transactions will be conducted through the Internet by 2002 (9).

High-speed, interactive data transmission, which will allow real-time exchange of digital video and multimedia, is projected to become more widely available in the year-end 2001–2002 time frame. In the interim, companies such as Hughes Network Systems, Scientific-Atlanta, and Gilat Satellite Networks offer to business enterprises of all sizes satellite-based intra- and intercorporate networks that may extend across the city or around the world. Called VSAT (very small aperture terminal) networks—in recognition of their easily installed 24-inch satellite dishes—they can be used for a variety of purposes, including videoconferencing, employee and customer training, credit card authorization at the point of sale, new product introductions to marketing employees and

retailers, inventory control, and electronic data interchange (EDI) for ordering merchandise from manufacturers and paying for it. There are more than 500,000 VSATs installed in the world, including those in underdeveloped nations where they may be used to provide remote villagers their first access to telephony.

For example, in a remote village in Thailand, a community telephone booth with a small VSAT dish on top can transmit and receive phone calls to and from any person or place on Earth. Operated by the Telephone Organization of Thailand (TOT), this telephone is one of 4000 remote terminals plus 21 public switched telephone network (PSTN) gateways located in Thailand's provinces. This network is the world's largest VSAT network dedicated to telephony. It is an example of the way satellites can provide telephony service where the existing wire-line telecommunications infrastructure is limited or non-existent and/or where the population density is too low and the terrain too challenging to build a commercially viable wire-line system for rural telephony.

Once inside the PSTN, telephone calls can be routed anywhere in the world by wire-line, underwater cable, satellite, and/or fiber to the intended recipient. By using multiple gateways, the network can route calls to the nearest entry point in the PSTN, thus minimizing connection times and consumer costs. The Thai network is used mainly to provide coin-operated pay phones and private lines in villages and small communities around the country. Like other such VSAT networks in Southeast Asia and Africa and throughout the developing world, satellite telephony via VSAT networks is connecting small businesses with the global marketplace, giving them the opportunity to transmit two-way data as well as voice, no matter what the distance or terrain. In the coming years, most telephone VSAT networks will be replaced by new "bandwidth-on-demand" broadband satellite systems (see later), whose wide and spot beam antennas will provide ubiquitous coverage of Earth.

Because of the vast and ever-increasing worldwide use of VSAT and Internet applications, it is sometimes said that the initials "www" stand not for the World Wide Web, but for the World Wide Wait. At this time, there is simply not enough bandwidth to meet user demands—from cable, from telephone lines, or from satellites. However, this challenge should be resolved in the next year or two, when a number of new satellite broadband companies are scheduled to begin operations. This is none too soon in a situation where world-wide demand for digital bandwidth continues to surge. Consider China, where the number of Internet users, now 10 million (June 2000), is doubling every 6 months. By some calculations, China will have the second largest population of Web users in the world, after the United States, by 2005 (10). Overall, in Asia there are currently (June 2000) 40 million Internet users. This number is expected to grow to 375 million by 2005. Meanwhile, in the United States, the market for satellite-based Internet services has grown by 314% during the last year and by 858% during the last 2 years (11).

Despite laudable efforts by cable and telephony organizations worldwide to convert their narrowband telecommunications infrastructures to broadband speed (defined as at least 1.544 megabits per second), satellite companies are accomplishing this more quickly and at lower costs. For example, U.S. telephone service provider SBC Communications is in the midst of a 3-year program to build a US \$6 billion fiber broadband system that will cover only the western

United States. By comparison, current estimates indicate that a satellite broadband system covering the entire United States will cost US \$1.4 billion (12).

At least seven satellite companies, Astrolink LLC, @ Home in the Sky, EuroSkyWay, INMARSAT's Broadband Global Area Network (B-GAN), iSky, Spaceway, and Teledesic, plan to provide broadband multimedia services from new Ka-band satellites to customers in the Americas, Europe, Africa, Asia, and the Middle East. Another company, called SkyBridge, will provide broadband services using the Ku band, a set of frequencies that is much used today, principally by commercial TV broadcasters. SkyBridge has engineered its system so that no interference will be created by frequency sharing.

It is projected that business-to-business electronic exchanges alone will constitute a US \$1.1 trillion market worldwide by 2003 (13). Also stimulating this growth will be the new, consumer-oriented concept of "bandwidth on demand," which enables users to pay only for the amount of satellite bandwidth they actually use. Their link into the satellite system will be via a low-cost satellite dish as small as 26 in. (66 cm) in diameter. It is likely that, together, bandwidth on demand plus low access charges will draw cost-conscious consumers and businesses away from cable and telephone connections for their broadband requirements. There is an additional feature of a bandwidth-on-demand satellite system. Because capacity is released only when needed, satellite systems will be able to support a much higher number of users compared with cable and wire-line technologies.

The launch of these next-generation Ka- and Ku-band broadband systems is expected to usher in a "golden age" for the satellite industry (14). The new systems could enhance broadcasting with data and multimedia services, deliver Internet content, and deliver business communications with high-power spot beams that can provide two-way, real-time communications. It is projected that revenues from broadband-over-satellite services will rise from US \$25 million in 2000 to US \$21 billion in 2007 (15).

As VSAT networks for rural telephony continue to be built throughout the world, new regional and global handheld systems for mobile satellite telephony are now being demonstrated. Proponents of mobile handheld satellite telephony have stated that data delivery by phone will be the next big commercial boom among consumers. Already, individuals can be in touch by voice virtually anywhere in the world anytime. In addition, their handheld phone sets can also enable E-mail, Internet access, and one-on-one videoconferencing with a small, built-in TV screen.

According to the financial services company, Morgan Stanley Dean Witter, satellite-based mobile phone use could explode from a few thousand users today to around 17 million by 2007 (16). It is projected that, nongeostationary (GEO) systems will produce revenues of US \$62 billion in the next 5 to 10 years (17). How quickly that money will materialize, or if it will materialize at all, is a question open to much debate after the failure of Iridium, a US \$5 billion, low Earth orbit satellite global telephony system of 66 satellites that ceased operations in February 2000, not long after its start-up in November 1998. Industry analysts attribute Iridium's fate to large and heavy phone sets that did not operate indoors or in cars and heavy capital expenditures that necessitated high usage fees of up to US \$7 per minute.

Iridium did, however, successfully demonstrate its pioneering technology. The 66 satellites were cross-linked and could perform onboard switching to relay signals directly to and from handheld phones where that was feasible. The satellites acted like cellular towers in the sky, wireless signals moved overhead instead of through ground-based cells. The Iridium network also integrated land-based phone lines and local cellular facilities to provide the quickest and most efficient call routing.

As of May 2000, a new global mobile satellite telephony system started operations, and another project will start up early in 2001. Both the Globalstar and New ICO systems (described in detail later) will not be as technologically sophisticated (or costly) as that of Iridium. Both will make more use of existing terrestrial systems, so that the telephony signals will not be beamed up to or down from the satellite directly. Each will use existing terrestrial wire-line and cellular phone paths for originating and receiving calls.

In the meantime, four regional—as opposed to global—mobile satellite telephony systems are either planning to serve or are already serving customers in North America, Asia, the Middle East, Europe, and Africa. Dual-mode cellular/satellite mobile phones provide access to a vast array of consumer services and serve as the basic connection for the new “office in the car.” For example, the 2000 Ferrari model 550 Maranello is a prototype equipped with all of the latest in multimedia and navigation gadgets. The car’s cockpit is equipped with a personal computer hooked up to a swiveling satellite antenna to navigate the Internet; send and receive E-mail and exchange documents; download road maps; read weather forecasts and traffic news; book hotels, theaters, and restaurants; and even obtain bank balances and the latest stock quotes. This prototype was created to show the potential of EuroSkyWay, the first European broadband satellite network completely reserved for interactive multimedia services. Developed by Alenia Aerospazio, the system is scheduled to begin operations in 2002. EuroSkyWay’s satellites will allow real-time video communications for videoconferencing, high-quality image transfer, and access to the Internet that is 30 times faster than terrestrial modes, according to the company. EuroSkyWay’s target customers are business people who need to be in touch with the office and cannot stop working, even while in traffic (18).

In the coming years, satellite antennas mounted on car roofs will become virtually omnipresent because of important and potentially life-saving new technologies first introduced by the U.S. Department of Defense and now in full development by the commercial sector. For example, General Motors (GM) now equips many of its car models with a dual cellular/satellite communications system called OnStar™. Using OnStar, drivers can navigate efficiently to their destinations with a series of maps and audio commands. More importantly, wherever they are, they can contact local police, fire, and rescue departments, as well as AAA operators, and their precise geographical location will be relayed simultaneously via satellite. This is accomplished by using the Global Positioning System (GPS), a constellation of 24 satellites that has evolved well beyond its U.S. military origins. For the U.S. military, GPS provides situational awareness for troops in the field anywhere in the world and precision weapon guidance. Through GPS-based data, voice, and video communications, military personnel can interact with commanders at headquarters and receive real-time maps of

allied and enemy positions, weather maps and forecasts, and progress images of guided weaponry advancing toward their targets.

Besides GM, Ford, DaimlerChrysler, and other car manufacturers also provide “telematics” systems, “telematics” is the buzzword for the convergence of wireless technology, global satellite positioning, and onboard electronics in automobiles. But to date, the General Motors system is the most technologically advanced. For example, if keys are locked inside the car, OnStar will unlock the doors via satellite. OnStar also offers a voice-activated Internet access package that, via an onboard computer, enables sending and receiving data, voice, imaging, and E-mail. OnStar is expected to have four million users by 2002, and there is analyst speculation that GM will spin off OnStar as a separate tracking stock.

As of May 2000, there were four million GPS users worldwide. The market for GPS applications is expected to double by 2003, rising from US \$8 billion in revenues to US \$16 billion. This can be attributed in part to the fast-growing demand for GPS features to be outfitted in cell phones (19). As of June 2000, the GPS feature will be incorporated in as many as 18 satellites that are awaiting launch or are in production. The U.S. government currently provides this service free of charge to users worldwide.

As shown, the worldwide demand for bandwidth is growing exponentially. Among the chief factors fueling the need for bandwidth is the skyrocketing demand for two-way, high-speed Internet access. Despite the large investments made by cable and telephone industries to expand their network capacities, the demand for high-speed bandwidth far outstrips the supply (20). Satellites will be used extensively to take up the slack and to provide unique services that only satellites can provide because of their ubiquitous reach and cost-insensitivity to distance.

As can be seen, new commercial satellite communications applications are developing rapidly, fueled by new technologies. Most of these applications will require major capital investments and involve significant technical and business risks. It is likely that some of the new applications discussed in this article—written in mid-2000—will undergo major changes or will even fail. Iridium is an example. It is equally likely that new applications not discussed here will develop. It is certain that commercial satellite communications applications will continue to evolve rapidly. The following sections provide a road map for these developments.

Digital Satellite Television Broadcasting

As mentioned previously (see article in this volume on Communications Satellites, Technology of), television programs in the United States have been transmitted from network hubs to affiliates and cable headends since the 1970s. In recent years, a growing number of U.S. households also receive TV broadcasts directly from satellites, using rooftop antennas for Ku-band satellites and backyard antennas for C-band transmission. The United States is not alone in using satellites to broadcast TV programming. A 1999 annual Eutelsat survey of 36 countries in Europe, North Africa, and large parts of the Middle East showed

that 107 million households also get satellite-delivered TV, either through a dish or a local cable company. This is up from 95 million homes in 1998. A total of 42.7 million households in these regions are dish homes (21). Asian direct-to-home broadcasts also are plentiful, due in great part to Rupert Murdoch's Star TV satellite system. In fact, News Corporation (of which Rupert Murdoch is chairman) controls 100% of Star TV, 40% of British Sky Broadcasting, and 36% of Sky Latin America. All are DTH systems, and there are more than 100 million subscribers on these platforms alone. The number of dish homes around the world will continue to grow quickly because of the 800 million TV households in the world, nearly 700 million are in regions that have limited access to multichannel television. Terrestrial systems, such as cable or multipoint microwave distribution service (MMDS), are too costly and time-consuming to install, compared with direct satellite transmission.

Today, around the world, more than 62 million ground receivers that are as small as 18 inches (45 centimeters) in diameter look at more than 60 high-powered geostationary satellites that deliver DTH TV. Many of the DTH satellites can deliver more than 100 channels of premium digital video entertainment and information directly to consumer households. For example, since 1990, AsiaSat of Hong Kong launched two satellites that cover 66% of the world's population in 53 countries that span Asia, India, and the Middle East. AsiaSat's biggest customer for its satellites is programmer STAR TV, also of Hong Kong. Along with Asian-originated programming, STAR and other Asian DTH broadcasters use AsiaSat's satellites (along with those of competitor APT Satellite Company, Ltd.) to transmit such American TV fare as HBO, MTV, ESPN, CNN, and The Disney Channel, along with the programming of the BBC and other major international programmers.

DBS is thriving throughout the developed world. In Japan, Sky PerfecTV!, which uses two high-power JCSAT satellites for its DBS service, has more than two million subscribers. Malaysia is served by a fully digital DTH TV service that is carried on two MEASAT (Malaysia-East Asia Satellite System) satellites. The coverage pattern also includes the region from Malaysia to the Philippines and from Beijing to Indonesia. In November 1998, Russia's first commercial communication satellite, BONUM-1, was launched from Cape Canaveral, Florida, and is providing multiple-language DBS TV in European Russia, the Urals, and western Siberia. In Central and South America and the Caribbean, the Hughes Galaxy Latin America DIRECTV service delivers up to 232 channels of programming to more than one million subscribers in 27 countries.

Two EUTELSAT satellites launched in 2000 will meet market demands for new digital TV platforms and Internet Protocol (IP)-based services in Russia and Africa. Nineteen transponders on EUTELSAT W4 constitute a high-power fixed beam across Russia. Sixteen of these transponders are used for DTH digital TV broadcasting by the Russian media group Media Most. Twelve transponders are pointed over sub-Saharan Africa, where they are used for digital pay TV and broadband Internet access (22). EUTELSAT is Europe's leading satellite operator and ranks as one of the largest globally. It reaches across Europe, large parts of Africa and the Middle East and has connectivity with North America. Currently, EUTELSAT satellites can broadcast more than 600 analog and digital channels to more than 81 million satellite and cable homes. In addition to DBS,

EUTELSAT satellites are used for high-speed Internet connections, Internet backbone traffic, inter- and intracorporate networks, SNG, telephony, and mobile voice, data, and positioning services.

In the United States, two companies dominate the DTH satellite services market: DIRECTV from Hughes Electronics Corporation in EI Segundo, California, and EchoStar Communications Corporation in Littleton, Colorado. At the end of 1999, DIRECTV, which debuted in 1994, offered some 210 channels of programming from four proprietary DBS satellites. The company estimates it will have 10 million subscribers by 2001. In addition, DIRECTV also offers a service called DIRECTV Para Todos (For Everyone), a Spanish-language programming service that consists of 30 additional channels. DIRECTV Para Todos is aimed at the growing number of bilingual households in the United States. Through alliances with America Online, TiVo, and Wink Communications, DIRECTV plans shortly to introduce a portfolio of new interactive and data-enhanced television services, including data-enhanced video, electronic commerce, webcasting, software downloads, and two-way Internet access. DIRECTV is also helping to accelerate the advent of high-definition TV by introducing this year two channels of HDTV programming and integrated DIRECTV/HDTV television sets and set-top electronics.

EchoStar, which began operations in 1990 with large C-band satellite backyard antennas, today broadcasts from five proprietary DBS satellites under the trademark DISH Network. These five satellites give DISH Network the capacity for more than 500 channels of digital video delivered to homes in the continental United States via a single satellite dish. As of year-end 1999, DISH Network boasted more than three million subscribers. At the same time, EchoStar introduced DISHPlayer, which it claims is the world's first combined interactive Internet device, satellite TV receiver, personal video recorder, and game player. DISHPlayer was developed jointly with Microsoft's WebTV Networks.

As described before, by the early 2000s, we will see the second generation of digital direct-to-home TV, which will have a satellite return path and Internet access. As mentioned earlier, through this new interactive system, consumers will be able to access companion data for sports, documentaries, news, and other programming. For example, viewers watching CNN could use their remote control devices to request the latest sports scores and local weather forecasts. Viewers of live sports telecasts will be able to access up-to-the-minute player and team statistics. When an advertiser's commercial's broadcast, viewers will be able to use their remotes to order more information or a coupon for the product or the product itself. Also in the early 2000s, digital satellite TV receivers will be built into newly manufactured TV sets, making these TV sets "satellite ready." They will require only an antenna to receive multichannel, even multinational, TV.

The 1999 Satellite Home Viewer Act is a major factor that will increase DTH broadcasting growth in the United States. This U.S. Federal Communications Commission (FCC) regulation, signed into law by President Clinton, mandates that local broadcasters make their local and network signals available to DBS providers. The intent of the regulation is to increase competition in the cable industry and to keep cable TV rates "reasonable," according to the FCC. In 1999, satellite TV reached about 14 million U.S. households, compared with about 70 million homes reached by cable service. It is projected that by 2003 more

North American TV households will receive digital TV signals via satellite than by cable. Moreover, it is projected that the number of DBS subscribers will triple between 2000 and 2003 (23).

Two satellite technologies, in particular, will fuel the growth of DBS: (1) spot beams aboard Ku-band satellites, and (2) Ka-band satellites. Current satellite technology will allow designing a spot beam satellite that has up to 50 spot beams to cover the continental United States. This technology of using spot beams enables frequency reuse and allows for an increased number of local program offerings to DBS subscribers. The introduction of Ka-band satellites with spot beams and real-time traffic management information will increase local channel availability and enable implementation of broadband interactive TV.

Digital Audio Broadcasting

Satellite-delivered digital audio services are beginning to emerge that provide 100 or more channels of CD-quality radio programming in multiple languages to both fixed and mobile receivers. The technology of digital audio radio service (DARS) was first demonstrated commercially in 1999 by WorldSpace International Network, a Washington, D.C.-based company that launched AfriStar, the first of three planned geostationary satellites. AsiaStar was launched in early 2000 and is expected to become operational by year's end. AmeriStar is planned for launch during the first half of 2001. When all three WorldStar satellites are operational, they will provide digital audio broadcasting service to 80% of the world's population. WorldSpace's three GEO satellites are intended to provide service to the emerging and underserved markets of the world, including Africa, the Middle East, Asia, Latin America, South America, and the Caribbean. Each WorldSpace satellite has three regional beams, and each beam can broadcast more than 50 channels of crystal clear audio directly to palm-sized portable receivers. Programming options include channels for entertainment, news, information, education, sports, and culture. On AfriStar, for example, there are 23 broadcast services in 16 different languages. The first generation of WorldSpace satellites will provide only stationary reception via small receivers. The AsiaStar service, for example, will be broadcast to 4-inch dish antennas built into small radios. Future generation receivers will be designed for mobile reception.

In late 2000, two more DARS operators, Sirius Satellite Radio and XM Satellite Radio, plan to begin commercial operations to provide CD-quality music, news, and variety programming in the United States. Seeking to accelerate the growth of the DARS industry and to achieve the largest possible audience for their products, Sirius and XM Radio formed an alliance in 2000 to develop a uniform standard for satellite radios. New York-based Sirius Satellite Radio, formerly CD Radio, plans a three-satellite constellation. The first satellite, Sirius-1, was successfully launched in June 2000. Sirius-2 is slated for launching in September 2000, and Sirius-3 in October 2000. All three Sirius satellites were designed specifically for satellite radio broadcasting and will be among the first in the world to use the S band to deliver audio content. Sirius intends to have 100 channels operational by year-end 2000.

The Sirius satellites will be placed in inclined elliptical orbits—rather than GEO orbits over the equator—to maximize the line of sight to the satellites. The elliptical path will ensure that each satellite spends about 16 hours a day north of the equator and that two satellites are right over the United States all the time. These orbits enable the satellites to relay the Sirius broadcast signal to the United States from a much higher angle than GEO satellites. This will result in improved signal strength and coast-to-coast coverage. Content will be fed simultaneously to several transmitters in major urban areas. These terrestrial repeaters supplement satellite coverage in urban areas, where tall buildings may block the satellite signal. The Sirius satellite system is designed to broadcast as many as 100 music, news, information, and entertainment programming channels to motorists throughout the continental United States. Inside the car, drivers will find a digital display showing, for instance, the song's title, artist, record label, and running time. As with XM Satellite Radio as well, listeners driving from coast to coast will be able to stay on their favorite channels all the way. Ford Motor Company, BMW, and Daimler Chrysler all have agreements in place with Sirius to install new Sirius/XM-ready radios in new cars as standard equipment. Space Systems Loral built the three Sirius orbiting satellite plus one ground spare.

Similar to Sirius is XM Satellite Radio, which will also use terrestrial repeaters and will operate in the S band. XM's first satellite is scheduled to be launched in November 2000, and commercial service is set to begin during the first half of 2001. XM Satellite Radio was founded in 1992 and has its headquarters in Washington, D.C. Its major investors are American Mobile Satellite Corporation (now called "MOTIENT"), General Motors, DIRECTV, and Clear Channel Communications. XM Satellite Radio plans to broadcast as many as 100 brand-new radio channels to consumers in their cars, homes, and offices using two high-power Hughes HS 702 geostationary satellites and very small antennas. Listeners using portable and fixed home radios will be served by built-in antennas that are 2.4 inches in diameter. Programming is scheduled to include music, news, talk, sports, entertainment, ethnic, and children's channels, 24 hours each day. XM estimates its potential market at 60 million subscribers, who will pay about US \$10 per month. XM has already contracted with General Motors to place XM satellite receivers in all GM cars and trucks. The XM satellites have a communications payload built by Alcatel in partnership with Hughes Electronics; they will be operated by Telecast Canada. The future generation of XM satellites will deliver messages, transmit E-mail, and provide E-commerce applications to mobile platforms, thereby supplementing and augmenting other mobile services. In addition, simple two-way connectivity using the XM spectrum may be possible.

VSAT Networks and Digital Data

In the developed world, VSAT technology is widely used to establish quick, reliable, and cost-effective two-way data, voice, and video distribution networks. Networks can be citywide or worldwide, regional or domestic. Typically, they are used by large organizations that want to communicate in real time with their

local or regional branch offices and geographically dispersed customers, suppliers, and employees. Among the world's leading automakers—Ford, Chrysler, General Motors, Toyota, Fiat, Saab, Volkswagen, and Peugeot—all have proprietary VSAT networks. Other major VSAT networks include those operated by the Bank of China, Federal Express, Hewlett-Packard, IBM, Texas Instruments, Xerox, Home Depot, and the China People's Daily newspaper. VSAT networks perform a myriad of functions. These include electronic funds transfer; credit card authorizations at the point of sale, including "pay at the pump" gas stations; inventory control; ordering parts and products from a company's distribution center; providing corporate headquarters with up-to-the-minute sales data from all outlets; and telecasting corporatewide announcements from the organization's key executives at headquarters. There are currently thousands of VSAT networks in operation. Most were installed by one of three major competitors: Hughes Network Systems, Scientific-Atlanta, and Gilat Satellite Networks.

The use of VSAT networks is also very important for distance learning in both the developed and developing regions of the world. Distance learning via VSAT networks is used extensively in the developed world primarily for corporate training. A geographically dispersed sales force no longer has to fly to corporate headquarters to learn about a new product, for example. And auto service technicians can receive instruction from experts at major manufacturing centers without ever leaving their local dealerships. Through interactivity, questions can be asked from any remote site and relayed instantaneously to all remote sites and to the presenter at the originating location. In addition, VSAT networks enable corporate employees to earn an academic degree from a university across town or across the continent. The return audio path is used to ask or answer questions, and the return data path is used to take examinations. Universities, such as the National Technological University in Colorado, now exist specifically to provide instructional programming via VSAT and other types of distance learning networks.

Using VSAT networks for distance learning may be most valuable when they are located in less populated regions of the world, where children and adults can be taught to read, write, speak their national language, and practice a trade. Indonesia was one of the first countries to use a VSAT network for distance learning. Its citizens, spread out over more than 10,000 islands, continue to have the opportunity to learn the national language, Bahasa Indonesia, by VSAT. In the less developed world, VSAT networks can also play a vital role in health care. A patient's chart and X-ray films can be transmitted to a consulting specialist, who may issue a diagnosis from halfway around the world. Special medicines can be ordered instantly. And programming about good nutrition and proper dental care can help teach preventive medicine. Recently, the U.S. TV programmer, Discovery Communications, began funding VSAT-based satellite education in developing countries, providing advanced technological resources and training to rural and disadvantaged schools and community centers around the world. Discovery's first efforts are focused on sub-Saharan Africa and Latin America (24).

The worldwide VSAT market will continue to increase—until, gradually in the coming years—it is superseded by the ultra-high-speed broadband networks expected to debut in the 2002–2005 time frame. In the meantime, to manage the

increasing demand for fast two-way Internet links, driven in large part by the exploding growth of business-to-business E-commerce, companies such as Hughes Network Systems and EchoStar Communications Corporation are coming up with satellite solutions. In fact, more than 11% of the world's Internet Service Providers (ISPs) now use satellite links to connect to the Internet backbone. In 1999, the total value of the "Internet Protocol (IP) Over Satellite" market was US \$210.4 million. By 2000, that value had risen to US \$710.9 million. Increasing use of two-way satellite terminals to provide high-speed Internet access among intra- and intercorporate sites allows network owners to bypass telephone and cable companies and maintain end-to-end control over their networks (25).

As stated in the introduction to this article, Hughes Electronics plans to roll out an ultra-high-speed broadband satellite system in 2003. But Hughes will not have to attract Spaceway subscribers from scratch. In the intervening years, Hughes is offering DirecPC, a two-way satellite-based broadband Internet delivery system that delivers Web pages and software programs to home and small office satellite dishes at the rate of 400 kilobits per second. For downloads, that is faster than an ordinary telephone line but slower than a cable modem. Upstream requests, once handled by ordinary telephone, can now travel by satellite at a rate that is three times faster than a dedicated ISDN line. When customers of the "old DirecPC" are switched over to Spaceway, data will be delivered at up to six megabits a second. This is faster than today's cable modem delivery. Spaceway also promises an uplink capability of two megabits per second. In June 1999, America Online said it was investing US \$1.5 billion in Hughes Electronics to partner with Hughes to offer AOL's new broadband service, AOL Plus, over DirecPC.

In the fourth quarter of 2000, Hughes Network Systems intends to supercharge DirecPC with two-way satellite capability. This is necessary to allow consumers to downstream movies, games, and concerts into the home over the personal computer and to allow businesses to hold real-time videoconferences without the slow motion, blurry, and jittery video seen on today's VSAT networks. Offering "always on" capability, the new two-way high-speed satellite service will allow consumers to bypass the dial-up telephone or cable system completely and avoid land-based bottlenecks on the Internet. The two-way satellite version of DirecPC will operate on the current medium-power Ku-band satellites operated by PanAmSat, which is 81% owned by Hughes Electronics. This early entry two-way satellite service will be offered to enterprises around the world. For example, S Kumars.com, an Internet kiosk operator in India, has bought 50,000 DirecPC terminals for use throughout India.

Satellite Broadband Communications

According to the Teal Group, satellite industry consultants, some 384 satellites dedicated to broadband multimedia will be launched between 2000 and 2008. This constitutes 38% of all satellites launched during this period. These new Ka- and Ku-band satellites will help create a market for new GEO and LEO broadband satellite services worth more than US \$9 billion annually by 2004 (26). As stated before, advanced satellite broadband communication systems provide

significantly more bandwidth and much higher data bit rates than the broadband and narrowband systems currently in service. Broadband technology also allows multitasking of applications, that is, satellite-based broadband communication systems can handle numerous applications at the same time, for example, a live, full-motion digital videoconference and data exchange.

Broadband satellite users will be able to accomplish a variety of digital interchanges ranging from data to voice to video and multimedia. They will be able to download entire CD-ROM databases in a fraction of the time it currently takes. For example, in 2000, it takes 9 minutes on a 28.8-kbps phone line to download the Sunday edition of the *Washington Post*. By using a 1.5 Mbps satellite link instead, the time is reduced to about 10.4 seconds. The interactive multimedia capabilities of these systems will dramatically change and speed up the way we work. For example, broadband satellite users will have simultaneous access to high-data-rate on-line computer networking and low-cost, high-resolution interactive desktop videoconferencing. This means that an architect in China, for example, can work via broadband technology with one or more colleagues anywhere in the world, exchanging CAD/CAM images instantaneously. Currently, 2 megabits of CAD/CAM content can take 70 seconds to transmit on conventional phone lines. A broadband satellite link will reduce that time to just 1.4 seconds.

Remote manufacturing and control will be another workplace application for satellite broadband networks. In today's global economy, goods are often designed, manufactured, and marketed in different distant locations, and raw materials and consumers are located in still other venues. A broadband remote manufacturing/control system will allow an electronic toy designer in Seattle, for instance, to send specifications for a new toy directly to a manufacturing plant in Korea. In turn, the manufacturer could order the necessary microchips on a timely basis. The manufacturer also could use the same satellite broadband network to send production status data to the worldwide distribution network to allow for just-in-time delivery and better inventory control. Finally, the manufacturer, together with the distributor, could keep marketing and advertising agencies apprised of exact product delivery dates in different regions of the nation or the world.

As chip prices fall and compression rates soar, more and more companies are announcing plans for global satellite broadband systems and services. According to Pioneer Consulting, total global broadband revenues will increase from around US \$200 million in 1999 to US \$37 billion in 2008 (27). Virtually all international satellite operators, such as PanAmSat, EUTELSAT, INMARSAT, Telesat (Canada), and New Skies (the commercial spinoff from INTELSAT) already have plans to acquire broadband satellites. INMARSAT (the International Maritime Satellite Organization), for example, has announced the purchase of three global mobile broadband satellites for its new Broadband Global Area Network, which is to become operational during 2004. The INMARSAT satellites will be 100 times more powerful than INMARSAT's current world-leading global mobile 64-kbit/s network. In addition, the Broadband Global Area Network (B-GAN) will provide at least 10 times more capacity for new users, enabling INMARSAT to fulfill the growing need of global corporate enterprises for on-line high-speed access to information and communications. INMARSAT projects high

demand for mobile broadband services, and its satellites will also provide a seamless extension to fixed networks. According to a year 2000 forecast from ING Barings, the mobile satellite market will be worth more than US \$4 billion in 2004 and will double to more than US \$8 billion in 2009.

It is forecast that business-to-business E-commerce will be a \$US1 trillion market by 2003 (28). Six companies—Astrolink, EuroSkyWay, iSky, SkyBridge, Spaceway, and Teledesic—have announced plans for new satellite broadband networks, which they believe will give them a piece of this lucrative new market. Teledesic was one of the first to announce such plans, a US \$10 billion project funded by cellular pioneer Craig McCaw, Microsoft Chairman Bill Gates, Saudi Prince Alwaleed Bin Talal, the Abu Dhabi Investment Company, Motorola, and Boeing. Teledesic is building what it calls a global broadband “Internet-in-the-Sky” that is scheduled to become operational in late 2003. In addition to providing advanced business services, Teledesic aims to accelerate the spread of knowledge throughout the world and facilitate improvements in global education, health care, and the environment. The ambitious system will comprise 288 low Earth orbit (LEO) operational satellites, plus in-orbit spares, operating in the uncrowded, high-frequency Ka band of the radio spectrum. (In this frequency band, it is possible to achieve compact antenna terminals half the size of traditional VSAT Ku-band systems.) To use the radio spectrum efficiently, the Teledesic system will allocate frequencies dynamically and reuse them many times within each satellite footprint. The 288 LEO satellites will be divided into 12 planes; each will have 24 satellites orbiting at 1375 km (854 mi) above Earth.

Teledesic chose a low orbit to eliminate the signal delay that can be experienced in communications through traditional geostationary satellites and that could seriously impair interactive communications. A low orbit also enables using small, low-power terminals and antennas. The laptop-size terminals will mount flat on a rooftop and connect inside to a computer network or personal computer. Ground-based gateways will enable service providers to offer seamless links to wire-line and wireless networks, although fewer terrestrial facilities will be needed because all 288 satellites will be interconnected via intersatellite crosslinks. This reduces the time it takes to establish a connection. The Teledesic network is designed so that from anywhere on Earth, a Teledesic ground terminal can always “see” a satellite nearly directly overhead and without obstruction. This is accomplished by having an elevation angle of 40° or higher at all times in all locations. A lower elevation angle would increase the likelihood of obstruction by surrounding buildings, trees, hills, or other topographic features.

Most Teledesic users will have two-way connections that provide up to 64 Mbps on the downlink and up to 2 Mbps on the uplink. Sixty-four Mbps represents access speeds that are more than 2000 times faster than those available via today’s standard analog modems. A key technical challenge for Teledesic will be to develop low-cost antennae that can track moving satellites. Unlike narrow-band mobile satellite terminals, which can use simple omnidirectional antennae, broadband Teledesic antennae must be continuously repositioned so that they point to the correct satellite. Like all of the other satellite broadband systems announced, Teledesic will offer “bandwidth on demand.” This means that users pay only for the bandwidth they actually use and do not have to reserve bandwidth in advance or agree to a minimum monthly or annual service agreement.

For the network operator, bandwidth on demand means that the network can support a much higher number of users because capacity is released only when needed. The Teledesic network will cover nearly 100% of Earth's population and 95% of the landmass. It is designed to support millions of simultaneous users. Teledesic, founded in 1990, is based in Bellevue, Washington. In mid-2000, Teledesic was behind in its deployment schedule, and it was rumored that the company was considering reducing the number of satellites to be deployed.

By comparison, the EuroSkyWay global satellite broadband system will use a cluster of five operational satellites, all in geostationary orbit. It will offer an aggregate capacity of 45 Gbps, which will be available either on an on-demand or reserved basis. EuroSkyWay's Ka-band satellites will feature digital onboard processing, which has already been successfully tested in orbit since 1991 aboard two Italsat satellites built by EuroSkyWay's founding company, Alenia Aerospazio. In fact, Alenia Aerospazio has been developing payloads and satellites using the Ka band and onboard processors since 1984 as the prime contractor of the European Space Agency. Alenia Aerospazio developed the first commercial multimedia onboard processor in the world. It has been operating in orbit since March 1998 onboard the Eutelsat Hot Bird 4 satellite.

Like Teledesic, EuroSkyWay's satellites will also be interlinked. Using digital onboard processing and intersatellite links, EuroSkyWay satellites will provide full connectivity between any pair of spot beams. The satellites will also handle any packet-type switching, such as that required for two-way Internet communications. To overcome the so-called latency problem generated by the use of the Internet protocol TCP/IP for GEO satellites, EuroSkyWay will use a proprietary system based on the asynchronous transfer mode (ATM) protocol. In the first of two projected operational phases, EuroSkyWay will provide coverage across Europe, the Middle East, Greece, Turkey, Africa, and some former USSR countries. The first satellite is planned for launching by the year 2001. In the second and final operational phase, three additional satellites will provide increased capacity plus coverage across Africa and Asia. EuroSkyWay was founded in Italy in March 1997 by Alenia Aerospazio Space Division, the satellite manufacturing company of the Finmeccanica Group.

In addition to providing fixed services, EuroSkyWay will also bring broadband services to mobile users by offering communication links at a speed that is up to 200 times faster than traditional cellular phones. The company identifies its key potential customers as large telecommunications companies and Internet services providers, large multinational corporations, and social service users. In this latter category, EuroSkyWay specifies hospitals, research centers, universities, and all users that require multimedia interactive connections for social needs. The provision of medical services is a special directive. The company's slogan is "move information, not patients." In fact, using existing Alenia Aerospazio satellite facilities, technical support has been provided in such areas as Sarajevo, Bosnia-Herzegovina, and Kosovo. Doctors at medical institutes in Milan and Rome assisted the injured via satellite-based telemedicine.

As mentioned, Teledesic intends to fly an all-LEO system, and EuroSkyWay an all-GEO system. The global Ka-band Spaceway system from Hughes Electronics Company will consist of eight GEO satellites and additional satellites that will operate in lower Earth orbits. Ground stations will range from user

terminals with antennas approximately 26 in. in diameter to larger gateways for connectivity to terrestrial backbone networks. The initial Spaceway GEO satellite system will provide ubiquitous coverage in four main regions of the world. North America will be first to be brought on line, as early as 2002–2003 with two Hughes-built HS702 geosynchronous satellites plus an in-orbit spare. Hughes plans to work with global strategic partners to extend the system into other regions as markets develop, including Europe, the Middle East and Africa, Latin America, and Asia. Once this initial system is operating and producing sufficient revenue, the complementary non-GEO system will be introduced. It will expand the network capability to offer additional broadband and interactive multimedia services in high-traffic markets. Spaceway will extend the reach of traditional VSAT networks. It will seamlessly integrate with existing land-based systems and will be fully compatible with a wide range of terrestrial transmission standards. Spaceway will allow corporations to consolidate their local and wide area networks into single high-speed networks. Uplink rates will be between 16 Kbps and 6 Mbps. The satellite system will employ onboard digital processing, packet switching, frequency reuse, and spot beam technology, and will offer mesh connectivity throughout the service area. This connectivity, for example, will allow customers to communicate directly via satellite with other customers without having to go through a terrestrial retransmission hub. It also permits direct, full broadcast capability throughout the service area. Hughes and its subsidiaries own and operate the largest privately owned fleet of commercial satellites in the world. The company is also the world leader in providing satellite-based private business networks. The capabilities of these networks will be greatly expanded through Spaceway.

Thus far, all of the promised broadband systems mentioned will operate in the relatively unused Ka band, where there is a large quantity of frequency to be shared among several companies desiring to offer bandwidth- and frequency-intensive services. The final broadband system to be discussed here will not use the Ka band, but rather the Ku band—a set of frequencies used primarily for satellite news gathering, network transmissions to broadcast and cable affiliates, corporate videoconferences, and satellite-to-home broadcasting. Beginning in 2003, SkyBridge GP, Inc. plans to operate a US \$6.1 billion Ku-band LEO satellite system that will provide end users access to high data rate multimedia services. Like the other Ka-band services planned, SkyBridge wants to take advantage of the fast growing market demand for high-speed Internet access, corporate intra- and extranets, LAN/WAN remote access, E-commerce, videoconferencing, and interactive video and audio entertainment. The SkyBridge service is aimed at both residential and business users. According to SkyBridge, up to 72 million residential users will seek to purchase broadband communications services by 2005, and by the same year, businesses will spend more than US \$100 billion per year on broadband services. The 80 LEO satellite constellation from SkyBridge is designed to limit use of terrestrial facilities—except where these are more cost-efficient—and thus solve the “local loop” or “last mile” problem by using satellite antennas that connect directly to satellites.

According to SkyBridge, it will offer telecommunications operators a flexible, timely, and cost-effective alternative to slow terrestrial roll-out programs, for example, cable, fiber. The 80 Ku-band satellites will orbit at an altitude of

913 mi (1469 km). This low Earth orbit allows the short signal propagation time—30 milliseconds—needed to provide real-time interactive services. The SkyBridge system will comprise about 200 gateway Earth stations for worldwide coverage. Each gateway will have a 234-mile (350-km) radius of coverage. The gateway stations will interface with all existing terrestrial facilities through an ATM switch that will ensure seamless integration with residential or business satellite terminals that will cost about US \$700.

The SkyBridge system is designed to operate in the 10 to 18-GHz Ku-frequency band without causing interference to either GEO satellite operators or terrestrial users. Frequency will be shared between SkyBridge and the many different Ku-band GEO satellite operators by limiting the power from the SkyBridge system into the GEO transmit arc. Specifically, each SkyBridge satellite will cease transmissions during all potential interference conditions. A SkyBridge satellite will stop transmissions to a gateway cell, and the SkyBridge Earth stations in the gateway cell (including all end-user terminals) will cease transmission to the satellite when the satellite enters that gateway's "nonoperating zone." This zone will span 10° on either side of the GEO arc as seen by any Earth station in the gateway cell. The traffic in that cell will be handed over to another satellite in the constellation. The SkyBridge satellite system will have neither onboard switching nor intersatellite links. The gateways and satellites will be preprogrammed to hand over traffic.

As do the other Ka-band broadband operators, SkyBridge intends to serve both developed and developing countries around the world with its ubiquitous "instant" infrastructure. As is the case with Hughes's Spaceway system, many international partners are being recruited to help pay for these expensive systems. Alcatel, a multinational telecommunications firm located in Paris, is the general partner of SkyBridge LP. To assist in the design, development, and manufacture of its system, SkyBridge has arranged a diversified international consortium. Participants include Boeing (U.S.), COM DEV International (Canada), CNES (Centre National d'Etudes Spatiales) (France), EMS Technologies (U.S.), Litton Industries (U.S.), Loral Space and Communications Company (U.S.), Mitsubishi Electric Corporation (Japan), Sharp Corporation (Japan), SNECMA (France), Toshiba Corporation (Japan), a Belgian banking institution, and others.

Satellite Handheld Mobile Telephony

According to the Teal Group, some 450 new satellites for mobile telephony will be launched between 2000 and 2008. This represents 44%—nearly half—of all new satellites to be launched during the coming years (29). [Teal Group, report titled "Commercial Communications Satellites, Satellite & Launch Services Market Forecast: 1999–2008," April 1999] According to many, data delivery by phone will be the next boom technology for consumers. Using their handheld satellite phone receivers, they will be able to receive E-mail, access the Internet, obtain the latest news and weather forecasts, trade stocks, and participate in videoconferences via a built-in TV screen.

As mentioned before, INMARSAT, the International Maritime Satellite Organization, which operates a global constellation of geosynchronous satellites,

pioneered a worldwide infrastructure for mobile telephony and data communications as early as 1979. Today, new regional and global mobile constellations of GEO, LEO, and MEO (medium Earth orbit) satellites are coming on-line to compete with INMARSAT. These include global mobile systems such as Globalstar and INMARSAT's own privatized spinoff, New ICO Global Communications. New regional systems include MOTIENT (formerly American Mobile Satellite Communications, or AMSC; Thuraya; Asia Cellular Satellite Communications (ACeS); and Asia Pacific Mobile Telecommunications (APMT)). All of these services are aimed at the individual who needs uninterrupted global phone, fax, data, or pager access. This can include the business traveler in remote areas of the world or in developing countries where the telecommunications infrastructure is inadequate or nonexistent. Other users include workers involved in oil and gas extraction, those providing disaster relief, and those working aboard commercial and government ships.

The first LEO satellite mobile telephony system to become operational, Iridium, began commercial service in November 1998. Although Iridium—that has 19 strategic partners from around the world—was forced to terminate service in March 2000 for financial reasons, the system did prove the technology. The Motorola-designed system required US \$5 billion and 11 years to create and was authorized to provide voice, fax, and data transmission services in more than 120 countries. Iridium's 66 satellites, each weighing just 700 kg, formed a cross-linked grid only 485 mi (780 km) above the Earth. The Iridium satellites could receive the signals of a handheld phone. They acted like cellular towers in the sky, where wireless signals could move overhead instead of through ground-based cells. The Iridium network integrated land-based phone lines, local cellular facilities, and satellites to provide the quickest and most cost-efficient call routing. The Iridium handheld telephone worked in two modes. As a mobile cellular phone, it sought out available service from existing land-based networks. In this mode, it operated in the same way as today's terrestrial cellular systems. When cellular service was not available, the Iridium phone would switch to satellite mode. At least one Iridium satellite was always available overhead to receive a transmission. The call was then relayed from satellite to satellite, until it reached its destination, either through a local Iridium gateway and the PSTN or directly from the satellite to a receiving phone.

According to industry analysts, Iridium's market failed to materialize for five reasons. First, the handsets were large and heavy; second, they cost US \$3000 apiece; third, they were not functional indoors; fourth, Iridium chose to build its entire system up-front; it cost US \$5 billion and resulted in unsustainably high consumer rates; and fifth, it took too long (11 years) to get to market, so that initial market assumptions and technologies became outdated. For example, by the time Iridium was launched, cellular and personal communications service (PCS) technology had improved dramatically and was so pervasive that for most people, a traditional cellular phone was the optimum choice. Its lower cost and weight deterred conversion to the Iridium service.

Globalstar, another global mobile satellite telephony service, is now commercially available in more than 30 countries (as of May 2000) in North America, South America, Central America, Latin America, Asia, and Europe. Globalstar has said that it expects to offer commercial service in at least 50 countries,

including Russia and South Africa, by the end of June 2000. The company, a consortium led by Loral Space & Communications and Qualcomm of the United States, plans to provide service in more than 100 countries on six continents. Like its erstwhile competitor Iridium, Globalstar uses satellites to extend traditional mobile and fixed phone services and offers the flexibility to make both satellite and cellular calls through one phone anywhere in the world. Also like Iridium, Globalstar supports data transmissions and Internet connectivity as part of an overall range of services. E-mail messages are received through the system at rates of 9600 kbps.

Unlike the satellites in the Iridium network, Globalstar's 48 LEO satellites are not cross-linked and perform no onboard processing. Also, users are not connected directly to or from a satellite. Instead, Globalstar is what is called a "bent-pipe" system. Calls are routed via a terrestrial path from a fixed phone or handheld or vehicular mobile phone to a gateway Earth Station, which uplinks the call to a satellite. The call is then routed by satellite down to another gateway Earth station and then transmitted through local terrestrial wire-line and wireless systems to the final destination. The Globalstar system can pick up signals from more than 80% of Earth's surface. In fact, several satellites pick up a call (via the terrestrial gateway), and this so-called "path diversity" ensures that the call does not get dropped, even if one satellite moves out of sight of the phone. Each Globalstar satellite consists of an antenna, a trapezoidal body, two solar arrays, and a magnetometer. The Globalstar satellites were manufactured by Space Systems Loral.

The satellites operate at an altitude of 1414 km (876 mi), so that there is no perceptible voice delay or echo effect. The satellites are placed in eight orbital planes of six satellites each, inclined at 52° to provide service on Earth from 70° North latitude to 70° South latitude. The Globalstar system uses Qualcomm's CDMA (code division multiple access) transmission technology, that offers better voice quality and security than terrestrial cellular networks. Small, lightweight multimode handsets are used for either satellite or terrestrial cellular service (e.g., when inside buildings) in such standards as GSM, AMPS, and CDMA. Placing a call takes roughly 10 milliseconds. In addition to offering mobile telephony, Globalstar also intends to serve users in underdeveloped parts of the world with affordable fixed-site telephones. For example, these could be located in coin-operated village telephone booths or small business offices that currently cannot enter the global marketplace, for example, a supplier of batik in Indonesia that needs to communicate regularly with a wholesaler in New York. In the first quarter of 2000, Globalstar began service in China. The company plans to bring communications services to vast reaches of the country outside the range of existing cellular and wire-line phone systems. Globalstar estimates that 50% of the world has little or no phone service and believes that satellite telephony eliminates the high cost and long times needed to build land-line or wireless network infrastructures. Beside Loral and Qualcomm, the Globalstar consortium's strategic partners include Alenia Aerospazio (Italy), China Telecom (Hong Kong), DACOM (Korea), DaimlerChrysler Aerospace (Germany), Chrysler Aerospace (U.S.), Hyundai (Korea), France Telecom, Alcatel (France), Elsacom (Finland), and Vodaphone AirTouch (U.K.). As of February 2000, all 52 Globalstar satellites (48 operational and four in-orbit spares) were in orbit. However, as of

August 2000, subscriber numbers lagged far behind projections, and Globalstar's fate was in question. Despite the relative technological simplicity of the Globalstar network (compared with Iridium), the total system cost between US \$2 billion and US \$3 billion.

Beginning in the first quarter of 2001, another satellite global mobile telephony service will be provided by London-based New ICO Global Communications—so named after ICO Global Communications emerged from bankruptcy protection in May 2000. Like Globalstar, the New ICO system also maximizes use of terrestrial wire-line and wireless (cellular and PCS) networks, and the satellites are not cross-linked. However, New ICO users do have the option to uplink their calls to the satellite directly from the handset. When terrestrial transmission is selected, a dozen satellite gateway Earth stations around the world will provide access to and from the satellite. Using digital onboard processing, the New ICO system can handle 4500 simultaneous phone calls per satellite. The New ICO space segment will comprise 10 satellites operating in medium Earth orbit at an altitude of 6430 mi (10,355 km) and inclined 45° to the equator. The 10 operational satellites will provide complete, continuous overlapping coverage of Earth's surface. Like Globalstar, the New ICO system will employ the same path diversity, where a caller has access to more than one satellite at a time. New ICO believes that its MEO system has at least two advantages over LEO systems like Iridium and Globalstar. First, because there are far fewer satellites to build and launch, the capital cost of the New ICO system is lower, and these savings can be passed on to the consumer. Second, a higher satellite orbit means fewer call handoffs from one satellite to another and thus superior quality of service. The call handoffs are minimized because of a MEO satellite's larger footprint across the ground, where the user is, and because these spacecraft travel more slowly than LEO spacecraft, allowing the user handset more time to "see" the satellite.

New ICO's dual-mode mobile phones will be similar in appearance, size, and weight to standard GSM phones used throughout Europe. New ICO will also supply fixed telephones for such places as remote offices and oil rigs and coin-operated telephones for community phone booths. New ICO service is directed toward satisfying the needs of five market segments: (1) maritime; (2) remote fixed, for example, business and residential users located in areas where there are no existing fixed telecommunications services; (3) handheld mobile users who have an ongoing need for telephony where existing infrastructure is insufficient, as well as users who wish to extend the area in which they can roam; (4) transportation, for example, land transport operators whose needs include vehicle tracking and fleet management applications; and (5) government, for example, military and disaster relief agencies.

The launch of New ICO's first satellite onboard a Sea Launch rocket in March 2000 was unsuccessful. However, New ICO mitigated the impact of this failure with its plans to build and launch a total of 12 satellites even though the intended service requirements call only for 10 operational satellites in orbit. Because US \$4 billion were already spent, New ICO will need another US \$2.1 billion in financing to take it to commercial launch. New ICO Satellite Communications, based in London, was established in January 1995. The New ICO investor consortium comprises two of the world's leading telecommunications

entrepreneurs, Craig McCaw and Subhash Chandra, plus more than 60 of the world's leading telecommunications operators and manufactures. These include INMARSAT (U.K.), COMSAT (U.S.), ARABSAT (Saudi Arabia), British Telecom (U.K.), NEC Corporation (Japan), PT Indonesian Satellite Corporation, Singapore Telecommunications Ltd, Telecom Egypt, Telecomunicaciones de Mexico, Telefonica de Espana (Spain), Telekom Malaysia Berhad, Telstra Holdings (Australia), TRW (U.S.), Deutsche Telekom (Germany), Ericsson Ltd. (Sweden), Mitsubishi Wireless Communications (Japan), Telkom South Africa, Hughes Space & Communications Company (U.S.) that is building the satellite system, and Hughes Network Systems (U.S.).

Along with the global mobile satellite telephony systems described before, there will also be several regional systems in different parts of the world. Two, MOTIENT and Asia Cellular Satellite System (ACeS) are already operational. Two others expect to be operational in the 2000–2001 time frame. These are Thuraya Satellite Telecommunications and Asia-Pacific Mobile Telecommunications (APMT).

MOTIENT was founded in 1988 as AMSC and has been operational since 1996, when its first satellite, AMSC-1, was launched into orbit. The company targets U.S. corporations that have fleet management needs and services a footprint covering North and Central America, the Caribbean, and surrounding U.S. waters. Mobile workers can be linked to their companies for voice, data, dispatch, and messaging transmissions. Recently, mobile access to the Internet has been added. MOTIENT provides its services to several markets, including fixed-site satellite telephone users in remote areas; land mobile cellular/satellite telephone users; the maritime industry, including managers of multiple vessels and off-shore oil rigs; transportable regional dispatchers, for communications with their fleets of trucks, ships and other vessels, and railcars; and aeronautical users, for making and receiving satellite-linked telephone calls in flight on commercial and military planes. Calls are uplinked directly from the MOTIENT handset to AMSC-1 and downlinked to the MOTIENT gateway outside Washington, D.C., and from there through the PSTN. AMSC-1 can serve up to 10,000 mobile users simultaneously. Located at 101° West longitude, AMSC-1 operates in the L band and uses switchable spot beams to serve an ever changing, on-the-go market.

The main priority of ACeS, based in Jakarta, Indonesia, is to provide cost-effective fill-in satellite service for cellular operators and users and thereby afford seamless coverage throughout Southeast Asia, India, China, Australia, Indonesia, and the Philippines, among other countries. Like MOTIENT, ACeS will provide mobile and fixed voice services, data, fax, paging, and Internet access. The US \$900 million system uses two GEO satellites, one in orbit and operational and the second an in-orbit spare that will first serve as a backup and then later as an active satellite for system expansion into western and central Asia, eastern Europe, and parts of North Africa. The Garuda 1 satellite was successfully launched in February 2000 aboard a Proton/Block DM rocket from the Baikonur Cosmodrome in the Republic of Kazakhstan. After testing, it will become commercially available in the second half of 2000.

ACeS is the first regional, satellite-based, handheld mobile telecommunications system designed exclusively for the Asia-Pacific region. It is also the first integrated GSM (general services for mobile)/satellite network in the world.

Garuda 1 is said to be "the most powerful commercial GEO satellite ever built" and can cover more than 11 million square miles. Lockheed Martin Global Telecommunications is the manufacturer. Each Garuda satellite has 11,000 circuits. Because of the high power of Garuda I, the satellite can handle direct satellite uplinking and downlinking from any user's mobile phone handset. The 205-g Ericsson R190 dual-mode (GSM/Garuda) satellite phone is said to be the smallest satellite phone available worldwide.

The GSM cellular standard is operational in more than 100 countries worldwide. Subscribers to GSM networks worldwide can use ACeS while traveling in Asia by using an authorization card and a leased or owned ACeS satellite terminal. Once out of cellular range, the phone will automatically switch to satellite mode to send or receive calls and will switch back to GSM when in GSM coverage areas. Consumer retail pricing for use of the ACeS system will be less than US \$1 per minute, which is the lowest price for any of the satellite handheld mobile telephony systems announced. Service will be offered initially in eight licensed Asian countries whose total population is 1.7 billion—less than 11% have access to wireless service. These countries are Indonesia, the Philippines, Thailand, India, Pakistan, Bangladesh, Sri Lanka, and Taiwan. After initial service rollout, ACeS will make its network available to an additional 26 countries with which it has already signed international roaming agreements. Significantly, because of its vast population and inadequate telecommunications infrastructure, China is one of the countries that has signed a roaming agreement with ACeS. The four strategic partners of ACeS are Pasifik Satelit Nusantara (Indonesia); Philippines Long Distance Company; Jasmine International (Thailand); and Lockheed Martin Global Telecommunications (U.S.), which owns a 30% interest in ACeS.

Founded in 1997, Thuraya Satellite Telecommunications Company of the United Arab Emirates will serve an area that spans the Indian subcontinent, central Asia, the Middle East, north and central Africa, Turkey, and Europe. This area, much of which is sparsely populated, has rugged terrain, little telecommunications infrastructure, and comprises approximately 100 countries and two billion people. This will be the first and largest mobile satellite service in these regions. Thuraya plans to begin commercial service in late 2000 or early 2001 after a scheduled launch in September 2000. The Thuraya system is valued at US \$1 billion, including one in-orbit satellite at 44° East longitude and one ground spare. Thuraya will operate a high-power geosynchronous satellite to provide services that include the transmission of voice, data, fax, and messages, as well as location determination using the Global Positioning System of the U.S. Air Force. Thuraya will transmit and receive calls via a single 12.25-meter-aperture reflector on the satellite. Calls can be uplinked directly to the satellite from the user handset or relayed via a terrestrial path to a gateway satellite Earth station. The satellite employs onboard digital signal processing to create more than 200 spot beams that can be redirected in orbit, enabling Thuraya to adapt to consumer demand in real time. The system can handle 13,750 simultaneous voice circuits. Thuraya's investors include some of the leading telecommunications operators from the areas to be served, including Emirates Telecommunications Corporation (UAE); Arab Satellite Communications Organization (ARABSAT) (Saudi Arabia); Qatar Telecom; General Post and

Telecommunications Company (Libya); and other telecommunications organizations from Oman, Yemen, Egypt, Morocco, Sudan, Tunisia, and Germany. Another key investor is Hughes Space & Communications International, which built the Thuraya orbital and ground systems.

Finally, Asia Pacific Mobile Telecommunications Company (APMT), an early market leader, that has a satellite already in an advanced construction phase in 1998, experienced a major setback in early 1999 when the U.S. government withheld an export license from Hughes Space & Communications for the sale of the APMT satellite. (All but one of APMT's owners were Chinese companies, and on the news, Singapore Telecom dropped out.) APMT immediately cancelled the US \$450 million contract with Hughes and has had to start from scratch to seek other suppliers outside the United States. This will considerably delay service introduction. The APMT satellite was originally scheduled for launching in late 1999, and commercial operations were scheduled to begin in 2000. APMT's aim was to complement and extend terrestrial fixed and mobile coverage at low cost. Its coverage and pricing were going to be virtually the same as ACeS, which leaves APMT at a distinct competitive disadvantage at this time.

Regulation

Regulation and the globalization of satellite communications are both very important factors in determining the future development of satellite communications. Therefore, we present here a short description of the current situation with respect to these activities.

International Telecommunication Union. All communications entities that use or require radio-frequency spectrum are subject to the rules and regulations of the International Telecommunication Union, a specialized agency of the United Nations headquartered in Geneva, Switzerland. In the case of satellite communications, these regulated entities include operators of fixed (geostationary), broadcast (direct-to-home), and mobile satellite services, as well as operators of satellite ground links. Most, if not all, are also subject to national legislation and to the rules of numerous national telecommunication regulatory agencies (such as the Federal Communications Commission in the United States).

The mission of the ITU is to facilitate the global development of telecommunications for the universal benefit of mankind, through the rule of law, mutual consent, and cooperative action (30). The ITU comprises 189 country members and some 600 members from the private sector (as of July 2000). Among its primary goals is to create and oversee an orderly, transparent system to ensure satellite interconnection and interoperability of different national, regional, and global satellite systems on a technical and administrative basis.

In support of this goal, the ITU attempts to establish fair and equitable regulatory processes, sets standards, allocates orbital slots, provides for the efficient use of radio spectrum, supports telecommunications development worldwide, and ensures freedom from harmful interference through efficient spectrum management. It is safe to say that we could not have the robust satellite systems and applications we have today—and look for tomorrow—without the ITU's

equitable regulation of the world's limited radio-frequency spectrum and its enforcement of those regulations.

One of the most important tasks of the ITU today is to ensure that increasingly scarce radio spectrum is not allocated for uses that are not currently feasible or practical. The ITU is aware that it must strike a careful balance between its "first-come, first-served" policy of spectrum reservation (even where no satellite system has been developed) and accommodating deserving, but later, applicants whose well-engineered systems are ready to go (31).

The ITU is also charged with recommending tariff and accounting rate principles to ensure nondiscriminatory treatment. Members and spectrum users pay an annual membership fee to the ITU, along with various filing fees when applying to operate a new system, but they do not pay for the spectrum they use. All ITU decisions are reached by membership vote. Only government members vote on decisions regarding spectrum (32).

The origins of the ITU date back to 1865, when telegraph communications were heating up. There was no international regulatory body to take the lead in providing for the interconnection of national networks or to standardize equipment, issue operating instructions, and lay down common international tariffs. On May 17, 1865, the International Telegraph Union, later to become the International Telecommunication Union, was established (33).

ITU activity in satellite communications took off after the launch of Sputnik. In 1959, a study group was formed to study space radio communication. In 1963, an Extraordinary Administrative Conference for space communications was held to allocate frequencies to the various space-based services (33). Since that time, the ITU has held timely regional and world administrative conferences to plan for and provide new telecommunication services. Each major innovation in the field of telecommunications is matched by specific action on the part of the ITU to integrate new technologies into the world network and to provide the necessary resources (e.g., radio spectrum, orbital slots) to respond effectively to the expectations of member states. For example, with the advent of non geostationary low and medium Earth orbit satellite systems, the ITU assigns orbits rather than orbital slots. The orbit is defined by five factors: spacing of the satellites, altitude, inclination, number of planes, and number of satellites per plane.

The ITU's workload has become increasingly heavy and complex since the end of the Cold War. As the bipolar Cold War environment gave way to the global marketplace, satellites began to assume an increasingly important role in the communications infrastructures of the new CIS republics (34). This is also true of numerous developing nations, which at this time also began to seek a means of entry into the global marketplace. Satellites emerged as the quickest and most cost-efficient route to global telecommunications, creating "instant" ubiquitous telecommunications infrastructures. Through satellites, any country could enter the global marketplace immediately—without waiting years for installing copper wire or fiber connections.

The significant capital required for these satellite-based infrastructures made use of private funds inevitable. In most cases, the governments of the CIS and developing nations could not afford this infrastructure on their own, so private companies moved in. Moreover, the economic value of satellite slots and

radio spectrum and the provision of satellite services drew in other competing private companies. In fact, today, competition in providing satellite communication services is pervasive throughout the world, domestically, regionally, and globally.

For the ITU, this altered satellite communications landscape meant dozens of new members, new requirements for satellite orbital slots and finite spectrum, member demands for timely action despite growing complexity, and increased politicization in the face of mounting worldwide competition. Meanwhile, new regional and global satellite services increased competition for space throughout the orbital arc. Previously, most applicants sought only to provide a national service—often with a single satellite; now applicants that seek to provide regional and global satellite services want to be everywhere. Hence, they require orbital assignments above countries throughout the world (34).

In addition, new satellite technologies have emerged. These include interactive direct-to-home broadcasting, handheld mobile telephony, and high-data-rate broadband systems for interactive multimedia. These new technologies place added pressure on the ITU, which must ensure their technical soundness and allocate new orbital and spectrum resources so as to prevent harmful interference with any existing or planned system and speed their entry into the highly competitive world marketplace.

To promote the proliferation of global mobile telephony, for example, the ITU, in March 1999, set a single worldwide standard to enable all mobile phones to work anywhere in the world. Previously, global roaming was not feasible because there were competing and incompatible standards among nations. For instance, U.S. wireless networks used code division multiple access (CDMA), but Europe and large parts of Asia used GSM global system for mobile communication. In adopting a single standard, the ITU took the best from both technologies.

Along with the new satellite technologies, there are also competing terrestrial systems, such as fiber-optic broadband and cellular that must be accommodated with a spectrum.

The World Trade Organization. Hand in hand with privatization and competition in satellite communications has come deregulation, whereby many governments now allow foreign competitors to provide satellite services in once-closed markets. On January 1, 1998, the World Trade Organization's landmark agreement on basic telecommunications took effect, supporting the creation of a multilateral framework for trade in telecommunication services and open competitive markets. Coincidentally, the same date marked the opening up of telecommunications markets within most member states of the European Union. Both actions have a common objective, namely, to ensure nondiscriminatory market access for service providers and to lower costs for end users.

The telecommunication sector, including communication satellites, is one of the major components of the world's economy. The value of telecommunication sales (equipment and services) exceeded US \$1 trillion in 1998. Moreover, telecommunication networks are a major facilitator of trade in other goods and services, as well as in the timely movement of capital throughout world markets. Because of the importance of telecommunications, the WTO has undertaken to ensure that (1) there is free market access, (2) regulation is

transparent and nondiscriminatory, and (3) pricing is fair and nondiscriminatory (31).

Before 1998, only a handful of countries permitted competitive provision of international telecommunications services. Of the WTO's 188 member states, 69 have voluntarily agreed to comply with WTO agreements to liberalize telecommunications trade. These 69 signatories account for more than 90% of international telecommunications traffic. The WTO believes that a significant by-product of this reform will be quicker introduction of new technologies and services in signatory nations.

The WTO agreement on telecommunications underscores the fact that telecommunications trade has moved from bilateral to multilateral status. In large part, communication satellites are responsible for this significant change, because satellites do not recognize geographic borders. Moreover, the cost of satellite transmission is insensitive to distance. Telecommunications traffic that once moved from one country to another now flows through vast networks that can comprise dozens of countries. Where interconnection rates used to be settled by two nations, now many nations are involved, introducing greater complexity. Reform and fairness in assessing accounting rates is a primary objective of the WTO. Specifically, the WTO seeks a framework that is nondiscriminatory, cost-based, transparent, and consistent with the principle of voluntary multilateralism (31).

Conclusions

Looking back, at the end of 1999, the worldwide satellite industry had generated more than US \$69 billion in annual revenues. Communication satellite services, the largest and fastest growing segment of the industry, generated US \$30.7 billion in 1999. The U.S. satellite industry accounted for US \$31.9 billion of the total, or roughly 46% of worldwide revenues (35). This rather unbalanced spreadsheet will change quickly as more and more non-U.S. countries provide regional services, for example, satellite handheld mobile telephony and direct-to-home TV, and strengthen their manufactures' ability to compete better with U.S.-based rivals. As we have seen, satellite handheld mobile telephony and broadband services are already proceeding without U.S. involvement. The loss of APMT's US export license virtually invites international rivalry in manufacturing.

In August 2000, the mobile satellite services (MSS) market was the riskiest of all satellite businesses discussed here. Despite cumulative investments in excess of US \$20 billion and 25 years of effort, MSS remains a niche market with only an estimated 600,000 users worldwide. The current market is professional and draws subscribers primarily from areas where terrestrial cellular systems are not available. INMARSAT and Qualcomm's Omni Tracs service are the dominant players. Due to the failure of Iridium in early 2000, many market analysts doubt the viability of MSS as a successful business. Still, based on current market projections and growth rates, one can forecast the existence of three million to four million MSS users by 2004. Most of the growth will come from niche and specialized markets and from converting the telephony system to a medium-rate

data system. Such conversion has already taken place as Globalstar and New ICO begin to offer data service. In the future, all MSS operators hope to boost traffic and revenue with data applications. A significant mobile satellite data market is most likely to require specialized providers to address a wide range of asset tracking and telemetry applications.

Looking ahead at global broadband satellite services, Pioneer Consulting has forecast that total revenues will increase from around US \$200 million in 1999 to US \$37 billion in 2008. Moreover, according to the Teal Group, by 2008, annual revenues deriving from all commercial satellite technologies and services worldwide will total US \$120 billion. These skyrocketing revenues can be attributed to at least eight trends that have propelled the commercial satellite industry this far: (1) global deregulation and privatization, (2) digital transformation, (3) market convergence, (4) globalization of services, (5) strategic international alliances, (6) the dynamic emergence of—and rapidly accelerating global demand for—satellite broadband services, (7) worldwide demand for more mobile services, and (8) overall demand for more satellite-based telecommunications services of all kinds.

Global Deregulation and Privatization. Deregulation and privatization of satellite services has occurred throughout the world. This has led to the provision of commercial satellite services by entities from foreign countries that had previously been banned from providing these services in certain highly regulated countries, for example, India, China, Mexico, and Greece. The ensuing competition in turn has led to better quality products and services; lower, more competitive pricing; introduction of new product and service offerings; and spectacular growth in demand. Likewise, the decision of the U.S. Air Force to make its Global Positioning System available commercially to anyone in the world has triggered myriad new service offerings at competitive prices. Finally, when examining privatization, the case of INTELSAT and its commercial spin-off, New Skies, demonstrates the consumer benefits. Before PanAmSat had grown its satellite fleet enough to compete with INTELSAT, only INTELSAT provided satellite coverage around the world. As a monopoly, INTELSAT's prices were high, and new services were slow to come to market. Now, with New Skies operating a commercial satellite fleet that covers most of the world, competition (with both INTELSAT and PanAmSat and other satellite operators) has brought its familiar benefits. In addition, New Skies has demonstrated its commitment to innovation. Several different satellite services are provided on a single C/Ku-band satellite: DTH satellite TV broadcasting, point to multipoint distribution to cable headends, corporate data networks, Internet access, and multimedia transmissions.

Digital Transformation. Fully packed chips and very high rates of digital compression help give consumers the advantage of advanced satellite-based services at ever lower prices. Being able to install more and more information on chips, coupled with soaring digital compression rates, is making possible the multiuse satellite; without these technologies, satellites would be too heavy and expensive to launch. For example, Eutelsat's SESAT satellite, which was launched into GEO orbit in April 2000, has 18 Ku transponders that are used for a full range of services, including data and video broadcasting, direct-to-home TV, inter- and intracorporate networks, satellite newsgathering, Internet

backbone connections, high-speed Internet access, distance learning, high-speed transfer of software, and messaging and positioning services for mobile users. The satellite was dedicated to communications satellite pioneer Arthur C. Clarke and is so named.

Market Convergence. In the area of service provision, market convergence is giving consumers a whole new range of satellite products and services. For example, the strategic partnerships between TiVo and AOL TV with Hughes' DIRECTV merge the content suppliers with the satellite operator. This gives consumers a variety of advanced services, such as watching TV while accessing the Internet, writing E-mail, or requesting an advertiser's annual report. There is also a new, wide-ranging alliance under which News Corp. provides access to Yahoo! Web sites through its global satellite systems and allows Yahoo! to use News Corp.'s news and entertainment products, such as Fox News Channel and the *London Times* as a major source of content for its computer sites. Another example is the convergence of the automobile industry, for example, General Motors' OnStar system with PanAmSat's satellite fleet. What was initially an emergency system for obtaining assistance while driving has evolved into much more. Today, drivers of upscale General Motors cars (and the cars of some other manufacturers) can use the onboard satellite system to obtain directions to a selected destination, choose a restaurant or hotel and make reservations, or find the nearest gas station or dry cleaner. As described before, the convergence of manufacturing with satellite technology providers has revolutionized multinational manufacturing and distribution operations. Today, numerous industries and small businesses worldwide are finding new ways to take advantage of satellite technologies.

Globalization of Services. As deregulation and privatization occur, satellite-delivered services have become globalized to the extent that satellite TV viewers in southeast Asia have become ardent viewers of such fare as MTV, Nickelodeon, and "ER." Of course, CNN is virtually ubiquitous, available on almost any TV set in the world. But America is no longer exporting only its TV programs. A new service on DIRECTV allows American viewers to experience various cultures from around the world. WorldLink TV, which is telecast via DIRECTV, delivers public affairs programming from Belfast to Beijing. Viewers can tune in to independent newscasts, social documentaries, world music, and documentaries on human rights issues, the environment, and the global economy. Meanwhile, Discovery Communications of the United States is funding and providing satellite education in developing countries. Discovery is providing advanced technological resources and training to rural and disadvantaged schools and community centers around the world. In its first phase of operations, Discovery is establishing learning centers equipped with satellite and video technologies in sub-Saharan Africa and Latin America.

Strategic International Alliances. Strategic international alliances have become an economic necessity in the light of today's expensive satellite programs, including satellite construction, launch, insurance, and ground systems. This is increasingly the case as new satellite services are global, so that strategic alliances are formed for economic reasons and also for marketing purposes. For example, the ill-fated Iridium global satellite telephony service spent US \$5 billion to build its system and relied on 19 strategic investors from around the

world. One of its successors, Globalstar, has 10 founding partners and many additional financial supporters. The regional Thuraya satellite mobile telephony system has 15 strategic partners and investors.

Turning to broadband, to come on line, the emerging satellite broadband systems will need anywhere from less than US \$1 billion for iSky, which is using satellite capacity on Telesat (Canada), to US \$10 billion for Teledesic. Numerous strategic partnerships for both financing and marketing these broadband systems are essential. The stakes are high. For example, a team of WTO economists estimates that by year-end 2000, there will be more than 300 million Internet users worldwide and that E-commerce will equal US \$300 billion. Because most of the satellite broadband systems will not be on line until the 2001–2002 time frame, these numbers reflect the use of cable and other terrestrial technologies. Satellite broadband technology is certain to eliminate the bottleneck and expand the number of commercial consumer and business users. Laying the groundwork for successful satellite broadband companies will require strategic partnerships that enhance the program's technological, marketing, and economic success.

Soaring Demand for Satellite Broadband Services. Meanwhile, Pioneer Consulting forecasted that total global broadband satellite revenues will increase to US \$37 billion in 2008. Residential service will represent the majority of revenue gains, accounting for almost US \$22 billion of revenues in 2008. Demand for satellite broadband services will skyrocket as more and more business and residential consumers access the Internet. Netscape founder Marc Andreessen has forecast that, by 2010, the Internet will be 1000 times bigger than it is today and that satellites will be a key conduit because of their ubiquitous reach. China's Internet growth—even though stymied to some extent by government prohibitions—says a lot for growth around the world. In 1999, the number of China's Internet users climbed from 2.1 million to more than 6.7 million. By 2003, it is predicted that China will have more than 33 million Internet users and that the number will grow at an annual rate of 60% through 2004. As a whole, Asia had 40 million Internet users as of June 2000; quickly escalating growth is expected to bring the total to 375 million by 2005.

Demand for "On the Go" Satellite Mobile Services. It is estimated that, by 2003, more than one billion mobile phones will be in use around the world. Wall Street, wireless service providers, and industry analysts believe that wireless data will be the next area of explosive expansion in the Internet economy. Users of wireless phone systems, and particularly satellite-based handheld mobile phones, will use their phones for everything from learning about the local weather to videoconferencing across a continent. The handheld satellite phone will have a screen for displaying both information and broadcast images. Throughout the world, business commuters and travelers lose important business resources that they take for granted when they are at their desktop personal computers. These include Internet access, E-mail and faxing capability, and word processing. Many of these resources will soon become available via mobile platforms, on demand for users on the go. For example, INMARSAT's satellite-based B-GAN network, scheduled to become operational during 2004, will deliver Internet and intranet content, video-on-demand, videoconferencing, fax, E-mail, voice and LAN access speeds at up to 432 kbit/s virtually anywhere

in the world via notebook or palm top computers. According to INMARSAT President and CEO Michael Storey, the new system will enable INMARSAT to "meet the high demand for mobile broadband services and provide a seamless extension to fixed networks." INF Barings has forecast that the mobile satellite market will be worth more than US \$4 billion in 2004 and will double to more than US \$8 billion in 2009. INMARSAT expects to generate wholesale revenues from its new B-GAN network in excess of US \$10 billion, "as global multinational enterprises....have access to global mobile broadband communications wherever they are in the world," Storey added. Similarly, Boeing is prepared to afford airline passengers global mobile high-speed on-line connections, television, and other entertainment. Passengers will be able to use laptops to surf the Net at speeds up to 140 times faster than the fastest standard modem service. They will also be able to send and receive E-mail, transmit/receive word processing documents, and much more. Commercial cars with multimedia cockpits are already making their appearance. A personal computer hooked up to a swiveling satellite antenna to navigate the Internet gives access to the same broad array of information resources a driver has at the office. Passengers can even watch films.

The Importance of 24/7 Backup. Whether on the go, at home, or at the office, people have become accustomed to using or enjoying satellite-delivered services, and all indications show that their reliance on such services will increase rapidly in the future. Meanwhile, new subscribers are signing up by the thousands all over the world, from cosmopolitan cities to rural villages in undeveloped countries. The worldwide commercial satellite industry is worth hundreds of billions of dollars in terms of the revenue generated by satellite services. This revenue is significant both to the satellite industry as a whole and to national economies. And in between are businesses whose own revenues depend on the availability of satellite-based telecommunications.

In fact, the real value of commercial satellite-based telecommunications, information, and entertainment services is so diversified that it may not be possible to quantify it exactly. However, a new U.S. satellite company has introduced a product that underscores the vital importance of commercial satellite services for operators, users, and national economies alike. The company, called AssureSat, Inc., will provide two high-powered, specially designed geostationary satellites that will provide in-orbit backup protection service beginning in 2002. Once in orbit, the AssureSat satellites will be able to provide backup protection to most fixed GEO satellite operators by moving quickly to appropriate orbital slots to take over the communications tasks of malfunctioning spacecraft or spacecraft whose launches have failed. In-orbit operational backup can provide a cost-effective way for a satellite operator to retain customers and protect both its revenue stream and its customer relationships. The unique design of the spacecraft will allow them to operate on all three International Telecommunication Union (ITU) region frequency plans, and the antennas will be steerable in flight to offer variable footprint coverage in both the C-and Ku-frequency bands. Each of the AssureSat satellites will carry 36 C-band transponders and 36 Ku-band transponders. AssureSat will not offer backup protection for mobile satellites, thus leaving a significant new business opportunity for another entrepreneurial satellite company.

COMMUNICATION SATELLITE DEVELOPMENT IN RUSSIA

Introduction

Work on the practical applications of artificial Earth satellites began in Russia (USSR) in 1961. The first of these satellites, the small low-altitude Strela series spacecraft of the “electronic mail” type, were developed by the Scientific Production Association for Applied Mechanics (NPO PM) and placed in orbit in 1964. One year later, the Experimental Design Bureau-1 (OKB-1), (currently S.P. Korolev Energia Rocket and Space Corporation) inserted the active relay satellite Molniya-1 into a highly elliptical orbit. In 1965, work on this spacecraft was transferred to NPO PM and, for the next 30 years, this organization was the only one in the country developing telecommunication satellites (Table 1). The first geostationary satellite was inserted into orbit in 1975.

It was not until 1997 that a communication satellite, Kupon, developed by another organization, the S.A. Lavochkin NPO, was placed in orbit, and in 1999, the communication satellite Yamal developed by Energia was launched. At present, work to design communication satellites is being conducted by the Machine Building NPO and the M.V. Khrunichev State Space Scientific Production Center.

The spacecraft that were and are being developed in Russia may be divided into three categories on the basis of the types of orbit:

- satellites in low circular orbits, primarily at an altitude of 1500 km (such satellites are used to form multisatellite communications systems);
- *Molniya* type satellites in highly elliptical orbit;
- satellites in geostationary orbit.

Satellites in Low Orbit

The first launch of a Strela type satellite took place on 22 August 1964. This was the first spacecraft to enable exchange of information among remote users. The satellites were launched together, five to eight at a time, into a circular near-polar orbit at an altitude of 1500 km. Each nonoriented small satellite had a mass of 50–80 kg and carried a retransmitter operating as part of an “electronic mail” system and a command and instrumentation system that transmitted telemetry data to Earth on the status of the satellite’s onboard systems and received control commands from Earth.

The satellites’ electric power supply came from a system consisting of solar cells and storage batteries. The solar cells provided energy for spacecraft equipment during the illuminated part of the orbit, during which the storage battery was also charged. In the dark part of the orbit, the equipment operated on power from the storage battery.

Table 1. The Spacecraft Developed by NPO PM and the Dates of Their First Launch

No.	Date	Satellite	Purpose(s)	Developer and manufacturer
1	8/22/64	Strela-1	Data relay	NPO PM
2	5/25/67	Molniya	Telephone, television broadcast	OKB-1 (manufactured by NPO PM)
3	7/2/69	Molniya-1B	Telephone, television broadcast	NPO PM
4	4/25/70	Strela-1M	Data relay	NPO PM
5	11/4/71	Molniya-2	Telephone, television broadcast	NPO PM
6	11/21/74	Molniya-3	Telephone, television broadcast	NPO PM
7	12/22/75	Raduga	Telephone, television broadcast	NPO PM
8	10/26/76	Ekran	Television broadcast	NPO PM
9	12/19/78	Gorizont	Telephone, television broadcast	NPO PM
10	12/17/81	Radio	Data relay	NPO PM
11	5/18/82	Potok	Data relay	NPO PM
12	4/22/83	Molniya-1T	Telephone	NPO-PM
13	10/25/85	Luch	Data, telephone, television broadcast	NPO PM
14	12/27/87	Ekran-M	Television broadcast	NPO PM
15	6/22/89	Raduga-1	Telephone	NPO PM (manufactured by Polet PO)
16	7/13/92	Gonets-D	Data relay	NPO PM
17	1/20/94	Gals	Telephone	NPO PM
18	10/13/94	Ekspress	Telephone, data relay	NPO PM
19	10/11/95	Luch-2	Data relay, telephone, television broadcast	NPO PM
20	2/19/96	Gonets-D1	Data relay	NPO PM
21	3/12/00	Ekspress-A	Telephone, television broadcast	NPO PM
22	4/18/00	Sesat	Telephone, television broadcast	NPO PM
23	7/20/01	Molniya-3K	Telephone	NPO-PM

The spacecraft equipment used only a small amount of power, and, thus, emitted only small amounts of heat. Thus, a passive thermal regulation system was used to maintain the thermal conditions required for equipment operation. These conditions were maintained by selecting the optical coefficients of the spacecraft and instrument exterior on the basis of the heat flux from the Sun and Earth.

The spacecraft design consisted of two assemblies, a pressurized container for the equipment and the exterior of the solar panels, which was approximately spherical in shape.

The Gonets type of satellite marked a further development of data relay systems. These satellites were also launched in groups into circular orbit of an altitude of 1500 km and an inclination of 82.5° . The Gonets-D satellite was designed to relay data in digital form among users located in global service areas in two modes of operation:

- “electronic mail”—with storage in the onboard memory and subsequent transmission to the user;
- real time, when the sender and recipient were in the radiovisibility area of the same satellite. Unlike Strela, the Gonets-D satellite had a magneto gravitational attitude control system, so that the long axis of the satellite was pointed at Earth with an error of 10° . The power supply system used both solar cells and a storage battery. The passive thermal control system consisted of heat pipes enabling removal of heat from the storage battery.

The main structural component uniting the blocks and assemblies of the spacecraft into a single system was the pressurized container. It served as the primary load-bearing element for connecting the spacecraft to the separation device by two brackets located diametrically on its cylindrical portion. The upper and lower frameworks for the solar cells were mounted on the upper end plate and cylindrical portion of the pressurized container, respectively. The lower framework was used as the mount for deployment of the antenna feeds and the magnetometer rods. The Gonets-D1 was launched on 2/19/96. This satellite was an updated version of the Gonets D, with an improved retransmitter to provide higher throughput. The major specifications of the Strela type (Fig. 1) and Gonets-D1 satellites (Fig. 2) are provided in Table 2.

Figure 1. Strela type spacecraft.

Figure 2. Gonets type spacecraft.

Satellites in Highly Elliptical Orbit

On 23 April 1965, the Molniya-1 satellite was launched, making it possible to establish communications among the most distant points in our nation. The introduction and use of this second-generation satellite enabled creation of

Table 2. Specifications of Strela and Gonets-D1 Satellites^a

	Strela	Gonets-D1
Orbit	Circular, altitude 1500 km and inclination of 85.5°	Circular, altitude 1500 km and inclination of 82.5°

^aThe Cosmos-3M and Tsiklon launch vehicles were used to insert these satellites into orbit. The Rokot launch vehicle could also be used.

the first national satellite communication system as well as distributed television broadcasting. One feature of the highly elliptical orbit is that, during the working phase, the spacecraft has radiovisibility of the entire territory of Russia (USSR).

The Molniya-1 was the first satellite launched into a highly elliptical orbit. The orbit had a perigee altitude of 460 km, an apogee of 40,000 km, and an inclination of 62.8°. There was a retransmitter on board, which received and transmitted digital and analog data in real time, and a control and instrumentation system for transmitting telemetry information to Earth on the status of onboard systems and receiving of commands from Earth. Telemetry sensors of signals and amplitude monitored retransmitter performance during routine use.

Molniya-1 consisted of a pressurized instrument container, two antenna blocks with directional antennas, solar panels, a thermal control system heat exchanger, and a cold gas control system. Inside the pressurized container was the instrument rack and its instruments. The pressurized container maintained the interior environment (temperature, humidity, pressure, and gas composition) and was the main load-bearing component of the structure.

To transmit a continuous signal to Earth the two antenna blocks were located in a single plane on opposite sides of the spacecraft. The antenna blocks were constantly pointed at the Earth using Earth-orientation sensors.

The spacecraft got its power from an electric power system consisting of a solar panel array and a storage battery. The solar array powered the satellite equipment during the illuminated part of the orbit, and during the dark parts, the storage battery was switched on. Having the panels of the solar array constantly pointed at the Sun provided the maximum possible energy. This was achieved by adjusting of orbital parameters with a cold gas system device. A station-keeping propulsion unit that had a liquid propellant engine was used to correct orbital parameters during insertion and maintenance in orbit.

A control system was used to hook up the electric power system to the onboard equipment and to control it, as well as the spacecraft systems. The control systems consisted of a control block, contact sensors, and separation switches. The control block's function was to turn the power supply on and off, perform logic processing and distribution of individual commands from the control and instrumentation system, and also to support ground-based tests. The command segment controlling the operations of the attitude control and stabilization system, the relay station and all commands for the electric power and thermal control system were issued by the control and instrumentation system, bypassing the control block.

The contact sensors functioned to close electric circuits transmitting signals to deploy the structural elements of the antenna blocks and solar panels. The disconnect switches functioned to generate a "disconnect switch" signal at the moment the device was disconnected.

The Molniya-1 equipment consumed a great deal of electricity and thus put out a great deal of heat. A multicomponent active thermal control system maintained the thermal conditions needed for the equipment to operate. This type of thermal control system maintained the temperatures of the attachment points for the apparatus mounted on the equipment rack within the pressurized container by a flow of liquid through pipes and adjustable electric heaters.

Figure 3. Molniya type spacecraft. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Using the Molniya-1 platform, the Molniya-1B was developed and launched in 1969, the Molniya-3 in 1971, and the Molniya-1 T in 1983. The structure and configuration of the spacecraft design was virtually unaltered; however, the active life of the equipment gradually increased as did channel capacity, increasing communications quality. The Molniya-3 K was launched in 2001 and has an active life span of up to 5 years. It has a new station-keeping propulsion unit, its temperature control system contains a new generation thermal regulator, new photovoltaics with improved performance have been installed on the solar panels, and the throughput capacity of the retransmitter has been improved (Fig. 3). The specifications of the Molniya type spacecraft are shown in Table 3. The Molniya launch vehicle was used to insert the spacecraft into orbit.

Table 3. Specifications of Molniya Spacecraft

Orbit	Highly elliptical at an inclination of 62.8°

Type of thermal control system	Active
Spacecraft mass, kg	1740
Orbital insertion procedure	Single

Spacecraft in Geostationary Orbit

The Raduga and Gorizont spacecraft were the first Russian communication satellites to operate in geostationary orbit (Fig. 4). They were designed to provide telecommunication services, including television, telephone connections, and data relay. The Gorizont, which is the most typical, was inserted into geostationary orbit by the Proton launch vehicle and the D or DM booster stage. An onboard propulsion system carried the spacecraft to the required longitude and maintained it there. Orbital inclination was not controlled. The first Gorizont spacecraft was launched on 19 December 1978, the last on 6 June 2000. During this period 33 satellites of this type were successfully launched.

The introduction of Gorizont made possible a substantial (approximately by a factor of 10) increase in the channel capacity of satellite communications in the interests of the economy and international collaboration within the Orbita and Intersputnik systems. Moreover, Moscow, a new distributive television broadcasting system, and the Volna system of communications with commercial ships at sea were developed for use on these satellites. A multi-transponder onboard retransmitter was installed on this spacecraft. The total output power of the

Figure 4. The Gorizont spacecraft.

onboard transponders is 195 W. The Gorizont retransmitter comprises six C-band transponders, one Ku-band transponder and one L-band transponder. The C-band transponders are multipurpose and can be used for relaying television, multichannel telephone, and radio broadcast signals, and images of newspaper matrices. One of the transponders has enhanced output capacity and is designed for transmitting television signals to a network of simplified receiving stations using a highly directional onboard antenna. The L-band transponder has a cross-link with one of the C-band transponders that allow using it for communications between a ship station in the L-band and a shore station in the C-band. Reception and transmission of radio signals is handled by a set of 11 onboard antennas.

The centimeter-band antennas provide various directional patterns and serve territories of various sizes on the Earth's surface. Regions of heavy traffic are served by highly directional antenna, and those with less traffic by global antennas. The highly directional transmitting antenna used in the Moscow system is equipped with a special device that allows it to be reaimed once. This makes it possible to serve stipulated regions on the Earth's surface in the event it became necessary to transfer the satellite from one spot in its orbit to another.

Despite the fact that Gorizont's development began in mid-1975, the basic technical designs for the onboard utility systems used in its development are still being used in current projects. The spacecraft's construction and configuration center around the pressurized instrument container. The instrument container is the main load-bearing component. It is used for mounting the structural units, instruments, and modules that comprise the satellite. The instrument container is a cylindrical pressurized module containing an instrument rack and components of the thermal control system. The interior of the container provides the most favorable climatic conditions for operating electronic instruments.

In orbit, the spacecraft is oriented so that the longitudinal axis of the instrument container, along which the onboard relay antennas are mounted, is constantly pointed at Earth, whereas the horizontal axes maintain a constant position in space. The station keeping propulsion units are located along the axis tangential to the orbit, and the axis that is binormal to the orbit corresponds to the axis of rotation of the solar panels. These panels are kept constantly pointed at the Sun by two one-stage electromechanical drives that rotate synchronously.

The spacecraft uses a triaxial attitude control and stabilization system. The sensor elements of the system include infrared Earth-orientation sensors, solar-orientation sensors, and gyroscopic angular velocity meters. The gyroscopic stabilizer and a cold gas engine act as servomechanisms. Analog devices control the system.

The orientation and stabilization system damps the movement of the satellite after it is separated from the booster stage and provides initial orientation to the Sun, initial orientation to Earth, and triaxial attitude control and stabilization of the satellite throughout its life in orbit with an error of $\pm(0.3-0.5)^\circ$.

The station-keeping propulsion units on the first Gorizont satellites utilized bipropellant liquid microthrusters that had a thrust of 45 g. The station-keeping propulsion unit had the form of two modules located so that the axes of the engine nozzles were pointed tangentially to the orbit on opposite sides. Given this configuration of the propulsion units, the onboard antennas could be pointed at

Earth without disruption, and thus it was not necessary to interrupt communication sessions when these units were on. The onboard spacecraft control system, along with a special module, controlled the propulsion unit. The station-keeping propulsion unit maintained the satellite within the stipulated longitudinal limits with an error no greater than $\pm 0.5^\circ$.

The spacecraft power supply system used a solar array with silicon photoconverters constantly pointed at the Sun, a cadmium nickel storage battery, and a voltage regulator that created optimum conditions for the common operation of the solar panels and storage batteries and stabilized the voltage in the range of (27 ± 0.81) V. The capacitance of the storage battery provided enough electric power for the onboard equipment to support uninterrupted operation of the retransmitter while the satellite was in the dark portion of the orbit. The power of the Gorizont electric power system at the end of the satellite's active life was 1280 W.

The solar array structure was redesigned to allow placing it in the limited volume of the launch vehicle nose cone during insertion into orbit. It had the form of two wings symmetrically located with respect to the instrument container. The wings were connected to electromechanical drives through articulated joints. Each wing consisted of four panels, the root, the end, and two side panels, which were connected to each other by intermediate joints. In the launch position, the wings were folded into a package and attached by special rods with a system of pins with mechanical locks that burst open after the spacecraft separated from the booster stage. The panels were rotated into operating position by spring-activated drives.

The temperature was maintained by an active, two-loop, gas-liquid thermal control system that consisted of a fan, a gas-liquid heat exchanger, a gas pipeline, a hydraulic pump, a thermoregulator, relief valves, a radiative heat exchanger, and a system control block. The required temperatures were maintained through forced gas circulation in the pressurized instrument container and forced coolant circulation through the satellite's liquid loop.

The system control block provides automatic control of the system components and, if necessary, shifts from the main components of the system to the backup components. Pressure sensors, sensors of coolant pressure differential, and check valves maintain and monitor the state of the liquid loop. The system is guaranteed to maintain the temperature in the instrument container in the range of 0 to 40°C , and the magnitude of outgoing heat flux is up to 1400 W.

The onboard control unit controls operation of the onboard spacecraft systems. The control unit consists of the equipment of the command and instrumentation system, which receives control commands from Earth, generates a signal to allow the ground control systems to locate the satellite in orbit, and transmits telemetry information on the status of onboard systems and instruments; the telemetry monitoring equipment, which provides storage and output of data from the telemetry sensors of the onboard systems to the transmitting equipment of the command/instrumentation systems; and the control block, which provides strict logic for deploying the mechanical devices and distributing electric power and control commands among the spacecraft systems and instruments.

The Ekspress and Ekspress-A satellites represent further developments of Gorizont. The development of Ekspress made maximum use of the technical experience that had been accumulated in developing the Luch-2 and Gals

spacecraft. Compared to its predecessors, *Ekspress* has significantly better technical and performance characteristics: 12 transponders for the onboard retransmitter; an improved station-keeping propulsion unit for maintaining orbital inclination, which was used for the first time on this satellite; improved precision for maintaining the satellite in orbit from 0.5° for longitude to 0.2° for longitude and latitude, and increased accuracy of spatial orientation of satellite axes in space up to 0.1 to 0.2° . With respect to design, *Ekspress* has the following distinguishing features, compared with *Gorizont*:

1. An information processing unit was added to the onboard control system for storage, maintenance, and transformation of control information to support satellite control, function, and onboard software. This software consists of a package of programs, which, in accordance with algorithms, receives information from the sensor systems, performs calculations, distributes the results, and controls the system or servomechanisms, or prepares information for other programs. The main equipment is the onboard digital computer. These control information processing and computing systems were first used on the *Potok* and *Luch* spacecraft.
2. The attitude control system has improved attitude control instruments, including a system of instruments that provides orientation to the North Star. Logic control over the system is the function of the control information processing and computing complex, which is part of the onboard control system. These measures increase the accuracy of the orientation of the satellite's axes in space to 0.1 – 0.2° .
3. New, more effective types of station-keeping and attitude control engine units were adopted. As a result of the new task of correcting orbital inclination and the associated need to produce significant thrust, with limited mass resources available, *Ekspress* uses a station-keeping propulsion unit, including stationary plasma engines whose specific impulse characteristics exceed the analogous performance of other types of engines by an order of magnitude ($I_{sp} = 1500$ s). This has made it possible to reduce the propulsion unit mass to a minimum by using only a small quantity of working fluid—xenon—and a small number of tanks to store it. Propulsion units of this type were first used on the *Potok* satellite. For orientation, because of the relative frequency with which the engines have to be turned on, a propulsion unit using thermocatalytic engines of relatively high specific impulse performance ($I_{sp} = 170$ s) and low power consumption is used.
4. The electric power system uses a storage battery with nickel hydrogen storage cells with high specific energy and efficiency characteristics compared to the cadmium nickel storage cells used on *Gorizont*.
5. *Ekspress* is similar in design to *Gorizont*, except for the location of the transmitters of the onboard retransmitter, which were removed from the pressurized instrument container and placed on the exterior framework where all of the onboard retransmission antennas are located.

A modification of this spacecraft—*Ekspress-A*—has 17 transponders and a 7-year active lifetime in orbit.

Figure 5. SESAT spacecraft.

Table 4. Specifications of Geostationary Spacecraft

	Gorizont	Ekspress-A	SESAT
Throughput, number of transponders (output power, W)	8 (195)	17 (510)	18 (1512)
Orientation precision, degrees	0.3–0.5	0.1–0.2	0.1
Longitude hold, degrees	0.5	0.2	0.1
Latitude hold, degrees	–	0.2	0.1
Power capacity, W	1280	2900	5300
Total impulse of station keeping propulsion, kN.s	118	1200	1600
Cold generation by the thermal control system, W	1400	2150	2550
Days of autonomous operation	–	30	–
Active lifetime in orbit, yr	3	7	10
Mass, kg	2200	2600	2600

Figure 6. Luch spacecraft.

A further step in the development of telecommunication satellites in this series is the SESAT spacecraft, which has a 10-year active orbital life time and 18 transponders in the Ku-range (Fig. 5). The Proton launch vehicle is used to insert all these types of spacecraft into orbit. The major specifications of the geostationary spacecraft developed by NPO PM are provided in Table 4.

Table 5. Specifications for Luch Spacecraft

Number of transponders	7
Retransmitter frequency band	Ku, P
Orientation precision, degrees	0.1–0.2
Longitude hold, degrees	±0.5
Deviation in latitude, degrees	±3.25
Electric power, W	1800
Spacecraft mass, kg	2400
Active lifetime, years	5

The geostationary satellites Luch are also telecommunication satellites developed by Russia. They are part of the satellite system of command and control of piloted and unpiloted spacecraft. Their development used technical designs validated on other spacecraft developed by NPO PM, such as Gorizont and Potok (Fig. 6). Their distinguishing feature is an antenna system with a high degree of transformability in the launch position, which is comprised of various different types of antennas. The electromechanical pointing system, which uses BCVM algorithms, makes it possible to track the user's low-orbital spacecraft. The specifications of this spacecraft are provided in Table 5.

COMMUNICATIONS SATELLITES, TECHNOLOGY OF

History

Early Theories. In 1895, a Russian scientist, Konstantin Tsiolkovsky, gave the world its first vision of a stationary satellite. He observed that an object orbiting Earth at 22,300 miles up would match the angular rotation of Earth and thus provide a seemingly stationary "star" overhead.

Fifty years later, the English science fiction writer and Royal Air Force electronics officer Arthur C. Clarke expanded on this vision. In 1945, he indicated that such an object orbiting Earth at 22,300 miles up must also have its orbit in the equatorial plane to be considered stationary. Clarke called the object a "satellite" and further noted that providing a satellite in this orbit with a communications repeater could produce a very valuable communications capability. Clarke named such satellites "geostationary communication satellites." Clarke postulated that three geostationary satellites spaced 120° apart would provide full global communications coverage for telephone and television service to the world's population (1,2).

Clarke's concept was ahead of the technologies needed to make it a reality. In 1945, the science of rocketry was still crude, and radio communications depended on large, unreliable vacuum tubes. However, rocketry and electronics technologies both began to advance rapidly, particularly after the development of the transistor in 1947. The first satellite launches, into a low Earth orbit (LEO), occurred during the Cold War following World War II. The United States and Soviet Union were intent on achieving military and technological superiority over each other. Satellites were seen as potentially valuable Cold War tools for reconnaissance and for maintaining reliable communications among far-flung troops.

The Earliest Satellites. On 4 October 1957, a Soviet satellite named “Prosteyshiy Sputnik” (“Simplest Satellite”) was launched into a low Earth orbit and began transmitting telemetric information for what would turn out to be 21 days. Sputnik weighed 184 pounds and was a sphere two feet in diameter. This dramatic Soviet achievement shocked the world, and particularly the U.S. public, which perceived it as a threat to national security. The event was likened to the surprise attack on Pearl Harbor, and it sparked a flurry of U.S. government activity in rocketry and satellites (3).

The rocket that lifted Sputnik into orbit was four stories high. Such heavy-lift launchers used technology similar to that of intercontinental ballistic missiles (ICBMs), so it was perceived that the launch vehicle was at least as important as the actual satellite. In the United States, the public feared that the Soviet Union’s ability to launch satellites translated into the capability to launch ballistic missiles that could carry nuclear weapons from Europe to America. The “Space Race” had begun (4,5). The Sputnik launch led directly to the creation of the U.S. National Aeronautics and Space Administration (NASA) (6). In October 1958, the National Aeronautics and Space Act launched NASA out of the old National Advisory Committee for Aeronautics (NACA), which had existed since 1915. NASA became responsible for civilian space science and aeronautical research, whereas the U.S. Department of Defense continued to carry out defense work.

The launch of Sputnik II on 3 November 1957, was a second blow to America’s perception of itself as technologically superior to the Soviet Union. A third blow came on 6 December 1957, when the first U.S. satellite, Vanguard, exploded on launch. But on 31 January 1958, the United States launched Explorer I, which successfully transmitted telemetric data for 5 months. Shortly thereafter, in December 1958, America launched Score, the first satellite to transmit a radio broadcast, President Eisenhower’s Christmas message. In 1960, two more satellites followed, Echo I and Courier. On 10 July 1962, NASA launched the first non-government-built satellite, AT&T’s Telstar 1, a LEO spacecraft for relaying transatlantic television and data. In that same year, Telstar was used for the first transoceanic television ever transmitted, a live broadcast that commemorated the first anniversary of the death of U.N. Secretary General Dag Hammarskjöld by a link-up of simultaneous ceremonies held at the United Nations in New York and Paris and Hammarskjöld’s tomb in Sweden (7). Relay I, launched by NASA in December 1962, was built by RCA, also for transoceanic communications. Meanwhile, in May 1958, Sputnik III was placed into orbit by the Soviet Union. This was a large satellite for the time and demonstrated that the Soviets were ahead of the United States in heavy-lift rocketry.

Geosynchronous Satellites. All of these early satellites were nongeostationary and nongeosynchronous [a geosynchronous (GEO) satellite orbits at 22,300 miles, but is not necessarily geostationary, that is, limited to the equatorial plane—see discussion later]. They were launched into low-altitude Earth orbits because the rockets of the day could not propel the satellites into an orbit 22,300 miles up.

In the early 1960s, when U.S. rockets could at last boost a satellite into geosynchronous orbit, one of the most important questions centered on which was the best orbit to use for a communications satellite, low Earth orbit or geosynchronous. Low-altitude systems had the advantages of lower launch costs,

heavier payloads, and relatively short radio-frequency propagative times. The main disadvantages were that many orbiting satellites were required to achieve continuous global communications, and these needed continuous tracking. Geosynchronous satellites, in contrast, had two key advantages. Only three satellites were needed for global coverage, and only minimal tracking was required. Their one primary disadvantage was relatively long radio-frequency propagative times. No one knew how the one-quarter-of-a-second transmission delay would affect the feasibility of using this orbit for telephony (see extended discussion later).

By 1959, a small team of scientists led by Dr. Harold Rosen from the Hughes Aircraft Company (now Hughes Electronics Corporation) was moving ahead, determined to create a geosynchronous communications satellite. By 1960, they had built a satellite prototype (8,9). Meanwhile, at AT&T's Bell Laboratories, similar work was taking place under the direction of Dr. John R. Pierce and with at least as much zeal. Arthur Clarke would later name John Pierce and Harold Rosen the "fathers of communications satellites." Pierce's team demonstrated the first active communications repeater, but Rosen and his team at Hughes are credited with making it possible, technically and economically, to have a continuous communications capability by satellite earlier than anyone thought feasible (10).

In August 1961, NASA contracted with the Hughes Aircraft Company for the first geosynchronous communications satellite, called Syncom (Fig. 1). Though the first Syncom launch failed in February 1963, a second attempt, the launch of Syncom II in July of the same year, succeeded. Syncom I had just one voice channel and was designed to weigh 86 pounds at the beginning of its life. Though it never attained orbit, it paved the way for Syncom II and Syncom III, satellites that, by August 1964, proved the feasibility and cost-efficiency of domestic and international satellite communications. The Syncom series also validated the concept of geosynchronous satellites, and by 1964, government and other users turned away from LEO satellites for voice, data, and video communications (11).

COMSAT, INTELSAT, and INMARSAT. The 1962 U.S. Communications Satellite Act had a profound impact on international satellite communications. It provided for the establishment of the Communications Satellite Corporation (COMSAT) (12), a privately financed and managed organization that had a minority of U.S. government representatives on its board of directors. AT&T emerged as COMSAT's largest shareholder. COMSAT was created (1) to govern the operation of communications satellites and ground facilities used to transmit to and from the United States and (2) to develop and manage a new international communications satellite organization, which, in 1964, emerged as the International Telecommunication Satellite Organization, or INTELSAT. COMSAT was responsible for the procurement, testing, and launch acquisition of all INTELSAT satellites, and it owned 61% of the organization (13,14). The global, commercial INTELSAT cooperative was formed on the initiative of U.S. President John F. Kennedy, who, at the time COMSAT was created, said, "I invite all nations to participate in a communications satellite system in the interest of world peace and closer brotherhood among peoples of the world." INTELSAT was the first organization to provide global satellite coverage and connectivity. In its role as a commercial cooperative and wholesaler of satellite communications capacity, INTELSAT provides service through its signatories in member

Figure 1. Hughes engineers Dr. Harold Rosen (right) and Thomas Hudspeth hold a prototype of the geosynchronous Syncom satellite atop the Eiffel Tower during the 1962 Paris Air Show (courtesy Hughes Electronics Corp.).

countries. Currently, COMSAT is the only U.S. signatory, though pending deregulation will encourage others (15).

COMSAT's initial capitalization of \$200 million was considered sufficient to build a system of dozens of medium Earth orbit (MEO) satellites. These orbit the Earth at about 3000 to 7000 miles up; fewer MEOs are needed for global coverage than LEOs. In 1964, when COMSAT was in the process of contracting for its first satellite, two Telstars, two Relays, and two Syncoms had operated successfully in space. For a variety of reasons, including cost, COMSAT ultimately rejected a joint AT&T/RCA bid for a MEO system that incorporated the best of Telstar and Relay. Instead, COMSAT chose the geosynchronous satellite offered by Hughes, based on Syncom technology. Procured by COMSAT but transferred to the newly formed INTELSAT, the Early Bird satellite (also called "INTELSAT I") was launched on 6 April, 1965, as the first commercial communications satellite. Built by Hughes, it was launched from Cape Canaveral on a Delta rocket and weighed 85 pounds—still about all that could be lifted to a geosynchronous orbit at that time by American technology.

Early Bird was designed to test the feasibility of synchronous orbits for commercial communications satellites and was a resounding success. The

satellite provided 240 transatlantic telephone circuits capable of carrying that many calls simultaneously. This greatly increased telephone capacity across the Atlantic. Early Bird could provide almost 10 times the capacity of a submarine telephone cable for almost one-tenth the price and thereby helped prove the cost-efficiency of communications satellites. Moreover, the public readily accepted the transmission delay. Early Bird was also designed for transmitting television. Though built for just 18 months of life, it could still transmit live pictures of the Apollo Moon landing in 1969. By 1967, three of these first-generation INTELSAT satellites were operating over the Atlantic and Pacific oceans, providing ubiquitous global telephone and television communications for the first time (16).

In February 1976, COMSAT launched a new kind of communications satellite, Marisat, to provide mobile communications services to the U.S. Navy and other maritime and aeronautical customers. Subsequently, in 1979, COMSAT transferred Marisat to the newly formed International Maritime Satellite Organization, INMARSAT. Sponsored by the United Nations, INMARSAT has an intergovernmental structure similar to INTELSAT's. Each signatory is required to provide an interface with land-based telecommunications networks and is assigned an investment share based on its actual use of the system. Today, COMSAT manages access to the global satellite fleets of both INTELSAT and INMARSAT on behalf of U.S. and foreign telecommunications operators that want to initiate or terminate their satellite transmissions in the United States. COMSAT currently enjoys an exclusive relationship with both INTELSAT and INMARSAT in providing this service.

As of June 1999, INTELSAT owned and operated 24 satellites and had a membership of 143 countries and signatories. The highly successful organization, expected to be privatized soon, provides voice, data, video, and Internet services on a nondiscriminatory basis to more than 200 countries and territories. Since its formation, INMARSAT has greatly expanded its services. Today, the organization provides satellite global mobile communications services on land, sea, and in the air. For maritime users, INMARSAT supports phone, telex, fax, electronic mail, and data transmission. Aeronautical applications include flight-deck voice and data, automatic passenger telephone, fax, and data communications. INMARSAT's land-based customers have access to in-vehicle and transportable phone, fax, and two-way data communications, position reporting, electronic mail, and fleet management for land transport. INMARSAT is also available for disaster and emergency communications, as well as news reporting, where alternative communications links are difficult to access or nonexistent (17). Initially, INMARSAT leased transponders on other organizations' satellites, but in October 1990, it launched the first of its own satellites, INMARSAT II-F. As of June 1999, INMARSAT had 85 member nations and a global fleet of four geosynchronous satellites.

The arrangement, mentioned earlier, whereby COMSAT enjoys monopoly status as an access point for U.S. domestic and international communications organizations, along with other "privileges and immunities" conferred on it by the U.S. government, is currently being challenged. In fact, there is a worldwide effort underway to push COMSAT, INTELSAT, and INMARSAT to serve their customers on a fully commercial basis, free of all government ties and protective

legislation and regulations. Both INTELSAT and INMARSAT have embarked on this path with the New Skies and ICO satellite systems, respectively. Today, COMSAT is partly owned by Lockheed Martin, a U.S. aerospace corporation and satellite manufacturer. As of June 1999, Lockheed Martin was seeking to buy all of COMSAT, for which it needs regulatory approval.

It is inevitable that INTELSAT will evolve to privatized organizations. These will remain one of history's best examples of successful international cooperation.

A Worldwide Industry. The use of communications satellites proceeded apace in the United States and other countries. In a number of cases, satellites offered cost savings and improved signal quality, compared with terrestrial and submarine cables. Importantly, satellite transmission was cost-insensitive to distance, as opposed to the way terrestrial transmission facilities were priced. Although the initial commercial launch vehicles and satellites were American, other countries had been involved in commercial and government satellite communications from the beginning. For example, as early as 1961, the German Post Office announced plans to construct a satellite-receiving ground station that could handle up to 600 phone calls simultaneously. The ground station interfaced with Telstar and Relay-type satellites. By the time Early Bird was launched, satellite Earth stations already existed in the United Kingdom, France, Germany, Italy, Brazil, and Japan.

In 1969, the Canadian government created Telesat Canada, a corporation charged with building and operating the world's first national satellite network. The first satellite, Anik A (Anik means "little brother" in the Inuit language), was launched in November 1972, and a three-satellite system was completed by May 1975. Anik was notable for introducing new spacecraft technologies, such as the shaped beam. Syncom, Early Bird, and Intelsat II used global beam technology, meaning that the satellites broadcast their signals across the entire third of the world they faced. Anik's shaped beam permitted a pattern, or footprint, that covered only Canada (18). Following the success of Canada's Anik system, both Europe and the United States developed domestic satellite systems. In 1974, Europe's first telecommunications satellite, Symphonie, was launched. In the United States, Western Union contracted with Hughes for three Anik-type satellites to serve the U.S. market. The first of these, Westar I, was launched in April 1974. In the following year, RCA launched its network system, and in 1975, the first live commercial television program was transmitted in the United States. Also in 1975, Home Box Office became the first national cable TV network to be delivered by satellite—and thus began a whole new entertainment industry. By the end of 1976, there were 120 satellite transponders available in the United States; each could provide 1500 telephone circuits or one TV channel (19).

Indonesia, the world's largest archipelago of more than 13,000 islands, launched its first Palapa satellite in 1976 and followed with another in 1977. Besides supporting telecommunications, Palapa-A1 and Palapa-A2 were intended for distance learning, including teaching the national language (20). By the mid-1980s, many nations had national satellite systems. These included Australia (OPTUS), Mexico (MORELOS), and Brazil (BRASILSAT). In 1999, this tally had grown to include most of the world's developed and developing countries. In addition, there are numerous private regional satellite systems, such as

Eutelsat (Europe); SES Astra (Europe); Europe*Star; Nahuel (Central and South America); Galaxy Latin America; Thuraya (Middle East and parts of Asia, Africa, and Europe); ACeS (Asia); and AsiaSat, which delivers service to China, Thailand, Malaysia, Pakistan, Hong Kong, Burma, and Mongolia (21).

Today, INTELSAT continues to own and operate the world's largest global satellite communications system (Fig. 2). However, there is now strong competition from such international entities as PanAmSat, which, it is projected will overtake INTELSAT in the near future. Loral, GE Americom, and Intersputnik also operate global fleets. Despite the early failure of Iridium (Motorola), Globalstar (Loral/Qualcomm) and ICO (a private INMARSAT spinoff) promise to provide worldwide satellite mobile services. Spaceway (Hughes), Teledesic (Boeing, Motorola, Matra Marconi Space), and Astrolink (Lockheed Martin, TRW, Telespazio) are among several companies that anticipate operating global satellite systems for high-speed data exchange, Internet applications, and interactive multimedia.

Satellite manufacturers and launch vehicle providers are found throughout the world, too. Satellite manufacturers in the United States, include Hughes, Loral, Lockheed Martin, TRW, Orbital Sciences, and Motorola. They are joined

Figure 2. The tiny Syncom satellite (foreground) would fit into one of the INTELSAT VI fuel tanks to which Dr. Harold Rosen is pointing (courtesy Hughes Electronics Corp.). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

by non-U.S. competitors such as Daimler-Chrysler Aerospace (Germany), Alenia Spazio (Italy), Aerospatiale (France), Matra Marconi (France) with British Aerospace (UK), Thomson CSF (France), and Alcatel (France). In the United States, launch vehicles are provided by Boeing (Delta and Sea Launch) and ILS-Lockheed Martin (Atlas). Other prominent launch vehicles include Ariane (France), Long March (China), ILS Proton (Russia), H-IIA (Japan), and Soyuz (Russia). It is likely that there will be consolidation of the many satellite and launch vehicle manufacturers and service providers in the future.

Today, communication satellites are a basic element of the world's telecommunications infrastructure and an indispensable tool of the global marketplace. More than 325 commercial communications satellites—mostly GEOs—now orbit Earth. New applications for these satellites and those in LEO or MEO orbits are constantly evolving, based on new technological developments and increasing demand for space-based communications. Among the newest applications are satellite mobile radio, high-speed broadband data exchange, interactive multimedia, handheld global mobile telephony, and direct-to-home TV featuring high-definition pictures—HDTV (see fuller discussion in the article on commercial applications). These business and consumer services are provided through GEO as well as LEO and MEO satellites.

The early satellites had one television channel, weighed less than 100 pounds, and could require a 30-meter diameter antenna for reception. Today, a communication satellite can transmit more than 200 digital television channels, weigh 10,000 pounds, and deliver signals to one-half-meter Earth stations or palm-sized receiver/transmitter units.

Satellite Technology

Communications Satellites—Yesterday and Today. In a few decades, communications satellites have become an indispensable part of the world's telecommunications infrastructure. They serve as repeaters in the sky and relay radio transmissions from/to terminals on Earth and in space, much as terrestrial microwave repeaters receive, amplify, and retransmit signals on Earth. During the years since Early Bird, communications satellites have grown in many aspects—size, weight, lifetime, power, and capacity. One way of illustrating this growth is by comparing Early Bird to a satellite designed for the early twenty-first century. The drum-shaped Early Bird was 71 cm (28 in) in diameter and only 58 cm (23 in) high. Its mass in orbit was 34.5 kg (76 lb). By contrast, a late-model, high-powered satellite called the HS 702 towers over Early Bird. In its stowed configuration, this Hughes-built satellite measures 2 m (6 ft 7 in) \times 3.15 m (10 ft 6 in), and rises to a height of 3.6 m (11 ft 11 in), not including its antennae. Deployed in space, it spans 40.9 m (134.5 ft) in length (Fig. 3). Its mass at launch is as much as 5200 kg (11,464 lb), depending on the type of fuel. Its dry weight (which excludes fuel) is as much as 3450 kg (7590 lb), two orders of magnitude greater than that of Early Bird. Early Bird was designed for 18 months of life, the HS 702 is designed for missions 15 years long. It can generate as much as 15 kW of direct current (dc) power, three orders of magnitude more than Early Bird. Its transponder capacity is nearly 100 times that of Early Bird.

Figure 3. Artist's concept of the Hughes-built HS 702 satellite deployed in space shows how the long solar panels collect light that is used to generate 15 kW of dc power (courtesy Hughes Electronics Corp.). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Orbits. Communications satellites travel in space along a gravity-induced path, or orbit, much as natural satellites orbit celestial bodies throughout the solar system (22–24). For the first 30 years of commercial service, communications satellite designers relied almost exclusively on geosynchronous or geostationary orbits. To observers on the Earth, a geostationary satellite appears to be “fixed” in space, although it is actually traveling at a speed of 11,062 km/h (6875 mph). From a position in geostationary orbit, approximately 35,880 km (22,300 mi) above the equator, a single satellite can illuminate a large oval-shaped area on Earth that is roughly one-third of the globe’s surface. Because the GEO satellite is “fixed” in space, ground stations within the illuminated area do not have to rotate their antennae to track the satellite, as they historically had to do for satellites in non-GEO orbits. Eliminating this bit of complexity was significant, especially in the early years when the antennae of ground terminals had to be large—of the order of 30 m (98 ft) in diameter—to receive weak signals from low-powered satellites. Large antennae were necessary to compensate for the loss of energy transmitted across the lengthy geosynchronous distances because energy received by a ground antenna is inversely proportional to the square of

the distance from the transmitting source. As the power transmitted from GEO satellites has increased over the years, satellite system operators have been able to reduce the size of ground antennae significantly.

At times, satellites can be operated usefully from nonstationary geosynchronous orbits. For example, when onboard fuel is nearing exhaustion, a GEO satellite can be allowed to drift north and south of the equator while still maintaining its longitudinal position. Under these conditions, its orbit develops a small inclination with respect to the equator that grows about 1° a year due to the pull of solar and lunar gravity. For some commercial applications, like TV distribution to cable operators, departure from the satellite's "fixed" north-south position is acceptable. In this event, the satellite would appear to a ground observer to trace out a figure eight pattern in the sky; the midpoint of the eight is centered on the equator.

Until the advent of personal mobile satellite communications late in the 1990s, all commercial and most military communications satellites operated in geosynchronous orbits (25). The GEO orbit is also favored for government weather, communications, and defense early warning satellites. However, a few of the first experimental military communications satellites and several precursors of today's commercial communications satellites were placed in much lower altitude orbits. The first version of the U.S. Defense Department's Strategic Communication Satellite System (DSCS 1) operated from an orbit that combined features of medium-altitude and geosynchronous orbits. A variety of other orbital geometries that range across many combinations of altitudes and inclinations, including widely employed 90° polar orbits, have been popular for weather, navigational, Earth resources, and surveillance satellites. The satellites of the Global Positioning System (GPS), for example, operate in six planes defined by 12-hour circular orbits—each plane separated from its neighbor by 55° —and are located 20,178 km (12,541 mi) above Earth (26).

In recent years, a number of non-GEO orbits have gained currency for such applications as personal mobile satellite communications (27,28). These include LEO and MEO orbits. The altitude of LEO orbits usually ranges from about 500 km (311 mi) to 1500 km (932 mi) above Earth, whereas MEO orbits are roughly 5000 km (3,107 mi) to 12,000 km (7457 mi). Orbital configurations at these lower altitudes are carefully chosen to avoid exposing a satellite's electronic components to life-limiting radiation in the Van Allen belts, unless the operator is willing to bear the cost and weight of radiation shielding. The belts are between about 2000 km (1243 mi) and 8000 km (4971 mi), and also above MEO, but well below GEO altitude. Still another type of orbit, the high Earth orbit (HEO), a form of the highly elliptical, 12-hour Molniya orbit extensively employed by reconnaissance satellites during the Cold War, has been adapted for broadcasting CD radio from space.

The historical attraction of GEO orbits is that they can provide service with few satellites and operate through fixed antennae on the ground. Moreover, they provide ubiquitous service for users throughout their broad coverage area. A satellite operator can offer service across nearly a third of the globe using one satellite—and can serve the entire Earth, excluding sparsely populated polar regions, with three. As the altitude of an in-orbit satellite system decreases, more satellites are needed for continuous global coverage because of the shrinking

area they can illuminate on Earth at any given time. However, the satellites themselves can be smaller and lighter, and therefore less costly than modern GEO satellites (29). The typical LEO satellite is shorter lived because of the effects of atmospheric drag and radiation at low altitude. Hence, it needs to be replaced more frequently than its GEO counterpart, adding to system cost. The cost of launching LEO satellites, however, is lower because they require less energy to boost them into low-altitude orbits. But the lower the altitude, the greater the need for extensive ground networks or complicated signal handoffs from one satellite to another, as the satellites pass within view.

This is so because lower altitude systems remain in view of the mobile satellite system user for very brief intervals, perhaps only minutes. By contrast, higher altitude satellites pass much more slowly through the viewer's field of vision. Consequently, at lower altitudes, a typical call will have to be handed over from one satellite to another more frequently than at higher altitudes. The greater the frequency of handovers, the greater the chance of a phone disconnect. Often, low-altitude satellites will appear close to the observer's horizon, increasing the likelihood that an obstruction such as a building will interrupt the call. This in turn means that the higher the satellite's elevation angle (i.e., the angle from the observer to the satellite) at any given time, the less likely that the call will be lost due to surrounding obstructions. Lower altitude satellite systems add to the cost and complexity of the ground infrastructure.

Communications Links, Frequencies, and Bandwidths. The communications link between satellite and ground station can be represented by a power balance equation expressed logarithmically in decibels (dB). This relationship takes into account the predictable factors in the communications loop. It indicates that the power received at the receiver is equal to a summation of all of the gains and losses in the link. Thus, power received equals the transmitted power, minus the waveguide losses, plus the gain of the transmitting antenna, minus the propagative path losses, plus the gain of the receiving antenna, minus the receiver waveguide losses. The free-space path loss is substantial and is fixed for a given frequency and distance. At GEO altitude, it amounts to 200 dB at the 12-GHz transmission range of a direct broadcast satellite and 196 dB at the 4-GHz band of a video distribution satellite (30). The measure of the difference between the power actually received and the threshold power required for reception is called the link margin. System designers try to provide sufficient link margin to ensure successful communications.

Frequencies allocated for use or potential use by satellites extend through a number of bands, or range of frequencies (31). Within those bands, separate portions are allotted for communications uplinks to and downlinks from the satellites to keep the two separated from one another. The satellite's transponder translates signals from the uplink frequencies into downlink frequencies. The bands are identified by letter designations, a practice derived from the World War II lettering scheme for military electronic equipment. Thus, satellite frequencies extend from longer wavelengths at L band up to very short wavelengths at Q band (32). Satellite communications service for mobile users, such as those aboard ships, barges, and oil rigs, are in the L band (1–2 GHz), where they have replaced unreliable short-wave radio. Other mobile services, including personal mobile communications, are in the S band (2–4 GHz) as well as the L band. Fixed

satellite service (telephony, data, and facsimile communications through Earth stations at fixed locations) is in the C (4–8 GHz), Ku (12.5–18 GHz), K (18–26.5 GHz), and Ka (26.5–40 GHz) bands. Broadcast satellite service (direct-to-user TV) is in the Ku and K bands. Military communications satellites use the X band (8–12.5 GHz) for fixed satellite service and Ka and ultra-high-frequency (300 MHz to 3 GHz) bands. Other bands in the high millimeter range, V (40–50 GHz) and Q (above 50 GHz) have promising applications for transmitting large quantities of information to small antennas.

Frequencies in the Ku, L, and C bands are regarded as prime real estate for communications satellites. C-band frequencies are most commonly employed by commercial communications satellites. Among available frequencies, the C band is least affected by man-made noise and atmospheric attenuation. But where broadband and high capacity are needed, the higher frequencies located in the Ku and Ka bands become more desirable. Portions of the Ku band, in particular, are widely used for business communications through small Earth terminals and for high-power TV broadcasting. The shorter frequencies (longer wavelengths) below the L band are subject to ionospheric disturbances that cause fading and other random signal disruption. This explains why L-band mobile satellite communication service quickly supplanted short-wave communications for ship-to-ship and ship-to-shore applications in the 1970s.

Bandwidth, the capacity of a satellite communications link, is the spread of usable (i.e., as allocated by regulation) frequencies available for transmitting intelligible information. Available bandwidth is divided among the transponders contained in the satellite's communications payload. Transponders (or repeaters) are electronic devices that receive radio signals, amplify them to increase their strength, and transmit them on command at different specific frequencies (33). At the heart of the transponder are either traveling-wave tube amplifiers (TWTAs) for high-power, higher frequency applications or solid-state power amplifiers (SSPAs) for lower frequency, usually lower power applications. Communications satellites that orbited in the late 1990s typically carried 48 transponders. The newest satellites entering service at the turn of the century offer as many as 94 transponders, plus backups. By the late nineties, the satellite fleets of major international satellite service providers such as INTELSAT and PanAmSat each provided service via about 800 orbital transponders.

How bandwidth is divided among transponders reflects a balance of factors, including the satellite's power resources, the number of TWTAs that can be carried, and the desired power per channel, or power per transponder. The following is an illustration. A satellite that can generate 8000 W of dc power might supply 7000 W to its communications payload, mainly for the TWTAs. If the TWTAs' portion of that figure—say, 6800 W—is converted to radio-frequency (RF) power at 60% conversion efficiency, there will be 4080 W of RF power available from the TWTAs. If satellite designers want 100 W of power per channel, there is sufficient power for 40 channels. For 200 W per channel, 20 channels can be created. If the choice is 20 channels—10 channels for each of two polarizations—the total available bandwidth will be divided by 10. If the bandwidth (capacity) available within the allotted “usable frequency” range is 250 MHz, there will be 25 MHz available per channel. Some of that bandwidth, perhaps 10%, has to be reserved for guardbands that separate the channels.

Consequently, the usable bandwidth will be 0.9 times 25, or 22.5 MHz per channel.

Onboard Antennas and Spot Beams. The area on Earth illuminated by communications satellites, or coverage area, is commonly referred to as the satellite's footprint. To improve efficiency, satellite designers usually configure antenna patterns to illuminate specific high-revenue-producing areas on the ground, or a particular country or group of countries for a domestic or regional satellite system. Traditionally, shaping beams to match the contours of specific areas on Earth requires directing energy from the transponders at a sculpted parabolic reflector by an array of feedhorns (Fig. 4) controlled by a beam-forming network. The reflector then collimates the energy on Earth. This is a complicated, costly process, made even more so as customer requirements have grown. As an alternative, designers can use mathematical techniques to contour the otherwise smooth parabolic reflector, so that it can produce the desired pattern when fed by only a single horn. The reflector surface is mechanically shaped and creates a rippling or dimpled appearance. The dimples are precisely positioned by extensive computation to produce the desired pattern, thereby supplanting

Figure 4. Feedhorn array that helps generate spot beams for INTELSAT VI satellite is checked out in simulation laboratory (courtesy Hughes Electronics Corp.). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

complex multiple feed arrays for directing radiated energy in the desired pattern. Elimination of the feed arrays reduces weight and expense.

There is increasing use of reconfigurable spot beams, narrowly shaped beams that illuminate specific areas, thereby increasing the power concentrated in those areas. By using onboard digital processing, modern satellites can generate many, even hundreds, of reconfigurable beams simultaneously. This has created the opportunity for satellite operators to obtain greater bandwidth by reusing the limited amounts of assigned spectrum. Using the same frequencies a number of times does not create interference if these frequencies are confined within spot beams directed at geographically separated regions (34).

Special Challenges: Attenuation and Echo Cancellation. Attenuation of electromagnetic energy becomes increasingly severe at higher frequencies above 12 GHz, as signals are absorbed by the atmosphere. Some spectral points experience more severe effects than others (35). At 22 GHz, energy is almost totally absorbed by water vapor, and at 60 GHz by oxygen, rendering these and some other higher frequencies useless for communications between satellites and Earth. Attenuation of microwave signals by rain droplets in the atmosphere can become a severe problem at higher frequencies because of the relatively large size of the droplets compared to the diminishing size of wavelengths at these frequencies (36). The droplets absorb and scatter the microwave energy. Rain attenuation in the Ku band can account for about 2 dB in signal loss and three to four times that amount in the Ka band. The presence of rain attenuation is not accounted for in the power balance equation because of the random nature and unpredictable magnitude of rain cells. Systems have to be designed with sufficient link margin to accommodate rain attenuation. This could mean increasing transmitter power and/or the gain of the transmitting antenna. The amount of attenuation will vary with geographic area and seasonal rain activity. A system designed for 99.5% availability—where attenuation is less than 2 dB in 99.5% of the time—could experience about 4 hours of outage in the months of heaviest rainfall. Under these conditions, a viewer's TV picture could freeze, and the sound would stop. A large telecommunications installation typically would need a 6- to 8-dB link margin to be certain that it could offset the effects of random rainstorms. Or the attenuation could be averted by using spatial diversity, transmitting from the satellite to two widely separated Earth stations (37).

Despite rain attenuation in space-to-Earth or Earth-to-space links, Ka-band frequencies are successfully used in space-to-space communications as intersatellite links. As cross-links for communicating between satellites, they are free from rain attenuation. Such links are used by some military satellites and new commercial personal mobile communications satellite systems. Intersatellite cross-links are transponder links that transmit and receive information between satellites, thereby establishing connectivity among satellites in a system. In military communications applications, cross-links permit authorities to pass information securely from one GEO satellite to another in achieving global or near-global connectivity without fear that potential enemies will eavesdrop on or jam these links. In the commercial satellite-based personal mobile communications systems coming on-line, cross-links are a key to providing global coverage. For example, each satellite in the system's six orbital rings is equipped with four Ka-band (23.18–23.38 GHz) antennae, two fixed and two gimbaled. A satellite can

communicate directly with the satellite before and after it in the same orbit through the fixed antennae. The gimballed antennae on a satellite allow communicating with the two neighboring satellites on either side in adjacent orbital planes. A user's call can be relayed via the cross-link from satellite to satellite until it reaches a satellite within reach of its destination. At that point, calls are downlinked directly to the desired parties, if they are system subscribers, or to local gateways and through the public switched telephone network to the intended individuals. Ka-band frequencies are expected to have widespread applications in broadband, high-power commercial satellite systems in the future.

Digital echo cancellers have been developed and installed in digital phone exchanges and satellite networks to eliminate the once-troubling problem of voice echoes on satellite-relayed telephone calls (38). The echoes were produced by the reflection of a party's speech created by a hybrid in the telephone network. The hybrid's function is to route energy between the two-wire phone pair connecting a caller in an office or at home to the four-wire trunk line on long-distance calls. Additional hybrids that may be present between the two parties in the network add to the problem. The difficulty is further compounded in a GEO satellite connection by the nearly 36,000-km separation between the speakers and the satellite. The round-trip propagative time for electromagnetic energy across the lengthy distance creates a 260-ms signal delay. In a satellite hookup, telephone parties could be disturbed by echoes of their own voices delayed by 260 ms in the midst of phone conversations. Digital echo cancellers in the form of software or firmware solve the echo problem by sampling a digitized version of speech and mathematically removing the echo. The echo is suppressed by a factor of 10,000 (39). Though the echo is essentially gone, the delay caused by the signal transit time to and from a GEO satellite is not. Some people are annoyed by the delay, but various studies indicate that 90% of telephone subscribers have no serious objection to it.

Ground Antennas (40). As satellites have grown in size and power, the size of Earth stations for accessing a satellite's communications capacity has dramatically declined, giving users greater flexibility, easier access, and lower costs. The antennae of large communications facilities today are about 3–9 meters (9.8–29 ft) in diameter for operation in the C and/or Ku band. At Earth stations, terrestrial signals typically are multiplexed, encoded, and modulated in the baseband section of the ground terminal. The signals are upconverted and amplified before transmission through the antenna to a satellite. Weak signals downlinked from the satellite are amplified through a low-noise amplifier, downconverted, and passed to baseband equipment for demodulation, processing, and interfacing with the terrestrial networks.

Customer premises antennae for offices or homes measure about a meter (3 ft) or less in diameter. Individual subscribers can receive TV programming broadcast to their homes by satellites operating in the Ku band through antennae as small as one-half meter (18 in) in diameter for some systems (e.g., Hughes' DIRECTV—see discussion in the article on Commercial Applications of Communications Satellite Technology). Subscribers to satellite-based personal mobile communications systems (e.g., Globalstar, Thuraya, and ICO) can speak to other parties via L-band satellites through handheld, cellular-like phones that have small omnidirectional antennae. The appearance of small, compact ground

terminals, called very small aperture terminals (VSATs), has led to the widespread use of satellite networks by businesses, schools, governments, and telecommunications organizations throughout the world. Typical VSATs vary in size, depending on application, but generally range from 0.85 m (2.8 ft) to 1.2 m (3.9 ft) in width or diameter for Ku-band systems.

Arranged in what is called “star,” or “hub-and-spoke,” network architecture, VSATs provide multipoint communications between a hub station at an entity’s headquarters or data center and a multiple number of remote sites. A computer at the hub handles switching for voice or video. The hub station broadcasts data via satellite to the VSATs at various remote sites. The terminals of individual remote sites are smaller and less powerful than the higher power, more expensive one at the hub. The remote sites can complete a return link to the hub through the satellite, thereby bypassing any terrestrial link, but their signals are too weak to be received by, or to interfere with, other sites in the network. (More expensive, “mesh” networks enable all sites to communicate directly with each other.) The “star” concept enables users to balance the higher cost of the hub against that of multiple lower cost VSATs. Manufacturers have reduced the size and weight of VSATs and increased their capability by adding more processing power. Size reductions help in two respects: the smaller the size, the lower the cost of installation on a customer’s premises, and the smaller the area occupied by the VSAT.

For all satellite applications, satellite systems are controlled and monitored from the ground by skilled technical personnel through one or more tracking, telemetry, and command (TT&C) stations. INTELSAT, for example, operates six such sites internationally to ensure reliable, line-of-sight contact with its entire orbital fleet (41). The exact positions of the satellite are determined from data secured by on-site tracking antennae. Personnel, consoles, and data processing equipment are housed in a satellite control center, which may or may not be collocated with a TT&C station. The satellite control center is manned and operated 24 hours a day throughout the year.

Spacecraft Design. Communications satellites have two fundamentally different designs. One is the spin-stabilized satellite, or spinner; the other is the three-axis, or body-stabilized satellite (42). The spin-stabilized satellite has a cylindrically shaped body that is spun about its axis, typically at a rate of 60 rpm to achieve stability inertially, much like a toy top becomes gyroscopically stable by spinning. The attitude and orientation of the satellite can be altered by a number of onboard thrusters. Almost the entire satellite spins, with the notable exception of its antennae, which are despun and pointed in a fixed direction toward Earth. Subsequent innovations in this concept led to a dual-spin design in which the entire payload, not just the antennae, is despun. To achieve stability, the body-stabilized design relies either on an internal gyro, called a “momentum wheel,” or a set of reaction wheels. The satellite’s control system compensates for changes in attitude by applying small forces to the spacecraft’s body.

The spinner design is the simpler of the two, and that simplicity translates into relatively low cost and long life without much ground intervention. The spinner employs a novel control system to maintain satellite attitude, or orientation, in space. A single axial thruster pulsed in synchrony with signals from an

onboard Sun sensor controls the attitude of the satellite's spin axis. When that thruster is operated in a continuous mode, it provides velocity control around the spin axis. Pulsed radial jets control velocity in a particular direction. The control concept is covered by what has become a seminal patent, referred to by the name of its inventor, Donald Williams, and validated in extensive legal proceedings. Prime power for the satellite comes from solar cells that cover the circumference of the spinning cylinder. More and more power has been squeezed from this design by enlarging the cylinder and by such steps as adding a second concentric solar-cell-covered cylinder that telescopes out from the first in space. But covering the spinning cylindrical surface with solar cells means that, at any given time, the Sun is illuminating no more than a third of the surface solar cells. The remaining two-thirds are not converting solar energy into electrical energy. This relatively inefficient use of energy resources becomes less acceptable when higher satellite power levels are necessary. As the power required exceeds 1 or 2 kW, the body-stabilized configuration becomes the preferred choice.

Because the three-axis stabilized spacecraft does not rely on a spinning body for stabilization, the satellite can assume any convenient shape, usually a box, for the convenience of its communications function. One surface of the box, on which antennae are mounted, is oriented toward Earth. Solar cells are mounted on flat panels that extend in wings from either end of the body and are oriented toward the Sun. The solar panels can be kept pointing at the Sun by motors aboard the satellite, as it revolves about Earth.

In addition to more efficient use of its solar cell resources and its potential for higher power levels, the body-stabilized satellite provides better pointing accuracy. This permits more accurate pointing of the satellite's antenna beams. Otherwise, the size of the antennae would have to be enlarged to ensure sufficient gain across the coverage area. When its solar wings and antennae are folded in a stowed position, the body-stabilized configuration lends itself to more efficient use of the volume within the shroud of a launch vehicle. And the box-like shape has more surface space for mounting antennae, permitting designers to employ more complex antennae. The drawbacks of the three-axis design stem from its relative complexity. Its momentum wheels have to be controlled in speed and pivoting. The satellite has to be commanded frequently, requiring an on-board computer. A typical spin-stabilized communication satellite can now be constructed in about 60% of the time required to produce a body-stabilized version. The difference in time is a measure of both the greater capability of the latter and the greater simplicity of the former.

Spacecraft Subsystems. An active satellite consists essentially of two parts—a payload and a bus. (A passive satellite is one that does not generate energy; an example is the Mylar-coated reflective balloons considered promising candidates for communications relay in the early 1960s. The payload contains the satellite's communications equipment and antennae that create an infrastructure for communicating with users throughout a continent or in regions or countries where service is supplied. The bus has the task of protecting the payload during the demanding launch period, placing the payload into its assigned orbit or orbital slot, and maintaining it there. The bus supports and maintains the payload throughout its lifetime (43).

A communications satellite contains seven subsystems (44):

- The communications subsystem (“payload”) contains the satellite’s radio-frequency equipment. A wideband receiver at the front end of the subsystem accepts incoming communications channels that occupy a specified band of frequencies. Then the channels are separated according to frequency by a multiplexer, or bank of filters, and apportioned among the payload’s various transponders. After amplification in the transponders, the channels are recombined by another multiplexer for retransmission to the ground.
- The power subsystem generates, regulates, and controls power obtained from the solar arrays and onboard batteries primarily for use by the communications payload. This subsystem also maintains operation of the satellite during periodic solar eclipses.
- The attitude control subsystem senses any deviations from proper pointing directions and keeps the spacecraft and the antennae pointing in the correct directions—the solar arrays pointing toward the Sun and the radiators away from the Sun.
- The propulsion subsystem generates thrust to place a GEO satellite into a desired orbital slot and to adjust its position periodically to offset movements in the (1) north–south direction due to solar and lunar gravitational attraction and (2) east–west direction due to the oblateness of Earth’s poles. The last-named function is called stationkeeping. GEO satellites contain either a solid rocket apogee kick motor (AKM) or a liquid bipropellant (separate fuel and oxidizer) system. The function of the AKM (45) and in part that of the bipropellant system is to insert the satellite into geosynchronous orbit when it reaches the apogee of a geosynchronous transfer orbit. The satellite is placed in an elliptical transfer orbit by a perigee kick motor during the final phase of the launch sequence. Besides performing the apogee kick function, the bipropellant system also helps raise the perigee of the transfer orbit to coincide with its apogee in geosynchronous orbit, a process called orbit raising. It also handles the stationkeeping duties. On satellites that have an AKM, a monopropellant system performs orbital positioning and stationkeeping duties. The tankage, valves, lines, thrusters, and fuel of this subsystem account for a significant portion of the mass of a satellite at launch and even after initial insertion into GEO orbit.
- The thermal control subsystem radiates the heat generated onboard the satellite into space. The thermal environment inside the satellite is kept at room temperature and all excess heat has to be radiated from the satellite. For this purpose, the subsystem uses such devices as thermal blankets and reflective mirrors. If the satellite has an AKM, as spinners do, an insulating wall and thermal barriers protect components from heat generated by the motor firing. New satellite designs are adding more TWTAs that have higher power outputs to their payloads. Despite increases in TWTA efficiency to as much as 70%, the remaining 30% is generated as useless heat that must be removed.
- The TT&C subsystem enables ground personnel to monitor the health and status of the satellite and issue commands to the satellite. It telemeters to

the terrestrial TT&C station information regarding satellite temperatures, remaining fuel, TWTAs performance, and pointing directions. The command portion accepts signals from the ground for controlling housekeeping functions, recharging batteries during solar eclipses, and dumping the energy buildup from the momentum wheels of a body-stabilized model. When the satellite comes to the end of its mission life as onboard fuel nears depletion, it can be commanded through the TT&C subsystem to deorbit and turn off its communications subsystem.

- The structures subsystem is the chassis that provides physical support and protection for sensitive equipment during launch when the satellite must survive the effects of severe acoustic and vibrational forces. It employs a truncated cone or trusswork with panels for mounting bus and payload electronics.

Reliability, Lifetime, and Cost. Satellite designers constantly seek to improve reliability so that service delivery by communications satellites is ensured throughout their contracted mission lives. Satellites have to operate in space without physical intervention for as long as 15 years in the case of newer GEO models. And the space environment is unforgiving; such phenomena as ionizing radiation pose hazards for sensitive electronics. Satellites are usually designed with redundancy for all critical components to prevent catastrophic failures. The increased reliability achieved through the years is attributable to numerous factors. Among them are better designs, fewer parts, improved manufacturing processes, and fewer electronic interconnections due to the application of semiconductor chips that have high circuit density. Potential life-limiting spacecraft elements are batteries, lubricants, thrusters, and TWTAs. Mechanical deployments of antennae and solar panels are another source of possible difficulties. Once a matter of great concern, TWTA technology and manufacturing know-how have advanced to the point where the chances of losing a transponder because of a TWTA failure are slim. Like other portions of a satellite, transponders are designed with redundancy to permit continued operation in the event of a failure. Now, transponders need only a single TWTA to back up three or four active TWTAs, not the one for two ratios of two decades ago. The TWTA suffers from only a single wear-out mechanism—its cathode. But the design of this element is well proven by millions of hours of actual operating experience. The infrequent failures that occur result from processing errors, not design inadequacies. This compels the tube manufacturer to maintain constant vigilance over production processes.

Commercial GEO satellites are actually designed for a lifetime as long as 18–20 years, but this life span, or design life, is limited by practical matters, such as the inability to replace degraded components and battery cells in an orbiting satellite. The satellite's design life is also limited by the onboard fuel supply. Therefore, the actual mission, or operational, life, of necessity, is shorter than the design life—no more than 12 to 15 years. Satellites in LEO orbits have shorter operational lifetimes—perhaps 5 to 8 years—limited as they are at very low altitudes by the effects of atmospheric drag and radiation. The contracts of GEO satellite manufacturers with their customers generally contain performance

incentives that reward the builder for achieving specific operational lifetimes. Just as Early Bird surprised its owners by unanticipated longevity, many other commercial satellites have as well. For example, Marisat 2, one of INMARSAT's satellites for mobile communications, had a 5-year mission life when placed in orbit in 1976. Twenty-two years later it was still providing service for the international maritime consortium, albeit from an inclined geosynchronous orbit.

Buying a satellite system involves a large investment by a communications entity. For instance, one major mobile communications satellite system, Thuraya, that was built in the late 1990s has an estimated value of \$1 billion. The figure includes the cost of two GEO satellites, the launch of one, ground facilities, training, and user equipment. (See further discussion of Thuraya in the article on Commercial Applications of Communications Satellite Technology.) The customer's cost of communications satellites, as measured by several key parameters, has been declining as a consequence of enhancements in satellite power, bandwidth, and lifetime. Thus, the satellite's price per kilowatt of power, price per transponder, and price per transponder year are all declining.

The costs of launching a satellite, the associated launch services, and insuring the launch and in-orbit satellite performance are a significant portion of the total price of acquiring and orbiting a satellite. The cost of insurance varies with the satellite, launch vehicle, recent claim experience, and available underwriting capacity, so that it varies to reflect current circumstances. During a period of 20 years, launch insurance premiums have varied from 6–20% of the insured value; the average is in the 10–13% range. In general, acquisition of the satellite represents slightly less than half the cost of a satellite in orbit; launch services and launch insurance account for the remainder.

New Technologies

Digitalization. The latest communications satellites incorporate greater amounts of digitalization to enhance their capabilities and flexibility (46). Digital signal processors of increasing capacity began to appear in satellite payloads during the 1990s. They can perform such roles as routing signals to any one of scores of individual spot beams and controlling and forming the beams. The beams are generated by a planar phased array antenna that contains multiple elements. In the process, called digital beam-forming, each element of the array captures a portion of the signal. The processor computes and controls the relative phase and amplitude of each element and can electrically bend the antenna beams into any desired shape. In this digital beam-forming antenna, the outputs from the array are sampled by an analog-to-digital converter and are stored in a processor that computes the phase changes needed to bend the antenna beam into the desired shape. A nearly unlimited number of these virtual antennae can be created. Each of them, shaped differently and pointed in a different direction, emanates from the one multielement phased array. They can be repointed quickly because the process of generating them is mathematical and there is no movement of mass involved in repointing. The ability of the processor to generate as many as 200 or 300 spot beams, to reuse limited frequencies extensively, and to support thousands of voice channels simultaneously makes possible such new

satellite services as personal mobile telephony, broadband data exchange, and multimedia communications. Digital processors give operators the freedom to satisfy changing customer demands by reconfiguring the power level, frequency, and beam shape after a satellite is in orbit (47).

Four separate generations of digital processors evolved in rapid sequence during the initial 10 years after they were introduced into communication satellites. They demonstrate successive improvements in circuit density, decreasing power consumption, and compactness that led to a progression in capability. The first generation, for example, for a military payload, used 13 different types of application-specific integrated circuits (ASICs); each circuit had about 15,000 gates. By the third generation, for application in a personal mobile communication satellite (Thuraya), the number of ASIC designs dropped to nine, but their density rose to 1.5 to 3.5 million gates per ASIC—a 100-factor jump over the first-generation level. By the fourth generation, for application in a broadband, multimedia satellite (Hughes's Spaceway, see discussion under "Commercial Applications of Communications Satellite Technology"), the ASICs count climbed to the four-to-seven million-gate range. Processor power consumption declined by approximately 50% from generation to generation. Consequently, the power required by the fourth generation was merely 13% of that of the first. The fourth-generation design provides 960 times the processing capability of the first, measured in raw processing power, or number of tera operations per second.

In a satellite application, a digital processor functions as a massively parallel digital computer with analog inputs and outputs. It converts analog radio signals received from individual terminals into numbers, performs the necessary computations entirely in the mathematical domain, and reconverts the resulting data into analog signals for retransmission to the terminals. This is called a "demod/remod" design. A demod/remod digital processor also performs filtering, switching, demodulation, modulation, beam-forming, and other functions without introducing distortion or drift. It can correct errors, reconstruct corrupted signals, and eliminate noise. The demod/remod design relies on known characteristics of the user's signals. An alternate design, the transponded system, knows nothing about the format of incoming signals and is insensitive to changes in them. Processors of this design perform little or no filtering. Also, they cannot flexibly allocate downlink power to accommodate different sizes of user terminals.

Power. Several technical innovations have contributed to the ongoing trend toward increased satellite power. The introduction of gallium arsenide solar cells marked a turning point in efforts to improve the efficiency with which photovoltaic cells convert solar light into electrical energy. Gallium arsenide cells achieved efficiencies of 21.6%, nearly doubling the 12.3% figure obtained from traditional silicon cells. The increase enabled designers almost to double the dc power output from solar arrays of comparable size and mass. The greater power can be translated into an increase in the capacity of the communications payload. Alternatively, when the extra power is not needed, the size and mass of the satellite solar cell arrays can be reduced, thereby decreasing satellite mass and possibly launch vehicle cost.

The initial gallium arsenide cells were dual-junction devices that have two semiconductor junctions—a gallium arsenide layer on a single crystal

germanium substrate and a gallium indium phosphide layer atop the gallium arsenide. The improved efficiency stems from the ability of each layer to convert a different part of the light spectrum into electrical power. When the Sun's rays strike the top layer of the cell, shorter wavelengths are converted to power. The top layer is transparent to the longer wavelengths, which penetrate the gallium indium phosphide layer and strike the gallium arsenide layer, where they too are converted to electrical power. The cells are grown in an epitaxial chamber by a gas reduction process. Continuing work has led to triple-junction gallium arsenide cells. These enhanced the efficiency of earlier gallium arsenide cells by 20%, and brought conversion efficiency up to 26.8%. Four-junction cells are expected to reward satellite manufacturers with still higher solar cell efficiencies in the early years of the new millennium. The solar arrays of the new body-stabilized Hughes HS 702 satellite employ gallium arsenide cells, as did several other satellites in the late 1990s. Gallium arsenide cells are an important contributor to the satellite's ability to generate as much as 15 kW of end-of-life (EOL) power. Satellite builders generally specify power levels expected at the end of the satellite's lifetime, as opposed to higher power levels at the beginning of life (BOL). The difference reflects anticipated degradation in the solar cell output due to the deleterious effects of X rays, solar protons and electrons, and other particles encountered in different orbits.

Innovative solar concentrators mounted along the satellite's solar wings add significantly to the power generated by the HS 702 satellite's solar cell panels. The angled solar reflector panels add 50% to the power output from the solar cell panels on the wings by concentrating more solar energy on the solar cells. The reflector panels are angled outward along both sides of the wings to form a shallow trough, and the solar panels are at the bottom. Sunlight that otherwise would not strike the flat panels is reflected back from the reflectors onto the solar panels. The HS 702 is configured to enable designers to tailor the power output from the arrays to satisfy specific customer requirements. This is done by choosing any one of six different solar array configurations that have up to five panels per wing.

Power subsystems of today's communications satellites rely primarily on nickel-hydrogen batteries for powering payloads during eclipses. But batteries are heavy and costly; they weigh of the order of 500 kg. The next battery technology expected to provide capacity for higher power satellites early in the new century was in the development stage in the closing days of the 1990s. Lithium ion batteries hold the promise of halving the mass of nickel-hydrogen satellite cells while offering a less expensive alternative. One possible version built of plastics contains a nonliquid electrolyte within the plastic. High-speed flywheels that extract the energy of a spinning mass are another promising technology but are further removed from application (48).

Propulsion. Beginning in the early 1960s, cesium and mercury electric ion propulsion systems flew aboard U.S. Air Force and NASA satellites. Since then, the performance of new commercial communications satellites has been getting a dramatic lift from a newer spacecraft propulsion system first flown on a non-commercial European Space Agency satellite in 1992. Also a form of electric propulsion (49), the xenon ion propulsion system (XIPS) makes possible reductions of as much as 90% in the mass of a satellite's fuel (Fig. 5).

Figure 5. Thruster for xenon ion propulsion system (XIPS) protrudes from PanAmSat PAS-5 satellite. The electric propulsion system complements the satellite's less efficient bipropellant propulsion system to reduce substantially the amount of fuel required by that system (courtesy Hughes Electronics Corp.). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Normally, at the beginning of orbital life, chemical propellants required by a satellite's bipropellant propulsion system for attitude control and stationkeeping throughout the mission account for at least 25% of satellite mass. This could amount to 500 to 700 kg (1102 to 1544 lb) for a conventional communications satellite. The comparable amount of fuel for the more efficient XIPS propulsion system would be only 75 to 105 kg (165 to 232 lb) of inert xenon gas. At a cost of about \$30,000 per kilogram to place that mass in orbit, millions of dollars could be cut from launch costs. The mass reduction can also be translated into an increase in satellite payload, or communications capacity. Or, with additional xenon, a longer satellite mission life can be obtained because the quantity of onboard fuel is the principal limiting factor on the satellite's operational life. Alternatively, the XIPS technology could produce benefits that combine these savings. A XIPS-equipped satellite uses the impulse generated by a thruster assembly and ejects electrically charged particles at high velocities. The entire system consists of a source of pressurized xenon propellant, a power processor, and the cylindrically shaped thruster assembly. Thrust is created by accelerating

positive ions generated within the assembly's ionization chamber through a series of gridded electrodes at one end of the assembly. The electrodes create more than 3000 tiny beams of thrust. The beams are prevented from being electrically attracted back to the thruster by an external electron-emitting device called a neutralizer. XIPS generates a very high specific impulse, expressed in seconds as the ratio of thrust to the rate at which the propellant is consumed. The higher the specific impulse, the less propellant required. The specific impulse of a XIPS system is 2600 to 3800 seconds, depending on the satellite configuration—roughly 10 times that of a bipropellant system. (Note that the 1964 NASA SERT I satellite, which used a combination of mercury and cesium ion, had a specific impulse of about 5000 seconds, but this was not proven sustainable or available all the time.)

The thrust level of a modern XIPS system is very small. For an HS 702 satellite, it is 0.165 newton, or 0.037 pound of force. In a satellite such as the HS 702, the XIPS system can also augment the satellite's bipropellant propulsion system in orbit-raising. Using XIPS to help circularize the elliptical transfer orbit further reduces the amount of chemical propellant needed on the satellite, thereby again shrinking satellite mass. The extra mass reduction gives customers even more latitude in choosing among the benefits of a less expensive launch vehicle, additional payload, or longer mission life. The HS 702 XIPS is designed for a maximum orbit-raising duration of 90 days, compared to 3 days for the higher thrust but less efficient bipropellant system. The trade-off for satellite customers is one of mass reduction benefits versus delayed arrival on station.

Systems. The power per kilogram of satellite mass has grown steadily. Early in the 1980s, when the current generation of spinners was introduced, the figure stood at about 1 W per kilogram. It climbed to 2 W per kilogram for the HS 702's predecessor, the three-axis HS 601, in the early 1990s. Later in the decade, the figure reached 4 W per kilogram for the HS 702. It is likely to rise for later generation satellites. The availability of higher power from a satellite like the HS 702 enables operators to increase transponder effective isotropic radiated power (EIRP), a measure of performance that takes into account transmitter power, antenna gain, and the losses in the transmitter waveguide. This is the satellite portion of the previously cited power balance equation. A high EIRP permits customers to use smaller Earth antennae such as the 45.7-cm (18-in) and 60-cm (24-in) home antennae for direct-to-home TV in the United States and Europe, respectively. Or operators can apportion available power among a larger number of transponders, effectively doubling the transponder complement and reducing cost per transponder in orbit. Still another option is to choose a combination of both performance benefits.

The newer, higher power satellites are the backbone of high-speed, broadband satellite services (e.g., Teledesic, Spaceway, Astrolink—see later) coming on line early in the new millennium. Because switching functions are handled by digital processors in the satellite rather than on the ground, whole new vistas will be opened for corporate and other VSAT users. The small terminals will be able to broadcast at data rates of multiple megabits per second, compared to the recent 128-kbps rate. And hundreds of megabits per second will be downlinked to them.

Digital compression techniques account for a panoply of new satellite-delivered entertainment and business offerings. Digital video compression

effectively increases the use of communications satellite capacity by factors of 4–8, and could double that by the early 2000s. Thus, a 16-transponder satellite could transmit 256 TV channels. The doubling could reduce an operator's operating and capital costs by an order of magnitude. Before the recent application of compression techniques, only one analog broadcast-quality video signal could be transmitted through each transponder on a satellite. Consequently, the number of video programming channels was limited by the transponder count. Now, using digital compression, broadcasters can convert analog video channels into digital data. The digital signals are compressed and transmitted by the satellite to end users. At the end user's set-top receiver, they are decompressed and converted back into the customary analog form for viewing. Each video channel occupies only a portion of the transponder's bandwidth, so additional channels can be squeezed into that transponder. The compression process involves representing video signals by a series of numbers, eliminating redundancy in the scenes, retaining only frame-to-frame differences, and reconstructing the video at the receiving end from the sequence of numbers.

A comparable transformation is occurring in the transmission of CD-quality audio by satellite. The entire contents of a compact disk amounting to 620 megabits can be compressed into 32 megabits and replaced by a "flash" random access memory (RAM) chip. The contents of the flash chip can be downloaded in 1.5 s from a satellite to a consumer by a direct-to-the-home transponder. There, it can be stored in the hard drive of a TV set-top box. A 10-gigabit hard drive has sufficient capacity to store the equivalent of approximately 300 CDs. Now the set-top box with speakers becomes the storage medium and solid-state "music player" for the home, replacing the stereo and compact disk player. Similarly, digitally compressed audio can now be transmitted by a satellite to a moving automobile through a "whip" antenna and stored in memory. Drivers can then select the music or audio programming they wish to hear. In another application of the same technology, pictures taken by a digital camera now can be sent around the world in seconds. A typical digital camera can store about 100 pictures on a flash chip. The chip can be removed and inserted into a computer to uplink the contents to a satellite for retransmission.

In recent years, there has been a resurgence of interest in both LEO and MEO orbits for communications satellites (50). The non-GEO orbits have won adherents among operators of global mobile personal communications systems. Those such as Globalstar, for example, permit subscribers who have handheld cellular phones to speak to others beyond the range of normal cellular transmission towers almost anywhere in the world. Note that the now-defunct Iridium handheld global mobile telephony system did not fail because of its LEO orbit, nor for any technical reason. Missteps in marketing and financing are generally cited. LEO orbits also are being used for two-way data communications and messaging systems (e.g., Orbcomm). All of these systems require that the user maintain line-of-sight contact with the satellite. Unlike terrestrial cellular phones, they have insufficient link margins to permit subscribers to place or receive calls from inside a building or other structure.

The interest in non-GEO orbits was stimulated by explosive growth in worldwide cellular phone usage and an accompanying upsurge in demand for greater telephony infrastructure. Designers of LEO systems rejected GEO orbits

on two counts (51). They believed that a GEO satellite system could not provide enough link margin for a satisfactory link between satellites and on-the-go mobile subscribers using small handheld phones that have omnidirectional antennae. They also maintained that the high latency, or 260-ms signal delay, from GEO orbit (plus any processing and speech compression delays) would be unacceptable to cellular phone subscribers. Other designers, however, concluded that an attractive compromise was offered by a MEO global mobile communications satellite system: global coverage that uses fewer satellites at high elevation angles; fewer handovers than a LEO system; and, at 100 ms, a shorter round-trip propagative delay than the 260-ms delay from geosynchronous orbit.

GEO mobile communications satellite builders resolved the margin issue by resorting to higher power satellites using very large deployable parabolic antennas of about 12.5 m (40 ft) in diameter (52). The combination of high spacecraft power and high gain of the large antenna ensures acceptable margins for satellite-based personal mobile communications. GEO systems of this type (e.g., Thuraya (53), and ACeS (54)—operated by PT Asia Cellular Satellite) offer mobile service to properly equipped subscribers anywhere in a region within the footprint of a single GEO satellite. But they do not offer global coverage. To do so would require additional satellites and, possibly, more than a single hop.

As for the latency issue, GEO satellite designers are convinced that users can accept as much as a 400-ms delay in voice communications. Consequently, GEO mobile systems are configured to keep the burdensome and unalterable round-trip propagative delay, plus compression and processing delays, within the 400-ms limit. At low orbital altitudes, LEO systems pay only a small penalty for shorter propagative delays, but they still must deal with appreciable processing, handover, and compression times, especially for geographically separated parties on long-distance calls.

Conclusions

Amidst the post-World War II Cold War environment, President John F. Kennedy urged all nations “to participate in a communications satellite system in the interest of world peace and closer brotherhood among people of the world.” By 1967, three INTELSAT satellites were operating over the Atlantic and Pacific oceans, providing ubiquitous global telephone and television communications in hundreds of languages. By the early to mid-1970s, new domestic satellite systems were created in many countries and regions, such as Canada, Europe, the United States, and Indonesia. By April 2000, the date this chapter was written, sophisticated communications satellites became a fundamental element of the world’s telecommunications infrastructure and an indispensable tool of the global marketplace. These satellites have enabled many new space-based applications to be introduced to businesses and consumers around the world. These include direct-to-home television broadcasting, handheld global mobile telephony, and high-speed broadband data exchange.

These sophisticated communications satellites have evolved since the mid-1960s. In 1965, the Early Bird (INTELSAT I) satellite weighed 76 pounds. The

mass of today's satellites can exceed 12,000 pounds. Strides in satellite technology have also extended the lifetime and transponder capacity by several orders of magnitude. The comparative sophistication of today's communications satellites derives from the application of several advanced technologies. These include digitalization, which is used for numerous functions to enhance their capabilities and flexibility. For example, by using onboard digital signal processing, modern satellites can generate hundreds of reconfigurable spot beams simultaneously. Among other things, this enables satellite operators to generate maximum revenue and to obtain greater bandwidth by reusing the limited amounts of assigned spectrum. Digital echo cancellers have also been developed and installed in digital phone exchanges and satellite networks to eliminate disturbing voice echoes on satellite-relayed telephone calls. Digital compression techniques have already increased satellite use capacity by a factor of 8, and soon a 16-transponder satellite might transmit 256 TV channels. This will greatly reduce an operator's operating and capital costs. Before the advent of digital compression, only one broadcast-quality analog video signal could be transmitted through each satellite transponder. Digitalization is also revolutionizing the transmission of CD-quality audio by satellite, thus enabling the start-up (to date) of three new satellite digital audio services: Sirius, XM Radio, and WorldSpace (see discussion under "Commercial Applications of Communication Satellite Technology").

Other advanced technologies are making their imprint on a satellite's power and propulsion. As gallium arsenide solar cells replaced traditional silicon cells, satellite power doubled and enabled satellites to generate as much as 15 kW of power at the end of life. As a replacement for mercury and cesium electric propulsion systems, xenon ion propulsion makes possible reductions of as much as 90% in the mass of a satellite's fuel requirements. At a cost of about \$30,000 per kilogram to place a satellite in orbit, millions of dollars can be saved in launch costs. This reduction can also be applied to an increase in satellite payload, longer satellite lifetime, or any combination.

These and all ongoing technological innovations are intended to provide maximum available bandwidth through frequency reuse; maximum flexibility for operators and users; lower launch and in-orbit operating costs; more space-based communications options for consumers; extended satellite lifetimes and greater reliability; larger satellite footprints, including those created by reconfigurable spot beams; higher power levels resulting from increased use of solar power; and reduced cost per transponder.

CONVERSION OF MISSILES INTO SPACE LAUNCH VEHICLES

This article begins with a brief history of the Yuzhnoye Design Office, one of the leading design bureaus in the Soviet Union and Ukraine. The Yuzhnoye Design Office designed numerous strategic missile systems, launch vehicles, and spacecraft (1). One interesting aspect of this history involves the conversion of missiles into space launch vehicles by a team of developers led by the Yuzhnoye Design Office, well in advance of the officially announced USSR conversion effort.

Brief History

The M.K. Yangel' Yuzhnoye State Design Office (initially known as Special Design Bureau 586, abbreviated OKB-586) was established on 10 April 1954 in

Dnepropetrovsk, a city on the banks of the Dniepr River in central Ukraine. Mikhail Kuz'mich Yangel' was named General Designer. Before this, he had been Director of the Scientific Research Institute 88 (NII-88) in Podlipki (now known as Korolev), a city near Moscow. In 1946, NII-88 became the USSR's main center for missile development.

A group of missile specialists from the General Designer's Department of All-Union State Plant 586 (the former Dnepropetrovsk Motor Vehicle Plant, now the State Enterprise Production Association Yuzhnyi Machine-Building Plant) formed the core of the newly established OKB-586. In 1951, Plant 586 started mass production of the R-1, R-2, and R-5 missiles developed by NII-88 and the NII-88 Special Design Bureau 1 (OKB-1), which was headed by General Designer Sergei Pavlovich Korolev. OKB-586 and Plant 586 joined forces to establish a missile design and production center where everything was under one roof. A nationwide network of developers and manufacturers for the components, systems, intermediate products, and hardware specified for use in OKB-586 missile production and development activities was also set up along with OKB-586 itself.

The Soviet Government's intention was to have this newly established system of production and development facilities headed by OKB-586 become (relative to the existing system) a stronger, more productive scientific production cooperative for developing future USSR strategic missiles. The intent was to promote missile development and also to increase substantially the military effectiveness of the missiles themselves. Despite the success of NII-88 in developing the R-1, R-2, and R-5 missiles, high-level military and government personnel understood that these missiles and any others that could be developed using the same principles could not meet future strategic requirements. Each of these missiles had substantial deficiencies that prevented them from being used in real combat conditions.

The new team would eventually eliminate these deficiencies by developing future missiles within a completely new conceptual framework. This conceptual framework was based on several principles developed by NII-88 personnel in 1952 under the leadership of M.K. Yangel'. These were the most important of the principles:

- development of a series of missiles having ranges consistent with strategic requirements;
- deployment of these missiles in hardened silo launchers constructed for concealment from the enemy;
- development of these missiles to use high-boiling-point propellants that could be stored long term and avoid using the low-boiling-point propellants previously used that had poor storage qualities;
- the use of autonomous onboard control systems protected against enemy electronic countermeasures and avoiding subsystems that might be vulnerable to noise.

The design concepts based on the high-boiling-point AK-27I and TM-185 rocket propellants developed by OKB-1 and Plant 586 General Designer's Department personnel for the R-11 and R-12 missiles in 1952 confirmed that these

principles were valid and sensible. The establishment of OKB-586 and the appointment of M.K. Yangel' as its General Designer were evidence that the Government supported this new conceptual framework for developing new missile systems. This conceptual framework guided OKB-586 in all of its activities and was continually developed and enhanced, as various new development projects were implemented. In the process, OKB-586's main mission became developing strategic missile systems capable of inflicting a highly effective second strike against any aggressor if the Soviet Union were the target of a nuclear attack.

Despite the organizational issues that arose during the establishment of OKB-586, a lack of essential equipment and experienced personnel, insufficient research on high-boiling-point propellants, delays in developing the rocket engine and autonomous onboard control system, and delays in constructing the silo launcher, the first medium-range missile system, the 8K63, was placed into service less than 5 years after OKB-586 was established. Two additional missile systems, the 8K65 medium-range missile and the 8K64 intercontinental ballistic missile, were placed into service at 2-year intervals. For some time, these missiles served as the primary weaponry in the USSR Strategic Missile Forces arsenal.

Within this brief period, under the leadership of M.K. Yangel', OKB-586 had become the USSR's leading design bureau for developing the strategic missile systems that were most important to the USSR's defense capability.

From 1954 to 1991, a total of 29 strategic missile systems were developed by OKB-586 (from 1966 on, known as the Yuzhnoye Design Office) and the team of engineers under the leadership of Academicians M.K. Yangel' and V.F. Utkin. Thirteen of these systems were accepted for military service by the Strategic Missile Forces and became the backbone of their forces (Fig. 1).

Some of these systems have no peers in missile technology. Examples include the 8K69, 15A14, 15A18, the 15A18 M, the 15Zh60 fixed solid propellant missile system 15Zh60, and the 15Zh61 rail-mobile missile system, all of which played an important role in enabling the Soviet Union to reach strategic parity with the United States and in negotiations of the Strategic Arms Limitations Treaties between the Soviet Union and the United States.

The four generations of missiles accepted into Missile Forces armaments are shown in Fig. 2, together with the dates when they were placed into service. Each of these missiles had a unique purpose and unique characteristics, and

Figure 1. General Designers: S.P. Korolev (1907–1966), M.K. Yangel' (1911–1971), V.F. Utkin (1923–2000), S.N. Konyukhov (1937–).

Figure 2. Military missiles developed by the Yuzhnoye State Design Office. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

there were substantial differences in specifications. They were all developed at different times, and each embodies the scientific, technical, and economic capabilities of the country at the time they were developed. In spite of these differences, however, it is possible to identify some trends typical of all four generations of missiles. The service life of the missiles tends to increase, the capabilities of the missile-defense countermeasures improve, the total energy output increases, the range increases and the operational specifications of the missiles all improve from one generation to the next.

The missiles of the fourth generation possess the highest military effectiveness. Whether in silos or during active flight, these missiles are able to preserve their performance in the face of any countermeasures. They are equipped with a very effective multifunctional antimissile system, which in combination with high survivability during active flight allows them to overcome with a high probability of success even a future adversary missile defense system. As of now the four types of the most highly developed military missiles 15A18, 15A18M, 15Zh60 and 15Zh61 are still deployed in the Russian Federation.

In addition to the missiles described, from 1957 on, OKB-586 also developed a variety of space launch vehicles. The most predominant idea involved developing a missile-based launch vehicle. This approach would lead to a substantial reduction in one-time and recurring costs, as well as a reduction in launch-vehicle development time due to the reduced amount of design and development work required and the ability to use the existing manufacturing infrastructure, the existing basic missile components available at the various manufacturing plants, and existing ground-based launch facilities.

This idea was implemented via the development of several launch vehicles based on the 8K63, 8K64, 8K66, 8K67, 8K68, 8K69, and 15A18 missiles; five of these launch vehicles—the 11K63 (Kosmos), 11K65 (Kosmos-2), 11K69 (Tsiklon-2), 11K68 (Tsiklon-3), and Dnepr—were in actual use. These five launch vehicles are the subject of this paper. Two additional launch vehicles, the Zenit-2 and Zenit-3SL, were developed without using military prototypes. By contrast with the missile-based launch vehicles, all stages of these launch vehicles used liquid

oxygen as the oxidizer and RG-1 kerosene as the fuel. A modified Zenit-2 first stage was used as a module in the Energia vehicle (Fig. 3).

The space ambitions of the Yuzhnoye Design Office were also embodied in the design and successful development of Module E, the lunar-lander portion of the lunar spacecraft developed as part of the lunar program. Since 1960, OKB-586 and the Yuzhnoye Design Office produced a series of research, commercial, applied scientific, and military spacecraft (more than 70 different types). This count includes the following Kosmos and Interkosmos spacecraft: AUOS, Okean, Taifun, Tselina, etc. Approximately 400 spacecraft designed by the Yuzhnoye Design Office and manufactured by the Yuzhnoye Machine-Building Plant have been launched into space, many of them aboard launch vehicles designed in-house (Fig. 4).

All design work at Yuzhnoye Design Office was performed under the direction of General Designer M.K. Yangel' before October 1971 and under General Designer V.F. Utkin between October 1971 and November 1990. M.K. Yangel' served as General Designer for the development of first-, second-, and third-generation missiles, but did not live to see the 15A14, 15A15, and 15Zh60 missiles certified for military use; however, these latter missiles were also based on his ideas, which he had to defend at many levels, up to and including the USSR Defense Council. M.K. Yangel' also attached a great deal of importance to space research. The 11K63 (Kosmos), 11K69 (Tsiklon-2), and 11K68 (Tsiklon-3) launch vehicles and Module E of the lunar spacecraft were developed under his leadership. At his initiative, a spacecraft design bureau was established at OKB-586 in 1960, spacecraft were produced at the Yuzhnoye Machine-Building Plant. Approximately three dozen types of spacecraft and several hundred spacecraft were launched under his leadership.

As Yuzhnoye Design Bureau Chief Designer, Vladimir Fedorovich Utkin had enormous influence on the development and delivery of the third- and

Figure 3. Launch vehicles developed by the Yuzhnoye State Design Office. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 4. Spacecraft developed by Yuzhnoye State Design Office. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

fourth-generation missiles, as well as the Tsiklon-3 and Zenit-2 launch vehicles. The Energia launch-vehicle module unit and approximately 40 other types of spacecraft were developed under his leadership. The highly efficient and reliable Zenit-2 launch vehicle served as the basis for developing the Zenit-3SL Integrated Launch Vehicle core of the offshore launch platform developed under the Sea Launch program. Work on the Sea Launch project began on 25 November 1993 when an agreement was executed between the American aircraft and missile company Boeing, the Russian Rocket and Space Corporation Energia, the Norwegian company Kvarner, and two Ukrainian enterprises—the Yuzhnoye State Design Office and the State Enterprise Production Association Yuzhnyi Machine-Building Plant. Geosynchronous satellite launches via Sea Launch began on 28 March 1999 with a demonstration launch of the Zenit-3SL launch vehicle.

As before, development of future launch vehicles remains at the center of attention. A more powerful launch vehicle, the Tsiklon-4, has been developed on the basis of the Tsiklon-3. Work is currently underway on the Air Launch and Mayak projects, and various approaches for modernization of the Tsiklon-2, Zenit-2, and Dnepr launch vehicles are also being explored.

From Missiles to Launch Vehicles—the First Missile (8K63) and Launch Vehicle (11K63)

8K63 (SS-4) Missile (Fig. 5). The first strategic missile to embody the new concept developed under the leadership of M.K. Yangel' was the 8K63 (SS-4). The Government task order for developing the missile was issued to coincide with establishment of the OKB-586 design bureau.

The major responsibilities for development of the 8K63 missile/missile system were allocated as follows:

- OKB-586, Chief Designer M.K. Yangel'—systems engineering of missile and missile system as a whole;

Figure 5. 8K63 missile. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

- KB-11, Chief Design Engineer S.G. Kocharyants—design of warhead and related equipment;
- NII-885, Chief Design Engineer N.A. Pilyugin—design of the autonomous onboard control system;
- NII-944, Chief Design Engineer V.I. Kuznetsov—design of gyroscopic instruments;
- OKB-456, Chief Design Engineer V.P. Glushko—design of RD-214 engines;
- Spetsmash State Special Design Bureau, Chief Design Engineer V.P. Barmin—design of aboveground and silo-based launch facilities.

These chief design engineers became the most active proponents of Yangel's approach to missile system development.

The 8K63 consisted of a monocoque single stage that had a nose cone section for the nuclear warhead, cylindrical fuel tanks, an instrument section that had an autonomous onboard control system, and a conical tail compartment containing a fixed RD-214 four-chamber engine using TM-85/AK-27I high-boiling-point propellants. The AK-27I oxidizer is an iodine-inhibited mixture of nitric acid (70%) and nitrogen tetroxide (27%), and TM-185 is a modified-kerosene hydrocarbon fuel. At the time, these were the best-known high-boiling-point propellants that had an adequate production infrastructure.

The missile had a launch weight of 41.7 metric tons, a length of 22.1 m, and a body diameter of 1.652 m. Its RD-214 engine produced a thrust of 648/744 kN and a specific impulse of 2300/2640 N · s/kg (sea level/vacuum). TG-02, a xylidine/triethylamine mixture, was used as an ignition propellant to ignite the fuel in the RD-214 combustion chamber. The engine turbopumps were operated using a gas-generator mixture obtained by decomposing hydrogen peroxide in the presence of potassium permanganate. The oxidizer and fuel tanks were pressurized by compressed air and compressed nitrogen, respectively, stored in high-strength cylinders. Four adjustable graphite control vanes were used; one vane was placed in the exhaust of each engine chamber. The main body of the missile was constructed from a lightweight, high-strength aluminum alloy.

The fuel tanks were made from nonreinforced cylindrical shells mounted between two bottom plates that were segments of spheres. The oxidizer tank was mounted forward of the fuel tank to control the center of gravity during flight. Moreover, an intermediate bottom plate was also mounted in the oxidizer tank for the same purpose, so that additional oxidizer would flow from the top to the bottom portion of the tank as the oxidizer was consumed from the bottom portion. The oxidizer feed line ran through a tunnel pipe built into the fuel tank. A riveted instrument compartment was located between the two tanks (Fig. 5). To shift the aerodynamic center of force closer to the center of mass, four fixed aerodynamic stabilizers were placed on the tail section of the missile.

This missile was flight-tested at the Kapustin Yar facility from July 1957 to December 1958. During this time, there were 24 launches of this missile, which confirmed that it was highly reliable. Some final design modifications were made, and the 8K63 missile was accepted into armaments for use with aboveground and silo launchers. The silo-launched version of this missile was assigned the code number 8K63U.

The requirement to develop both aboveground and silo-based launch facilities for this missile was largely dictated by the need to reduce the amount of time required for final development of the missile. Constructing a silo launcher would have required a large amount of time, so most test launches of this missile were done from a hastily constructed aboveground launch facility.

The tactical, engineering, and operational characteristics of the 8K63 represented a considerable advance over previous missiles. The 8K63 had a reaction time of 20 min and could deliver a 2.3-MT warhead to a maximum range of 2080 km. For some time, this was the main missile used by the Strategic Missile Forces (established December 1959). At the same time the 8K63 was on

operational duty in the Strategic Missile Forces, it also served for 25 years as the primary launch vehicle for testing new technology and designs of warheads and antimissile defense systems. The 8K63 was decommissioned in July 1988 pursuant to the Treaty on the Elimination of Intermediate-Range and Shorter-Range Missiles (INF Treaty).

11K63 (SL-7) Launch Vehicle (Fig. 6). Even the first few launches of spacecraft into low Earth orbit had demonstrated a wide variety of new opportunities to study Earth and near-Earth space using space-based instrumentation. These opportunities stimulated wide interest among scientists, businesspeople, and the military in obtaining information on Earth's surface, Earth's upper atmosphere, Earth's magnetic field and cosmic rays, the interaction between these particles and Earth's magnetic field, and the effects of space environment on objects launched into space.

This generated a requirement to launch a large number of spacecraft into low Earth orbit for various purposes. A need for low-cost launch vehicles therefore arose. The three-stage launch vehicle then (late 1950s) in use in the Soviet Union, the 8K72 Vostok, was not appropriate for frequent use as a launch vehicle due to the relatively high cost of launch, the relatively large amount of time required to prepare it for launch, and the fact that it was generally used to address more prestigious problems. Thus, in late 1959, OKB-586 embarked on an initiative to develop a two-stage launch vehicle based on the mass-produced 8K63 missile. This proposal was supported by the USSR Academy of Sciences and Ministry of Armaments, each of which were interested in the development of an inexpensive launch vehicle to address their specific needs using small spacecraft placed in low Earth orbit.

OKB-586 received the Government order to develop this launch vehicle, which came to be called the 11K63, in August 1960. The Government authorized the production of ten 11K63 launch vehicles and use of these vehicles to launch 10 spacecraft; each was for a different purpose and carried different instrumentation. Two of these spacecraft, designated the MS series, were developed by OKB-1, and the remaining eight spacecraft, designated the DS series, were developed by OKB-586.

The main tasks required for developing the 11K63 launch vehicle involved developing a second stage and aerodynamic fairing and adapting these components to a first stage that was virtually identical to the 8K63 missile. The second stage and aerodynamic fairing weighed ~ 7.7 metric tons, giving the 11K63 launch vehicle a launch weight of 49.4 metric tons, and a length of 30 m.

The second-stage fuel and dry compartments of the launch vehicle were similar to the corresponding first-stage compartments. However, there were also several differences due to the fact that the second-stage RD-119 engine required liquid oxygen and unsymmetrical dimethylhydrazine (UDMH) as propellants. This engine had been developed by OKB-456 for use on the Vostok launch vehicle but ended up not being used for a variety of reasons. The RD-119 engine was fairly well developed and also had relatively good energy performance characteristics (thrust and specific impulse in vacuum 106 kN and 3454 N·s/kg, respectively). The existence of these additional propellants undoubtedly made operation of the launch vehicle more complicated, but the availability of a fully developed engine reduced the effort and time required to develop the launch

Figure 6. 11K63 launch vehicle. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

vehicle. Therefore, OKB-586 decided to use the RD-119 engine in the second stage of its first launch vehicle.

The RD-119 engine is a fixed, single-chamber, liquid-fueled engine installed on the second stage in combination with several movable low-thrust nozzles used to control the second stage in pitch, yaw, and roll. The engine is started using a pyrotechnic device. Positive pressure in the oxidizer tank was maintained by evaporating oxygen in a heat exchanger mounted on the engine's turbine exhaust pipe. Positive pressure in the fuel tank was maintained by using a mixture of producer gas and UDMH vapor. The RD-119 engine was only capable of single-use operation; as a result, spacecraft were launched to place them directly into orbit—primarily low-level highly elliptical orbits. To increase the amount of UDMH that could be stored in the second-stage fuel tank, it was initially cooled to -45°C . The second stage was mated to the first stage using a tubular beam that had a conical heat shield attached to the lower chord to protect the first stage from the exhaust of the RD-119, as it pushed away the first stage during the stage separation process.

The spacecraft was initially housed under a conical/cylindrical aerodynamic fairing (jettisoned during the boost phase of the flight after passing through the dense layers of the atmosphere). The spacecraft was separated by using pusher springs. Like the first stage, the second stage of the launch vehicle had an autonomous onboard control system developed by the newly established OKB-692 in Kharkov (now NPO Khartron-Arkos) under the direction of Chief Designer B.M. Konoplev). Initially, the 11K63 was to be launched from the 8K63U launcher at the Kapustin Yar Test Site, and an appropriate operational scenario was developed for the launch vehicle under this assumption (including use of a silo launcher that was shorter than the launch vehicle).

The first launch of the 11K63 from a silo took place on 27 October 1961. Both the first and the second launches were unsuccessful. Nearly 5 additional months were required to eliminate all of the problems. The third launch of the 11K63 took place on 16 March 1962 and was successful. The first spacecraft designed and built by OKB-586 personnel, the DS-2, had been placed into Earth orbit. After 37 standard 11K63 silo launches from the Kapustin Yar Test Site, all further 11K63 launches were from a new, aboveground facility at the Plesetsk Test Site, which was developed by the Design Bureau for Transportation Machinery directed by Chief Designer V.N. Sobolev.

There were several differences between the operational configuration of the 11K63 for silo launches and that for surface launches. During a silo launch, final assembly of the launch vehicle occurred during placement in the silo. The first and second stages (including spacecraft) were tested in the launch support facility, transported to the launch facility separately in the horizontal position, and then placed in the silo in the correct order. During a surface launch, final assembly of the launch vehicle took place in the launch support facility, and the assembled launch vehicle was transported to the launch facility, where it was raised into a vertical position using special equipment rather than the gantry.

The 11K63 could place a payload of up to 450 kg into circular low Earth orbit (200 km altitude and inclination 82°). The 11K63 became the first Soviet launch vehicle to be mass-produced. It was accepted for operational use in 1965, along with the DS-P1-Yu spacecraft (developed by OKB-586) and the new

aboveground launch facility at the Plesetsk test facility. The 11K63 was launched a total of 165 times, of which 143 were successful. Numerous Kosmos- and Interkosmos-series spacecraft were launched using the 11K63. It was used for 16 years until the final launch on 18 June 1977.

8K65 (SS-5) Missile and 11K65 Launch Vehicle (Fig. 7). The 8K65 became the second missile developed by OKB-586 within its new conceptual framework. The government task order for developing this missile was received in early July 1958. The goal was to develop, within 2 years, a missile that had

Figure 7. 8K65 missile. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

twice the range of the 8K63, which was then in the final stages of development. This promised to be a more difficult effort than the 8K63 had been and would be made even more difficult by the fact that OKB-586 had already been working for a year and a half on developing the 8K64 intercontinental ballistic missile, for which OKB-586 had received the task order in December 1956.

However, gaining experience, OKB-586 enthusiastically began work on developing the 8K65. The only decision valid at that point was made: Use the engineering design solutions that had proved themselves during the 8K63 design effort, as well as several of the basic design solutions that lay at the core of the 8K64 design. It was decided to use a monocoque, single-stage design for the 8K65 similar to that for the 8K63, but using a higher energy propellant combination. The 8K63 used the same propellant combination used in the 8K64; unsymmetrical dimethylhydrazine (UDMH) was the fuel, and AK-27I was the oxidizer. This propellant combination enabled a 15% increase in the total energy output of the 8K65 over the TM-185/AK-27I propellant combination. The use of UDMH enabled the entire missile to operate on only two propellants, thereby eliminating one deficiency of the 8K63—the fact that several propellants were required. One important quality of the propellants selected was that they would ignite on contact and thereby eliminated the need for an ignition propellant. This also simplified development of the turbopump-boost gas generators, which could use the same propellant combination.

The opportunity to use UDMH in the 8K65 resulted from the success achieved by the State Institute for Applied Chemistry (director V.S. Shpak) in researching this fuel and setting up the appropriate manufacturing facilities. However, the decisive factor enabling its use in the 8K65 was that the engine designers at OKB-456 had developed a two-chamber, liquid-fueled rocket engine (that had a thrust of 735 kN) that used this propellant combination. Two of these engines together as a single engine module [given the code number RD-216, whose thrust and specific impulse were 1481.3/1741.3 kN and 2413.3/2835.1 N·s/kg, respectively (sea level/vacuum)], were used on the 8K65.

The increased range required a corresponding increase in the amount of fuel and oxidizer carried, and thus, an increase in the diameter of the missile. To standardize production, a diameter of 2.4 m was adopted for the 8K65 main body; this was identical to the diameter of the 8K64 second stage.

The 8K65 was designed by virtually the same team of developers as the 8K63, and there were significant similarities to the 8K63 in both design and external appearance. Like the 8K63, the 8K65 was a single-stage monocoque design that had a conical warhead compartment (containing the same nuclear warhead as was used on the 8K63); a conical warhead mounting adapter, cylindrical fuel and oxidizer tanks; an instrument compartment containing the autonomous onboard control system that was located between the tanks; and a conical tail section that had a fixed RD-216 engine module. The 8K65 used exactly the same tank pressurization system, actuator-control design, and structural materials as the 8K63. Just as in the 8K63, the oxidizer tank was located forward of the fuel tank, and four fixed stabilizers were mounted on the tail section. The major differences between the 8K65 and the 8K63 were the new fuel; the increased fuel capacity; the larger diameter of the missile; the new, more powerful engine; and the new control system.

The 8K65 engines were ignited by taking advantage of the hypergolic nature of the propellants as they mixed in the combustion chamber, thereby simplifying the engine design. Using the same basic fuel/oxidizer components also enabled simplifying the gas generators used in the turbopump-boost system.

However, there were also some additional differences. For example, the cylindrical fuel tank fairings on the missile were made from reinforced molded panels. A system for simultaneously emptying the tanks (not available on the 8K63) was used to reduce the amount of unused fuel and oxidizer by synchronizing the consumption rates. This missile also marked the first use of a gyro-stabilized platform, that gave the missile the same accuracy as the 8K63, despite the factor of 2 greater range. The warhead unit was separated by braking the missile body using solid-rocket motors mounted on the missile instrument compartment housing.

The 8K65 was twice as heavy as the 8K63, but was only 2.3 m longer. It could deliver a warhead identical to that used in the 8K63 to a maximum range of 4500 km. Like the 8K63, the 8K65 was developed and placed into military service for use from surface and silo-based launch facilities. The silo-launched version had the code number 8K65U. Silo launches of the 8K65U were similar to those of the 8K63U; they involved the use of a launch canister and the gas pressure generated by the missile engines after being started in the silo. The 8K65 was flight-tested at the Kapustin Yar Fourth State Central Test Site. Forty-four launches of the 8K65 or 8K65U missile were performed as part of the flight/development testing program. The 8K65 became the second, longest range missile in the Strategic Missile Forces arsenal. The 8K65 enabled targeting strategic facilities maintained by potential adversaries in Europe, Asia, and even Africa that were out of range of the 8K63. The missile remained on operational duty for 15 years, starting in 1962, and was decommissioned in 1987 pursuant to the INF Treaty.

11K65 (SL-8) Launch Vehicle (Fig. 8). The second launch vehicle, designated the 11K65, was developed by OKB-586 pursuant to a USSR Government Decree issued on 30 October 1961. According to the stated requirements, the 11K65 launch vehicle would launch one (or more) spacecraft into Earth orbit. The orbits were required to be either elliptical or circular, the circular orbits had a maximum altitude of 2000 km. Stringent requirements were also imposed on the accuracy of the resulting orbital parameters.

The spacecraft to be launched by the 11K65 were expected to remain active for long periods of time, and therefore would weigh more. In view of all these requirements, the 11K65 had to have approximately three times the total spacecraft launch capacity of the 11K63. Preliminary studies performed by OKB-586 indicated that such a launch vehicle could be built quickly and at minimal expense in terms of materiel, if the 8K65 missile were used as a first stage. Design optimization of the launch-vehicle parameters revealed that it would be desirable to design the second stage so that it would have the same diameter, use the same propellants as the first stage, and weigh ~24 metric tons. Placing such a stage on the 8K65 missile required partially modifying its frame configuration and developing a new interstage compartment that could bear the load of the second stage and also provide an outlet for the gas generated by the steering nozzles on the second-stage engine during stage separation. To reduce the length and

Figure 8. 11K65 launch vehicle. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

weight of the second stage, it was decided to use a somewhat different design compared with that of the first stage. The second-stage fuel tanks were combined into a single cylindrical propellant compartment that had three spherical-segment bottom plates and a common intermediate bottom plate separating the propellant compartment into an upper cavity containing the oxidizer and a lower cavity containing the fuel. The instrument compartment was located above the propellant compartment, and a spacecraft adapter and clamshell nose fairing were attached to the top of the instrument compartment to protect the spacecraft against the air flow while the launch vehicle moved through the lower atmosphere and to protect the spacecraft during ground operations.

The requirements that the 11K65 reach a high-altitude circular orbit and launch heavy spacecraft into such orbits led to the use of a two-burn orbital insertion procedure for placing spacecraft into such orbits. In this procedure, the launch vehicle second stage and spacecraft were placed into an elliptical transfer orbit whose apogee was equal to the desired altitude of the circular orbit, and were then transited into the desired circular orbit. The problem came in obtaining the appropriate magnitude and direction of the velocity vector required for the second stage to reach the perigee of the elliptical transfer orbit and then the circular orbit. Implementation of this procedure affected the design concepts for the control system, the second-stage engine, and the propellant feed system.

The second-stage engine, which came to be known as the S5.23, actually consisted of two subengines: a single-chamber main engine and a four-chamber steering engine. The main engine was fixed relative to the missile. The four steering-engine nozzles were combined with the four small thruster nozzles to form four combined, steerable units mounted on the main engine. The steering engine enabled control of the second stage while the main engine was in operation; the thruster system was used for stabilization and attitude control of the second stage during the passive portion of the trajectory. This engine was developed by OKB-2 (now known as the Chemical Machinery Design Bureau) under the direction of Chief Designer A.M. Isaev. Features of the S5.23 engine included three thrust modes (vernier, intermediate, and primary) and the capability of reusing the primary-thrust mode. In primary mode, the engine thrust was produced by the main engine and its four steering nozzles and was equal to 157 kN (specific impulse 2913.6 N·s/kg). In intermediate-thrust mode, only the steering nozzles were used (thrust 5.4 kN). This mode was used during engine start-up and shutdown. The low-thrust mode (thrust 0.1 kN) was supported by the passage of gas produced in a special gas generator through small nozzles. Between the two engine firings, the fuel and oxidizer for the second engine firing, and for the engine firing in the stabilization/attitude control mode during the passive portion of the trajectory, was stored in two small tanks located on the outside of the second-stage propellant compartment.

The oxidizer and fuel tanks were pressurized by using compressed air and compressed nitrogen, respectively, stored in high-pressure cylinders.

The control system for the second stage was developed by OKB-692 under the direction of Chief Designer V.G. Sergeev. To meet the requirements for increased accuracy of spacecraft placement into orbit, relatively high-speed computers and high-accuracy control devices (that had increased throughput and special software and algorithms) were used for the first time. The engineering

design solutions implemented for the 11K65 gave it the ability to place up to eight spacecraft that had a maximum total weight of 1500 kg into Earth orbit (circular orbit, altitude 200 km, and inclination 51°) in a single flight. OKB-586's role in developing the 11K65 was limited to preparing the preliminary design and design documentation, as well as fabrication and design/flight-testing of the first 10 launch vehicles. Due to the workload related to developing the new 8K67 missile, the 11K65 development task was transferred to OKB-10 (now known as the Academician M.F. Reshetnev Scientific Production Association for Applied Mechanics) in late 1962.

Development flight-testing of the 11K65 began on 18 August 1964 at the Baikonur Cosmodrome from a modified aboveground launch facility designed by the Novokramatorsk Machinery Plant Design Office. Routine 11K65 operations have been conducted at the Plesetsk Test Site since 1967 and the Kapustin Yar Test Site since 1973. Aboveground launch facilities that had movable gantries were built at each of these test sites. These launch facilities were designed by the Design Bureau for Transportation Machinery. Between 1965 and 1967, OKB-10 upgraded the 11K65 to improve its operational specifications, after which it was renamed the 11K65 M (Kosmos-3). To date, there have been more than 500 launches of the 11K65 or 11K65 M that carried more than 1000 Kosmos- and Interkosmos-series spacecraft into Earth orbit, including more than 130 DS-1P, Tselina, Tyul'pan, Taifun, and AUOS ("automated universal orbital stations") spacecraft designed by OKB-586 (Yuzhnoye Design Office). The 11K65 remains one of the most reliable, highly productive launch vehicles in the Russian Federation inventory. For some time, a modified version of this launch vehicle, the K65M-R, has also been used for testing warhead units and missile-defense countermeasures.

8K69 (SS-9 mod 3) Missile—The Basis for the 11K69 and 11K68 Launch Vehicles (Fig. 9). The Government task order for developing the 8K69 missile was issued on 14 April 1962, simultaneously with the task order for developing the 8K67. The 8K67 was given an accelerated development schedule. Many of the requirements for the 8K67 and 8K69 missiles were either very similar or identical, so the decision was made to standardize these missiles in areas where the engineering design solutions were consistent. Thus, both stages of the 8K67 were used in the 8K69, after a few slight design modifications, mainly related to the fact that the 8K69 used a warhead different from the 8K67.

The 8K69 was developed as a countermeasure to U.S. deployment of the Safeguard missile defense system, which protected U.S. territory against missile attack from the north. This missile had several unique features. It had unlimited range and could reach targets from any direction; therefore, it could deliver a nuclear warhead to any area of the United States by evading the missile defense system (and rendering it useless). At the time, these features led to calling the 8K69 a "global missile." The 8K69 warhead could come in from various directions by being placed into Earth orbit at various azimuths and then reentering from orbit and hitting the target.

Like the 8K67, the 8K69 was a two-stage monocoque design in which the stages were on top of each other and stage separation occurred around the circumference of the missile (launch weight 181.3 metric tons and length 32.65 m). Both missile cases were cylinders 3 m in diameter. Both stages (and the warhead)

Figure 9. 8K69 missile. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

used the same fuel/oxidizer pair: unsymmetrical dimethylhydrazine (fuel) and nitrogen tetroxide (oxidizer). This fuel/oxidizer pair gave the missile a high total energy output and also substantially increased the guaranteed military readiness lifetime (to 7 years).

The first stage consisted of four sections: a stage transition section, an instrument section, a tail section, and propellant-tank section. The second stage had three sections: an instrument section, a propellant section, and a tail section. The second-stage propellant tanks were combined into a single section that had three spherical-segment bottom pieces. The second-stage instrument section was conical. All “dry” sections (stage transition section, instrument sections, and tail sections) in the missile and the warhead section were riveted, whereas the fuel tanks were welded. The fuel-tank design used molded panels and molded stock hollow frames, which led to a substantial reduction in the number of processes required, as well as an overall simplification of the tank fabrication process. To reduce the structural weight, light, high-strength aluminum alloy was used for all missile and warhead sections.

The first-stage propulsion system consisted of an RD-251 main engine and an RD-855 steering engine (total thrust 2651.6/2974.3 kN and specific impulse 2627.1/2945.9 N·s/kg at sea level and in vacuum, respectively). Structurally, the RD-251 main engine consisted of three identical engines affixed to a single frame. Each of these engines had two chambers, a turbopump unit, a gas generator, a solid-fuel starter, automatic control systems, and various other components. The RD-251 engine was attached to a frame, which was in turn attached to the fuel tank bottom frame, and was enclosed by the tail section. Solid-fuel starters were used to start all three engines simultaneously within a few seconds of steering engine start-up. The engines could also be turned off simultaneously a few seconds before the steering engine, in response to a command from the command system.

The RD-855 steering engine controlled the missile in roll, pitch, and yaw. It consisted of four steerable chambers and a stationary turbopump unit, gas generator, solid fuel starter, automatic control systems, and various other components. The steering engine chambers were steered by using hydraulic actuators: UDMH was obtained from the motor turbopump unit as the working fluid. The steering motor was started and turned off by the missile control system in accordance with a timed cycle schedule. The steering engine chambers were mounted in four fairings on the exterior surface of the tail section. Two of these fairings also contained solid-rocket motors to decelerate the first stage after stage separation.

The second-stage propulsion unit consisted of an RD-252 main engine and an RD-856 steering engine (total thrust 9955.7 kN and specific impulse 3093.1 N·s/kg in vacuum). The RD-252 design and systems were similar to those used in the first-stage, two-chamber, liquid-fuel engine but had larger nozzles for a higher maximum altitude. Like the RD-251, the RD-252 was affixed to an engine frame that was in turn attached to the fuel tank bottom frame, and was enclosed by the second-stage tail section.

The RD-856 steering engine was designed to control the second stage, which operated in a less-dense atmosphere. Therefore, the engine had much lower thrust than the RD-855 but was similar in design and was based on similar

systems. The second-stage engine was mounted similarly to the first-stage engine. The steering chambers were likewise housed in four compartments mounted on the exterior surface of the second stage. Solid-propellant motors were also mounted in two of the compartments; these motors were used for second-stage braking after warhead separation. Second-stage engine start-up and operation were supported by using a control system similar in design to that used for first-stage engine start-up and operation. The main engines for both stages were developed by OKB-456, the steering engines were developed by OKB-586, and the retroengines were designed by the Iskra Machinery Plant in Moscow.

The fuel and oxidizer tanks for each stage were pressurized by using hot gases produced from the primary propellants using special gas generators (the steering-engine propellant feed system was a source).

The 8K69 autonomous onboard control system supported prelaunch missile preparation and silo-based launches. The control system also supported fairly high readiness and target accuracy. To improve the reaction time of the missile, the control system used gyro units that could be forced into operational mode. The orbital weapon unit (OWU) consisted of a relatively large single warhead, as well as a reentry stage and an interstage bay that connected the orbiting weapon unit to the second-stage instrument bay. The OWU reentry stage included an instrument bay that held the control system and toroidal fuel tanks; an RD-854 retro-engine and vernier thruster were located in the interior cavity between the tanks. The RD-854 is a fixed, single-chamber liquid-fueled engine (thrust 75.5 kN, specific impulses $3063 \text{ N} \cdot \text{s/kg}$), that uses eight fixed exhaust nozzles to control the orbital weapon unit during braking maneuvers. This engine was started by using a pyrotechnic starter. The vernier thruster (8 nozzles, thrust 0.03 kN) was used for OWU damping after OWU separation from the second stage, for OWU trajectory stabilization during passive flight, and for OWU attitude stabilization before retroengine start-up. The RD-854 engine and thruster were designed by OKB-586. The control systems for the missile and orbital weapon were designed by OKB-692, and the gyro instruments were developed by NII-944.

The missile was silo-launched using the gas pressure generated by the first-stage missile engines after they were started in the silo. The missile was launched from a stationary launch platform located inside the launch silo. After the missile left the silo, it was turned toward the target azimuth in roll using the first-stage steering engines. Missile-mounted hooks slid along guides in the launch canister to assure the safety of missile launches. In the interests of launch safety while the engines were in operation, the gas outflow from the first-stage engines was directed away from the missile by special baffles.

Ground-based firing-stand tests of the OWU reentry stage and aircraft-based testing of the OWU reentry stage under weightless conditions were followed by development flight-testing of the 8K69 missile, which involved some 19 missile launches. Final design modifications of the first and second stages had already been made as part of the 8K67 missile development project, so flight-testing of the 8K69 was limited in scope and basically involved integration testing of the OWU and missile. The 8K69 was accepted into armaments in 1968 and remained in military service for 15 years.

11K69 (SL-11) and 11K68 (SL-14) Launch Vehicles (Figs. 10, 11). OKB-586 began developing the 11K68 and 11K69 launch vehicles in August 1965

Figure 10. 11K69 launch vehicle. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 11. 11K68 launch vehicle. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

pursuant to a government decree. The USSR Ministry of Defense, the main party interested in developing these launch vehicles (LVs), hoped to use them as delivery systems for both long-term or tactical space-based reconnaissance systems and antisatellite defense systems. As a result, these launch vehicles had to be extremely flexible and rapidly launched. The 8K69 missile was selected as the basis for both LVs. Virtually identical versions of the first two stages of this missile were used in both the 11K68 and 11K69 LVs. This led to standardization of many launch-support-facility and launch-facility components for these LVs, as well as a reduction in development cost.

There were various reasons behind selecting the 8K69 missile as the basis for the 11K68 and 11K69 launch vehicles. The 8K69 missile, which could place orbital warheads into Earth orbit, could already, after some modification, place other spacecraft into orbit. Additionally, the 8K69 had a relatively high total energy output and could place payloads of up to 3000 kg into low Earth orbit. It could also be readied for launch fairly rapidly, thereby laying the groundwork for meeting the 11K68 and 11K69 requirements for flexibility and rapidity of launch.

Another consideration was the fact that the first and second stages of the 8K69 were already in final development as part of the 8K67 missile and the necessary series production facilities had been established for them. This enabled reducing the one-time development costs for the 11K68 and 11K69 LVs. These considerations served as the basis for the decision to base the 11K68 and 11K69 LVs (which later came to be called, respectively, the Tsiklon-3 and Tsiklon-2) on the 8K69 missile.

The 11K69 LV is an 8K69 missile in which the orbital warhead has been replaced by one of two nose units containing either a reconnaissance spacecraft or an anti-satellite system. The anti-satellite system consisted of a guidance stage [developed by the Central Machinery Design Bureau (TsKBM), Chief Designer V.N. Chelomei], and an antisatellite weapons system (developed by Comet Design Bureau, Chief Designer A.I. Savin). Each of these standard 11K69 payload types can be placed under a standard nose fairing.

The launch vehicle is assembled in the Launch-Support-Facility Test and Assembly Building, with the launch vehicle and nose units in horizontal position. The 11K69 LV is transported to the launch pad in assembled form using a custom transporter-erector. Various assemblies installed on the transporter-erector ensure proper mating (or demating) of all pneumatic lines, hydraulic lines, electrical lines, and mechanical joints, the appropriate lines and connections to the launcher are made as the transporter-erector moves over them. The LV is placed into vertical position using the transporter-erector, which is also used for all further servicing (no gantry tower is used).

The 11K69 LV marked the first use of a safe, automated, crewless launch system that completely eliminates any need for operations personnel in the vicinity of the launch facility during the most hazardous launch operations. This system of operations also led to a substantial reduction in the amount of time required to prepare the LV for launch.

The 11K69 space launch system was developed in cooperation with the Design Bureau for Transportation Machinery, the Elektropribor Design Bureau, and various other organizations. The space launch system for the 11K69 LV was located at the Baikonur Cosmodrome (Scientific Research Test Site 5). Standard

11K69 launches have been performed since 6 August 1969. This LV holds a unique record in rocketry and space history. All 103 launches of this launch vehicle have been successful, and the 11K69 is still in regular use.

The 11K68 LV differs from the 11K69 LV in that the former has a newly developed third-stage, nose fairing, and interstage-skirt section. This interstage-skirt section consists of an inverted frustrum of a cone because the mating diameter of the nose cone was greater than that of the second-stage instrument bay. The nose cone is intended to protect the spacecraft and third stage from external effects during ground and flight operations. The nose cone consists of a conical cylindrical “clamshell” whose two halves are held together by a special locking device embedded in the longitudinal surface of the nose cone. Once the dense layers of the atmosphere have been traversed, the mechanical linkage between the two halves is severed, and they are jettisoned from the launch vehicle.

The third stage of the 11K68 launch vehicle includes a spacecraft adapter, an instrument section, fuel/tail section, RD-861 main engine, 11D75 vernier thruster, a control system, and a telemetry system. To reduce the weight of the third stage, the instrument compartment uses a space-frame design. In addition to the control system devices, the instrument compartment also houses a spherical high-pressure tank containing helium used by the propellant-tank pressurization system. The telemetry system instruments are mounted on the exterior of the instrument section, along with the all-riveted spacecraft adapter structure. The third stage uses a number of engineering design solutions tested during basic design of the orbital-weapon-unit (OWU) braking engine assembly on the 8K69 missile. Like the OWU, the third stage was sealed. The third stage also used the same propellants as the OWU, nitrogen tetroxide and unsymmetrical dimethylhydrazine. The third stage can be stored for several years in the fueled and gas-filled state and transported to the launch pad in this state as part of a launch vehicle. This engineering design solution led to a significant reduction in launch preparation time. Both the third stage and the OWU used a toroidal fuel compartment that had a fixed main engine mounted in the interior cavity. The thruster was also fixed and was mounted in the third-stage tail compartment.

By contrast with the OWU, the third stage toroidal fuel section was cylindrical rather than conical and had one and a half times the volume. A common intermediate bottom plate divides the section into an upper cavity for the oxidizer and a lower cavity for the fuel. The cavities include baffles to prevent propellant oscillation, intake assemblies, and other fittings. Fine-mesh mist extractors were used to support propellant feed into the main engine during start-up under weightless conditions.

The RD-861 main engine is an improved version of the RD-854 engine used in the OWU and has a higher total energy output (thrust 78.1 kN, specific impulse 3374 N·s/kg) than the RD-854. However, its main features are its ability to be fired twice under weightless conditions and extended operational life. These features enabled using a two-impulse spacecraft launch trajectory that had an elliptical transfer orbit and resulted in the ability to increase the altitude of the orbits that could be reached, as well as the mass of the spacecraft that could be placed in such orbits.

The RD-861 main engine is a single-chamber, liquid-fueled engine that has an open-loop turbopump-based propellant feed system; the generator gas used to

operate the turbopumps is discharged through eight nozzles operated by the third-stage flight-control actuator system while the main engine is in operation.

The 11D75 vernier thruster is an improved version of the OWU thruster on the 8K69. Just as for the main engine, both the number of times the thruster can be operated and the operating lifetime have been improved; the functions performed by the thruster were also expanded. It was used for attitude control and stabilization of the third stage and also to support main-engine restart in weightless conditions. To this end, the thruster was equipped with two special nozzles to create a micro-overload in the longitudinal direction for approximately 100 seconds until the third-stage main engine restarted. The 11D75 thruster has an independent fuel system that is filled from the primary third-stage fuel tanks while the first two stages of the 11K68 launch vehicle are in flight. The RD-861 and 11D75 engines were developed by the Yuzhnoye Design Office.

The 11K68 control system consists of two interconnected systems; one has equipment installed in the first- and second-stage instrument sections, and one has equipment installed in the third-stage instrument sections. The control system for the first two stages of the launch vehicle supports prelaunch preparations, launch, and flight-control functions until third-stage separation, and the second control system controls the third stage during subsequent spacecraft orbital insertion phases. The control system for the first and second stages of the LV was developed by the Elektropribor Design Bureau; that for the third stage was developed by the Kiev Radio Plant (now the Kiev Radio Plant Production Association) Design Bureau. Like the 11K69, the 11K68 was operated in horizontal mode. Like the 11K69, preparation of the 11K68 for launch was automated using standardized assemblies, command lines, actuator lines, and data lines.

The ground facility for these launch vehicles was developed by the Design Bureau for Transportation Machinery and located at the Plesetsk Test Site. To date, there have been 119 launches of the 11K68 launch vehicle; 114 were successful. Several launches have supported the deployment of up to six spacecraft in one flight. More than 10 different types of spacecraft have been deployed into a variety of orbits using the 11K68.

15A18 (SS-18 mod 4) Missile (Fig. 12). The 15A18 is one of the most powerful ballistic missiles ever developed by the Yuzhnoye Design Office; it is designed to deliver 10 warheads weighing approximately 8.5 metric tons to a range of up to 11,000 km. The missile had a launch weight of 211.1 metric tons, a length of 34.3 m, and a case diameter of 3 m. One such missile can destroy up to 10 arbitrarily located targets within an area several hundred kilometers across using the nuclear warheads carried by the missile. The 15A18 has the capability of high-accuracy strikes on enemy facilities even after multiple enemy nuclear strikes against 15A18 deployment areas.

The government task order for developing the 15A18 missile system was issued on 16 August 1976. The new missile was to be based on the 15A14 missile system, and the main reason for developing the new system was to modernize the 15A14 for increased military effectiveness and increased launch-facility hardening. The improved 15A14 missile was designated the 15A18. The task order called for increasing the yield of the nuclear warheads, improving the

Figure 12. 15A18 missile. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

effectiveness of the missile-defense countermeasures used, increasing the target accuracy, increasing the range, and increasing the dimensions of the area targetable by the reentry vehicles to meet certain specifications. This task was successfully accomplished.

These requirements were met through the following developments:

- high-strength reentry vehicles carrying higher-yield nuclear warheads;
- multipurpose missile-defense countermeasures;
- two-level weapons compartment that has clamshell fairing;
- high-energy output liquid-fueled reentry-vehicle stage separation units and missile-defense countermeasures;
- missile control systems that have gyroscopes of enhanced accuracy and an improved onboard digital computer; and
- targeting systems that remain functional and ensure highly accurate targeting, even in the event of multiple enemy nuclear attacks on the 15A18 deployment area.

A launch silo that had improved hardening against nuclear explosions was also developed.

The 15A14 missile was used for the first and second stages of the 15A18 after several modifications. These missile stages have a highly compact layout to maximize the amount of propellant carried within the limited dimensions of the missile. The first-stage propulsion unit is a module consisting of four single-chamber RD-264 engines developed by the Design Bureau for Power Machinery (total thrust 4167.3/4524.4 kN and specific impulse 2877.3/3123.5 N·s/kg at sea level and in vacuum, respectively). The second stage uses an RD-229 single-chamber, fixed, main engine and an RD-0230 four-chamber steering engine (total thrust 760.3 kN and specific impulse 3193.5 N·s/kg in vacuum). Both of the second-stage engines were developed by the Design Bureau for Automated Chemical Equipment. To increase the specific impulse, the RD-264 and RD-0229 engines had a closed-loop design in which the gas-generator output used to operate the turbopump assemblies was also burned in the combustion chambers.

The RD-864 engine on the RV bus was developed by the Yuzhnoye Design Office (thrust 19.6 kN and specific impulse 2848 N·s/kg). It is a four-chamber, liquid-fueled engine built to a new design; before engine start-up, the chambers are moved outward from the body of the bus and are stopped at a certain specific angle to the longitudinal axis of the bus so that the stage appears to be drawn forward. This simplified the system for separating the warhead unit and missile-defense countermeasures system components from the RV bus.

The first stage is controlled during flight by gimbaling the RD-264 engine, and the second stage and reentry stage are controlled by gimbaling the RD-0230 and RD-864 steering chambers. The chambers are gimbaled using hydraulic actuators where UDMH is the working fluid (the UDMH is fed by the turbopumps for each of these respective engines).

The tanks were prepressurized before engine start-up using a chemical pressurization system based on injecting a metered amount of oxidizer into the fuel tank and fuel into the oxidizer tank. In-flight pressurization of the first two stages of the missile used hot gas produced in special gas generators. The reentry stage used a gas-cylinder-based pressurization system.

The missile stages and warhead were separated by using braking systems on the first and second stages based on the impulse generated by blow off of pressure from the fuel tanks in each missile stage.

The missile was launched mortar-style from a launch canister placed in the silo. Launching the missile mortar-style provided the following advantages: substantial simplification of both the shock-absorption system for the surface test and launch equipment and the launch-silo design; improved protection against nuclear blast effects; reduction in launcher cost; and a reduction in the time required for launch silo construction and for placing the missiles into military service. The missile was flight tested at the Baikonur Cosmodrome. The flight-testing program for the 15A18 included 19 launches, of which 17 were successful. **Dnepr Launch Vehicle (Fig. 13).** The SALT-I and SALT-II treaties authorized the use of decommissioned strategic missiles for spacecraft launches. In this context, the Yuzhnoye State Design Office proposed a design for a missile/space system, called the Dnepr, based on the 15A18 (RS-20B) missile, which was then being decommissioned. The project was supported by the National Space Agency of Ukraine and the Russian Space Agency.

An international corporation, Kosmotras, including the following Ukrainian and Russian enterprises, was established to pursue this project: the Yuzhnoye State Design Office, the State Enterprise Production Association Yuzhnyi Machine-Building Plant, the Khartron Joint-Stock Corporation, and the Design Bureau for Special Machinery. The resulting company took responsibility for developing, operating, and marketing the system. The project was based on the availability of a significant base of materiel that could be used to address the purpose at hand: more than 150 15A18 missiles on duty in launch silos and stored in arsenals, as well as the experimental 15A18 ground facility at Baikonur Cosmodrome. Implementation of this project required some slight modifications to the missiles, including the onboard control systems and the launch support facility/launch facility at Baikonur Cosmodrome.

The Dnepr launch vehicle is essentially a modified 15A18 in which the weapon section is replaced by a spacecraft payload. The high energy output and high orbital inclinations reachable by using the Dnepr launch vehicle will enable it to be used for placing communications, remote-sensing, and scientific satellites into low Earth orbit. The first launch of the Dnepr took place on 21 April 1999, placing the British UoSAT-12 spacecraft into orbit. The second launch of the Dnepr launch vehicle took place on 26 September 2000, placing the following five spacecraft into orbit: UniSat and MegSat-1 (Italy), SaudiSat-1A and SaudiSat-1B (Saudi Arabia), and TiunSat-1 (Malaysia).

Treating space research as a highly valuable engine of scientific, technical, and economic progress, the Yuzhnoye Design Office, which began production of rocketry and space hardware more than 45 years ago, is continuing its space activities in developing new spacecraft launch systems for the Ukrainian national space program and other international space programs.

COSMONAUTS SELECTION AND PREPARATION

Cosmonaut Training Center History and Accomplishments

The Soviet Union's launch of the world's first artificial Earth satellite on 4 October 1957 and its subsequent achievements in developing rockets and space technology and flying living beings in its space flight program marked the beginning of preparations for the first human spaceflight. The issue of human spaceflight was discussed in the USSR Academy of Sciences as early as the very beginning of 1959. The USSR Council of Ministers Resolution "On Preparing Humans for Space Flight" was issued on 22 May 1959.

In late 1959, at the initiative of S.P. Korolev, Chief of Rocket and Space Technology Design, a resolution was passed to create a special Center within the Air Force to train humans for the first piloted spaceflight. This Center was given the world famous name of Cosmonaut Training Center (further referred to as the Center). The founding date of the Center is traditionally considered 11 January 1960, when, in accordance with the previously mentioned resolution, the Air Force Commander in Chief published a directive that defined the organizational and personnel structure of the Air Force Cosmonaut Training Center. The site selected for this institution was a picturesque region on the outskirts of Moscow, currently known as Zvezdnyy Gorodok (Star City).

As the challenges confronting Soviet cosmonautics increased in complexity, the Center's structure and status altered. In 1965, the Air Force Cosmonaut Training Center was renamed the First Cosmonaut Training Center, and in 1968, it was named for the planet's first cosmonaut, Yu.A. Gagarin. In 1969, it was restructured as the Yu.A. Gagarin Scientific Research and Test Center for Cosmonaut Training and was granted the rights and status of a category 1 scientific research institute. In 1995, by Russian Federation (RF) Government Resolution, the former Gagarin Training Center and the 70th Individual Testing and Training Special Purpose Aviation Regiment were merged to create the Gagarin Russian State Scientific Research And Testing Center for Cosmonaut Training under the jurisdiction of the Russian Ministry of Defense (Air Force) and the Russian Aviation and Space Agency. The objective of this merger was to increase the efficiency with which the RF's scientific and technological potential in the area of piloted space flight and cosmonaut training was used to implement federal space programs and meet Russia's international commitments (Fig. 1).

Figure 1. The Center (bird's eye view). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Starting with Yu.A. Gagarin, the first person on Earth to fly in space, all Soviet, and then Russian cosmonauts, and also many cosmonauts and astronauts from foreign countries were trained and certified for space travel at the Cosmonaut Training Center. The most significant numerical indicators of the Center's performance are thus the flights and training of cosmonauts. Between 1961 and 2000, 90 crews and 125 cosmonauts flew on Russian spacecraft and space stations. Of these, 71 cosmonauts flew once, 27 twice, 21 three times, 3 four times, and 3 five times. Thirty-three flights included citizens of 18 foreign countries (Austria, Afghanistan, Bulgaria, Cuba, Czechoslovakia, France, Germany, Hungary, India, Japan, Mongolia, Poland, Rumania, Slovakia, Syria, the United Kingdom, the United States, and Vietnam.) The Center trained a total of 326 prime, backup, and reserve crews (a total of 447 cosmonauts of whom 78 were foreigners) for the flight programs of Russian spacecraft and stations.

Each year, on average, 24 cosmonaut candidates went through general space training, 22 cosmonauts underwent group training, and 12 crews (prime, backup, and reserve) underwent crew training at the Center. Cosmonauts were trained for the flight programs of the Vostok, Voskhod, and Soyuz spacecraft and the Salyut, Almaz, and Mir long-term orbital stations, the lunar program, and programs for testing the Energia-Buran space shuttle system and advanced aerospace systems. At the present time, crews are being trained for the International Space Station program.

Selection of the first cosmonauts began in October 1959 among men in Air Force units. It was believed that the best candidates for the first piloted space-flight would come from the ranks of military pilots. Documents for more than 3000 fighter pilots, aged 35 or below, were examined to select the first cosmonaut candidates. On the basis of interviews and outpatient medical examination, 206 pilots were allowed to move on to the medical selection phase. These candidates then underwent a final inpatient examination between October 1959 and April

1960. Only 29 pilots passed all phases of medical selection and, of these, 20 were accepted into the spaceflight training program (subsequently, requirements for cosmonaut health standards were relaxed somewhat).

The first group of cosmonauts trained at the Center included Yu.A. Gagarin, who completed an orbital flight of 1 hour 48 minutes on the Vostok-1 piloted spacecraft on 12 April 1961. After Gagarin's flight, G.S. Titov was trained to perform a 1-day space flight. This flight was completed in August 1961.

The next phase of the Center's activity focused on training cosmonauts for group flights. In August 1962, A.G. Nikolayev and P.R. Popovich completed the first such flight on Vostok-3 and Vostok-4. The program of training cosmonauts for flights on the Vostok series spacecraft was completed with the flights of B.F. Bykovskiy on Vostok-5 and the first female cosmonaut, V.V. Tereshkova, on Vostok-6 between 16 and 19 June 1963. The completion of the Vostok program provided a unique experience in training of cosmonauts for piloted flights.

Subsequently, the Center entered a phase in which cosmonauts were trained for flights on the multiman piloted spacecraft of the Voskhod series, which had just been developed. Training these crews emphasized the use of the new capabilities these spacecraft had for conducting scientific, technological, and biomedical experiments and enabling extravehicular activity. Only two flights were made within the Voskhod program. The first flight, on Voskhod-1, was piloted by a crew consisting of V.M. Komarev, commander, K.P. Feoktistov, flight engineer, and B.B. Egorov, physician. The second flight, on Voskhod-2, was piloted by P.I. Belyayev, commander, and A.A. Leonov, copilot. During the second flight on Voskhod-2, on 18 March 1965, the first space walk (by A.A. Leonov) was completed.

In 1966 Center specialists began to train cosmonauts in a program involving testing and a series of flights on the new multiperson, multipurpose piloted spacecraft of the Soyuz series, which possessed technical capacities that significantly exceeded those of Vostok. One of the main goals of cosmonaut training here was to enable mastery of spacecraft approach and docking — key operations in the use of long-term orbital piloted stations designed for long periods of living and working in space.

At the same time (1966–1971) as cosmonauts were being prepared for piloted flights on Soyuz, the Center was providing training for flight programs on other types of spacecraft. Thus, between 1966 and 1968, cosmonauts were trained for long-term (up to 10 days) flights on Voskhod series spacecraft. In 1966, a separate group of cosmonauts was formed for training on the program for the Spiral aerospace system (device-50). Crew training on this program was discontinued in the early 1970s, and the cosmonauts in it were transferred to training for flights in the Soyuz and Soyuz-VI, as well as for the Salyut and Almaz space station programs.

During these years, the Center began actively training cosmonauts for translunar flights and lunar landing (lunar programs: 7K-L1, N1-L3) programs, which continued until the early 1970s. Work on the lunar programs is little known to the general public because these flights were never implemented. The group being trained for these programs included 15 military pilots, 7 specialists from industry, and 4 scientists from the USSR Academy of Sciences. A.A. Leonov and V.F. Bykovskiy were named the commanders of the first crews. Based on the

results of crew training, the Air Force command concluded that they were ready to complete a flight to the Moon.

During this same period, the Center was training cosmonauts on programs for orbital flights on Soyuz-7K-OK, Soyuz-VI-7K-VI, the Salyut long-duration space station, and the Almaz space station. Crew flights on the first long-duration space station, Salyut, began after it was inserted into orbit on 19 April 1971. After this, the Center's mission included training cosmonauts for long-duration spaceflights.

In 1972, it was decided to begin targeted training of crews for flights on the Almaz space station program, developed under the direction of the General Designer, Academician, V.N. Chelomey. In September 1972, ground-based tests of the Almaz station began, including tests of its thermal control and life support systems, which required long periods of confinement by the Center's cosmonauts and observers in a facility simulating the conditions of spaceflight. The first Almaz station was inserted into orbit in early 1973, but, after several days of unpiloted flight, it lost pressurization, and the crew that was all set to fly had its orders canceled. Crews began to be trained for flights on the next station.

The second Almaz manned station (launched as Salyut-3) was successfully inserted into orbit on 25 June 1974, and the third (called Salyut-5) began its flight on 22 June 1976. The Almaz program comprised five flights, and three crews lived and worked on the stations (one on Salyut-3 and two on Salyut-5). In 1977, the flights in this program were suspended. The official decision to cancel the Almaz program was not made for a number of years. Throughout this period, the Cosmonaut Training Center continued to train crews for the Almaz program until the early 1990s. Cosmonauts who had been assigned to this program were on "active standby" status until 1984. The flight of Salyut-5 marked the culmination of a major phase of work associated with the development, testing, and practical validation of the first generation of space stations.

While the Almaz stations were operating, the Center was also training crews for the Salyut program. Because the 3 April 1973 launch of the next station in this program, Salyut-2, was unsuccessful (all of the propellant the station carried was expended during the first orbital pass), crews designated for flight on Salyut were transferred to the international Apollo-Soyuz experimental program, based on a U.S.-U.S.S.R. agreement signed in May 1972) for a joint spaceflight. Four crews were formed for this flight. For the first time, instructors and cosmonauts at the Center had to train both their own and U.S. crews for a spaceflight at their own facility and at the U.S. Apollo-Soyuz base. During the training process, major difficulties arose as a result of the language barrier and the constraints imposed by the security restrictions of that time period.

On 26 December 1974 the Salyut-4 long-duration space station was launched; two crews lived and worked on it. The Apollo-Soyuz project culminated in the successful docking and joint flights of Soyuz-19 and Apollo 18 between 15 and 21 July 1975. The prototype of the first international manned space station was thus assembled in orbit.

Since that time, the Center has been directly involved in tasks related to cosmonaut training and piloted spaceflight implementation as entailed by international collaboration. This type of collaboration was continued in the Interkosmos program. In the fall of 1976, the first group of candidates for Interkosmos

program flights arrived for space station flight training in Star City from Czechoslovakia, East Germany, and Poland. A second group, which arrived in 1978, consisted of citizens of Bulgaria, Hungary, Vietnam, Cuba, Mongolia, and Rumania. These groups consisted primarily of pilots who had been trained in the Soviet Union's military academies or military flight schools. Interkosmos program flights began in 1978.

On 29 September 1977, the first of the new (second) generation space stations (Salyut-6) was inserted into orbit. The Center began plan-driven work to train cosmonauts to use this station for scientific research and industrial applications, especially those associated with the study of Earth in the interests of the economy and environmental protection. The fact that the station had two docking ports enabled a significant increase in the number of manned flights (because they made it possible for prime and visiting crews to work together on the station). This required intensifying the cosmonaut training process as well. The Center's success in solving problems related to cosmonaut training for long-duration spaceflights made it possible to set successive records for crew flight duration, of 96 days, 140 days, 175 days, and 185 days. Flights on Salyut-6 terminated in May 1981. A total of five prime crews had lived and worked on this station. These crews had been joined by 11 visiting crews. The Salyut-6 program included 16 piloted flights, of which 9 were Interkosmos flights. For its significant contribution to implementation of long-duration spaceflights and Interkosmos flights, the Center was awarded the Order of Friendship Among Peoples.

On 19 April 1982, the long-duration space station Salyut-7 was placed in orbit to replace Salyut-6. Six prime crews were trained for and flew on Salyut-7. Four visiting crews were trained for the station. Training for flights on Salyut-7 took place in 1986.

Starting in the second half of the 1970s, the Soviet Union actively worked on developing the Buran space shuttle. It was successfully tested in the unmanned mode on 15 November 1988 (launch from the Baykonur Cosmodrome, insertion into the predetermined orbit by the Energia booster rocket, a flight of two Earth orbits, prelanding maneuvers, and landing in automated mode on the landing strip at Baykonur). From 1979 up to the termination of this program in 1995, the Cosmonaut Training Center periodically trained (refresher course) cosmonaut candidates for Buran flights. A total of more than 20 people underwent such training.

The most intensive and large-scale training of cosmonauts was conducted as part of the 15-year implementation of the Mir Space Station program. The station's core module was inserted into orbit on 20 February 1986. The Mir station differed from previous stations by virtue of the fact that it had six docking ports, two along the long axis of the station and four perpendicular to it. The presence of six docking ports made it possible to assemble a scientific research complex in orbit from a number of modules, each of which had its own functional purpose. One of these modules had the capacity to dock with the U.S. Space Shuttle. From 8 September 1989 to 28 August 1999, the Mir station operated continuously in manned mode. The crews relieved each other in flight. The station was equipped with unique scientific instrumentation and experimental apparatus (more than 240 setups with a total weight of approximately 11.3 tons), which had been developed in 27 nations. Between 1986 and the moment the Mir station ceased to exist (23 March 2001), 28 prime crews were trained and flew on

that station. These crews had as members 35 Russian cosmonauts, 7 U.S. astronauts, and 1 crewmember each from the European Space Agency and France. In addition to the prime crews, Mir was visited by 16 visiting crews who remained from 1 week to 1 month; of these, 15 crews were part of a program of international collaboration with participants from Syria, Bulgaria, Afghanistan, France (5 crews), Japan, United Kingdom, Austria, Germany (2 crews), the European Space Agency, and Slovakia. A total of 104 cosmonauts and astronauts lived and worked on the station, including 62 foreign nationals (from 11 countries and the European Space Agency). These cosmonauts performed more than 23,000 scientific experiments and research studies on the station as part of national and international programs. In accordance with the Mir-NASA program, 9 visiting crews were transported to the station on Space Shuttles, including 37 U.S. astronauts. The total duration of the flights of foreign cosmonauts on Mir was 4.3 years, which represents 32% of the total time the station functioned in manned mode. The Mir Space Station served as a unique testing ground for developing of technological processes associated with training international crews, and for developing international cosmonaut training systems, which have subsequently been applied in the International Space Station program.

Starting in 1993, pursuant to Russia's international commitments to develop and use the International Space Station, the Center has been participating directly in training cosmonauts and astronauts to support the International Space Station Program.

Objectives, Structure, and Technical Facilities of the Yu.A. Gagarin Russian State Scientific Research and Testing Cosmonaut Training Center

As space technology developed, the conditions of spaceflight changed, more practical experience was gained, and the goals, structure, and technical facilities of the Center continually underwent adjustment and change. Now, the Center is organized into the following divisions: the cosmonaut corps, the professional and biomedical cosmonaut training, the scientific research and testing divisions and laboratories, the flight divisions, the prototype production divisions, a special separate aviation test and training regiment, and the support divisions.

These are the main areas of Center activity:

- to serve as the lead organization for selecting cosmonaut candidates and training cosmonauts in all categories and specialties for flights on any spacecraft, developing and improving cosmonaut training systems, medical support of cosmonaut training and cosmonaut postflight rehabilitation, and developing and deploying technical devices (technical facilities) for cosmonaut training;
- to provide general spaceflight training to cosmonaut candidates, to provide group and crew training, to support and upgrade trainee qualifications, and to train foreign astronauts (cosmonauts);
- to conduct fundamental, exploratory, and systems research, development work and scientific testing to improve the quality of cosmonaut training, the

efficiency of spacecraft crew performance, and spaceflight safety; and to advance spaceflight technology and the development of Center technical facilities;

- to participate in flight tests of spacecraft, ergonomic evaluations, and scientific and technical oversight tracking of the development and use of piloted spacecraft;
- to train and certify scientific work forces;
- to participate in developing of Russian Federation policies regarding space exploration, to draft proposals for inclusion in the Federal Space Program of Russia, to develop draft regulations on issues relating to space exploration, and to draft collaboration agreements with foreign countries in the area of space exploration, and to perform public relations functions publicizing Russia's achievements in spaceflight research and applications.

Cosmonaut candidates are selected from among Russian Federation citizens who have expressed the desire to participate in spaceflights and who meet the established professional and medical requirements. Individuals who pass the special selection process are accepted into the cosmonaut team of the Russian Federation (Center) and appointed to the position of candidate cosmonaut pilot or candidate mission specialist. Candidate cosmonaut pilots are selected from among fighter pilots, pilots, and other specialists who have received higher technical education in the area of space technology. Candidates for mission specialist are selected from among scientists, engineers, physicians, and military and other specialists who have academic training and appropriate professional skills for implementing scientific research and experimental programs on spaceflights.

When the professional selection system was developed, one of the initial tenets was that cosmonaut selection is a continuous process, based on a systematic evaluation of candidates' health, physical and psychological qualities and educational level by using a set of methods for social, educational, medical, and psychological selection. Social selection methods include analyzing and evaluating an individual's moral and ethical qualities, as well as motivations, interests, needs, intragroup relationships, resistance to social pressure, and ability to adapt to a new social environment. Educational selection involves analyzing and evaluating the level of knowledge, skills, and professional experience a candidate has acquired to prepare for learning the chosen profession of cosmonaut. Medical selection is directed at identifying individuals whose health status and physical fitness would permit them to function as cosmonauts. Psychological selection methods are intended to identify the presence and strength of the set of personality traits that are required for becoming a cosmonaut and are conducive to successful mastery of this profession.

Cosmonaut training for flights involves three phases:

- general spaceflight training for cosmonaut candidates;
- training cosmonauts in groups based on specialization, types of piloted spacecraft, or area of activity;
- training designated cosmonaut crews (prime, standby, and backup) for spaceflight on specific piloted spacecraft.

Cosmonauts on the cosmonaut team, who have not been included in a group or crew and whose health status meets the standard requirements, periodically undergo short refresher courses according to a specially developed training curriculum to maintain their knowledge, skills and abilities at the requisite level. The major objective of general spaceflight training for cosmonaut candidates is to ensure their mastery of the principles of cosmonautics and related fields and their acquisition of the capacity to become cosmonaut pilots or mission specialists. The major objective of cosmonaut group training is to improve their professional qualities, their specialization in particular types of spacecraft or areas of work, monitor their status and maintain their health, and also maintain high performance capacity. The major objective of cosmonaut crew training is to ensure that crews are prepared to complete the flight program on a specific spacecraft. This sequence of training phases is mandatory for everyone. Candidates receive general spaceflight training once; however, they may pass through the other training phases more than once.

These are the goals of the first cosmonaut training phase:

- to learn the theoretical principles underlying cosmonautics;
- to study the design and principles of construction of the basic spacecraft, its utility, and special-purpose systems and equipment;
- to gain an overview of systems on a piloted spacecraft;
- to learn the principles for conducting tests, research, and experiments on board a piloted spacecraft;
- to learn about international legal standards for the use of space;
- to gain experience with the effects of dynamic spaceflight factors;
- to acquire theoretical knowledge and the elementary practical skills for working in spacesuits;
- to acquire theoretical knowledge and elementary practical skills for EVAs;
- to develop practical skills for landing in various extreme climatic or geographical areas;
- to undergo flight and parachute training;
- to undergo a series of biomedical measures and exercises directed at monitoring status, maintaining and strengthening health, and identifying the individual psychophysiological characteristics of each cosmonaut candidate;
- to learn how to ensure the safety of spaceflight.

These are the goals of the second phase of cosmonaut training:

- to study the design, layout, and onboard systems of specific piloted spacecraft;
- to develop skills needed to work with onboard systems and scientific equipment;
- to develop skills needed to perform flight procedures and the components of the flight program;
- to master generic operations for EVA;

- to develop skills for performing generic operations involved in technical maintenance, repair, and inventorying of equipment;
- to undergo medical measures directed at maintaining cosmonauts' good physical condition and functional psychophysiological capacities, high performance level for professional tasks, and practical skills for diagnosing illnesses and conditions and providing medical aid to themselves and other crew members.

These are the goals of the third phase of cosmonaut training:

- to study the design characteristics of a specific piloted spacecraft, its systems, scientific and specialized equipment, and also guidelines for using them;
- to study the program for the scheduled flight, onboard documentation and documents regulating crew interactions with ground control and flight support groups.
- to improve skills and develop abilities to control a spacecraft and use its systems and equipment during all flight phases in standard and contingency modes;
- to gain practical mastery of flight program components;
- to acquire experience with interactions among crew members and between the crew and ground control groups;
- to undergo medical measures directed at ensuring a state of good health, high crew performance capacity, and readiness to perform the biomedical section and flight program as a whole.

Training of cosmonaut candidates and cosmonauts has the following forms:

- study of theoretical disciplines, designs, and the principles of construction of a piloted spacecraft and its utility and special purpose systems and equipment;
- practical exercises and training on training simulators of various types and purposes, aircraft, test stands, mock-ups, setups, airborne laboratories, underwater laboratories, centrifuges, and barochambers;
- participation in tests of space technology, research, and performance of expert evaluations (Figs. 2 and 3).

The list of types of cosmonaut training (relevant to all phases) includes

- technical training;
- comprehensive and specialized training on simulators and test stands for teaching control of spacecraft and transport vehicles and use of onboard systems and equipment;
- flight and special parachute training;
- biomedical training;
- training under simulated spaceflight conditions;
- mastery of the set of life support system components for cosmonauts in an artificial environment;

Figure 2. Soyuz Transport Spacecraft mock-up. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

- comprehensive training in the EVA program;
- training in performing applied scientific research and experiments;
- training in navigational and ballistic support of spaceflight (space navigation);
- training to use movie cameras, television cameras, and to work with the onboard videotape system;
- training in what to do upon landing in various extreme climatic and geographic conditions;
- training in the operations involved in technical maintenance and repair of spacecraft and their onboard systems;
- training in controlling space robotic systems and manipulators;
- training in onboard and flight documentation, flight programs, and rules for structuring crew work on board;
- training to perform experimental work and testing of spacecraft and their systems;
- training in what to do in contingency (emergency) situations;

Figure 3. Mock-up of Russian section of the International Space Station. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

- psychological training;
- humanitarian training (legal, linguistic, culture-specific training, and training for symbolic activity).

All phases of cosmonaut candidate and cosmonaut training are held at the Center facilities. If necessary for training cosmonauts, the technical devices of other organizations and businesses are brought in on a contractual basis.

The Center's facilities consist of equipment, which can be grouped on the basis of their function or purpose. These are the most important:

1. Comprehensive trainers simulating transport spacecraft and space station modules to foster mastery of all flight programs on transport spacecraft and space stations, under standard conditions and in various contingency and emergency situations, including performance of repairs.
2. Specialized trainers simulating transport spacecraft and space station modules to simulate individual phases, operations, and modes of flight (trainers simulating approach, berthing and docking the spacecraft with an orbital station, including remote control and manual control of the trajectory for atmospheric reentry using a centrifuge, control of robotic, space-suit, life support, and airlock decompression systems).
3. Simulators of space and spaceflight conditions.

- CF-18 centrifuge (18-meter rotational arm, maximum G-force of 30 G, maximum G-force gradient of 5 G/s, replaceable cabins simulating spacecraft work stations), designed for physiological studies and cosmonaut (pilot) training in tolerance of G-forces controlled with respect to magnitude and direction under conditions of altered microclimate (pressure, temperature, humidity, and atmospheric composition), and for testing aerospace technology and performing experiments (a specialized dynamic trainer simulating

manual control of reentry of the Soyuz TMA spacecraft with deceleration conditions created by the CF-18 centrifuge) (Fig. 4);

- CF-7 centrifuge (7-meter rotational arm, maximum G-force of 10 G, maximum G-force gradient of 7 G/s, replaceable work station in the cabin), designed for training and study of human tolerance of various types of G-force (a specialized dynamic trainer simulating manual control of reentry of the Soyuz TMA spacecraft under exposure to deceleration created by the CF-7 centrifuge base);
- underwater laboratory (pool diameter of 23 meters, height of 12 meters, number of windows: 45, capacity of platform on which mock-ups are placed: up to 8 tons), for training cosmonauts for EVAs under conditions of simulated weightlessness in an underwater environment and for developing methods for training cosmonauts and testing space technology (Fig. 5);
- aircraft laboratories:
 - (a) Il-76MDK-2, designed for flights creating short periods of weightlessness and decreased weight for training spacecraft crews, conducting biomedical research, and testing equipment (can create weightlessness lasting up to 28 seconds; on one flight can generate periods of weightlessness up to 20 times during a flight of 1.5–2 hours) (Fig. 6);
 - (b) Tu-154M-LK-1 and Tu-134LK, designed for training cosmonauts on navigation and orientation and conducting research on natural and artificial objects on Earth's surface using remote sensing) (Fig. 7);
- outer space planetarium for classes and training on the stars in the sky and development of cosmonaut skills in celestial navigation and celestial orientation (the planetarium reproduces 9000 stars and makes it possible to simulate stars at altitudes up to 500 kilometers with a variation of angular velocities of rotation of the star field in increments of 0.002–5.0°/s with a reproduction error of angular distances between stars of 12 arc minutes);
- “Dry Land” and “Ocean” special training simulators (specially equipped mock-ups of reentry modules) for training cosmonauts to survive after emergency reentry module landings in various climatic and geographic areas;

Figure 4. CF-18 centrifuge. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 5. Cosmonaut training in an underwater environment. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

- a set of instruments and equipment for biomedical cosmonaut training;
- means for flight (training aircraft) and special parachute training;
- SBK-80 stationary barochamber (the main chamber has a volume of 7.5 m^3 with work space for four people; the pressure differential chamber is 1.8 m^3 in volume with work space for one; the maximum atmospheric rarefaction created is 41 mmHg, which corresponds to 20 km above sea level, the ascent time to 12 km is 100 seconds, and the emergency altitude decrease time from 20 km to 0 kilometers is not less than 10 seconds), designed for altitude training of cosmonauts under ground-based conditions to evaluate their physiological tolerance of rarefied atmospheres, and for conducting medical research and testing of life support systems.

The training simulators for the Russian portion of the International Space Station are a flexible, expandable set of programmable hardware devices for various training configurations developed on the basis of crew training tasks, as well as the evolution of the International Space Station in the process of its assembly and use. The training complex for the modules of the Russian station segment are being created phase by phase (add-on method) as the flight prototypes are developed.

The devices used for cosmonaut training also include actual space technology and apparatus prototypes, life size mock-ups of spacecraft, stations and their

Figure 6. Cosmonaut training under conditions of simulated weightlessness in an aircraft. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

modules, various research and functional simulation stands, a training simulator facility and devices for physical and medical cosmonaut training, and reproduction of equipment and communications devices using personal computer training systems.

In addition to Center equipment and facilities, cosmonaut training may use equipment belonging to other organizations and departments (the test stand facilities of organizations that develop piloted spacecraft and their systems, equipment belonging to the Cosmodrome and the Flight Control Center, search and rescue equipment, Naval vessels and Air Force helicopters, and equipment belonging to experimental and research organizations). International collaboration has required that training also use equipment from foreign countries and international organizations participating in joint international space programs.

Center activity is not limited to training cosmonauts for flight. During the 30 years of its existence, the Center has performed more than 1500 tests of various devices. The Center has participated in 93 flight tests and development tests of piloted spacecraft and conducted 260 tests of cosmonaut training technology and various other equipment. Approximately 450 testing and research

DEEP SPACE NETWORK, EVOLUTION OF TECHNOLOGY

The Deep Space Network

The Deep Space Network (DSN), managed by the California Institute of Technology's Jet Propulsion Laboratory (JPL), has provided vital communications and navigation services for NASA deep space exploration missions for more than 40 years. The remarkable technical achievements of the planetary exploration program executed by NASA would not have been possible without the extensive and sophisticated communications and data handling systems that comprise the Deep Space Network. The high-resolution pictures of Jupiter's satellites that were transmitted by the Galileo spacecraft are an example of this. Another is the ability to continue communicating with a spacecraft that was launched 30 years ago and is now more than 7 billion miles from Earth (Pioneer 10). These capabilities are the result of a sustained effort to improve the data rate capability and the sensitivity of the receivers by the research and development staff of the Jet Propulsion Laboratory in Pasadena California.

The principal facilities of the DSN are three major ground station complexes, one in the United States (Goldstone, California), one near Madrid, Spain, and one near Canberra, Australia. Each of the complexes has several tracking antennae; the largest has a diameter of 70 meters, and smaller ones have diameters of 11–34 meters. In addition to antennae, the DSN also has a complex of computers and signal processing capabilities that permit very thorough and sophisticated analysis of signals sent back from distant spacecraft.

In addition to receiving data from very distant spacecraft, the facilities of the network are also used to control the spacecraft. The network and the associated spacecraft are designed so that if a failure of a spacecraft should occur,

there are often means available to effect a recovery. Perhaps the best example of this is the work-around that was developed as a result of the failure of the high-gain antenna on the Galileo spacecraft. In spite of this setback, the Galileo mission was judged more than 70% successful because of the measures taken to adapt the data receivers and the processors to the failure. Finally, the continuing improvements in the technology of the network have greatly increased the useful lives and capabilities of the spacecraft that use the network. The example of Pioneer 10 has already been mentioned. It was originally designed for a life of about 5 years, and because of continued technical improvements in the network, can still be tracked by the network 30 years later.

A thorough history of the DSN is available in a recent published book *Uplink-Downlink: A History of the Deep Space Network* (1) in which these achievements are described in detail.

No history of the DSN would be complete without full appreciation of the contribution made by advanced technology to the successful development of the Network. The wellspring of new and innovative ideas for increasing the existing capability of the Network, improving reliability, operability, and cost-effectiveness, and for enabling recovery from potential mission-threatening situations has resided, from the very beginning of the Network's history, in a strong program of advanced technology, research, and development. Many of the accomplishments of the technology program, known during much of this time as the DSN Advanced Systems Program, can be found in Ref. 2.

The Great Antennae of the Deep Space Network

To enable 24-hour coverage of deep space spacecraft, NASA/JPL maintains a complex of large antennae at each of three geographic locations; Goldstone, California, Madrid, Spain, and Canberra, Australia. A photograph of the NASA Deep Space Communications Complex (DSCC) near Canberra, Australia, is shown in Fig. 1.

The large antennae at the complexes are quasi-parabolic reflector antennae; one has a diameter of 70 meters, the others are 34 meters in diameter. These are used for deep space mission support. Other smaller (26-m or 11-m) antennae provide occasional tracking support for selected Earth-orbiting missions.

Each of the antennae has what is termed a Cassegrain configuration and has a secondary reflector mounted on the center axis just below the focal point of the primary reflector "dish." The secondary reflector relocates the antenna focal point closer to the surface of the main dish and thus establishes a more convenient location for low-noise amplifiers, receivers, and powerful transmitters.

The efficiency with which parabolic antennas collect radio signals from distant spacecraft is degraded to some extent by radio noise radiated by Earth's terrain surrounding the antenna. This form of radio noise, known scientifically as "blackbody radiation," is a physical characteristic of all material that have a temperature above absolute zero (-273°F . or 0K). The magnitude of noise power radiated by a material body depends on its temperature. It is incredibly small at the temperature of typical Earth surfaces, but it is enormous at the temperature of the Sun, for instance. All parabolic, radio antennae have side

Figure 1. Deep Space Communications Complex; Canberra, Australia. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/ant_1.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

lobes in their beam patterns, and the magnitudes of those side lobes can increase as the antennae deviate from the ideal shape. The shape of the beam and its “side lobes” are essentially the same whether the antenna is used for transmitting or receiving signals. The “side lobes” are analogous to the circles of light surrounding the main beam of a flashlight when it is held close to a reflecting surface.

When an antenna is used for transmitting a strong signal to a spacecraft, the side lobes are of no great consequence. However, when the antenna is receiving a weak signal from a distant spacecraft, particularly at or near the horizon, “Earth noise” picked up by the side lobes can be sufficient to obscure the spacecraft signal in the extremely sensitive receivers used on the DSN antennae. This produces errors in the data stream being delivered to spacecraft engineers and scientists and may cause the DSN receivers and antennae to lose the spacecraft signal altogether; in that case, the data stream is completely lost.

The earliest antennae in the DSN were of commercial design and were parabolic. Then, as now, the actual efficiency of the antenna represented a compromise between maximum signal gathering capability and minimum susceptibility to radio noise picked up from surrounding Earth.

Improved technology to reduce the side lobes and increase the signal collection capability (gain) of future DSN antennae appeared in the DSN’s Advanced Systems Program in the early 1970s. The new technology was based on a “dual-shape” design wherein the surface shapes of both the primary and secondary reflectors were modified to illuminate the slightly reshaped “quasi-parabolic” surface of the main reflector more uniformly (3). However, it was not until the 1980s when the first 34-meter high-efficiency antennae were built that the new “dual-shape” design saw operational service in the Network.

These antennae were needed by the DSN to support the two Voyager spacecraft in their tour of the outer planets. At the time, the DSN was in transition from the lower, less capable, S-band (2.3 GHz) operating frequency for

which the early spacecraft and antennae were designed, to the X band (8.4 GHz), a higher, more capable operating frequency. When X-band technology became available (1975) in the DSN, all later spacecraft and DSN antennae were designed to operate at X-band frequencies. These antennae were, therefore, the first to be optimized for best performance in the X band.

As the Voyager 2 spacecraft headed outward toward Neptune, it was recognized that increased signal collecting area was needed on Earth to support this unique scientific opportunity effectively. The DSN's largest antennae at the time were 64-m parabolas of the original design. Calculations showed that the best investment of scarce construction funds would be to modify these antennas using the dual-shape design and expanding their diameter to 70 m. It was also apparent that the upgraded large antennas would benefit the planned Galileo and Magellan missions.

Completed in time for support of Voyager 2 at Neptune, the 70-m enhancement project (Fig. 2) resulted in an increase of more than 60% in the effective collecting area of these large antennae. Fully half of the increase was attributed to the dual-shape design.

Figure 2. The 70-meter antenna with dual-shaped reflector design. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/ant_4.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

By the end of the century, several new 34-m antennae employing the dual-shaped reflector design in conjunction with beam waveguide (BWG) techniques had been constructed for operational use in the Network. The dual-shaped reflector design enhanced the radio performance of the antenna, whereas the beam waveguide configuration greatly facilitated maintaining and operating of the microwave receivers and transmitters. Using a series of additional secondary reflectors to relocate the focal point into a stationary room below the main dish, the BWG design feature enabled mounting these critical components in a fixed environment rather than in the more conventional type of moving and tipping enclosure mounted on the antenna itself.

Beam waveguide antennae had been used for many years in Earth communications satellite terminals where ease of maintenance and operation outweighed the consideration of losses introduced into the microwave signal path by the additional microwave reflecting mirrors. For deep space applications, however, where received signal power levels were orders of magnitude smaller, any losses in the signal path were a matter of great concern, and the losses associated with BWG designs kept such antennas out of consideration for DSN purposes for many years. Researchers in the DSN Advanced Systems Program, nevertheless, pursued the idea of BWG antennas for the DSN and by 1985 were ready to conduct a collaborative experiment with the Japanese Institute for Space and Aeronautical Sciences (ISAS), using its new 64-m beam waveguide antenna at Usuda, Japan (4). Using one of the DSN's low-noise microwave receivers installed on the Usuda antenna to receive a signal from the International Cometary Explorer (ICE) spacecraft, the researchers made very precise measurements of the microwave losses, or degradation, of the downlink signal.

The results of the experiment were very surprising. The measured losses attributable to the BWG design were much smaller than expected, exhibited similar performance at zenith and better performance at low elevation angles than traditional antennae, and confirmed the efficacy of the BWG configuration.

Encouraged by this field demonstration, researchers sponsored by the Advanced Systems Program moved forward with the construction of a prototype BWG antenna for potential application in the Network.

This new prototype BWG antenna, built at the Venus site at Goldstone, replaced an aging 26-m antenna that had served for many years as a field test site for technology research and development (R&D) programs. The designers used microwave optics analysis software, an evolving product of the technology program, to optimize the antenna for operation across a wide range of current and future DSN operating frequency bands. When completed, the antenna successfully demonstrated its ability to operate effectively in the S band, X band, and Ka band (approximately 2, 8, and 32 GHz, respectively).

Figure 3 shows the completed BWG antenna, and Fig. 4 shows the interior of the equipment room below the antenna structure.

The various frequencies and modes of operation for the BWG antenna were selected by rotating the single microwave mirror at the center of this room. Lessons learned by Advanced Systems Program personnel in constructing and evaluating this antenna were incorporated into the design of the operational BWG antennae for the rest of the Network; the result was that their performance somewhat exceeded that of the prototype, especially at lower frequencies.

Figure 3. The 34-meter beam waveguide antenna at DSS 13. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/ant_5.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Forward Command/Data Link (Uplink)

The large antennae of the DSN are used for transmitting radio signals carrying instructions and data to the spacecraft, as well as for receiving signals back from them. Getting data to distant spacecraft safely and successfully requires

Figure 4. Stationary equipment room below BWG Antenna. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/ant_6.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

transmitting substantial power from the ground, directed in a narrow beam toward the spacecraft. For most “normal” situations, the compatible design of spacecraft and the DSN is such that power of about 2 to 20 kW is adequate. However, situations in space are not always normal. Unexpected events can redirect a spacecraft’s main antenna away from Earth, leaving only a low-gain or omnidirectional antenna capable of receiving anything from Earth. Transmitter power up to 400 kW in the S band can be sent from the 70-m antenna during attempts to regain contact with a spacecraft in an emergency.

The initial design and evaluation of R&D models of the high-power transmitters and their associated instrumentation were carried out under the Advanced Systems Program. Much of the essential field testing was carried out as part of the planetary radar experiments. This cooperative and productive arrangement provided a realistic environment for testing without exposing an in-flight spacecraft to an operationally unqualified uplink transmission. Later, DSN engineers implemented fully qualified operational versions of these transmitters in the Network at all sites.

Pointing the narrow forward link signal to the spacecraft is critical, especially when making initial contact without having received a signal for reference, as is typical of emergencies. The beam width of the signal from the 70-m antenna in the S band is about 0.030° , and that of the 34-m antenna in the X band is about 0.017° . Achieving blind pointing to that precision requires thorough understanding of the mechanics of the antenna, including the effects of gravity and wind on the dish, specifics of the antenna bearing and positioning mechanisms, as well as knowledge of the spacecraft and antenna positions, atmospheric refraction, and other interferences.

Forward link data delivered to a spacecraft, if incorrectly interpreted, may cause that spacecraft to take undesirable actions, including some that could result in an emergency for the spacecraft. To guard against that possibility, the forward link signal is coded with additional redundant data that allow the spacecraft data system to detect or correct any corruption in that signal. Operating on the presumption that it is always better to take no action than an erroneous one, the forward link decoder accepts only data sets for which the probability of error is extremely small and discards those that cannot be trusted (5).

Return Telemetry/Data Link (Downlink)

Throughout the Network, the stations use the same antennae for both the forward link and the return data link signals. Because the strength of a signal decreases as the square of the distance it must travel, these two signals may differ in strength by a factor of 10^{24} in a single DSN antenna. Isolating the return signal path from interference by the much stronger forward signal poses a significant technical challenge. Normally, these two signals differ somewhat in frequency, so at least a part of this isolation can be accomplished via dichroic or frequency selective reflectors. These reflectors consist of periodic arrays of metallic/dielectric elements tuned for the specific frequencies that either reflect or pass the incident radiation. These devices must be frequency selective, and they also must be

designed to minimize the addition of extraneous radio noise picked up from the antenna and its surroundings, which would corrupt the incredibly weak signals collected by the antenna from the desired radio source in deep space.

The DSN Advanced Systems Program developed the prototypes for almost all the reflectors of this type currently used in the Network. As an adjunct to this work, powerful microwave analytical tools that can be used to affix design details for almost any conceivable dichroic reflector applicable to the frequency bands of the DSN were also developed under the Program.

Low-Noise Amplifiers. The typical return data link signal is incredibly small and must be amplified before it can be processed and the data itself reconstructed. The low-noise amplifiers that reside in the antennae of the DSN are the most sophisticated in the world and provide this amplification while adding the least amount of noise of any other such devices.

Known as traveling-wave masers (TWMs), the quietest (in adding radio noise) of these operational devices amplify signals that are propagated along the length of a tuned, ruby crystal. Noise in a TWM depends on the physical temperature of the crystal; those in the DSN operate in a liquid helium bath at 4.2 K. (Zero K is equivalent to a temperature of -273.18°C . Therefore, the temperature of the helium bath is equivalent to approximately -269°C) Invented by researchers at the University of Michigan, early development of practical amplifiers for the DSN was carried out under the DSN Advanced Systems Program (6). The quietest amplifiers in the world today (Fig. 5), which operate at a temperature of 1.2 K, were developed by the DSN Advanced Systems Program and demonstrated at the Technology Development Field Test Site, DSS 13 (7).

Some of the low-noise amplifiers in the DSN today are not TWMs but are a special kind of transistor amplifier using high-electron mobility transistors (HEMTs) in amplifiers cooled to a temperature of about 15 K (8).

Developed initially at the University of California at Berkeley, these amplifiers were quickly adopted by the scientific community for radio astronomy applications. This, in turn, spawned the JPL development work that was carried out via collaboration involving JPL, radio astronomers at the National Radio Astronomy Observatory (NRAO), and device developers at General Electric (9,10). This work built on progress in the commercial sector with uncooled transistor amplifiers. In the 2-GHz DSN band, the cooled HEMT amplifiers were almost as noise-free as the corresponding TWMs, and the refrigeration equipment needed to cool the HEMTs to 15 K was much less troublesome than that for TWMs. Primarily for this reason, current development efforts in the DSN are focused on improving the noise performance of HEMT amplifiers for higher DSN frequency bands.

The first DSN application of cooled HEMT amplifiers came with outfitting the NRAO Very Large Array (VLA) in Socorro, New Mexico, for collaborative support of the Voyager-Neptune encounter (9). The VLA, designed to map radio emissions from distant stars and galaxies, consists of 27 antennas, each 25 m in diameter, arranged in a triaxial configuration. Within the funding constraints, only a small part of the VLA could be outfitted with TWMs, whereas HEMTs for the entire array were affordable and were expected to give an equivalent sensitivity for the combined full array. In actuality, technical progress with the HEMTs during the several years taken to build and deploy the needed X-band

Figure 5. Ultra-low-noise amplifier at DSS 13. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/return_2.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

(8 GHz) amplifiers resulted in better performance of the fully equipped VLA than would have been possible with the VLA partially equipped with more expensive TWMs. Since that time, many of the DSN operational antennae have had cooled HEMT amplifiers installed for the 2- and 8-GHz bands.

Phase-Lock Tracking. Once through the first stages of processing in low-noise amplifiers, there are still many transformations needed to convert a radio signal from a spacecraft into a replica of the data stream originating on that spacecraft. Some of these transformations are by nature analog and linear, and others are digital with discrete quantization. All must be performed with virtually no loss in fidelity in the resultant data stream.

Typically, the downlink signal consists of a narrowband “residual carrier” sine wave, together with a symmetrical pair of modulation sidebands, each of which carries a replica of the spacecraft data. (Specifics of the signal values vary greatly but are not essential for this general discussion.) If this signal is

cross-correlated with a pure identical copy of the residual carrier, the two sidebands will fold together, creating a baseband signal that contains a cleaner replica of the spacecraft data than either sideband alone. Of course, such a pure copy of the carrier signal does not exist, but must be created, typically via an adaptive narrowband filter known as a phase-locked loop (11). The re-created carrier reference is thus used to extract the sidebands. The strength of the resultant data signal is diminished to the extent that this local carrier reference fails to be an identical copy of the received residual carrier. Noise in the spectral neighborhood of the received residual carrier and dynamic variations in the phase of the carrier itself limit the ability to phase lock the local reference to it.

These dynamic variations are dominated by the Doppler effect due to the relative motion between a distant spacecraft and the DSN antenna on the surface of spinning Earth. Over the years, the DSN Advanced Systems Program has contributed significantly to the theory and design practices for phase-locked loops and to the impacts of imperfect reference tracking on phase-coherent communications (12,13).

Synchronization and Detection. Further steps in converting a spacecraft signal into a replica of the spacecraft data stream are accomplished by averaging the signal across brief intervals of time that correspond to each symbol (or bit) transmitted from the spacecraft and by sampling these averages to create a sequence of numbers, often referred to as a “symbol stream.” These averages must be precisely synchronized with the transitions in the signal as sent from the spacecraft, so that each contains as much as possible of the desired symbol and as little as possible of the adjacent ones. Usually, a subcarrier, or secondary carrier, is employed to shape the spectrum of the spacecraft signal, and it must be phase-locked and removed before final processing of the data themselves. The Network contains several different generations of equipment that perform this stage of processing. Designs for all of these have their roots in the products of the DSN Advanced Systems Program. The oldest equipment is of a design developed in the late 1960s. This equipment was mostly analog and, while still effective, was subject to component value shifts with time and temperature and thus, required periodic tending and adjustments to maintain desired performance.

As digital devices became faster and more complex, it became possible to develop digital equipment that could perform this stage of signal processing. Digital demodulation techniques were demonstrated by the Advanced Systems Program in the early 1970s in an all-digital ranging system. Similar techniques were subsequently employed for data detection in the second generation of the Demodulator-Synchronizer Assembly (14,15).

A Digital Receiver. Rapidly evolving digital technology in the 1980s led researchers to explore the application of digital techniques to various complex processes found in receiving systems such as those used in the Network. The processes of filtering, detection, and phase-lock carrier tracking, formerly based on analog techniques, were prime candidates for the new digital technology.

In this context, the Advanced Systems Program supported the development of an all-digital receiver for Network use. Known as the Advanced Receiver (ARX), the developmental model embodied most of these new ideas and demonstrated capabilities far exceeding those of the conventional analog receivers then installed throughout the Network (16,17).

Encouraged by the performance of the laboratory model, an engineering prototype was built and installed for evaluation in an operational environment at the Canberra, Australia, tracking complex. Tests with the very weak signal from Pioneer 10 spacecraft, then approaching the limits of the current DSN receiving capability, confirmed the design's performance and significantly extended the working life of that spacecraft.

As a result of these tests, the DSN decided to implement a new operational receiver for the Network that would be based on the design techniques demonstrated by the ARX. The new operational equipment, designated the Block V receiver (BVR), would include all of the functions of the existing receiver in addition to several other data processing functions, such as demodulation and synchronization, formerly carried out in separate units.

As the older generation receivers were replaced with all-digital BVR equipment, the Network generally improved weak signal tracking performance and operational reliability. The receiver replacement program was completed throughout the Network by 1998.

Encoding and Decoding. Data generated by scientific instruments must be reliably communicated from the spacecraft to the ground, despite the fact that the signal received is extremely weak and the ground receiver corrupts the signal with additive noise. Even with optimum integration and threshold detection, individual bits usually do not have adequate signal energy to ensure error-free decisions. To overcome this problem, structured redundancy (channel encoding) is added to the data-bit stream at the spacecraft. Despite the fact that individual "symbols" resulting from this encoding have even less energy at the receiver, the overall contextual information, used properly in the decoding process on the ground, results in more reliable detection of the original data stream.

High-performance codes to be used for reliable data transfer from spacecraft to DSN were identified by research performed under the Advanced Systems Program and adopted for standard use in the Network, while the search for even more powerful and efficient codes continued. New, more efficient, block codes that used the limited spacecraft transmitter power better by avoiding the need to transmit separate synchronizing signals were developed and first demonstrated on the Mariner 6 and 7 spacecraft in 1969 (18). By putting the extra available spacecraft transmitter power into the data-carrying signal, the new block code enabled the return of Mars imaging data at the astonishing (for the time) rate of 16,200 bits per second, an enormous improvement over the 270 bits per second data rate for which the basic mission had been designed. Of course, conversion of the encoded data stream back to its original error-free form required a special decoder. The experimental block decoder developed for this purpose formed the basis for the operational block-decoders implemented in the Network as part of the Multimission Telemetry System, shortly thereafter (19).

While the JPL designers of the Mariner spacecraft were pursuing the advantages of block-coded data, the designers of the Pioneer 9 spacecraft at the NASA Ames Research Center (ARC) were looking to very complex convolutional codes to satisfy their scientists. The scientists agreed to accept intermittent gaps in the data, caused by decoding failure in exchange for the knowledge that successfully decoded data would be virtually error-free. In theory, a convolutional

code of length $k = 25$ would meet the requirement, but it had a most significant drawback. The decoding process was (at the time) extraordinarily difficult.

Known technically as “sequential decoding,” this was a continuous decoding operation rather than the “one block at a time” process used by the DSN for decoding Voyager data.

Originally, it was planned to perform the decoding operation for Pioneer 9 in nonreal time at ARC, using tape-recorded data provided by the DSN. However, Pioneer engineers, working in conjunction with the DSN Advanced Systems Program, explored and demonstrated the potential for decoding this code in real time via a very high-speed engineering model sequential decoder (20). The rapid evolution in the capability of small computers made it apparent that decoding Pioneer’s data in such computers was both feasible and economical. Subsequent implementation of sequential decoding in the Network was done via microprogramming of a small computer, guided by the knowledge gained via the efforts of the technology development program. The subsequent Pioneer 10 and Pioneer 11 spacecraft flew with a related code of length $k = 32$ and were supported by the DSN in a computer-based decoder.

The DSN standard code, flown on Voyager and Galileo, consisted of a short convolutional code that was combined with a large block-size Reed–Solomon code (21,22). The standard algorithm for decoding convolutional codes was devised in consultation with JPL researchers and demonstrated by simulations. Prototypes of the decoding equipment were fabricated and subsequently demonstrated at JPL.

The application of coding and decoding technology in the DSN was paced by the evolution of digital processing capability. At the time of the Voyager design, a convolutional code of length $k = 7$ was chosen as a compromise between performance and decoding complexity that would grow exponentially with code length. Equipment was implemented around the DSN to handle this code for Voyager and subsequently for Magellan, Galileo, and others. But modern digital technology permitted constructing much more complex decoders, so a code of length $k = 15$ was devised (23). This code was installed as an experiment on the Galileo spacecraft shortly before its launch. The corresponding prototype decoder was completed soon afterward. Though not used for Galileo because of its antenna problem, the more complex decoder was implemented around the Network to support the Cassini and subsequent missions.

Research in the technology development program provided the theoretical understanding to predict the performance of these new codes. Figure 6 displays the reliability of the communication error (actually, the probability of erroneous data bits), as it depends upon the spacecraft signal energy allocated to each data bit for uncoded communication and several different codes. In Fig. 6, the first set of curves shows the Voyager $k = 7$ code, both alone and in combination with the Reed–Solomon code. The second set of codes illustrates the $k = 15$ code, which was to be demonstrated with the Galileo’s original high-rate channel, shown alone and in combination with the Reed–Solomon code, either as constrained by the Galileo spacecraft data system ($I = 2$), or in ideal combination. The third set shows the $k = 14$ code, devised by the Advanced Systems Program researchers for the actual Galileo low-rate mission, both alone and in combination with the selected variable-redundancy Reed–Solomon code and a complex four-stage decoder. The

Figure 6. Telemetry communication channel performance for various coding schemes. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/return_5.htm.

added complexity of the codes, which has its greatest effect in the size of the ground decoder, clearly provides increased reliability in correct communication.

Research on new and even more powerful coding schemes such as turbo codes continued to occupy an important place in the Advanced Systems Program. Turbo codes are composite codes made up of short constraint length convolutional codes and a data stream interleaver (24,25). The decoding likewise consists of decoders for the simple component codes, but use iterative sharing of information between them. These codes that push hard on the fundamental theoretical limits of signal detection can result in almost a full decibel of performance gain over the best previous concatenated coding systems.

Data Compression. Source encoding and data compression are not typically considered part of the DSN's downlink functions, but the mathematics that underlie coding and decoding are a counterpart of those that guide the development of data compression. Simply stated, channel encoding is the insertion of structured redundancy into a data stream, whereas data compression is finding and removing of intrinsic redundancy. Imaging data are often highly redundant and can be compressed by factors of at least 2, and often 4 or more, without loss in quality. For Voyager, the combined effect of a very simplified image compression process, constrained to fit into available onboard memory, and the corresponding changes to the channel coding, was about a factor-of-2 increase in the number of images returned from Uranus and Neptune.

The success of data compression technology in enhancing the data return from the Voyager missions firmly established the technique as an important consideration in designing all future planetary downlinks. The original telecommunication link design for the Galileo spacecraft used data compression to double almost the amount of imaging data that the spacecraft could transmit from its orbital mission around Jupiter. The failure of the spacecraft's high-gain antenna before Galileo's arrival at Jupiter prompted an intense effort to find even more complex data compression schemes that would recover some of the Jupiter imaging data that otherwise could not have been returned (26).

Arraying of Antennae

The technique of antenna arraying, as practiced in the Deep Space Network, used the physical fact that a weak radio signal from a distant spacecraft received simultaneously by several antennae at different locations is degraded by a component of radio noise that is independent at each receiving station. By contrast, the transmitted spacecraft signal is dependent, or coherent, at each receiving site. In theory, therefore, the power of the signal, relative to the power of the noise, or signal-to-noise ratio, (SNR) can be improved by combining the individual antennae so that coherent spacecraft signals are reinforced and independent or noncoherent noise components are averaged.

In practice, this involved a complex digital process to compensate for the time, or phase, delays caused by the different distances between each station and the spacecraft and by the different distances between the various antenna locations and the reference station, where the combining function was carried out. This technique became known as antenna arraying, and the digital processing function that realized the theoretical "gain" of the entire process was called "signal combining" (27).

By 1970, conceptual studies had described and analyzed the performance of several levels of signal combining, and two of these schemes, carrier and baseband combining, were of potential interest to the Network. Both techniques involved compensation for the time, or phase, delays due to the various locations of the arrayed antennas. The difference lay in the frequency at which the combining function was performed. "Carrier" combining was carried out at the carrier frequency of the received signal, whereas "baseband" combining was carried out at the frequencies of the subcarrier and data signal that modulated it. Each had its advantages and disadvantages, but "baseband" combining proved easier to implement and was, obviously, tried first.

The "arraying and signal combining" concept was first developed and demonstrated in 1969 and 1970 by J. Urech, a Spanish engineer working at the Madrid tracking station (28,29). Using signals from the Pioneer 8 spacecraft and a microwave link to connect two 26-m stations located 20 m apart (DSS 61 and DSS 62), he succeeded in demonstrating for the first time the practical application of the principle of baseband combining in the Network. Because of the low baseband frequency of the Pioneer 8 data stream (8 bits per second) and close proximity of the antennae, no compensation for time delay was necessary.

Within the bounds of experimental error, this demonstration confirmed the R&D theoretical estimates of performance gain and encouraged the JPL researchers to press forward with a more complex form of baseband combining at a much higher data rate (117 kilobits per second) in real time.

The demonstration took place at Goldstone in September 1974, using the downlink signals from the Mariner–Venus–Mercury (MVM) spacecraft during its second encounter with the planet Mercury (30). Spacecraft signals from the two 26-m antennae, DSS 12 and DSS 13, were combined in an R&D combiner with signals from the DSS 14 64-m antenna in real time at 117 kbps. The less-than-predicted arraying gain obtained in this demonstration (9 versus 17%) was attributed to small differences in performance between key elements of the several data processing systems involved in the test. Although this experience demonstrated the practical difficulty of achieving the full theoretical gain of an arrayed antenna system and the critical effect of very small variations in the performance of its components, it also established the technical feasibility of baseband arraying of very weak high-rate signals.

In 1977, using the lessons learned from these demonstrations as background, the DSN started to develop an operational arraying capability for the Network. The Voyager 1 and 2 encounters with Saturn in 1980 and 1981, respectively, would be the first to use the arraying in the Network. A prototype baseband real-time combiner (RTC), based on the analysis and design techniques developed by the earlier R&D activity, was completed in the fall of 1978. Designed to combine the signals from DSS 12 and DSS 14 at Goldstone, it was used with varying degrees of success to enhance the signals from the Voyagers at Jupiter in March and July 1979 and the Pioneer 11 encounter with Saturn in August and September of that year.

Like the previous demonstration, this experience emphasized the critical importance of having all elements of the array—receivers, antennae, and instrumentation—operating precisely according to their specified performance capabilities. With this very much in mind, the DSN proceeded to the design of operational versions of the RTC for use at all three complexes to support the Voyager 1 and 2 encounters with Saturn. The operational versions of the RTC embodied many improvements derived from the experience with the R&D prototype. By mid-August 1980, they were installed and being used to array the 64-m and 34-m antennae at all three complexes, as Voyager 1 began its far-encounter operations. During this period, the average arraying gain was 0.62 dB, that is, about 15% greater than that of the 64-m antenna alone. While this was “good,” improvement came slowly as more rigorous control and calibration measures for the array elements were instituted throughout the Network. By the time Voyager 2 reached Saturn in August 1981, these measures, supplemented by additional training and calibration procedures, had paid off. The average arraying gain around the Network increased to 0.8dB (approximately 20%), relative to the 64-m antenna alone, clearly a most satisfactory result and the best up to that time. Antenna arraying had become a permanent addition to the capability of the Network.

While researchers working within the Advanced Systems Program continued to explore new processes for arraying antennas, engineers within the DSN took advantage of the long flight time between the Voyager Saturn and

Uranus encounters to refine the existing RTC configuration. During the next 5 years, the formerly separate data processing functions of combining, demodulation, and synchronization were integrated into a single assembly, and performance, stability, and operational convenience were improved. By the time Voyager 2 approached Uranus in 1985, the new baseband assemblies (BBAs), as they were called, had been installed at all three complexes. In addition, a special version of the basic four-antenna BBA was installed at the Canberra Complex. This provided for combining the Canberra array of one 64-m and two 34-m antennae with signals from the 64-m Parkes Radio Telescope, 200 km distant (Fig. 7).

In January 1986, this arrangement was a key factor in the successful return of Voyager imaging data from the unprecedented range of Uranus (20 AU). But even greater achievements in antenna arraying lay ahead.

In 1989, the DSN used a similar arrangement with great success to capture the Voyager imaging data at a still greater range—from Neptune (30 AU). This time the Goldstone 70-m and 34-m antennas were arrayed with the 27 antennas of the Very Large Array (VLA) (Fig. 8) of the National Radio Astronomy Observatory at Socorro, New Mexico (31).

Figure 7. Parkes Radio Telescope, Australia. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/array_1.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Figure 8. The Very Large Array (VLA) of the National Radio Astronomy Observatory (NRAO) at Socorro, New Mexico. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/array_2.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

DSN support for the Voyager encounter with Uranus was further augmented by the Canberra–Parkes array in Australia, which the DSN had reinstated with the addition of new BBAs, new 34-m antennae, and the upgraded 70-m antenna.

The success of these applications of the multiple antenna arraying technique provided the DSN with a solid background of operational experience. The DSN drew heavily on this experience a few years later when it was called upon to recover the scientific data from Galileo after the failure of the spacecraft's high-gain antenna in 1991. Together with the data compression and coding techniques discussed earlier, the Network's Canberra/Parkes/Goldstone antenna arrays succeeded in recovering a volume of data that, according to the Galileo project, was equivalent to about 70% of that of the original mission.

With time, arraying of multiple antennae within complexes, between complexes, or between international space agencies, came into general use to enhance the downlink capability of the Network. In the latter years of the century, most of the enhancements in arraying in the DSN were driven by implementation and operational considerations, rather than by new technology, although the Advanced Systems Program continued to explore the boundaries of performance of various alternative arraying architectures and combining techniques.

Radio-Metric Techniques

In addition to being able to exchange forward and return link data with an exploring spacecraft, it is equally important to know the precise location of the spacecraft, its speed, and direction (velocity). Information about the position and velocity of the spacecraft can be extracted from the one-way or two-way radio signals passing between the spacecraft and the DSN. When these data are extracted by appropriate processing and further refined to remove aberrations

introduced by the propagative medium along the radio path between spacecraft and Earth, it can be used for spacecraft "navigation."

Radio-metric techniques similar to those used for spacecraft navigation can also be used for more explicit scientific purposes, notably radio science, radio astronomy, and radio interferometry on very long baselines (VLBI).

Since its inception, the DSN Advanced Systems Program has worked to develop effective radio-metric tools, techniques, observing strategies, and analytical techniques that furthered the DSN preeminence in these unique fields of science. More recently, the program demonstrated the application of Global Positioning System (GPS) technology to refine further radio-metric data generated by the DSN.

Doppler and Range Data. If Earth and the spacecraft were standing still, the time for a radio signal to travel from Earth to the spacecraft and back would be a measurement of the distance between them. This is referred to as the round-trip light time (RTLTL). However, because Earth and the spacecraft are both in motion, the RTLTL contains both position and velocity information, which can be disentangled through multiple measurements and suitable analysis. The precision of such measurements is limited by the precision at which one can attach a time-tag marker to the radio signals and by the strength of the signal in proportion to the noise mixed with it, or by the signal-to-noise ratio (SNR).

Precise measurements of changes in this light time are far easier to obtain by observing the Doppler effect resulting from the relative motions. Such measurements are mechanized via the phase-locked loops in both spacecraft and ground receivers using the spacecraft's replica of the forward link residual carrier signal to generate the return link signal and counting the local replica of the return link residual carrier against the original carrier for the forward link signal. The raw precision of these measurements is comparable to the wavelength of the residual carrier signal, that is, a few centimeters for an X-band signal (8 GHz). Numerous error sources tend to corrupt the accuracy of the measurement and the inferred position and velocity of the spacecraft derived therefrom. The observed Doppler contains numerous distinct contributions, including the very significant component due to the rotation of Earth. As Earth turns, the position of any specific site on the surface describes a circle, centered at the spin axis of Earth, falling in a plane defined by the latitude of that site. The resultant Doppler component varies diurnally with a sinusoidal variation, which is at its maximum positive value when the spacecraft is first observable over the eastern horizon, and is at its corresponding negative value as it approaches the western horizon. A full-pass Doppler observation from horizon to horizon can be analyzed to extract the apparent spacecraft position in the sky, although the determination is somewhat weak near the equatorial plane. Direct measurements of the RTLTL are useful for resolving this difficulty (32).

Three distinct generations of instruments, designed to measure the RTLTL, were developed by the Advanced Systems Program and used in an ad hoc fashion for spacecraft support before a hybrid version was designed and implemented around the DSN (33–35). The third instrument designed, the Mu-II Ranging Machine, was used with Viking Landers in a celestial mechanics experiment, which provided the most precise test, until that time, of the general theory of relativity (36).

These devices function by imposing an additional “ranging” modulation signal on the forward link, which is copied on the spacecraft (within the limits imposed by noise) and then imposed on the return link. The ranging signal is actually a very long-period coded sequence that provides the effect of a discrete time tag. The bandwidth of the signal is of the order of 1 MHz, giving the measurement a raw precision of a few hundred meters, resolvable with care to a few meters. Among other features, the Mu-II Ranging Machine included the first demonstrated application of digital detection techniques that would figure strongly in future developments for the DSN.

Timing Standards. The basic units of measurement for all radio-metric observations, Doppler or range, derive from the wavelength of the transmitted signal. Uncertainties or errors in the knowledge of that wavelength are equivalent to errors in the derived spacecraft position. The need for accurate radio metrics has motivated the DSN to develop some of the most precise, most stable frequency standards in the world. Although the current suite of hydrogen maser frequency standards in DSN field sites was built outside of JPL, the design is the end product of a long collaboration in technology development; research units were built at JPL and elsewhere (37,38).

Continued research for improved frequency standards resulted in the development of a new linear ion trap standard (Fig. 9) that offered improved long-term stability of a few parts in 10^{16} , as well as simpler and easier maintenance than that required by hydrogen masers (39).

Earth’s Rotation and Propagative Media. Radio-metric Doppler and range data enable determining the apparent location of a spacecraft relative to the position and attitude of rotating Earth. Earth, however, is not a perfectly rigid body at constant rotation, but contains fluid components as well, which slosh about and induce variations in rotation of perhaps a few milliseconds per day.

Figure 9. New linear ion trap frequency standard. This figure can also be seen at the following website: http://deepspace.jpl.nasa.gov/technology/95_20/radio_1.htm. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Calibration of Earth's attitude is necessary so that the spacecraft's position in inertial space can be determined, which is a necessary factor in navigating it toward a target planet. Such calibration is available via the world's optical observatories, and with greater precision via radio techniques, which will be discussed further in later sections titled "VLBI and Radio Astronomy" and "Global Positioning System."

The interplanetary media along the signal path between Earth and the spacecraft affect the accuracy of Doppler and range observations. The charged ions in the tenuous plasma that spreads out from the Sun, known as the solar wind, slightly bend and delay the radio signal. Likewise, charged ions in Earth's own ionosphere and water vapor and other gases of the denser lower atmosphere bend and delay the radio signal. All of these factors are highly variable because of other factors, such as the intensity of solar activity, season, time of day, and weather. All factors must be calibrated, modeled, or measured to achieve the needed accuracy. Over the years, the DSN Advanced Systems Program has devised an increasingly accurate series of tools and techniques for these calibrations (37–43).

Radio Science. Radio science is the term used to describe the scientific information obtained from the intervening pathway between Earth and a spacecraft by using radio links. The effects of the solar wind on the radio signal path interfere with our efforts to determine the location of a spacecraft, but if the relative motions of Earth and a spacecraft are modeled and removed from the radio-metric data, much of what remains is information about the solar wind and, thus, about the Sun itself. Other interfering factors are also of scientific interest.

In some situations, the signal path passes close by a planet or other object, and the signal itself is bent, delayed, obscured, or reflected by that object and its surrounding atmosphere. These situations provide a unique opportunity for scientists to extract information from the signal about object size, atmospheric density profiles, and other factors not otherwise observable. Algorithms and other tools devised to help calibrate and remove interfering signatures from radio-metric data for use in locating a spacecraft often become part of the process for extracting scientific information from the same radio-metric data stream. The precision frequency standards, low-noise amplifiers, and other elements of the DSN are key factors in the ability to extract this information with scientifically interesting accuracy. Occasionally, engineering model equipment is placed in the Network in parallel with operational instrumentation for ad hoc support of metric data gathering for some unique scientific event.

The effects of gravity can also be observed by means of the radio link. Several situations are of interest. If the spacecraft is passing by or in orbit about an object that has a lumpy uneven density, that unevenness will cause a variation in the spacecraft's pathway that will be observable via radio-metric data. If the radio signal passes near a massive object such as the Sun, the radio signal's path will be bent by the intense gravity field, according to the theories of general relativity. And in concept, gravitational waves (a yet-to-be observed aspect of gravity field theory) should be observable in the Doppler data from a distant spacecraft (44).

VLBI and Radio Astronomy. The technical excellence of the current DSN is, at least in part, a result of long and fruitful collaboration with an active radio

astronomy community at the California Institute of Technology (Caltech) and elsewhere. Many distant stars, galaxies, and quasars are detectable by the DSN at radio frequencies. The furthest of them are virtually motionless when viewed from Earth and can be considered a fixed-coordinate system to which spacecraft and other observations can be referenced. Observations relative to this coordinate set help to reduce the distorting effects of intervening material in the radio signal path and uncertainties in the exact rotational attitude of Earth during spacecraft observations.

Little precise information can be extracted by observing these objects one at a time and from a single site, but concurrent observation at a pair of sites will determine the relative position of the two sites referenced to the distant object. The observing technique is known as very long baseline interferometry (VLBI). If three sites are used in VLBI pairs and multiple objects are observed, the positional attitude of Earth and the relative positions of the observed objects can be determined. If one of the observed items is a spacecraft transmitting a suitable signal, its position and velocity in the sky can be very accurately defined (45). A demonstration of this technique led to operational use for spacecraft such as Voyager and Magellan.

VLBI can also be used in conjunction with conventional radio-metric data types to provide calibration for the positional attitude of Earth. Such observations can be made without interfering with spacecraft communication, except for the time use of the DSN antennae. In addition to determining the attitude of Earth, the observations measure the relative behavior of the frequency standards at the widely separated DSN sites, and thus help to maintain their precise performance.

The DSN equipment and software needed for VLBI signal acquisition and signal processing (correlation) was designed and developed in a collaboration involving the Advanced Systems Program, the operational DSN, and the Caltech radio astronomy community. The tools needed to produce VLBI metric observations for the DSN were essentially the same as those for interferometric radio astronomy. Caltech was funded by the National Science Foundation for this activity. Both Caltech and the DSN shared in the efforts of the design and obtained products that were substantially better than any that they could have been obtained independently.

Another area of common interest between the DSN and the radio astronomy community is that of precision wideband spectral analysis. Development efforts produced spectral analytical tools that have been employed by the DSN in spacecraft emergencies and in examining the DSN's radio interference environment and have served as preprototype models for equipment for the DSN (46,47). Demonstration of the technical feasibility of very wide band spectral analysis and preliminary observations by a mega channel spectrum analyzer fielded by the Advanced Systems Program helped establish the sky survey planned as part of the former SETI (Search for Extraterrestrial Intelligence) Program.

Another technique (one similar to using of VLBI as a radio-metric reference) is used if two spacecraft are flown to the same target. The second can be observed relative to the first and can provide better target-relative guidance, once the first has arrived at the target.

The Global Positioning System. The Global Positioning System (GPS) is a constellation of Earth-orbiting satellites designed (initially) to provide for military navigation on Earth's surface. Research under the Advanced Systems Program showed that these satellites could provide an excellent tool to calibrate and assist in radio-metric observations of distant spacecraft. GPS satellites fly above Earth's atmosphere and ionosphere in well-defined orbits, so that their signals can be used to measure the delay through these media in a number of directions. Using suitable modeling and analysis, these measurements can be used to develop the atmospheric and ionospheric calibrations for the radio path to a distant spacecraft (48).

Additionally, because GPS satellites are in free orbit about Earth, their positions are defined relative to the center of mass of Earth, not its surface. They provide another method for observing the uneven rotation of Earth.

GPS techniques can also be used to determine the position of an Earth-orbiting spacecraft relative to the GPS satellites, as long as the spacecraft carries a receiver for the GPS signals. GPS signals were subsequently used by the TOPEX/POSEIDON Project for precise orbit determination and consequent enhancement of its scientific return (49).

Goldstone Solar System Radar

The Goldstone Solar System Radar (GSSR) is a unique scientific instrument for observing nearby asteroids, the surfaces of Venus and Mars, the satellites of Jupiter, and other objects in the solar system. Although the GSSR uses the DSN 70-m antenna for its scheduled observing sessions, its receiving, transmitting, and data processing equipment is unique to the radar program. The GSSR is a product of many years of development. In the early days of the DSN, the Advanced Systems Program took ownership of the radar capability at the DSN's Goldstone, California, site and evolved and nurtured it as a vehicle for developing and demonstrating many of the RF and signal processing capabilities that the Network would need elsewhere.

Scientific results abounded as well, but were not its primary product. Timely development of DSN capabilities was the major result. Preparations for radar observations of asteroids at the DSN Technology Development Field Site bore many resemblances to those for a spacecraft planetary encounter, because the radar observations could be successfully accomplished only during the few days when Earth and the radar target were closest together.

In the conventional formulation of the radar sensitivity equations, that sensitivity depends on the aperture, temperature, power, and gain of the system elements. Here, aperture refers to the effective size, or collecting area of the receiving antenna, and temperature is a way of referring to the noise in the receiving system, a lower temperature means less noise. Power refers to the raw power level from the transmitter, and gain is the effective gain of the transmitting antenna, which depends in turn upon its size, its surface efficiency, and the frequency of the transmitted signal. When the same antenna is used both to transmit and receive, the antenna size and efficiency appear twice in the radar equations.

Significant improvements in the DSN's capability for telemetry reception were to come from the move upward in frequency from S band (2 GHz) to X band

(8 GHz) on the large 64-m antennae. Performance of these antennae at higher frequencies and the ability to point them successfully were uncertain, however, and these uncertainties would best be removed by radar observations before spacecraft with X-band capabilities were launched (50). The radar had obvious benefit from the large antenna and the higher frequency. The first flight experiment for X-band communication was carried out on the 1973 Mariner Venus Mars mission. Successful radar observations from the Goldstone 64-m antenna demonstrated that the challenge of operating the large antennae at the higher X-band frequency could be surmounted.

High-power transmitters were needed by the DSN for its emergency forward-link functions, but were plagued by problems such as arcing in the waveguide path when power densities became too high. High-power transmitters were essential for the radar to “see” at increased distances and with increased resolution. Intense development efforts at the DSN Technology Development Field Site could take place without interference or risk to spacecraft support in the Network. Successful resolution of the high-power problems for the radar under the Advanced Systems Program enabled successful implementation of the high-power capability needed by the Network for uplink communications.

Low-noise amplifiers were needed by the DSN to increase data return from distant spacecraft. Low-noise amplifiers are also essential for the radar to enable it to detect echoes from increasingly distant targets or to provide increased resolution of already detectable targets. The synergistic needs of both the radar system and the Network led to development of the extremely low-noise maser amplifiers that became part of the standard operational inventory of the DSN.

Digital systems technology was rapidly evolving during this period and would play an increasing role in the developing DSN. Equipment developed by the Advanced Systems Program for its radar application included (1) digital encoders to provide spatial resolution of parts of the radar echo, (2) computer-driven programmable oscillators to accommodate Doppler effects on the signal path from Earth-to-target-to-Earth, and (3) complex high-speed digital signal processing and spectral analysis equipment. Much of the digital technology developed this way would transfer quickly to other parts of the signal processing work under the Advanced Systems Program and eventually into the operational DSN. Some of the elements would find direct application, such as programmable oscillators, which became essential for maintaining contact with the Voyager 2 spacecraft following a partial failure in its receiver soon after launch. And the signal analysis tools developed to understand and optimize radar would be called on many times over the years to help respond to spacecraft emergencies.

Some of the products of early radar observations were both scientific in nature and essential for providing information for planning and executing of NASA's missions. One notable “first” was direct measurement of the astronomical unit (51). (One astronomical unit (AU) is equal to 1.5×10^8 km, i.e., the mean distance between Earth and the Sun.) It sets the scale size for describing distances in the solar system. The measurement was made to support preparations for Mariner 2 to Venus and provided a correction of 66,000 km from conventional belief at that time. It also enabled corrections that brought the mission into the desired trajectory for its close flyby of the planet. The GSSR was also used in qualifying potential Mars landing sites for the Viking Landers and continues to

provide information about the position and motion of the planets, which is used to update the predicted orbits for the planets of the solar system.

Telecommunications Performance of the Network

The progress of deep space communications capability during the 40-year history of the Network is shown in Fig. 10. In Fig. 10, the timeline on the horizontal axis of the figure covers the first 40 years of actual Network operational experience through the close of the century, and extends for a further 20 years to forecast the potential for future improvements through the year 2020. The vertical axis displays the growth in space-to-Earth, downlink capability of the Network. The downlink capability is given in units of the telemetry data rate (bits per second) on a logarithmic scale, and represents the equivalent data rate capability for a typical spacecraft at Jupiter distance (750 million kilometers). Significant events in the history of deep space telecommunications and deep space exploration are appropriately annotated on both axes.

In interpreting the data presented in Fig. 10, it will be observed that the logarithmic scale that displays the data rate gives an impression that the early improvements are more significant than the later improvements because the steps represent fractional or percentage increases, rather than the magnitudes of the actual increases, which are much larger in the later years.

Figure 10. Profile of deep space telecommunications performance: 1960–2020. This figure can also be seen at the following website: <http://deepspace.jpl.nasa.gov/dsn/history/album/images/dsn71.gif>. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Presented this way, however, the figure clearly shows that, from inception through 1997, the downlink capability of the Network grew from an equivalent Jupiter data rate of 10^{-6} bits/s to nearly 10^{+6} bits/s. Note, however, that the drive to switch to “faster-better-cheaper” missions in the late 1990s resulted in decreased capabilities on the spacecraft and eroded the actually implemented capabilities by approximately two orders of magnitude. Nevertheless, that still represents 10 orders of magnitude of improvement.

This remarkable progress is not, of course, solely due to improvements in the Network. Many of the steps result from “cooperative” changes on the part of both the DSN and the spacecraft. Coding, for example, is applied to the data on the spacecraft and removed on Earth. A change in frequency has resulted in some of the larger steps shown by making the radio beam from the spacecraft more narrowly focused. Such a change necessitates equipment changes on both the spacecraft and on Earth.

Other steps represent advances that are strictly spacecraft related, such as increases in return-link transmitter power or increases in spacecraft antenna size, which improves performance by more narrowly focusing the radio beam from the spacecraft. Still other steps depict improvements strictly resulting from the DSN, such as reducing receiving system temperature, increasing the size of ground antennae, or using arrays of antennae to increase the effective surface area available for collecting signal power.

Other Deep Space Network Activities

A number of other DSN activities and developments are worth mentioning.

Cost Reduction Initiatives. Pressures have always existed to reduce costs in the DSN. In 1994, a Network automation work area was set up to develop automated procedures that would replace the extremely operator-intensive work of running a DSN tracking station during a spacecraft “pass.” This effort soon produced demonstrable results. A fully automated satellite-tracking terminal for near-Earth satellites was demonstrated in 1994 (52). A software prototype controller that reduced the number of manual inputs for a typical 8-hour track from 900 to 3 was installed at DSS 13 and used to support Ka-band operations at that site (53). Eventually, this technology found its way into the operational Network. A contract for a new, small, deep space transponder offering lower size and power needs, and most importantly lower production costs, was initiated with Motorola in July 1995 (54). This became an element in JPL’s future low-cost (faster-better-cheaper) spacecraft.

Prototypes of a new class of low-cost, fully automated, autonomous ground stations that would simplify implementation and operation and reduce the life-cycle cost of tracking stations in the DSN were introduced in 1995, 1996, and 1997. The first of these terminals was designed for tracking spacecraft in low Earth orbit and was named LEO-T. It was enclosed in a radome and mounted on the roof of a building at JPL where it accumulated more than 2 years of unattended satellite tracking operations without problems. Prompted by the success of LEO-T, the program undertook a fast-track effort to develop a similar automated terminal for deep space applications. It would be called DS-T. The

prototype DS-T was to be implemented at the 26-m BWG antenna at Goldstone. Automation technology was carried one step further into the area of Network operations in 1997, when Automated Real-time Spacecraft Navigation (ARTSN) was introduced (55). In addition to the antenna system, the DS-T included an X-band microwave system, a 4-kW transmitter, and an electronics rack containing commercial, off-the-shelf equipment to carry out all baseband telemetry downlink, command uplink, and Doppler and ranging functions. It was planned to demonstrate DS-T with the Mars Global Surveyor early in 1998 and to use this technology (autonomous uplink and downlink) in the Network with the New Millennium DS-1 spacecraft later that year.

Ka-Band Development. In the past, the most significant improvements in the Network's communication capabilities were made by moving to higher frequency bands. Recognizing this, research and development in the Ka band (32 GHz) was started in 1980. Initial efforts were directed toward low-noise amplifier development and system benefit studies. However, it was also clear that the performance of existing antennas (which were designed for much lower frequencies) would severely limit the improvement in performance that could be realized from the higher operating frequency. Accordingly, in 1991, a new antenna specifically designed for research and development in the Ka band was installed at the DSS 13 Venus site at Goldstone. It was used as the pathfinder for developing large-aperture beam waveguide (BWG) antennae that were, in due course, implemented throughout the Network.

Small imperfections in the surface of an antenna cause larger degradations in the Ka band than at lower frequencies, and, because of the narrower beam width, small pointing errors have a much larger effect. In 1994, improvements in antenna efficiency and in antenna pointing were made in the research and development Ka-band antenna at DSS 13 and in the new operational antenna at DSS 24 (56). These improvements were effected by using microwave holography for precise determination of antenna efficiency and a special gravity compensation system to counteract the effect of gravitational sag as a function of antenna elevation angle. In a search for further downlink improvement, a new feed system consisting of a maximally compact array of seven, circular, Ka-band horns was designed and tested at DSS 13 (57). Each horn was connected to a cryogenically cooled low-noise amplifier, a frequency down-converter, an analog to digital converter, and a digital signal processor. The signals from each horn were optimally combined in a signal processor and presented as a single output whose quality was equivalent to that of a signal from an undistorted antenna. The measured gain in downlink performance was 0.7 dB.

The technology program continued to develop operational concepts that eventually led to the adoption of the Ka band for deep space missions. Trade-off studies between the X band and Ka band showed that the overall advantage of the Ka band, taking due account of the negative effects inherent in its use, was about a factor of 4, or 6 dB, in data return capability (58). Obviously, end-to-end system demonstrations were needed to instill confidence in the new technology. In 1993, the Mars Observer spacecraft carried a non linear element in its transmission feed to produce a fourth harmonic of the X-band signal. The demonstration (called KABLE for KA-band link experiment) provided a weak Ka-band signal for the tracking antenna at DSS 13. A second demonstration (KABLE II)

was conducted using the Mars Global Surveyor mission in 1996. This experiment was used to characterize Ka-band link performance under real flight conditions and to validate the theoretical models derived from the studies mentioned above.

KABLE II required additions to the MGS spacecraft radio transponder to generate a modulated Ka-band downlink from which the improvements that had been made to the DSS 13 to improve Ka-band performance could be evaluated. Though the main objective of KABLE II was to evaluate the Ka band for future operational use, it also served as a test bed for new Ka-band technology applications in both flight systems and ground systems.

In the course of transition to simultaneous X/Ka-band operation, the DSN needed the capability to support various combinations of X- and Ka-band uplinks and downlinks. These included Ka-band receive only, X/Ka-band simultaneous receive, with or without X-band transmit, and full X-band transmit/receive simultaneously with Ka-band receive/transmit. The technology program developed new microwave techniques using frequency selective surfaces and feed junction diplexers to provide the frequency and power isolation necessary to realize the performance required by a practical device. In late 1996, a demonstration at DSS 13 showed that these four different modes of operation could coexist on a single, beam waveguide antenna within acceptable performance limits (59). This work provided a viable solution to the problem of simultaneous X/Ka-band operation on a single antenna that would be needed by the operational network to support the Cassini radio science experiment (search for gravitational waves) in 2000.

Recognizing the need for a cheaper, smaller, less power-consuming radio transponder to replace the existing device on future deep space missions, the Advanced Development Program embarked on a joint program with other JPL organizations to develop the Small Deep Space Transponder (SDST). The concept employed microwave monolithic integrated circuits in the RF circuits and application specific integrated circuit (ASIC) techniques to perform digital signal processing functions and a RISC microprocessor to orchestrate overall transponder operation (60). The transponder would transmit coherent X-band and Ka-band downlinks and receive an X-band uplink. Besides minimizing production costs, the principal design drivers were reductions in mass, power consumption, and volume. The Small Deep Space Transponder was flown in space for the first time onboard the DS-1 New Millennium spacecraft in July 1998.

To provide better understanding of the performance of Ka-band links relative to X-band links from the vantage point of a spaceborne radio source, the DSN technology program engaged in developing a small, low Earth orbiting spacecraft called SURFSAT-1. Launched in 1995, the experiment provided an end-to-end test of Ka-band signals under all weather conditions and DSS 13 antenna elevation angles, as the spacecraft passed over Goldstone. The SURFSAT data was also used for comparison with the KABLE data received from MGS. Later, the SURFSAT X-band and Ka-band downlinks were used to great advantage to test and calibrate the DSN's new 11-meter antennas, before their support of the VSOP (HALCA) Orbiting VLBI mission in 1996.

Optical Communications Development. Beginning in 1980, the technology program supported theoretical analyses that predicted, under certain system

and background light conditions typical of deep space applications, the ability to communicate at more than 2.5 bits of information per detected photon at the receiver. Laboratory tests later confirmed these theoretical predictions (61,62). However, detection power efficiency was only one of the many factors that needed to be studied to bring optical communications to reality. Others included laser transmitter efficiency, spatial beam acquisition, tracking and pointing, link performance tools, flight terminal systems design, definition of cost-effective ground stations, and mitigation of Earth's atmospheric effects on ground stations.

Several system-level demonstrations were carried out as this work progressed. The first, in December 1992, involved detecting a ground-based pulsed laser transmission by the Galileo spacecraft during its second Earth fly by. Transmitted laser signals generated from two ground-based telescope facilities were successfully detected at spacecraft–Earth distances up to 6 million km (63). The second demonstration was carried out during the period November 1995 to May 1996 between JPL's optical telescope facility at Table Mountain, California, and the Japanese Earth-orbiting satellite ETS VI at geosynchronous Earth-orbit altitudes (40,000 km). Data-modulated transmissions were successfully detected in both uplink and downlink directions at a data rate of 1 Mbps (64).

Both experiments yielded important observational data in support of theoretical studies and encouraged the further development of optical communications technology with follow-on supportive flight demonstrations.

DSN Science. Science and technology were always closely coupled in the DSN. Since the very beginnings of the DSN, its radio telescopes provided world-class instruments for radio astronomy, planetary radar, and radio science. Many technology program achievements were of direct benefit to these scientific endeavors, and DSN science activities frequently resulted in new techniques that eventually found their way into the operational Network.

In the period reported here, the program supported radio astronomy investigations related to the formation of stars, to the study of microwave radio emissions from Jupiter, and to radio science measurements of the electron density in the solar plasma outside the plane of the ecliptic (Ulysses spacecraft). The DSN also supported a program of tropospheric delay measurements, which would be of direct benefit to the Cassini gravitational wave experiment. The Goldstone Solar System Radar (GSSR) continued its highly successful series of Earth-crossing asteroid (ECA) observations, which began in 1992 with images of Toutatis (asteroid 4179) and Geographos (asteroid 1620) in 1994 and Golevka (asteroid 6489) in 1995 (65). This work was expected to increase in the years ahead as new and improved optical search programs enabled the discovery of more ECAs.

Note

Douglas J. Mudgway, currently of Sonoma, California, was formerly with JPL.

EARTH ORBITING SATELLITE THEORY

Introduction

The objective of this article is to provide an introduction to the theory of satellite orbital motion. Although the discussion focuses on Earth-orbiting satellites, the theory is equally valid for computations around other primary bodies including the Moon, the Sun, and the planets. The majority of the discussion focuses on the problem of two bodies. The solution provides sufficient accuracy for many problems in astrodynamics. Perturbations from the two-body problem are discussed because a number of applications require greater accuracy. The solution of these more complex problems is generally accomplished using numerical integration techniques, which is beyond the scope of this chapter. The reader is encouraged to study References 1–7 for a more in-depth treatment of these problems.

Basic Principles of Orbital Motion

The basic principles governing the orbital motion of satellites were first formulated by Johannes Kepler and Isaac Newton in the 1600s. In 1619, Kepler, using the very precise observational data of Tycho Brahe, published what have become known as Kepler's laws:

1. The orbit of each planet is an ellipse where the Sun is at one focus.
2. The line joining the planet to the Sun sweeps out equal areas in equal times.
3. The square of the period of a planet is proportional to the cube of its mean distance to the Sun.

Kepler's laws described the kinematics of the motion of the planets, but the dynamic principles describing this motion were not solved until Isaac Newton published the *Principia* in 1687. Newton's three laws of motion are given as:

1. Every body continues in its state of rest or of uniform motion in a straight line, unless it is compelled to change that state by forces impressed upon it.
2. The change of motion is proportional to the motive force impressed and is made in the direction of the straight line in which that force is impressed.
3. To every action, there is always opposed an equal reaction, or the mutual actions of two bodies upon each other are always equal and directed to contrary parts.

The *Principia* also presents Newton's universal law of gravitation which can be stated as "any two point masses attract one another with a force proportional to the product of their masses and inversely proportional to the square of the distance between them." For a satellite orbiting the Earth, this law can be described mathematically as

$$\vec{F} = -\frac{GMm}{r^2} \left(\frac{\vec{r}}{r} \right), \quad (1)$$

where $G = 6.673 \times 10^{-20} \text{ km}^3/\text{kg s}^2$ is the universal gravitational constant, M is the mass of Earth, m is the mass of the satellite, \vec{r} is a vector from the center of mass of Earth to the center of mass of the satellite (both of which are assumed to be point masses here), and \vec{F} is the force acting on the satellite along \vec{r} .

These laws form the foundation upon which our understanding of satellite motion is built. Albert Einstein later explained small differences between observations and Newtonian dynamics, but Newton's laws provide a remarkably accurate model of satellite motion. The laws include some important concepts that will be used in the remainder of this chapter, including the concept of a *point mass* m , where all of the mass of a body is concentrated at a single point (or equivalently a uniform sphere), and the concept of an *inertial reference frame*. The concept of a force \vec{F} and variable time t are also fundamental to the laws of motion.

Two-Body Problem. Newton's laws of motion and law of gravitation allow us to derive the equations of motion of the satellite with respect to Earth. Using Newton's law of gravitation and his second law of motion, we can write the equations of motion of Earth and a satellite in an arbitrary inertial reference frame (Fig. 1) as

$$\vec{F}_{\text{sat}} = m\ddot{\vec{r}}_{\text{sat}} = -\frac{GMm}{r^2} \left(\frac{\vec{r}}{r} \right), \quad (2)$$

$$\vec{F}_{\text{Earth}} = M\ddot{\vec{r}}_{\text{Earth}} = \frac{GMm}{r^2} \left(\frac{\vec{r}}{r} \right). \quad (3)$$

We can then subtract one of these equations from the other to obtain the equations of motion of the satellite with respect to Earth (but still in the

Figure 1. Derivation of the two-body problem (Fig. 3-1, Reference 6).

inertial frame):

$$\ddot{\vec{r}} = \ddot{\vec{r}}_{\text{sat}} - \ddot{\vec{r}}_{\text{Earth}} = -\frac{Gm}{r^2} \left(\frac{\vec{r}}{r} \right) - \frac{GM}{r^2} \left(\frac{\vec{r}}{r} \right) = -\frac{G(m+M)}{r^2} \left(\frac{\vec{r}}{r} \right). \quad (4)$$

It is common to ignore the mass of the satellite (as it is quite small with respect to the mass of Earth) and to define the gravitational constant $\mu = GM = 398600.44 \text{ km}^3/\text{s}^2$, so that Equation 4 may be written as

$$\ddot{\vec{r}} = -\frac{\mu \vec{r}}{r^3}, \quad (5)$$

which is a nonlinear, second-order, vector differential equation, often referred to as the “two-body equation.” It is important to remember the assumptions behind this equation:

1. The mass of the satellite is negligible with respect to the mass of the primary body (Earth).
2. The coordinate system is inertial.
3. Each of the two bodies behaves as a point mass (i.e., they are spherically symmetric and have uniform density).
4. Only the gravitational force between the two bodies is considered; no other forces (atmospheric drag, solar radiation pressure, or gravitational influence of other planets) are present.

Now, we will proceed to develop a solution to this equation, so that we may describe the shape of the satellite orbit about Earth and the position of the satellite in this orbit as a function of time. Let us examine the motion

of the center of mass of the two-body system. The definition of the center of mass is

$$\vec{R}_{\text{CM}} = \frac{M\vec{r}_{\text{Earth}} + m\vec{r}_{\text{sat}}}{M + m}. \quad (6)$$

Combining Equations 2,3 and 6 gives

$$\ddot{\vec{R}}_{\text{CM}} = 0 \rightarrow \ddot{\vec{R}}_{\text{CM}} = \vec{A}t + \vec{B}, \quad (7)$$

where \vec{A} and \vec{B} are constants of motion. Taking the vector cross-product of \vec{r} with Equation 5, it may be shown that an object subject only to two-body dynamics has a constant angular momentum vector:

$$\vec{r} \times \ddot{\vec{r}} = 0 \rightarrow \frac{d}{dt} (\vec{r} \times \dot{\vec{r}}) = 0 \rightarrow \vec{h} = \vec{r} \times \dot{\vec{r}} = \text{const.} \quad (8)$$

Thus, the angular momentum vector is constant, and the motion of m with respect to M is planar. Taking the dot product of $\dot{\vec{r}}$ with Equation 5, we can also show that the energy per unit mass of the motion of m with respect to M is a constant:

$$\xi = \frac{v^2}{2} - \frac{\mu}{r} = \text{const.}, \quad (9)$$

where r and v are the magnitudes of the position and velocity vectors, respectively. Also note that this equation represents the sum of the kinetic and potential energy. In summary, we have found 10 *integrals of motion* ($\vec{A}, \vec{B}, \vec{h}, \xi$), and we need to find two more to solve the two-body problem completely.

The two-body expression, Equation 5, is one of the few dynamic equations in orbital mechanics that can be solved analytically. Because the orbit of the satellite is planar, we can search for two-dimensional solutions to the problem. It is convenient to express Equation 5 in terms of polar coordinates, as shown in Fig. 2 (for an alternate derivation, see Reference 7). Using the following definitions,

$$\begin{aligned} \vec{r} &= r\vec{u}_r, \\ \dot{\vec{r}} &= \dot{r}\vec{u}_r + r\dot{\theta}\vec{u}_\theta, \\ \ddot{\vec{r}} &= \ddot{r}\vec{u}_r + \dot{r}\dot{\theta}\vec{u}_\theta + \dot{r}\ddot{\theta}\vec{u}_\theta + r\ddot{\theta}\vec{u}_\theta - r\dot{\theta}^2\vec{u}_r \\ &= (\ddot{r} - r\dot{\theta}^2)\vec{u}_r + (2\dot{r}\dot{\theta} + r\ddot{\theta})\vec{u}_\theta, \end{aligned} \quad (10)$$

we can rewrite Equation 5 as

$$r \text{ component: } \ddot{r} - r\dot{\theta}^2 = -\frac{\mu}{r^2}, \quad (11)$$

$$\theta \text{ component: } 2\dot{r}\dot{\theta} + r\ddot{\theta} = 0. \quad (12)$$

First note that Equation 12 can be expressed as

$$\frac{d}{dt} (r^2\dot{\theta}) = 0. \quad (13)$$

Figure 2. Use of polar coordinates for the two-body problem (Fig. 4-1, Reference 6).

Because $h = \vec{r} \times \dot{\vec{r}} = r^2 \dot{\theta} \vec{u}_h$ which is equal to a constant, from Equation 13, this again illustrates the conservation of angular momentum. The solution to Equation 11 is best found by making a change of variables of $r = 1/q$ and $t = \theta$ which gives the following differential equation:

$$\frac{d^2 q}{d\theta^2} + q = \frac{\mu}{h^2}. \quad (14)$$

This is a simple harmonic oscillator with a solution of

$$q = \frac{\mu}{h^2} + K \cos(\theta - \omega), \quad (15)$$

where K and ω are our last two integrals of motion. It can be shown that $K = \mu/eh^2$, where

$$e = \sqrt{1 + \frac{2\zeta h^2}{\mu^2}}. \quad (16)$$

Thus, after transforming variables again, Equation 15 can be written as

$$r = \frac{h^2/\mu}{1 + e \cos(\theta - \omega)}. \quad (17)$$

It can be shown that when $\theta - \omega = 0$, r is a minimum (called *periapse*), and when $\theta - \omega = \pi$, r is a maximum (*apoapse*). Thus, ω is referred to as the *argument of periapse*, and the location of the satellite relative to periapse is defined by the *true anomaly* $f = \theta - \omega$. Thus, using $p = h^2/\mu = a(1 - e^2)$ (called the *semiparameter* or *semilatus rectum*), the final solution to the two-body problem can be expressed as

$$r = \frac{p}{1 + e \cos f}, \quad (18)$$

which is the equation of a conic section, either an ellipse, a parabola, or a hyperbola. The size of the conic section is described by the semimajor axis a , and the shape of the conic section is described by its eccentricity e . The position of the satellite on the conic section is described by the true anomaly f , which is the angle of the satellite with respect to periapse (the point of closest approach to the planet). A satellite on an elliptical orbit ($0 < e < 1, a > 0$) has been captured by

the primary body and will not leave unless otherwise perturbed, and a satellite on a hyperbolic orbit ($e > 1, a < 0$), such as a planetary flyby, will never return to the primary body. A parabolic orbit ($e = 1, a = \infty$) is similar to a hyperbolic orbit and not normally encountered except in theory, and a circular orbit ($e = 0$) is a special case of an elliptical orbit.

For an elliptical orbit, there are some useful equations relating the semimajor axis a , the semiminor axis b , and the periapse (r_p) and apoapse (r_a) distances:

$$\begin{aligned} b &= a\sqrt{1 - e^2}, \\ r_p &= a(1 - e), \\ r_a &= a(1 + e). \end{aligned} \quad (19)$$

An alternative form can be derived for the energy of the orbit in terms of the semimajor axis:

$$\zeta = \frac{-\mu}{2a}, \quad (20)$$

which can be combined with Equation 9 to give a useful expression for the velocity:

$$V = \sqrt{\mu \left(\frac{2}{r} - \frac{1}{a} \right)}. \quad (21)$$

We can evaluate this equation for $r = a$ (circular orbit), $r = r_p$, and $r = r_a$, to get equations for the velocity of a circular orbit (V_c), the velocity at periapse (V_p), and the velocity at apoapse (V_a):

$$\begin{aligned} V_c &= \sqrt{\frac{\mu}{r}}, \\ V_p &= \sqrt{\frac{\mu(1 + e)}{a(1 - e)}}, \\ V_a &= \sqrt{\frac{\mu(1 - e)}{a(1 + e)}}. \end{aligned} \quad (22)$$

For an elliptical orbit, we can derive an expression for the period P of the orbit that is, the time it takes the satellite to make one revolution in its orbit. From Equation 13, we know that the magnitude of the angular momentum vector is

$$h = r^2 \frac{df}{dt}, \quad (23)$$

but we also know from calculus that the area swept out by the radius vector as it moves through a given angle is given by

$$dA = \frac{1}{2} r^2 df, \quad (24)$$

which, combined with the previous equation, gives

$$dt = \frac{2}{h} dA, \quad (25)$$

which proves Kepler's second law because h is constant. Integrating this equation over 2π radians of f gives an expression for the orbital period:

$$P = \frac{2\pi ab}{h}. \quad (26)$$

Then, if we substitute the relations $h = \sqrt{\mu p}$ and $b = \sqrt{ap}$ to obtain the most commonly used representation for the orbital period,

$$P = 2\pi \sqrt{\frac{a^3}{\mu}}, \quad (27)$$

which is also an expression of Kepler's third law.

Keplerian Orbit Elements. For an elliptical orbit, the semimajor axis a and the eccentricity e describe the size and shape of the ellipse, respectively, and the true anomaly determines the position of the satellite on the ellipse (Fig. 3). To determine the orientation of the ellipse in inertial space, we need to define three new angles, as shown in Fig. 4. The inclination i of the orbit is the angle between the angular momentum vector and the z axis of the coordinate system (K) (the

Figure 3. Diagram of an elliptical orbit (Fig. 3.3, Reference 2).

Figure 4. Definition of orbital elements (Fig. 3-6, Reference 15).

“tilt” of the orbital plane with respect to the equator). The longitude of the ascending node Ω is the angle between the line of nodes (the intersection of the plane of the orbit with the equatorial plane) and the x axis of the coordinate system. Finally, the argument of periape ω is the angle between the eccentricity vector (the vector that points toward periape) and the line of nodes. Together, a , e , i , Ω , ω and f at some time t constitute a set of Keplerian orbit elements that describe perfectly the motion of the satellite around a point mass planet (when coupled with Kepler’s equation in the next section). They can be considered equivalent to knowing the vector position and velocity at some time epoch, which can be used to determine the motion of the satellite by integrating Equation 5. Later, we will discuss how to determine orbit elements from position and velocity vectors and vice versa.

Although not an orbital element, another useful quantity to compute is the *flight-path angle*. The flight-path angle is the angle between the velocity vector and the local horizontal (as defined by a perpendicular to the position vector), and for noncircular orbits (circular orbits always have a flight-path angle of 0°), the flight-path angle is positive when the satellite is between periape and apoapse, and negative between apoapse and periape). It can be computed in the following manner:

$$\begin{aligned}\cos(\phi_{\text{fpa}}) &= \frac{1 + e \cos v}{\sqrt{1 + 2e \cos v + e^2}}, \\ \sin(\phi_{\text{fpa}}) &= \frac{e \sin v}{\sqrt{1 + 2e \cos v + e^2}}, \\ \phi_{\text{fpa}} &= \tan^{-1} \left(\frac{\sin \phi_{\text{fpa}}}{\cos \phi_{\text{fpa}}} \right),\end{aligned}\tag{28}$$

where the sine and cosine are explicitly given, so that the inverse tangent may be easily computed without a quadrant check.

Kepler's Equation. Kepler's equation allows us to determine the angular position of the satellite in its orbit as a function of time. We will not derive Kepler's equation here (see Reference 7 among others), however, this can be easily done using Kepler's second law and by defining a new position angle, the eccentric anomaly E , shown in Fig. 5. The eccentric anomaly is the angle between periapse and the satellite position projected onto an auxiliary circle with respect to the center of the ellipse (Fig. 5). Kepler's equation relates the eccentric anomaly to the mean anomaly M as

$$M = E - e \sin E \quad (29)$$

The mean anomaly is not a physical angle like the eccentric and true anomalies; it can only be defined mathematically:

$$M = n(t - t_p), \quad (30)$$

where t is time, t_p is the time of the satellite passage of periapse, and n is the mean motion, or the mean angular velocity of the satellite. The mean angular velocity of the satellite around one orbit is simply the orbital period divided by 2π :

$$n = \frac{P}{2\pi} = \sqrt{\frac{\mu}{a^3}}. \quad (31)$$

Thus, knowing the time past periapse passage and the semimajor axis of the orbit, we can compute the mean anomaly. Using the orbit eccentricity, we can then compute the eccentric anomaly from Kepler's equation. Finally, the true anomaly can be computed from the eccentric anomaly as

$$\tan\left(\frac{f}{2}\right) = \sqrt{\frac{1+e}{1-e}} \tan\left(\frac{E}{2}\right). \quad (32)$$

Note that this formulation is valid only for eccentric orbits; different formulations are needed for hyperbolic and parabolic orbits. Also, determining Kepler's equation for the eccentric anomaly is a nonlinear process, usually accomplished using

Figure 5. Definition of the eccentric anomaly (Fig. 7-1, Reference 6).

the Newton–Raphson iteration. If we define a function $f(E) = M - E + e \sin E = 0$, we can then expand this function in a Taylor series about some initial guess E_0 as

$$0 = f(E) = f(E_0 + \delta) = f(E_0) + f'(E_0)\delta + \text{higher order terms.} \quad (33)$$

Ignoring higher order terms, we can solve for δ as

$$\delta = \frac{f(E_0)}{f'(E_0)}. \quad (34)$$

Because we are ignoring higher order terms, we must iterate the solution for δ , and thus a general solution after taking the indicated derivative in Equation 34 is

$$E_{i+1} = E_i + \frac{M - E_i + e \sin(E_i)}{1 - e \cos(E_i)} \quad (35)$$

which should be iterated until $|E_{i+1} - E_i|$ is less than some prescribed tolerance.

Now, we have the tools to determine the satellite position as a function of time. Of the six Keplerian elements, only f varies with time (for two-body dynamics). At a given time t , we can compute M from Equation 30, and then E and f from Equations 29 and 32.

Computing Orbital Elements From Position and Velocity and Vice Versa. Computations in astrodynamics often require the ability to compute orbital elements from position and velocity vectors and vice versa. This arises because the satellite's orbital position as a function of time is most easily determined using orbital elements (in an analytical sense—numerical integration techniques work equally well with position and velocity), but other computations, such as determining satellite visibility at a ground station, are most easily accomplished using the position vector.

Until this point, we have not talked in detail about coordinate system definitions, but before we discuss the calculation of positional and velocity vectors, we must first define the inertial coordinate system in which they are represented. For Earth-orbiting applications, this is usually accomplished by using a geocentric equatorial system (Fig. 6), denoted here as Earth-centered inertial (ECI) or IJK . As shown in Fig. 6, the fundamental plane (IJ) is Earth's equatorial plane. The I axis points towards the vernal equinox on a particular date (the position of the Sun against the stars as it ascends across the equator near March 21); the K axis points toward the North Pole, and the J axis completes the right-handed system, 90° to the I axis. Currently, the J2000 system, which is a geocentric equatorial frame defined at the J2000 epoch (noon on 1 January 2000), is the most commonly used ECI reference frame. The ECI frame is by definition non-rotating, because it is quasi-inertial. However, for many applications, such as describing the location of tracking stations, we also need to define a body-fixed rotating reference frame. This is typically referred to as the Earth-centered Earth-fixed (ECEF) frame (IJK_{ECEF}), where the I_{ECEF} axis is pointed at 0° longitude on the equator (the Greenwich meridian), the K_{ECEF} axis points at the North Pole, and the J_{ECEF} axis completes the right-handed system (points at 90° longitude). In the absence of the relatively small effects of precession, nutation, and polar motion, the K and K_{ECEF} axes are equivalent, and the IJ and IJ_{ECEF}

Figure 6. Coordinates systems used in the orbit problem (Fig. 1-20, Reference 7).

axes are related through Greenwich sidereal time θ_{GST} (Fig. 7), which is the angle between the I axis and the Greenwich meridian (0° longitude). This angle varies between 0° and 360° as the Earth rotates. Additional rotations are required to account for the effects of precession, nutation, and polar motion (see Reference 7).

Converting between the ECI and ECEF frames, as well as other conversions we will discuss later, can be accomplished using principal axis rotations which are defined as follows:

$$\begin{aligned}
 \text{ROTX}(\theta) &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & \sin \theta \\ 0 & -\sin \theta & \cos \theta \end{bmatrix} \\
 \text{ROTY}(\theta) &= \begin{bmatrix} \cos \theta & 0 & -\sin \theta \\ 0 & 1 & 0 \\ \sin \theta & 0 & \cos \theta \end{bmatrix} \\
 \text{ROTZ}(\theta) &= \begin{bmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{bmatrix}
 \end{aligned} \tag{36}$$

where each matrix, when used to premultiply a given vector, will rotate that vector by an angle θ around the indicated axis. Thus, ignoring precession, nutation, and polar motion, the transformations from ECI to ECEF and back are as follows:

$$\begin{aligned}
 \vec{r}_{\text{ECEF}} &= \text{ROTZ}(\theta_{\text{GST}}) \vec{r}_{\text{ECI}}, \\
 \vec{r}_{\text{ECI}} &= \text{ROTZ}(-\theta_{\text{GST}}) \vec{r}_{\text{ECEF}}.
 \end{aligned} \tag{37}$$

The position of the vernal equinox changes in time, and thus a specific date must be assigned to the equinox used to define the reference frame. A commonly

Figure 7. Relationship between the ECI and ECEF coordinate systems (Fig. 1-31, Reference 7).

employed reference is the mean equator and equinox of J2000.0. Mean sidereal time accounts for the precession of the equinox, and apparent sidereal time includes secular and periodic motions of the equinox; the difference is referred to as the equation of the equinoxes. Generally, we use Greenwich mean sidereal time, which can be approximately represented as

$$\begin{aligned}\theta_{\text{GST}} &= \theta_{\text{GST}0} + \omega_e \Delta t \\ \theta_{\text{GST}0} &= 1.753368560 + 628.3319706889 \Delta T \\ &\quad + 6.7707 \times 10^{-6} \Delta T^2 - 4.5 \times 10^{-10} \Delta T^3,\end{aligned}\tag{38}$$

where θ_{GST} is given in radians, ω_e is the rotational rate of Earth ($7.29211585530 \times 10^{-5}$ rad/s), ΔT is the number of Julian centuries elapsed from the epoch J2000.0 (1 January 2000, 12 hrs) for the day of interest, and Δt is the number of seconds from the beginning of the day.

Now, we are ready to describe the transformation of position/velocity to orbit elements and back. Given a vector position \vec{r} and velocity \vec{v} defined in the ECI frame, we can compute orbital elements using the following procedure.

Position/Velocity to Orbital Elements. The vectors used in this discussion are illustrated in Fig. 4. We can find the semimajor axis using the energy integral (Eq. 9) as follows:

$$a = \left(\frac{2}{r} - \frac{v^2}{\mu} \right)^{-1}.\tag{39}$$

For several reasons, it is convenient to define the eccentricity vector (which points at periapse, Fig. 4) as

$$\vec{e} = \frac{\vec{v} \times \vec{h}}{\mu} - \frac{\vec{r}}{r}.\tag{40}$$

The eccentricity of the orbit can be found from the magnitude of the eccentricity vector, or using Equation 16,

$$e = |\vec{e}| = \sqrt{1 + \frac{2\zeta h^2}{\mu^2}}. \quad (41)$$

The inclination i of the orbit, is the angle between the angular momentum vector and the K axis. Thus using the law of cosines ($ab \cos \alpha = \vec{a} \cdot \vec{b}$),

$$i = \cos^{-1} \left(\frac{\hat{K} \cdot \vec{h}}{|\hat{K}| |\vec{h}|} \right). \quad (42)$$

The longitude of the ascending node is the angle measured in the equatorial plane from the I axis to the satellite (i.e., it is the angle between I and the node vector $\vec{n} = \hat{K} \times \vec{h}$). Thus,

$$\Omega = \cos^{-1} \left(\frac{\hat{I} \cdot \vec{n}}{|\hat{I}| |\vec{n}|} \right) \quad (43)$$

The ascending node may be computed from Equation 43 if a quadrant check is performed (if the y component of the node vector is less than zero, the ascending node lies between 180 and 360°). The argument of periapse ω is the angle between the node vector and the eccentricity vector (Fig. 4). Thus,

$$\omega = \cos^{-1} \left(\frac{\vec{n} \cdot \vec{e}}{|\vec{n}| |\vec{e}|} \right), \quad (44)$$

where again the quadrant must be checked (if the z component of the eccentricity vector is negative, ω lies between 180 and 360°). Finally, the true anomaly is the angle between the position vector and the eccentricity vector.

$$f = \cos^{-1} \left(\frac{\vec{r} \cdot \vec{e}}{|\vec{r}| |\vec{e}|} \right), \quad (45)$$

where the quadrant must be checked using the flight-path angle (if $\phi_{\text{fpa}} < 0$, $180^\circ \leq \nu \leq 360^\circ$). Although these formulas are reasonably general, several special cases can arise that require a different approach, namely, circular and/or equatorial orbits (see Reference 7).

Orbital Elements to Position/Velocity. Orbital elements are best transformed to position/velocity by using the principal axis rotations defined earlier. First, we write the position and velocity vectors as expressed in a “perifocal” reference frame, which has x pointed at periapse, z normal to the orbit plane, and y completing the right-hand system (Fig. 8). In this frame, the position and

Figure 8. The perifocal reference frame (Fig. 3-3, Reference 15).

velocity can be written as a function of orbital elements:

$$\begin{aligned} \vec{r}_{\text{PER}} &= \begin{bmatrix} r \cos f \\ r \sin f \\ 0 \end{bmatrix}, \\ \vec{v}_{\text{PER}} &= \begin{bmatrix} -\sqrt{\frac{\mu}{p}} \sin f \\ \sqrt{\frac{\mu}{p}}(e + \cos f) \\ 0 \end{bmatrix}, \end{aligned} \quad (46)$$

where r is computed from Equation 18 and $p = a(1 - e^2)$ is the semiparameter. Once the position and velocity vectors are defined in the perifocal frame, they may be rotated to the ECI frame through simple rotations of $-\omega$ about z , $-i$ about x , and $-\Omega$ about z , as follows:

$$\begin{aligned} \vec{r}_{IJK} &= \text{ROTZ}(-\Omega)\text{ROTX}(-i)\text{ROTZ}(-\omega)\vec{r}_{\text{PER}}, \\ \vec{v}_{IJK} &= \text{ROTZ}(-\Omega)\text{ROTX}(-i)\text{ROTZ}(-\omega)\vec{v}_{\text{PER}}. \end{aligned} \quad (47)$$

In summary, the equations of motion for the two-body problem can be solved and yield a conic section that is best described using Keplerian orbital elements. Given a Cartesian position and velocity for a satellite at a given time, a set of orbital elements may be computed using the preceding equations. These elements may be easily propagated in time because only M varies in time via Kepler's equation. The propagated elements may be converted back to inertial Cartesian position and velocity using Equations 46 and 47 and into the ECEF frame via Equations 37. The Cartesian position in the ECEF frame is related to geocentric latitude ϕ , longitude λ and radius r as

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} r \cos \phi \cos \lambda \\ r \cos \phi \sin \lambda \\ r \sin \phi \end{bmatrix}. \quad (48)$$

Thus, the latitude and longitude of the satellite may be computed as

$$\begin{aligned} r &= \sqrt{x^2 + y^2 + z^2}, \\ \phi &= \sin^{-1} \frac{z}{r}, \\ \lambda &= \tan^{-1} \frac{y}{x}. \end{aligned} \quad (49)$$

It is sometimes also desirable to compute the position of the satellite relative to some fixed point on Earth, such as a tracking site. This can be done by defining a site-fixed topocentric south-east-up (SEZ) reference frame, where the x axis is pointed south, the y axis is pointed east, and the z axis points toward the zenith. Given the Cartesian position of the satellite relative to the site in ECEF frame,

$$\begin{aligned} \vec{\rho}_{\text{ECEF}} &= \vec{r}_{\text{ECEF}} - \vec{r}_{\text{siteECEF}}, \\ \vec{r}_{\text{siteECEF}} &= \begin{bmatrix} r_{\text{site}} \cos \phi_{\text{site}} \cos \lambda_{\text{site}} \\ r_{\text{site}} \cos \phi_{\text{site}} \sin \lambda_{\text{site}} \\ r_{\text{site}} \sin \phi_{\text{site}} \end{bmatrix}. \end{aligned} \quad (50)$$

The transformation of a vector from the ECEF frame to the SEZ frame is given as

$$\vec{\rho}_{\text{SEZ}} = \text{ROTY}(90^\circ - \phi_{\text{site}}) \text{ROTZ}(\lambda_{\text{site}}) \vec{\rho}_{\text{ECEF}}. \quad (51)$$

The azimuth and elevation of the satellite relative to the site are related to the position in the topocentric frame via

$$\vec{\rho}_{\text{SEZ}} = \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} -\rho \cos el \cos az \\ \rho \cos el \sin az \\ \rho \sin el \end{bmatrix}, \quad (52)$$

and thus the azimuth and elevation may be easily computed as

$$\begin{aligned} \rho &= \sqrt{x^2 + y^2 + z^2}, \\ el &= \sin^{-1} \frac{z}{\rho}, \\ az &= \tan^{-1} \frac{y}{-x}. \end{aligned} \quad (53)$$

Perturbation Theory

The discussion to this point has assumed that Earth can be represented by a point mass, that is, a spherically symmetrical homogeneous body, and that no nongravitational forces act on the satellite. In reality, Earth's shape and mass deviate significantly from a sphere, and a satellite is subject to the significant perturbations of atmospheric drag and solar radiative pressure among other nongravitational forces. The influence of these other effects on the orbit will now be described.

Perturbations Due to Earth's Nonspherical Shape. The shape of Earth and the distribution of mass within it are quite complex. Normally, we describe Earth's gravity field in terms of its potential, and then take the gradient of the potential to determine the force on the satellite. For example, the two-body equations, Equation 5, can be expressed in this way:

$$\begin{aligned}\ddot{\mathbf{r}} &= \nabla U, \\ U &= \frac{\mu}{r},\end{aligned}\tag{54}$$

where ∇U is the gradient of the potential U . The potential shown here includes only a point mass term. Deviations of the gravity field from a point mass are described by using an expansion of the potential in terms of spherical harmonic functions as

$$\begin{aligned}U &= \frac{\mu}{r} \left[1 - \sum_{l=2}^{\infty} J_l \left(\frac{R_{\oplus}}{r} \right)^l P_l(\sin \phi_{\text{sat}}) \right. \\ &\quad + \sum_{l=2}^{\infty} \sum_{m=l}^l \left(\frac{R_{\oplus}}{r} \right)^l P_{lm}(\sin \phi_{\text{sat}}) (C_{lm} \cos m\lambda_{\text{sat}} \\ &\quad \left. + S_{lm} \sin m\lambda_{\text{sat}}) \right],\end{aligned}\tag{55}$$

where P_l are the Legendre polynomials of degree l , P_{lm} are the Legendre associated functions of degree l and order m , r is the magnitude of the satellite position vector, ϕ_{sat} and λ_{sat} are the satellite latitude and longitude, R_{\oplus} is the radius of Earth (~ 6378 km), J_l are zonal gravitational coefficients describing the latitudinal gravity variations, and C_{lm}/S_{lm} are the sectorial ($l=m$) and tesseral ($l \neq m \neq 0$) gravitational coefficients describing the longitudinal gravity variations. The gravitational coefficients are a function of the mass distribution within Earth. The $l=2$ terms are related to the moments and products of inertia of Earth as

$$\begin{aligned}J_2 &= \frac{2I_{zz} - I_{yy} - I_{xx}}{2MR_{\oplus}^2}, \\ C_{2,1} &= \frac{I_{yz}}{MR_{\oplus}^2}, \quad S_{2,1} = \frac{I_{xz}}{MR_{\oplus}^2}, \\ C_{2,2} &= \frac{I_{yy} - I_{xx}}{4MR_{\oplus}^2}, \quad S_{2,2} = \frac{I_{xy}}{2MR_{\oplus}^2}.\end{aligned}\tag{56}$$

The J_2 term describes the oblateness of Earth, and the J_3 coefficient describes its slight “pear shape.” The $l=1$ terms are normally considered zero if the origin of the coordinate system coincides with Earth's center of mass.

Note that taking the gradient of U in Equation 54 is not trivial because U is expressed in terms of a body-fixed position of the satellite r , ϕ , and λ . Thus, the

gradient should be computed in spherical coordinates as

$$\nabla U = \frac{\partial U}{\partial r} \vec{u}_r + \frac{1}{r} \frac{\partial U}{\partial \phi} \vec{u}_\phi + \frac{1}{r \cos \phi} \frac{\partial U}{\partial \lambda} \vec{u}_\lambda. \quad (57)$$

Then, we must rotate this vector quantity from the satellite-fixed polar coordinates to ECEF coordinates and finally to JK inertial coordinates. Thus the final expression for the force of the gravity field can be expressed as

$$\vec{F}_g = \text{ROT3}(-\theta_{\text{gst}}) \text{ROTZ}(-\lambda) \text{ROTY}(\phi) \nabla U. \quad (58)$$

Note that the first term in our expression of the potential (Equation 55) is just the point mass potential, and we know how the orbit behaves in the presence of a point mass. Thus, it is customary to define the *disturbing potential* and the resulting force due to the nonsphericity of the gravity field as

$$R = U - \frac{\mu}{r}, \quad (59)$$

$$\vec{F}_{\text{ns}} = \text{ROTZ}(-\theta_{\text{gst}}) \text{ROTZ}(-\lambda) \text{ROTY}(\phi) \nabla R.$$

The gravitational coefficients of Earth (J_l , C_{lm} , S_{lm}) have been determined from tracking observations of artificial Earth satellites (see Reference 8 for a review). The orbital perturbations due to Earth's gravity field can be classified as either secular (varying linearly in time), short period (approximately the satellite orbital period), and long period (weeks to months). All of these perturbations can be important for some applications, but we will restrict our discussion to secular perturbations because they do not average zero over time. The largest coefficient in the spherical harmonic expansion is the J_2 term, which describes the ellipsoidal shape of Earth. Now, we need to describe the technique for determining the effect of J_2 on the orbit.

General versus Special Perturbations. To determine how a given perturbative force acts on a satellite, one could perform a straight numerical integration of the equations of motion on a computer, referred to in the astrodynamics community as *special perturbations*, or one could analyze the perturbations using analytical techniques, referred to as *general perturbations*. The former technique is quite useful for propagating orbits with complex dynamics that do not lend themselves to an analytical treatment, or when an exact representation is required. The latter technique often leads to a more thorough understanding of the effects on the orbit, at the expense of inaccuracies due to linearization of the forcing functions. Some forces are so complex that applying the general perturbation technique is quite unwieldy. The use of the Lagrange planetary equations is a particularly useful general perturbation technique for examining gravitational perturbations.

Lagrange Planetary Equations. Most general perturbation techniques rely on a method called *variation of parameters*. Euler and Lagrange initially developed this method to describe conservative (gravitational) accelerations, and Gauss' method also applies to nonconservative accelerations. Essentially, these techniques use the two-body orbit as a solution to an unperturbed system and

then linearize the perturbations around the unperturbed system. Equations can be developed that describe the secular change of the orbital elements from an unperturbed system. The Lagrange planetary equations present these equations as a function of the disturbing potential R as

$$\begin{aligned}
 \frac{da}{dt} &= \frac{2}{na} \frac{\partial R}{\partial M_0}, \\
 \frac{de}{dt} &= \frac{1-e^2}{na^2e} \frac{\partial R}{\partial M_0} - \frac{\sqrt{1-e^2}}{na^2e} \frac{\partial R}{\partial \omega}, \\
 \frac{di}{dt} &= \frac{1}{na^2\sqrt{1-e^2}\sin i} \left(\cos i \frac{\partial R}{\partial \omega} - \frac{\partial R}{\partial \Omega} \right), \\
 \frac{d\omega}{dt} &= \frac{\sqrt{1-e^2}}{na^2e} \frac{\partial R}{\partial e} - \frac{\cot i}{na^2\sqrt{1-e^2}} \frac{\partial R}{\partial i}, \\
 \frac{d\Omega}{dt} &= \frac{1}{na^2\sqrt{1-e^2}\sin i} \frac{\partial R}{\partial i}, \\
 \frac{dM_0}{dt} &= \frac{1-e^2}{na^2e} \frac{\partial R}{\partial e} - \frac{2}{na} \frac{\partial R}{\partial a}.
 \end{aligned} \tag{60}$$

Note that these equations require the partial derivatives of the disturbing potential with respect to the orbital elements, whereas the previous expression for the disturbing potential is in terms of satellite position (latitude, longitude, and height). Expressing the disturbing potential R in terms of orbital elements is described by Kaula (9), who used this with the Lagrange planetary equations to investigate gravitational perturbations to the orbit. As the manipulation of the equations is somewhat complex, we will examine the procedure only for J_2 .

J_2 Perturbations and the Secular Precessing Ellipse. As previously mentioned, the J_2 gravitational coefficient is by far the most significant term in the definition of the nonsphericity of Earth's gravity field. The secular effect of J_2 on the orbital elements can be determined by isolating this term in the disturbing potential and substituting it in the Lagrange planetary equations. The J_2 term of the disturbing potential is

$$R_{J_2} = -\frac{\mu J_2}{r} \left(\frac{R_\oplus}{r} \right)^2 \frac{3}{2} \left(\sin^2 \phi_{\text{sat}} - \frac{1}{3} \right). \tag{61}$$

This equation can be expressed in terms of orbital elements using $\sin \phi_{\text{sat}} = \sin i \sin(\omega + f)$ and a trigonometric identity. Because we are interested in secular effects, we can ignore terms containing ω and f . If we further average the disturbing potential over one orbital revolution, the final result is (7)

$$R_{J_2} = -\frac{3}{2} n^2 R_\oplus^2 J_2 \frac{1}{(1-e^2)^{\frac{3}{2}}} \left(\frac{\sin^2 i}{2} - \frac{1}{3} \right). \tag{62}$$

Then, this can be substituted in the Lagrange planetary equations (60) to yield (ignoring higher order terms in J_2)

$$\begin{aligned}
 \frac{da}{dt} &= 0, \\
 \frac{de}{dt} &= 0, \\
 \frac{di}{dt} &= 0, \\
 \frac{d\Omega}{dt} &= -\frac{3J_2 R_\oplus^2 n \cos i}{2p^2}, \\
 \frac{d\omega}{dt} &= \frac{3nR_\oplus^2 J_2}{4p^2} (4 - 5 \sin^2 i), \\
 \frac{dM_0}{dt} &= \frac{3nR_\oplus^2 J_2 \sqrt{1-e^2}}{4p^2} (3 \sin^2 i - 2).
 \end{aligned} \tag{63}$$

The last equation describes secular changes in the rate of change of the mean anomaly (i.e., changes in the mean motion). The secular changes in the longitude of the ascending node and the argument of periapse have led to the description

Figure 9. Precession of the longitude of the ascending node (Fig. 8-3, Reference 7).

Figure 10. Precession of the argument of periapee (Fig. 8-5, Reference 7).

secular precessing ellipse, as the orbit precesses around the z axis (Fig. 9), and periapee moves around the orbit (Fig. 10). The rate of change of the node can vary by $\pm 10^\circ/\text{day}$, depending on the orbit characteristics. It is zero for a satellite at 90° inclination, and negative/positive for inclinations less/greater than 90° . The rate of change of the argument of periapee can have a similar magnitude and is zero for an inclination of 63.4° or 116.6° , called the *critical inclination*. Thus, under only the influence of J_2 , the secular change of the orbital elements can be written as

$$\begin{aligned}\Omega(t) &= \Omega(t_0) + \frac{d\Omega}{dt}(t - t_0), \\ \omega(t) &= \omega(t_0) + \frac{d\omega}{dt}(t - t_0), \\ M(t) &= M(t_0) + \left(\frac{dM_0}{dt} + n \right)(t - t_0),\end{aligned}\tag{64}$$

where the other orbital elements (a , e , i) remain constant.

The Lagrange planetary equations are useful only for evaluating conservative forces that can be represented in terms of a potential. There is a Gaussian form of the equations that can be used to study nonconservative forces (7). The evaluation of other perturbations using a general perturbation technique can become quite complex and is beyond the scope of this article. Thus, the remaining perturbations will be described in terms of their contribution to the two-body

equations of motion (5), under the assumption that a special perturbation technique (numerical integration) will be used to determine their effect on the orbit.

Perturbations Due to Drag and Solar Radiative Pressure. Atmospheric drag can be one of the largest perturbing forces for low altitude Earth satellites. The drag force per unit mass can be represented as

$$\vec{F}_{\text{drag}} = -\frac{1}{2}\rho\left(\frac{C_D A}{m}\right)V_r \vec{V}_r \quad (65)$$

where ρ is the atmospheric density, C_D is the drag coefficient, \vec{V}_r is the satellite velocity relative to the atmosphere, m is the mass of the satellite, and A is the cross-sectional satellite area. The quantity in brackets is sometimes referred to as the *ballistic coefficient*. The atmospheric density drops off approximately exponentially with increasing altitude, and it can have considerable temporal and spatial variation, due to the location of the subsolar point and solar and geomagnetic activity. Commonly used models for the atmospheric density include those in References 10–12. These models commonly use geomagnetic indexes and solar flux values to model the temporal variations of the density. The models are far from perfect, and deficiencies in the models are usually accounted for by estimating the drag coefficient in a piecewise continuous fashion using tracking data. Atmospheric drag is the leading factor that determines the lifetime of the satellite.

Atmospheric drag decreases the energy of the satellite over time, as manifested by decays in the semimajor axis and eccentricity of the orbit. For an eccentric orbit, the periape radius will remain roughly constant, whereas the apoapse radius decreases over time, corresponding to a decrease in the semimajor axis and the eccentricity of the orbit.

Radiative pressure is also an important force for precise modeling of satellite dynamics. Direct solar radiation is the largest effect, but reflected and emitted radiation from Earth can also be important. The force per unit mass due to solar radiative pressure is given by

$$\vec{F}_{\text{SRP}} = -P \frac{vA}{m} C_R \vec{u}_s, \quad (66)$$

where P is the momentum flux from the Sun, \vec{u}_s is the unit vector from the Sun to the satellite, A is the cross-sectional area in the direction of \vec{u}_s , C_R is the reflectivity coefficient whose values are between 1 and 2, and v is a shadow factor equal to 1 if the satellite is in sunlight, 0 if the satellite is in shadow (umbra), and between 0 and 1 if it is in partial shadow (penumbra). Earth radiative pressure can be modeled similarly; however, P would be modified to account for the spatial variations of albedo and emissivity over Earth's surface. In a manner analogous to drag, satellite reflectivity is sometimes estimated (using satellite tracking data) to account for errors in modeling solar radiative pressure.

Errors in the models for atmospheric drag and solar radiative pressure are quite complex, even when the drag and reflectivity coefficients are estimated. One commonly used method for representing these errors, as well as errors due to other nonconservative forces, is to estimate empirical forces acting on the

satellite. Because these orbit errors typically have a frequency of once per orbital period, the form of the empirical force is taken as $A + B \cos \alpha t + C \sin \alpha t$, where α is a frequency of once per revolution and the coefficients A , B , and C are estimated from the tracking data. This force is often represented by vector components in the radial, transverse, and normal directions.

N-Body Perturbations. It is often necessary to include the perturbative effects of other planetary bodies, such as the Moon, Jupiter, and Saturn, in the equations of motion for an Earth-orbiting satellite. This is usually done by considering each of the bodies as a point mass. Using an inertial coordinate system, as shown in Fig. 11, the equations of motion of the satellite with respect to Earth in the presence of a third body can be written as

$$\ddot{\vec{r}} = \ddot{\vec{r}}_{\text{sat}} - \ddot{\vec{r}}_{\oplus}. \quad (67)$$

Newton's second law and the law of gravitation give

$$\begin{aligned} M\ddot{\vec{r}}_{\oplus} &= \frac{GMm\vec{r}_{\oplus\text{sat}}}{r_{\oplus\text{sat}}^3} + \frac{GMm_{\odot}\vec{r}_{\oplus\odot}}{r_{\oplus\odot}^3}, \\ m\ddot{\vec{r}}_{\text{sat}} &= -\frac{GMm\vec{r}_{\oplus\text{sat}}}{r_{\oplus\text{sat}}^3} - \frac{Gm_{\odot}m\vec{r}_{\odot\text{sat}}}{r_{\odot\text{sat}}^3}, \end{aligned} \quad (68)$$

that can be substituted in Equation 67 to yield (after rearranging terms)

$$\ddot{\vec{r}} = -\frac{G(M+m)\vec{r}}{r^3} + Gm_{\odot} \left(\frac{\vec{r}_{\text{sat}\odot}}{r_{\text{sat}\odot}^3} - \frac{\vec{r}_{\oplus\odot}}{r_{\oplus\odot}^3} \right). \quad (69)$$

We recognize the first term in this equation as the two-body term from Equation 5. The second term represents the perturbation from two-body motion. It is composed of a *direct effect*, because it is the direct acceleration of the third body on the satellite, and an *indirect effect*, because it represents the perturbation of the third body on Earth and is not function of the satellite position. We can generalize this

Figure 11. Perturbations due to a third body (Fig. 2-6, Reference 7).

equation from a single third body to N “third” bodies as

$$\begin{aligned}\ddot{\vec{r}}_{\oplus\text{sat}} &= -\frac{G(m_{\oplus} + m_{\text{sat}})\vec{r}_{\oplus\text{sat}}}{r_{\oplus\text{sat}}^3} + \vec{F}_{N\text{-body}} \\ \vec{F}_{N\text{-body}} &= G \sum_{j=1}^N m_j \left(\frac{\vec{r}_{\text{sat}j}}{r_{\text{sat}j}^3} - \frac{\vec{r}_{\oplus j}}{r_{\oplus j}^3} \right)\end{aligned}\quad (70)$$

This equation may be solved only by using numerical integration techniques (special perturbations), although several integrals do exist (7). For a single third body, the *restricted three-body problem* (13), where it is assumed that the satellite has no effect on the motion of the other two primary masses and the primary masses move on circular orbits, does have solutions.

Summary. For nonspherical gravitational perturbations only, the time rate of change of the orbital elements may be computed analytically using the Lagrange planetary equations, such as for the secular J_2 perturbations to Ω , ω , and M . However, if a precise representation is needed that includes the effect of non-gravitational forces, direct numerical integration of the equations of motion is best. The expanded equations of motion would be

$$\ddot{\vec{r}} = -\frac{\mu\vec{r}}{r^3} + \vec{F}_{\text{NS}} + \vec{F}_{\text{drag}} + \vec{F}_{\text{SRP}} + \vec{F}_{\text{ERP}} + \vec{F}_{N\text{-body}} + \vec{F}_{\text{other}}, \quad (71)$$

where \vec{F}_{other} might represent relativistic effects, satellite thermal venting, or magnetic effects. Note that for each force component, care must be taken to represent each in a common coordinate system, usually the inertial J2000.0 system.

Types of Orbits

Polar, Prograde, and Retrograde Orbits. Choosing the inclination of an orbit is a critical component of the mission design. Specifying the inclination of the orbit immediately determines the maximum latitude on Earth over which the satellite will pass. When considered in context with Earth’s rotation, the satellite ground track can evolve quite differently if the orbit is *prograde* versus *retrograde*. A prograde orbit has an inclination less than 90° (thus the satellite’s motion is in the same direction as Earth’s rotation), and its nodal precession rate ($\dot{\Omega}$) is negative. A retrograde orbit has an inclination greater than 90° (thus it moves in a direction opposite to Earth’s rotation), and its nodal precession rate is positive. A *polar* orbit has an inclination of 90° and is noteworthy because the orbit plane does not precess due to zonal gravitational perturbations ($\dot{\Omega} = 0$).

Equatorial and Geosynchronous Orbits. If the inclination of the orbit is 0° , then it is referred to as an *equatorial* orbit, and the satellite’s ground track never leaves the equator. A *geosynchronous* orbit has a period equal to Earth’s rotational period, which implies that it can be obtained by properly selecting the semimajor axis:

$$P = 2\pi\sqrt{\frac{a^3}{\mu}} = 1 \text{ sidereal day} \quad (72)$$

Solving for the semimajor axis gives $a \cong 42,164$ km to attain a geosynchronous orbit. If the satellite is also in an equatorial orbit, then it stays over the same geographical point on Earth at all times, and the orbit is referred to as *geostationary*. This is the orbit used by many communications satellites.

Sun-Synchronous Orbits. As the name implies, *Sun-synchronous* orbits maintain a constant orientation of the orbit plane with respect to the Sun throughout the year. This is accomplished by setting the orbit's nodal precession rate (caused by the perturbations of J_2) equal to the angular rate of Earth's orbit around the Sun of about a degree per day ($360^\circ/365.25$ days = 0.0172028 rad/s). Setting this equal to our equation for the nodal precession rate,

$$0.0172028 = -\frac{3nR_\oplus^2 J_2}{2p^2} \cos i, \quad (73)$$

gives an equation for determining the orbital parameters of a Sun-synchronous orbit. For example, for a circular orbit ($e=0.0$) at 800 km altitude ($a=p=7178$ km), solving for the inclination gives $i=98.6^\circ$. This is a common orbit for Earth observation satellites because the solar illumination conditions (i.e., local time) at Earth's surface are identical each time the satellite passes over the same latitude on the ground.

Other Orbits. A *frozen orbit* refers to a case where the secular variations of eccentricity and argument of perigee are designed to be zero, so that global variations in altitude are minimized. Orbits whose ground track repeats over a selected period of time are said to have a *repeating ground track*. These orbits are often used when it is desired to collect measurements over certain locations on the surface of Earth at regular time intervals. The former Soviet Union designed a unique orbit for reconnaissance satellites referred to as the *Molniya* orbit (after the satellite of the same name). This orbit is characterized by its high eccentricity (0.7), 12-hour period, and critical inclination of 63.4° . The latter allows fixing apoapse over the former Soviet Union to permit long periods of communication.

Orbital Maneuvers

The subject of orbital maneuvers could be a separate article unto itself; however, we can provide an introduction here. We focus our discussion on the Hohmann transfer, the most common technique for transferring a satellite from one orbit to another.

Hohmann Transfer. Hohmann (14) proposed that the minimum-energy transfer between two coplanar orbits could be achieved using tangential burns, where the direction of the velocity change is tangential to the orbit. Hohmann considered only circular orbits, but the theory can be extended to elliptical orbits when the burns are applied at periapse or apoapse (where the flight path angle is zero). Figure 12 demonstrates the geometry of the *Hohmann transfer* for these two cases. If r_{initial} is the radius of the lower orbit (or the periapse radius for the elliptical case) and r_{final} is the radius of the higher orbit (or the apoapse radius of the final elliptical orbit), the semimajor axis of the transfer orbit and the

Figure 12. The Hohmann transfer (Fig. 5-4, Reference 7).

transfer time can be readily computed:

$$a_{\text{trans}} = \frac{r_{\text{initial}} + r_{\text{final}}}{2},$$

$$T_{\text{trans}} = \frac{P_{\text{trans}}}{2} = \pi \sqrt{\frac{a_{\text{trans}}^3}{\mu}}. \quad (74)$$

The magnitude of the two velocity changes can then be computed as

$$\Delta v_1 = v_{\text{trans}}^a - v_{\text{initial}},$$

$$\Delta v_2 = v_{\text{final}} - v_{\text{trans}}^b,$$

$$v_{\text{initial}} = \sqrt{\frac{2\mu}{r_{\text{initial}}} - \frac{\mu}{a_{\text{initial}}}},$$

$$v_{\text{trans}}^a = \sqrt{\frac{2\mu}{r_{\text{initial}}} - \frac{\mu}{a_{\text{trans}}}},$$

$$v_{\text{final}} = \sqrt{\frac{2\mu}{r_{\text{final}}} - \frac{\mu}{a_{\text{final}}}},$$

$$v_{\text{trans}}^b = \sqrt{\frac{2\mu}{r_{\text{final}}} - \frac{\mu}{a_{\text{trans}}}}. \quad (75)$$

A common application of the Hohmann transfer is transferring communications satellites from the initial low Earth orbits, into which they were launched, to

their final geostationary orbits from which they operate. Another common application is for interplanetary navigation (e.g., Earth to Mars).

Orbit Determination

A detailed discussion of the subject of orbit determination is outside the scope of this book. See References 15–17 for a thorough treatment of this topic. However, the concept that we have available an initial position and velocity for the satellite (or equivalently a set of Keplerian elements) is fundamental to much of this article, and thus a brief discussion of the topic is warranted.

The process of orbit determination can be described as developing a dynamic model for a satellite orbit, including its position and velocity at some reference epoch, that best agrees (usually in some least squares sense) with space- and ground-based tracking observations of the satellite. Tracking measurements can be provided in a variety of forms [azimuth/elevation, range, range-rate (Doppler)] and can be made from Earth-fixed tracking stations or from other satellites such as the Global Positioning System (GPS) (18) or the Tracking and Data Relay Satellite System (TDRSS). The tracking observations tend to be nonlinear functions of the satellite position, and the dynamic models that describe the motion of the satellite are nonlinear as well. Thus, the basic approach to orbit determination involves linearizing the measurement and dynamic models, numerically integrating the equations of motion for the satellite using a guess of the initial position/velocity, and then adjusting the state vector (which contains the initial position/velocity of the satellite, drag parameters, gravity parameters, empirical parameters, and tracking station coordinates) to provide the best agreement in a least squares sense between the tracking observations and the numerically integrated orbit. Such a dynamic technique is usually necessary because of gaps in the tracking observations, although new continuous methods such as GPS are allowing implementation of more kinematic methods.

Summary

This article has presented the basic theory for the motion of Earth-orbiting satellites. Although the assumption of two-body dynamics is quite limiting, this theory forms the basic tools used in astrodynamics today. When coupled with general or special perturbation techniques, a high degree of accuracy can be obtained. Indeed, orbit determination accuracies for some Earth satellite missions have approached the few centimeter level (19), as demanded by the science applications.

EARTH-ORBITING SATELLITES, DATA RECEIVING AND HANDLING FACILITIES

Ground support of spacecraft is often referred to as “TT&C,” for tracking, telemetry and command. Tracking generally refers to measuring the position of a

spacecraft, telemetry to information carried on the radio-frequency (RF) downlink signal, and command to information transmitted from the ground to a spacecraft. Increasingly, these terms are somewhat narrow to describe the action fully, as, for example, transmission of voice and video on the uplink. Though these functions were initially stand-alone elements of space operations, technological advances and economic pressures have blurred distinctions, both among them and with related operational activities. For example, computing power and reliability have advanced sufficiently that many functions can be economically accomplished at the point of ground receipt or of application, rather than at a centralized facility. For Apollo, the separate functions of command, telemetry, tracking, and voice communications were integrated into a single radio-frequency (RF) system. Readers should be aware that the boundaries of data receiving and handling functions are dynamic.

The genesis of data receiving and handling facilities was primarily in the military launch ranges. Differences and limitations necessitated changes as space activities developed. Geographically, coverage expanded globally. Operationally, mission durations became more continuous and ground activities increasingly interactive.

Early space flights were brief. Operations were simple, few, and far between. With no existing infrastructure, supporting systems, procedures, and operators had to be put in place for each mission—usually unique for each flight. Preplanning an entire mission has gradually been replaced by continual interaction by both flight controllers and mission scientists—resulting in far more productive missions. Led by the interplanetary designs, spacecraft have become much more autonomous—more robust and require less, and less critical, ground control. Some ground operations systems evolved from “specialized mission unique” to “general purpose multimission.” Even as multimission applications shared hardware, they often retained unique software. Generally, RF systems became more standardized (strongly prompted by international spectrum allocations), as have terrestrial communications as these needs are increasingly met commercially. However, many data systems and operating procedures remained quite unique. Sharing multipurpose assets is itself quite expensive, and technology has reduced costs sufficiently that in many cases it now makes economic sense to consider dedicated systems again—though constructed of standardized components.

Although much of this discussion focuses on NASA, it is in a larger sense the history of most space operations and thus has broader significance. In the Cold War environment the Soviet systems evolved independently, but most other agencies and countries followed NASA's lead, primarily to take advantage of existing designs, systems, and infrastructure. NASA originally had three separate networks of ground stations for controlling and tracking spacecraft. The Space Tracking And Data Network (STADAN) initially spanned the globe north and south across the Americas. It was used primarily for near-Earth scientific satellites. Telemetry and command systems were independent of each other, and tracking relied primarily on radio interferometry. The Deep Space Network (DSN) was used for interplanetary spacecraft; its notable characteristic was large antennae and very sensitive receivers. These stations were located around the world so that all directions in the celestial sphere were continuously in view of one of the stations. The Manned Space Flight Network (MSFN) was

established just for “manned” missions. These stations were located primarily along the ground track of early orbits launched from Florida.

By the late 1960s, NASA had about 30 ground stations around the world. In Spain, Australia, and California, one station of each of the three networks was located within a few kilometers of the other two—each independently operated and often having incompatible systems. Responding to budget reductions after the Apollo program, the agency consolidated the STADAN and MSFN facilities into the Space Tracking and Data Network (STDN). This consolidation was primarily in name, and years passed before it evolved into an integrated network. Systems and RF spectrum differences accounted for much of this delay. The ground stations slowly became more standardized, but the control centers frequently preserved their individuality. With the advent of relay satellites (see TDRSS Relay Satellites section following), NASA closed most ground stations and colocated remaining STDN facilities with the three DSN stations. The Tidbinbilla station (Fig. 1) near Canberra, Australia, is typical; the other two stations are located in California’s Mojave Desert and near Madrid, Spain.

These tracking stations were originally the focal points for executing space operations. Prepass planning was accomplished by the flight projects and the plan communicated—often via teletype messages on HF radio—to the stations. For the Mercury and Gemini missions, flight controllers were dispatched to the MSFN stations and interacted with the astronauts during the brief contact periods. As ground communications became sufficiently reliable, control was centralized in Houston for Apollo; the ground stations became remote communications and tracking terminals. The STADAN and DSN underwent similar evolution; control became real time and centralized at mission control centers as reliable communications became available.

Figure 1. NASA’s Tidbinbilla, Australia, Tracking Station is one of three that provide communication with most NASA spacecraft beyond geosynchronous orbit. Antennae are (from left) a 26-meter STDN dish built for Apollo at Honeysuckle Creek and relocated to Tidbinbilla; the 70-meter diameter DSN antenna (expanded from 64 meters); the newest, a 34-meter beam waveguide DSN dish; and the original DSN antenna, a 26-meter dish expanded to 34 meters.

The subsequent evolution of data receiving and handling methods was synergistically enabled by advances in technology, although arguably more influenced by competitive factors than by either technical performance or economics. As often happens early in the evolution of a technology, there was little reason to standardize, and various designers developed somewhat different approaches to the same basic tasks. In space operations, the spacecraft manufacturer usually determined the design of the telemetric system. Industrial participants, of course, sought competitive advantages by perpetuating proprietary concepts. Internecine battles both between and even within space agencies also inhibited standardization. Ground facilities were usually viewed as infrastructure and were funded separately from the spacecraft programs. Thus space-ground cost trades were seldom a major consideration. As a result, ground facilities must often accommodate a number of different approaches to command and telemetry. This has led to such situations as one NASA Center now using four different ways to transmit telemetric data to the ground: time division multiplex (TDM) and three different packet data formats—each requires singular ground data-handling systems.

The economic benefits of standardization are persistently apparent, and progress is slowly being made. The Consultative Committee for Space Data Systems (CCSDS) was established by the major space agencies in 1982 to promote international standardization of space data systems. In 1990, CCSDS entered into a cooperative arrangement with the International Standards Organization (ISO), and many CCSDS recommendations have now been adopted as ISO standards. The reader is referred to the CCSDS for the latest information (<http://ccsds.org>).

Tracking

Initially, “tracking” was accomplished primarily by measuring the angle of the spacecraft’s path as a function of time from ground observing stations. Both optical and RF observations were used. Optical was by tracking telescopes, and, of course, depended on favorable lighting conditions. RF tracking was passive—receiving a spacecraft beacon signal at fixed antennae on the ground and determining angles using interferometry. NASA’s STADAN system was called the Minitrack. Radars were also used—transmitting signals from ground-based antennae and observing the reflections from the satellite. Radars provided another important parameter: range. Doppler information could also provide range rate data. Primarily due to weight and power limitations, few satellites carried transponders, and radars had to rely on skin tracking. The tracking data parameters measured by most of these methods were then transferred to central facilities with highly skilled specialists and usually the latest mainframe computer systems for processing and reduction. Except for a very few critical activities such as Apollo maneuvers, orbit determination was far from a real-time process. The tracking tasks included determining where the spacecraft had been when observations were made and also predicting its future orbital path. This propagation activity requires quite sophisticated modeling of such parameters as Earth’s shape and mass distribution, solar pressures, and outgassing and

venting from the spacecraft. The Apollo USB system measured range and range rate using a pseudorandom code carried on the uplink to the spacecraft, then turned around and retransmitted to the ground on the downlink. Some programs chose a simple tone rather than a pseudorandom code. Angles were also measured but were increasingly of secondary importance relative to the range–range rate data.

Spacecraft designers are beginning to incorporate GPS receivers onboard, permitting the spacecraft to determine its own orbit and transmit the data to the ground via telemetry. One of the more precise “tracking” examples to date has been the Topex-Posidon spacecraft, where GPS was used in the differential mode to measure the spacecraft orbit to about 2 centimeters. This precision was necessary because the spacecraft orbit was the reference from which changes in sea level were determined. Corner reflective mirrors are carried on some spacecraft, permitting range to be measured quite accurately by using ground-based lasers. Many of the applications of this technique were not to determine the spacecraft orbit, but rather to measure tectonic drifts on Earth—movement of the ground station.

Differences among various concepts include different protocols for time-tagging tracking parameters. Even within the same agency, some programs chose to read all parameters at the same instant, whereas others chose to read each parameter sequentially, each had its individual time tag. Such differences were necessarily reflected in different systems for ground processing. Today much of the activity in orbit computations has been transformed from art to science, mostly executed in software. At the same time, the tools—computers—have become cheap and reliable. Commercial vendors now offer software packages that determine orbit functions using low-cost computer platforms. This, along with the use of GPS, has greatly simplified the tracking function.

Telemetry

Telemetry—literally, measuring at a distance—is the transmission of data from a spacecraft to ground facilities. This often consists of measured parameters (either analog or digital) and could relate to either the status of the spacecraft or to observations made by the spacecraft scientific instruments (often referred to as “science data”). Occasionally this telemetry is simply relayed from another source via the spacecraft, for example, emergency locator beacons from downed aircraft and meteorological measurements collected from buoys. Voice communications from people onboard a spacecraft are often handled as “telemetry.”

Telemetric systems have been used in aeronautical and space flight testing for more than 50 years. Early telemetric systems were based on analog signal transmission. These systems used frequency multiplexed/frequency modulation (FM/FM) techniques. In this technique, each sensor channel is transmitted by mixing the sensor output with a local oscillator using dual-sideband suppressed-carrier (DSBSC) amplitude modulation (AM). The outputs of each mixer are then summed and used as the input to a frequency modulator for transmission. In this technique, each of the local oscillators forming the frequency multiplexed signal need to be different and separated in frequency to keep the channel signals from overlapping in the frequency domain.

The FM/FM techniques were used in the Mercury manned spacecraft program as well as in the early, unmanned programs such as the Ranger and Lunar Orbiter spacecraft. The need for a large number of oscillators and the lack of flexibility gave way rapidly to digital techniques. For example, the Gemini program began using digital techniques after the Mercury program, and this continued on to Apollo and the Shuttle (the major exception was the real-time video data that has remained in their TV-compatible analog format). Deep space missions to the Moon and planets have also been using digital techniques for sensor data since the mid-1960s. These systems are based on pulse code modulation (PCM) for the data acquisition. The modulation techniques can be either analog frequency modulation (FM) or phase modulation (PM) or digital techniques based on phase shift keying (PSK) or frequency shift keying (FSK).

In the following sections, we will examine the basics of the data acquisition system and data encoding. Then we will look at the digital modulation techniques and finally at the error-correcting codes used in current space systems. The International Foundation for Telemetry is a nonprofit organization formed in 1964 to promote telemetry as a profession. Interested readers are referred to <http://www.telemetry.org> for further information.

Data Acquisition. Sensor data is collected within the spacecraft, and the sensor output is typically in an analog form such as a voltage or a current. The analog value is converted to a digital code word by an analog-to-digital circuit in a process called pulse code modulation. The code word takes on a value from 0 through $2^N - 1$ where N is the code word size. Typical values for N range from 8 to 16 depending upon the degree of resolution required. The sample rate is determined by the bandwidth of the underlying analog signal. By the Nyquist sampling theorem, the sensor needs to be sampled at a rate at least twice the signal bandwidth, although sample rates at least five times the signal bandwidth are often used to allow for higher quality signal reconstruction and additional signal processing. In PCM systems, one needs also to specify the data encoding method and the time multiplexing format. Data encoding determines the channel transmission characteristics, and the multiplexing format determines the signal sampling discipline.

Data Encoding. The data format for transmission represents a trade-off among occupied bandwidth, data clock recovery, and immunity to phase reversals. As part of the overall telemetric system specification, the data encoding methodology needs to be specified. Typical data formats used in space telemetry systems include

- NRZ-L: Different voltage levels are assigned for logic 0 and logic 1 values, and the voltage level does not change during the bit period.
- NRZ-M: The voltage level remains constant during the bit period, and a level change from the previous level occurs if the current data value is a logic 1; no change is made if the current data value is a logic 0.
- NRZ-S: The voltage level remains constant during the bit period, and a level change from the previous level occurs if the current data value is a logic 0; no change is made if the current data value is a logic 1.

- Bi- ϕ - L: The NRZ-L signal is modulo-2 added with the data clock to show the logic level during the first half of the bit period and its complement during the second half of the bit period.
- Bi- ϕ - M: A level change is made at the start of the bit period, and a second change is made for the second half of the bit period if the logic level is a 1.
- Bi- ϕ - S: A level change is made at the start of the bit period, and a second change is made for the second half of the bit period if the logic level is a 0.

The M and S representations are called differential waveforms and are generally considered immune to phase reversals for correct decoding. However, the NRZ-M and NRZ-S techniques suffer from a higher error rate because when a single bit error occurs during transmission, two bit errors occur upon detection. Despite this higher error rate, the phase reversal immunity is considered a greater advantage, and differential NRZ encoding is frequently used. The L representations require correct phase determination to recover the data correctly. The Bi- ϕ representations generally require twice the transmission bandwidth of the NRZ representations. However, they have better clocking capabilities. Because of this, typical space telemetry transponders will have specifications detailing the maximum number of consecutive 0 or 1 values and the minimum number of transitions in a block when NRZ coding is used.

Data Packaging. For transmission from the spacecraft to the ground station, the data needs to be packaged to allow for synchronization, error detection, and accounting of data sets. Additionally, data may need to be tagged for routing to specific analysis centers. To accomplish this, data are typically packaged into one of two formats: telemetric frames and telemetric packets.

Telemetric frames are based on time-division multiplexing of the spacecraft sensor data for transmission across the space channel. Each sensor is transmitted at least once per frame cycle; more critical data is transmitted at a higher rate. The telemetric frame is based on a highly structured format that has embedded synchronization codes and accounting information to allow quick synchronization and verification of the transmission of all data. Normally, the frames are sent continuously to keep the channel filled to maintain synchronization and detect link dropouts. If link dropouts occur, the repeating, structured pattern of the frames allows rapid receiver resynchronization once the signal returns. The IRIG-106 standard developed for missile and aeronautical telemetry is often used in the space channel as well. The frames are processed in software upon reception using a database that shows the location of each sensor value in the overall frame structure and applies any necessary calibration to convert the raw PCM code value back to a meaningful datum.

As link reliability increases, a different philosophy for data packaging can be considered. Computer networking technology developed for ground telecommunications networks has been used as the basis for developing packet telemetric systems. The advantage of the packet system over the frame-based system is that the transmission can be more easily customized to the needs of the data sources, not sending data merely to maintain a fixed sampling discipline. The packets also allow distributed data processing.

The Consultative Committee for Space Data Systems (CCSDS) packet format is based on a structure consisting of a header that contains data source and destination information and other related system information. The body of the packet contains the data. Following the data, error detection, correction codes, and other information can be added. This packet system has been successfully used on many spacecraft, and commercial vendors supply standard ground station hardware for processing CCSDS packet telemetry.

Modulation. Once the telemetric data are packaged in a frame or packet format, they are transmitted across the radio link using some form of modulation. There are a large number of permutations for radio modulation depending upon mission needs, power requirements, and data rates. In this section, we examine the basic technologies used in data transmission.

The PCM/FM and PCM/PM techniques are often used in missiles and sounding rockets even today. The technique first uses the PCM technique to sample the data. The data are encoded using one of the data formats described and are placed in telemetric frames. Finally, the baseband data is routed to the input of either a frequency modulator (FM) or phase modulator (PM) for transmission. The advantage of using FM and PM is the constant envelope signal on the output.

The PCM/PSK/PM technique is an extension of the PCM/PM technique. The PCM output is used as the input to a phase shift keying (PSK) modulator. The PSK process used is binary PSK (BPSK) modulation which is a DSBSC AM process described by

$$s(t) = \sqrt{E}d(t) \cos(\omega t), \quad (1)$$

where \sqrt{E} is the normalized signal strength, $d(t)$ is the PCM output data as a function of time, and ω is the PSK subcarrier frequency. This technique has been used, for example, in the Voyager telemetric system. The additional PM modulation step provides two advantages. First, the technique allows mixing other subcarriers with the PSK data stream to provide a total composite signal. This technique also maintains a constant transmission envelope that can be important when transmitting through nonlinear amplifiers.

The use of the PM modulator does add a degree of system complexity, so that data transmission at the PSK modulator output level is frequently used. In the PSK system, many different combinations give different efficiencies (bandwidth and performance). These PSK techniques are supported in the standard TDRSS transponder hardware.

Binary-phase shift keying (BPSK) was described before. BPSK transmits one PCM bit per channel symbol and is the simplest of the PSK techniques. It also has the lowest transmission efficiency.

Quadrature-phase shift keying (QPSK) can be considered as two orthogonal BPSK channels transmitted at the same time. The transmitted signal takes two of the PCM bits at a time and forms a single channel symbol, where the channel symbol changes state every two bit periods. The two channels are called the “in phase” or I channel and the “quadrature phase” or Q channel. There is a total of four possible carrier phase states in QPSK, where the carrier is described by

$$s(t) = \sqrt{E_i}d_i(t) \cos(\omega t) + \sqrt{E_q}d_q(t) \sin(\omega t), \quad (2)$$

where $\sqrt{E_j}$ are the normalized signal strengths, $d_i(t)$ and $d_q(t)$ are the PCM output data as a function of time, and ω is the PSK carrier frequency. In the TDRSS system, the relative I and Q channel signal strengths can be varied; typical values are 1:1 for equal strength and 1:4 for nonequal strength. These are defined by the user profile when using the TDRSS system.

The QPSK modulation technique allows the possibility that the channel symbol state can cause a 180° phase shift. This can cause undesired harmonic generation in nonlinear amplifiers. To mitigate against this, a delay is added to one of the two bits used to form the channel symbol that keeps phase changes to a maximum of 90° . This technique is called offset QPSK (OQPSK). It is also known as staggered QPSK (SQPSK). The transmitted signal is then described by

$$s(t) = \sqrt{E_i}d(t + T)_i \cos(\omega t) + \sqrt{E_q}d_q(t) \sin(\omega t), \quad (3)$$

and the variables are as described for QPSK. The delay of one bit period T is seen added to the in-phase data channel. Upon reception, a similar delay is added to the quadrature-phase channel to bring the two bits back into alignment.

In many payloads, there are two independent PCM data streams: one for health and welfare data and one for high-rate scientific data. The TDRSS system allows considering the I and Q channels as two independent data channels that have different data rates on each. This form of transmission is called unbalanced QPSK (UQPSK). This technique has the advantage that it does not send the low-rate channel at the higher data rates, thereby degrading performance. The system also has the advantage of OQPSK that it does not have frequent 180° phase shifts. The mathematical description for the carrier is the same as that given before for QPSK.

By applying waveform shaping to the I and Q data signals used in the QSPK modulation signal, a form of frequency shift keying is made. The Advanced Communications Technology Satellite used the minimum shift keying (MSK) technique. The carrier can be described by

$$s(t) = d(t)_i \cos\left(\frac{\pi t}{2T_b}\right) \cos(\omega t) + d_q(t) \sin\left(\frac{\pi t}{2T_b}\right) \sin(\omega t), \quad (4)$$

where T_b is the bit period. The data filtering functions are half-period sinusoids. This technique can be demodulated by using a coherent QPSK demodulator.

The wireless communications industry is using another form of filtered QPSK called Gaussian minimum shift keying (GMSK). Instead of sinusoidal filter functions, Gaussian-shaped filters are used to prefilter the data before mixing with the carrier. The MSK techniques are being examined because of their transmission bandwidth efficiency compared with QPSK. A related, patented form of filtered QPSK developed by Feher is currently being evaluated for telemetric systems. This FQPSK modulation system uses proprietary filter functions in a manner similar to GMSK. Preliminary results indicate that it has an improved spectral efficiency for data transmission. Tests are currently being conducted within NASA and the U.S. DoD to evaluate this technique for ground and space telemetric systems.

Data Transmission. Several techniques are used for transmitting this modulated RF signal from a spacecraft to the ground. The original, and still most

common, method is direct transmission to receiving antennae on the ground. These transmissions may be initiated by ground command or instructions stored onboard or may be broadcast continuously. Signals are usually directed to specific TT&C stations, although transmission of some types of meteorological data, for example, is simply broadcast to all interested users. For weak signals, ground antennae are occasionally arrayed to provide increased gain.

Another technique increasingly used is relay through another satellite, usually one in geosynchronous orbit (see TDRSS section following). This technique involves a space-to-space cross-link in addition to the relay-sat-to-ground link, but it offers several advantages. Communications with Earth-orbiting satellites are possible almost any time, any place. (Depending on specific geometry, some limitations may exist in polar regions.) This avoids the need for a large network of ground stations. Such ground networks are usually expensive to build and operate and are subject to disruption due to local political and environmental conditions. It also centralizes the point of data reception on the ground, avoiding the need for subsequent terrestrial relay. Although cross-links can present some technological challenges, they also offer freedom from interference and interception.

Like the evolution of tracking data handling described before—and for similar reasons—telemetric data is usually transferred from the ground receiving station to a central facility for processing. Even though the telemetric data rates of today are greatly increased, economical hardware exists to perform much of this processing in a “black box” in real time at the ground station. However, as will be discussed under Future Trends, other factors limit this evolution.

The characteristics of the transmission medium and path are different in the space-to-ground link and in the terrestrial link from the ground station back to the control and central data handling centers. Although the latter was sometimes HF radio in very early days, it is normally satellite or coax/fiber today. These differences reflect directly that the “best” protocols for the terrestrial link are different from those for the space-to-ground link. Thus, the ground receiving station is required either to reformat the data, or commonly, encapsulate the first protocol into the second, increasing overhead.

As the Internet has grown, considerable interest is developing in using standard Internet data protocols (Transmission Control Protocol/Internet Protocol, TCP/IP) in spacecraft. This is still a research area, but there is considerable interest among scientific investigators and systems designers in providing Internet-to-space support. The ground-based TCP/IP protocols have some recognized difficulties in the space environment. For example, the long link delays and relatively high channel error rates lower the throughput of these protocols. To mitigate against these effects, research is currently ongoing into modifications of TCP/IP for space. Progress is also being made within CCSDS to develop the Space Communications Protocol System (SCPS) that is based on the TCP/IP protocol stack but modified for use in the space channel environment.

As part of the long-term trend for space communications, system designers are investigating the application of commercial telecommunications technology to space communications. This emphasis comes from two drivers: the need to reduce system cost and the need to use system bandwidth better. By using commercial telecommunications satellites and associated ground networks, spacecraft operating costs can be reduced because infrastructure costs may be

shared with commercial users. The need to use more efficient modulation techniques has led system designers to consider techniques used in the wireless industry. Modulation techniques such as GMSK and FQPSK were designed for the commercial wireless communications industry. The FQPSK technique is currently being evaluated within the U.S. Department of Defense for use in missile and aeronautical telemetry. Their relatively higher bandwidth efficiency over PSK methods makes them good candidates for use in constrained-bandwidth environments for space as well.

Data Processing. Telemetry was originally processed in decommutators that were essentially giant patch panels, reconfigured for each spacecraft. As computing power grew, processing was accomplished using software in mainframe computers. (Like IBM, many space pioneers found it difficult to advance beyond this stage.) The next step was use of application-specific integrated circuit (ASIC) technology. As ASIC technologies became practical, they proved much more efficient for repetitive processes such as telemetric processing than general purpose machines controlled by software. Also, processing in chips rather than mainframes permitted substantial increases in throughput telemetric rates, avoiding the need for expensive buffering to reduce processing rates. (They also proved considerably more reliable because most operating failures were in the connections.) The current state of the art is to use programmable gate arrays—combining the speed of a hardware approach with the flexibility of a software solution. Numerous vendors now offer such products.

Processing of data is often broken down into four levels: Level 0 through Level 3. Though the Level 0 step is still common, it is primarily an artifact of reel type onboard data recorders. Data were recorded serially onboard onto a recorder for playback (dump) to a ground station when one was in view. This data was then usually dumped with a reverse playback—avoiding the need to rewind and cue the recorder. The Level 0 function is to remove the space-to-ground transmission protocols, restore the reversed data stream to its original direction, and separate the various multiplexed parameters into their original components. Level 1 data processing involves appending axillary data from other sources, such as orbit and attitude data. Levels 2 and 3 processing require active involvement and judgment of the scientists in analyzing and presenting the data. Levels 1 through 3 are normally considered part of scientific data processing rather than the ground data-handling function.

The solid-state recorders increasingly used on spacecraft today, of course, do not need to be dumped in the reverse direction. Second, data can be read out of the recorder in any desired sequence, obviating the need to demultiplex a serial data stream on the ground. Third, using economical hardware and relatively simple software, space-to-ground protocols can be stripped and data reformatted for terrestrial transmission in realtime, even at 100-Mbps rates. This effectively obviates the need for Level 0 processing. Using GPS for onboard orbit determination, as described earlier, similarly obviates this Level 1 step.

Error-Correction Coding

Error-correcting coding has been studied by theorists since Shannon's work in the late 1940s. Error-correcting coding techniques became widely used in space

communications in the 1970s with the advent of good techniques by Viterbi and Fano for decoding convolutional codes. Current data services used with NASA's Deep Space Network and the TDRSS network permit the user to select from standard error-correction coding techniques.

Forward Error-Correcting Codes. Transmission over the space channel introduces errors into the data stream. The goal for space-to-ground transmission accuracy for most telemetric data has historically been a bit error rate (BER) of 10^{-5} , or no more than one error in 100,000 bits. (For comparison, coax and fiber generally deliver data at BERs better than 10^{-10} .) Two basic techniques are used for recovery: request a retransmission of the data, or add an error-correcting code to the data. On missions that have long propagative delays, requesting retransmissions often reduces the data throughput to unacceptably low levels. Thus the error-correction technique is usually preferred because it requires less memory and processing capabilities on the spacecraft.

Here, we discuss the two common error-correcting coding techniques used in space systems. They permit correction of the data upon reception, so they are called forward error-correcting (FEC) techniques. They accomplish this task by adding redundant information to the transmitted data. This implies that a higher transmission rate is needed and consequently more transmission bandwidth to achieve the same raw data throughput. This is considered acceptable when achieving a much higher data quality. The FEC can permit the system to operate as if it had a 3- to 6-dB higher received signal-to-noise ratio that it actually has—a significant benefit.

The FEC that has the longest history in space communications has been convolutional coding. This has been used on missions since the 1970s and even for deep space missions like Voyager. The convolutional encoder is built around a fixed-length shift register whose length is known as the constraint length K . Once each bit time, a new data bit enters the shift register, and multiple outputs are computed as a function of the current shift register contents. Typically two or three outputs are generated for each bit time, giving rise to a rate one-half or rate one-third coding. A Viterbi decoder is used to decode the data and correct for transmission errors. NASA requires that all S-band services on TDRSS use a rate one-half convolutional encoder. Typically the constraint length is $K=7$. TDRSS also supports the rate one-third coding, but it is not part of the CCSDS recommendations.

The Reed–Solomon coding technique is a form of block coding where the data stream is partitioned into fixed-length blocks and redundant information is added to the end of the block to form the transmitted signal. Reed–Solomon block coding is characterized by the number of information symbols and the number of code symbols in a transmitted block. The CCSDS recommends Reed–Solomon encoding using transmitted blocks of 255 total symbols that have 223 information symbols in the block. This is written as a (255,223) R–S code.

The CCSDS standards recommend using Reed–Solomon codes either by themselves or in conjunction with convolutional codes, as discussed in the following section. The TDRSS does not support Reed–Solomon decoding as a basic service but will pass encoded data to the user for decoding. Reed–Solomon codes can be used without convolutional coding through TDRSS if Ku-band services are being used, but not in the S-band services.

Concatenated Coding. It is known that the output of the Viterbi decoder produces errors in a burst pattern. To compensate for this, missions can use a concatenated coding technique. First, a Reed–Solomon code is applied to the data stream to form what is known as the “outer code.” These coded data are then encoded with a convolutional or “inner code.” The convolutional code removes the bulk of the channel transmission errors, and the Reed–Solomon code removes the burst errors from the convolutional decoder. The CCSDS recommendation for concatenated coding is to use a (255,223) R–S outer code with a rate one-half, $K=7$ convolutional inner code.

A recently discovered coding technique called turbo codes has begun to be seriously investigated for application in space communications. These codes were first published in 1993. They have the advantage of providing performance near the Shannon limit for channel performance, even at low signal-to-noise ratios. Recent experiments have shown cases with TDRSS where the ground station receivers could not lock onto the signal in low SNR environments even though the symbol decoding was still functioning. Turbo codes are based on convolutional codes on the encoding side and are decoded using iterative solution techniques in the receiver. Current research involves determining optimal code structures and decoding techniques for use in the space channel.

Command

Command is essentially the reverse of telemetry: digital data is modulated in one of several ways on the uplink carrier. Basic differences are that data rates are much lower, and transmission integrity is usually more critical because these data normally control the spacecraft. The command system generally can be thought of as providing instructions for the onboard spacecraft systems to initiate some action. Two classes of command strategies are commonly used in modern spacecraft: single command words and command files. Many early spacecraft command systems were basically tone response systems, that is, when a given tone of a specific frequency was received by the spacecraft, a specific action was undertaken. Tone commands are still often found in rocket command destruct systems.

CCSDS has published standards used by many programs. Differences are primarily in the intermediate transmission path between the originating control facility and actual transmission from the RF transmitter. Some concepts transmit the command message directly from the control center in “real time,” whereas others stage it at intermediate points such as the remote ground station. In the latter case, it is error checked and stored at this intermediate location, awaiting a transmit instruction either as a function of time or on electronic or verbal instruction from the control center. A “command echo” is frequently used for verification: a receiver at the ground antenna detects the command on the RF link, which is returned to the control center for comparison with the intended command structure. The term “command” is often used to describe all signals modulated on the uplink signal; however, such uplinks can include both analog and digital voice communications with astronauts, and video uses are planned in the future.

The command word will typically look like a binary computer instruction that has a system address, command instruction number, and command data value. Sometimes the command will use a simple check sum for error detection. Other error check strategies that have been used in spacecraft include repeating the command bits twice and then performing a bit-wise check for agreement before executing. In all cases, the command received word would be echoed in the telemetric data stream as a specific telemetric word, so that the operator could check for command validity. The spacecraft would be configured for two possible modes of command acceptance: execute the command upon passing the received error check, or wait until a ground operator sends an execute command after verifying that the operational command was correctly received. In operations, routine commands would be executed immediately upon passing error validation. Commands that could be dangerous for spacecraft operations, for example, firing a thruster or exploding pyrotechnic bolts, would have the operator in the loop. The operator would wait for the configuration command to be correctly echoed in telemetry and then would send the execute command to initiate the actual operation.

Command files are more appropriate for sequences of operations, especially those for a spacecraft beyond Earth orbit. For example, the Voyager planetary encounters would operate by loading a file of command sequences for camera settings and spacecraft attitude before the encounter where the communication times could be in excess of hours. The operators would verify that the file had been loaded into the spacecraft memory by playing back the memory through the telemetric stream. Any transmission errors could be corrected before the encounter, and then the spacecraft would operate in automatic mode, without immediate operator interaction, during the encounter. The structure of the commands within the files can resemble those found in the individual command mode. The file organizes the commands for bulk transmission.

All of the modulation and coding techniques used for telemetric transmission apply to command transmission as well. In general, very sophisticated FEC is not done because of onboard processing limitations. However, parity checks or check sums are often used to identify command errors. For low Earth orbit (LEO) operations, repeating commands that are found in error is often sufficient.

TDRSS Relay Satellites

In the mid 1970s, NASA began developing a communications and tracking network in space—the Tracking and Data Relay Satellite System (TDRSS). The basic concept was demonstrated during the Apollo Soyuz Test Project mission using the Applications Technology Satellite ATS-6. By using the relay satellite concept, communications with a fixed ground station for LEO satellites can be increased from 5 to 10 minutes per contact at a fixed ground station to more than 85% of the total orbit time. (The TDRSS concept used a single ground station that had two active relay satellites located above the horizon of this station. This resulted in a “zone of exclusion” on the opposite side of Earth that had no coverage. This ZOE region was later covered by another relay satellite, using a

second ground station, to meet the needs of the CGRO satellite, and increased TDRSS coverage to 100%.)

TDRSS was first seen as just another station of the STDN, except that it was located in the sky. However, technical differences such as signal levels and Doppler rates made it clearly a very different kind of station. The primary motivation for building TDRSS was economic, more for cost avoidance than cost reduction. Costs of upgrading the STDN to meet Space Shuttle needs, it was estimated, would be more than the cost of developing and deploying a relay satellite system. A second consideration was political; operations at ground facilities on foreign territory were disrupted several times by political disputes. The first TDRSS satellite was launched in April 1983. It was stranded halfway to geosynchronous altitude by an explosion of its upper stage rocket, but by using its tiny maneuvering thrusters, eventually it reached its operational location over the Atlantic that summer. Launching the second satellite was the objective of the ill-fated Challenger mission in January 1986. Completing the TDRSS constellation was a high priority because so many new programs depended on it. Thus, the third satellite was aboard Discovery in September 1988 on the first Shuttle mission after Challenger. It was completely successful; four more spacecraft have since been successfully launched.

From technical and performance standpoints, TDRSS has proven outstanding. In addition to supporting users at standard S-band frequencies, TDRSS provides a high-frequency service in the Ku-band region and commercial service at C-band. (This commercial service was added by the spacecraft contractor to spread the costs of the satellites and thus reduce costs.) This complex system has demonstrated its ability to relay data at more than 400 megabits per second from user spacecraft virtually anywhere over Earth. Each relay satellite can communicate with two high-rate users simultaneously, and the system can handle an additional 20 low-rate users. This low-rate system—termed multiple access—was one of the first systems to successfully use code division multiple access (CDMA) techniques that permit multiple users to share the same radio spectrum and is now employed in some cellular phone systems. TDRSS provides more than six times the global coverage of the ground network it replaced, at data rates six times as high. It enables real-time contact virtually anytime, anywhere—an especially valuable feature of the relay satellite approach. It also has unanticipated applicability to small systems and has been successfully used with high-altitude balloons, with aircraft to relay real-time infrared images for forest fire fighting, and with handheld transmitters for voice and data.

A fixed price procurement approach was selected even though extensive development was needed, and NASA became directly responsible for launching the satellites. Thus, substantial government–industry cooperation was required in the face of a somewhat adversarial contractual relationship. Another significant challenge was that of dealing with two distinctly different cultures: a communications industry accustomed to a highly regulated environment and the engineering focused aerospace industry. The difficulties were more complex than can be summarized here; interested readers are referred to Aller, R.O. *Issues in NASA Program and Project Management*. From a program perspective, the TDRSS system was deployed late and cost more than original estimates. Even so, the cost of

Figure 2. Second generation of NASA's TDRSS spacecraft, used for tracking and communications with most near-Earth-orbiting spacecraft. From geosynchronous orbit, the two large movable antennae each provide communication at high data rates with spacecraft far below. A phased array antenna on the Earth-facing panel permits simultaneous communications with 20 users at lower data rates. The small dish antenna relays signals to/from the ground control station in New Mexico.

augmenting the STDN for the Shuttle was avoided, and closing most of the STDN in the 1980s and shifting to TDRSS actually reduced costs. Amortized development and launch costs plus operating expenses of the TDRSS are less than the operating costs alone would have been for the ground network it replaced.

NASA procured three follow-on TDRSS spacecraft in the mid-1990s. Hughes (now Boeing) won the competition with a design based on its HS-601 bus. An artist's rendition of this design is shown in Fig. 2. The first of this series was successfully launched in 2000.

Radio-Frequency Spectrum Issues

By the nature of space operations, "wireless" communications links are necessary. Thus ground data-receiving facilities are strongly influenced by radio spectrum issues. The International Telecommunication Union (ITU) was established in 1865 (as the International Telegraph Union). The ITU is now under the United Nations and endeavors to coordinate radio spectrum use internationally. Radio waves have no respect for political boundaries, so this coordination has become critical. As transmitters and receivers moved from terrestrial locations into the air and then into space, signals radiate far more of Earth. As the private sector sought to capitalize on the economic potential of freedom from "wires" that technology subsequently enabled, extreme pressures have developed for spectrum allocations. This stage and the extremely rapid development of associated technologies presented an especially vital but difficult challenge to the somewhat cumbersome ITU processes. Not surprisingly, these pressures have focused on

the lower frequencies. Technology is more proven in this region, and signal characteristics such as power, directionality, and interference favor this region for widespread commercial use. Because wave-lengths are longer, hardware manufacturing tolerances are also less critical and costs are reduced.

For largely these same reasons, space activities initially operated in the lower frequency regions, primarily the VHF region. However, factors such as interference from other RF users in this region and the need for greater bandwidth slowly drove space programs to vacate this region in favor of higher frequencies. NASA chose the S-band region, transmitting uplinks near 2100 MHz using downlinks above 2200 MHz. Some other U.S. agencies elected to downlink at these same frequencies, but to transmit at lower frequencies (L-band, near 1700 MHz). This S-band spectrum was originally allocated internationally for space use in a footnote to the allocations table, specifically noting that such use was permitted on a secondary basis. This secondary allocation meant that use must not interfere with the use of this spectrum by those holding primary allocations and that conversely, holders of secondary allocations had no recourse if primary users interfered with them. Interestingly, this applied to programs such as NASA's Apollo and Space Shuttle programs: their primary operating frequency was authorized only as a secondary allocation, legally subject to these previously stated constraints. (Note that deployment of the TDRSS relay satellite had an interesting effect on this situation because TDRSS transmits downward to low Earth-orbiting satellites at the normal uplink frequency and conversely, receives signals transmitted upward at the downlink frequency.)

This intense competition for spectrum, together with need for additional bandwidth and desire for primary allocations, is driving space programs to adopt higher frequencies—mostly in the Ku and Ka-band regions. Initial use of optical frequencies is also being considered. Technologies for these higher frequencies is not as mature as those for lower frequencies, but they do offer advantages in bandwidth and in the power and weight of communications terminals in space. Disadvantages, in addition to less mature technologies, include the need for high pointing precision of antennae and susceptibility to atmospheric interference, especially rain and clouds. Certainly, costs of necessary modifications to the ground infrastructure inhibit these moves to higher frequencies.

Future Trends

As has been said, predictions are difficult, especially about the future! Tempting as it is to focus on the evolution of relevant technologies as the indicator of future trends, history suggests that sociological factors soon dominate technology and economics. Recall that for years after technology replaced the steam locomotive with diesel power, railroads retained firemen even though they no longer had boilers to stoke! Early TT&C facilities had the characteristics of "infrastructure," and infrastructures are especially adept at self-preservation, aided by the detachment from their customers. We will attempt to place data-receiving and data-handling facilities in the context of the historical evolution of technology and from this perspective identify factors determining trends. Finally, we will hazard some guesses about near-term trends.

Typically a technology evolves from an era of a few specialists proficient in using it, through one where the process becomes increasingly understood, standardized, and automated, so that necessary expertise and skill levels drop. Eventually tools become available that those unskilled in this particular technology can readily use to meet their needs. Entrepreneurs see market potential and derive new, more efficient products and processes by employing the technology. However, progress is frequently intermittent as other factors come into play. Those finding careers, organizations, and profits threatened summon political and industrial support to resist change, and efforts at standardization are soon caught up in competitive battlegrounds. Note that much of the early effort necessarily involved “inventing” the needed data-receiving and data-handling facilities. The entities formed for this purpose specialized in designing, rather than using, solutions. Once created, these entities usually strive to reinvent custom solutions for each application, rather than using or adapting existing alternatives.

Technologies that existed early in the space age determined the technical approaches for meeting satellite communications and data-handling requirements, and more importantly, they also determined the structure of the organizations and processes for meeting these requirements. Yet, technology seldom conveniently evolves within the boundaries of established management and fiscal structures. Matters that should be simple engineering issues whose solutions are submerged in silicone, for example, instead become contentious interorganizational issues. Few comprehend the technical implications as technology expands across borders, and interpersonal relationships—influenced by individual, provincial, and fiscal interests—dominate resolution.

The result of this confluence of technological, sociological, and political realities is that future trends are dominated by the heritage of the particular organization. New players usually adopt the latest economical technology and employ commercially available solutions when they enter the arena; thereafter they become increasingly bound by their own heritage. The pace and direction of technology limit advancement, but they are only two factors determining future directions. Implicit in this hypothesis is the view that few of the concepts and facilities commonly used today for receiving and handling space data from satellites are state of the art. Prudent conservatism is certainly warranted. Challenges of adopting state-of-the-art technologies are that performance risks are often increased due to immature development, costs are usually relatively high in the early stages, and amortization of changeover costs is difficult to justify. However, if a truly competitive marketplace develops using a given technology, this usually stimulates the private sector to evaluate objectively the economics of advances in that technology.

Although the expanding technologies of communications and computing are often said to be converging, semantics must be understood. Many of the recent advances in communications result from computing advances: the ability, effectively and economically, to digitize, package, route, and unpack material being moved. Transmitter and receiver advances, especially at higher RF frequencies as well as optical, contribute directly to space operations. (Other communications technology advances such as fiber are very significant, of course, but are not directly applicable to space-to-ground communications.) Considering the

computing aspect, approaches that combine the speed of a hardware approach with the flexibility of a software solution, as now offered by programmable gate arrays, will become dominant. Chip technology offers tremendous increases in processing speed over the old mainframe approach, due in part to the small dimensions.

Other prognostications: space programs will rely increasingly on navigation satellites (GPS, Glonass, Galileosat) to determine orbit onboard. A TCP/IP-like transmission protocol such as SCPS, adapting to the space channel environment, will probably become popular. Use of embedded chips at the points of application greatly streamline data processing, allowing eliminating some previously required no-value added steps such as transport to centralized facilities. Techniques such as turbo codes that promise to perform near the Shannon limit, even under low signal-to-noise ratio conditions, will be pursued. Constraints on spectrum and bandwidth will focus attention on more efficient modulation techniques, such as FQPSK. Spectrum competition and the need for additional bandwidth are also driving space programs to higher frequencies—mostly in the Ku- and Ka-band regions. Optical transmission will become a serious contender for the space-to-ground channel—circumventing RF spectrum restrictions, avoiding RF interference, and permitting increased security. Technology is improving the power limitations of light transmitting diodes, and spatial diversity (multiple receiving sites) will avoid cloud cover. Adoption of customized commercial hardware and software solutions in preference to unique solutions will greatly increase, especially among new users. Even noncommercial users will gravitate in this direction. Numerous, mostly small, vendors now offer space operations products commercially and competitively.

EASTERN LAUNCH FACILITIES, KENNEDY SPACE CENTER

Introduction

The Eastern Test Range (ETR) is the familiar designation of a group of bases, facilities, and installations that support space vehicle launches from Cape Canaveral Air Station (CCAS) and the Kennedy Space Center (KSC) and ballistic missile test launches from or near the Cape Canaveral Air Station. It is operated by the United States Air Force's 45th Space Wing, which provides services to itself as a launch agency as well as to the other Government and private agencies that use the launch bases at Cape Canaveral and KSC. The expression "familiar designation" is used because the current official designation of the Range is simply the Eastern Range (ER). However, the term "ETR" is probably used more frequently than "ER." The Kennedy Space Center is the popular name of the National Aeronautics and Space Administration (NASA) launch installation on Merritt Island as well as the name of the NASA center that manages and operates it. The formal designation of the center is the John F. Kennedy Space Center, NASA.

Eastern Test Range

The ETR, or "The Range" as it is often called, extends from the Atlantic Coast of central Florida, including the well-known Cape Canaveral launch base and its Headquarters about 20 miles south at Patrick Air Force Base, southeast along the Bahamas, the West Indies, and on to Ascension Island in the South Atlantic Ocean. Recently, bases in Bermuda and Newfoundland have been added to support launches that have more northerly azimuths.

Patrick Air Force Base serves as the administrative center of the ETR and functions also as a data processing facility and as the location for some instrumentation such as radars and telemetry antennae that benefit from a different perspective of the vehicles in the early launch phase. Patrick also has an operating airfield that serves as a home base for both fixed-wing planes and helicopters supporting launches.

History. In 1946, after the end of World War II, a committee, established to determine the site of a long-range proving ground for missiles, chose Cape Canaveral, Florida, as the launch base. Actually, the Cape Canaveral site was the group's second choice. The preferred site was El Centro, California, whose range was down the Gulf of California along the coast of Baja California. This site had several advantages, including more predictable weather and the proximity to many of the American aerospace contractors. However, the government of Mexico refused to allow overflights of Baja California. Flight along the coasts of the Bahamas from Cape Canaveral was acceptable to the British government, which then controlled the Bahamas. A third candidate, in northern Washington State that had a range along the Aleutian Islands, was rejected for reasons of weather and remote location (1).

Cape Canaveral, even as a second choice, had many advantages, both technical and administrative. As shown in Fig. 1, the area was located on a promontory extending into the Atlantic Ocean and was not near any large population centers. It would allow launch over open water but still near enough to a number of islands that could support instrumentation for tracking the missiles.

In retrospect, the Cape Canaveral option proved exceptional in a way only visionaries at the time could have foreseen. When the Space Age dawned, the easterly launch azimuth presented the designers of space launch vehicle with an additional velocity contributed by the Earth's rotational velocity. El Centro whose launch azimuth was approximately south would not have had this

Figure 1. This map shows the location of Cape Canaveral on the east with respect to other Florida locations such as Tampa Bay on the west. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

advantage, and the Aleutian range that had a generally westerly azimuth would have had the penalty of having to provide additional velocity to compensate for the Earth's rotational velocity. A secondary advantage of Cape Canaveral was its lower latitude, a consideration that became important only after the advent of geosynchronous satellites. Of course, the eventual need for polar orbiting satellites would necessitate establishing a West Coast launch base that could safely accommodate southerly launch azimuths. Interestingly, when this need was recognized, the choice of such a base was not El Centro, but the area now known as Vandenberg Air Force Base in California.

The new range would be a joint project of the Air Force, the Army, and the Navy under the management of the Air Force. In the course of its history, there would be several changes of name, both of the Range itself and the military organizations managing it. The managing organizations included Advance Headquarters, Joint Long Range Proving Ground; Headquarters, Long Range Proving Ground Division; Headquarters, Air Force Missile Test Center (AFMTC); Headquarters, Air Force Eastern Test Range (AFETR); Detachment 1 SAMTEC, ETR; Headquarters, Eastern Space and Missile Center (ESMC); and finally in 1991, 45th Space Wing. The Installation would also undergo a number of different designations starting with Bahamas Long Range Proving Ground, Long Range Proving Ground, and proceeding through Florida Missile Test Range, Atlantic Missile Range, and Eastern Test Range to the present title of simply Eastern Range. There were good and sufficient reasons for the changing terminology, but the basic mission of the establishment remained substantially the same as always. Some variations were necessitated by the changes of clientele from aerodynamic missiles to ballistic missiles, and to the current situation where most of the customers are involved in launching spacecraft into Earth orbit.

After sufficient preliminary work had been accomplished, the new range was ready for its first launch, which, ironically, was not one of the aerodynamic missiles for which it had been designed. On 24 June 1950, a vehicle called Bumper, a two-stage vehicle consisting of a captured German V-2 as a first stage and a liquid propellant WAC Corporal as a second stage, was launched from Complex 3. The launch, historic though it was, was not a success; the vehicle was destroyed by Range Safety. Less than a week later, a second Bumper was launched but it was not a complete success (2). Although the launches did not meet their mission objectives, there were some positive results. The launch complex was validated, the tracking devices worked, and the capability of Range Safety to destroy a potentially dangerous missile was proven.

During the next several years, many different missile projects were launched and tested at the Cape. Early projects included Lark, Matador, Mace, Snark, Bomarc, and Navajo. The Eastern Range was also the launch and test site for the Redstone, Jupiter, Thor, Polaris, Poseidon, Trident, Atlas, Titan, and Minuteman missile systems.

The coming of space vehicles was signaled by the selection of the Vanguard Earth Satellite Project which was intended to launch at least one instrumented satellite into Earth orbit as part of the U.S. contribution to the International Geophysical Year in 1957 and 1958. The Navy was selected to manage this program based partly on the Naval Research Laboratory's experience with the

Viking sounding rocket and its associated scientific payloads. Although it was assigned to the Navy, it was an essentially civilian project that would not interfere with the Department of Defense military missile projects and did not carry the high priorities assigned to those projects. After the Soviet Union launched Sputniks 1 and 2 in October and November 1957, before Vanguard had attempted to launch a full-up vehicle, the Army was directed to proceed with preparations to launch a vehicle that would add a fourth stage to the Jupiter-C and attach to the stage a small scientific satellite. After the first Vanguard attempt to orbit a satellite failed in December 1957, the Army team launched the first U.S. satellite, Explorer 1, on 31 January 1958. Second attempts by both the Vanguard and Jupiter-C teams failed in February and March, before the first Vanguard success, Vanguard 1, on 17 March 1958.

The creation of NASA in October 1958 added a new presence to the Range. Immediately, the only discernible difference was the transfer of the Vanguard Project to the new agency, but soon a NASA Atlantic Missile Range Operations Office (AMROO) was established to represent NASA interests at the Range. The new NASA projects leaned heavily on the military IRBMs and ICBMs. The Delta (sometimes called Thor-Delta) was a further adaptation of the Vanguard upper stages that had the Thor as a first stage and was designed to place a variety of scientific and applications payloads into Earth orbit. NASA used a new Air Force launch vehicle, called the Atlas Agena that used the Atlas as a first stage and a new hypergolic propellant upper stage called Agena for many of its early lunar and planetary missions. The versatile Agena was also used as the upper stage for the Thor and the Titan at Vandenberg Air Force Base, but only Atlas Agena vehicles were launched from the ETR. The capability of the Atlas to place payloads into orbit without an upper stage allowed using it in NASA's first manned space program, the well-known Mercury project. Interestingly, the early space launches followed the pattern of the aerodynamic missiles and the succeeding ballistic missiles in suffering many failures, either of the launch vehicle or of the payload after a successful launch, in the early days of spaceflight.

The next logical step in spaceflight, after demonstration of the achievability and usefulness of space as a scientific and applications medium, was the introduction of the human into the space arena as a part of the mission aloft, rather than as a ground-based operator. The first of these to impact the Range was Project Mercury, a program designed to demonstrate that humans could successfully operate in space and be safely returned to Earth. Seven suborbital flights of spacecraft without astronauts aboard were conducted using both the Redstone and the Atlas as launchers between September 1959 and March 1961. Two successful flights and one unsuccessful flight were flown aboard Atlas, and three successes and one failure were experienced with the Redstone. One suborbital launch, Mercury Redstone 2 (MR-2), carried as a passenger a chimpanzee nicknamed "Ham" and resulted in a successful flight and recovery on 31 January 1961, the third anniversary of the launching of Explorer 1.

The Mercury and Gemini Programs. On 5 May 1961, Astronaut Alan Shepard was launched on a Mercury Redstone 3 rocket to a range of 260 nautical miles with subsequent successful recovery of the pilot and the spacecraft Freedom 7. On 21 July of the same year, Astronaut Virgil Grissom

made a similar flight aboard the spacecraft Liberty 7, although the spacecraft was not recovered.

Even before the Shepard and Grissom suborbital flights, an unsuccessful flight of an unmanned spacecraft on Mercury Atlas 3 occurred, followed by the successful flight of Mercury Atlas 4, also unmanned, on 13 September 1961. The next Mercury Atlas flight on 29 November 1961 carried the chimpanzee called "Enos" into a planned three-orbit flight with successful deorbiting and recovery of both the passenger and the spacecraft, although the flight was shortened to two orbits because of some flight anomalies. The program was now ready for the manned orbital phase that consisted of four flights of increasing duration. All resulted in successful flights and recoveries, though not without some anomalies and difficulties.

Astronaut John Glenn became America's first man in orbit aboard Friendship 7 launched into a three-orbit mission and successful recovery on 20 February 1962 by Mercury Atlas 6. Astronaut Scott Carpenter in Aurora 7 followed on 24 May 1962 on another three-orbit mission marred by an overshoot of the intended landing area by several hundred miles. On October 3, Astronaut Walter Schirra in his Sigma 7 spacecraft flew a successful six-orbit flight with subsequent successful landing and recovery. The Mercury program concluded on 16 May 1963, when Astronaut Gordon Cooper in Faith 7 spacecraft splashed down safely after a flight of 22 orbits of the earth, 34 hours and 20 minutes after lifting off from Complex 14 aboard Mercury Atlas 9 (3).

The next step in the manned programs was the Gemini Project, which would demonstrate the capability to rendezvous and dock in space, as well as amassing more experience on manned flight to achieve longer time in orbit and at higher altitudes. The program, as indicated from its name (the name of the constellation Gemini translates to The Twins), would use a two-person spacecraft and an Agena stage, called the target vehicle, modified to achieve multiple restarts and equipped with a docking adapter, by which the Gemini and the target vehicle would be physically attached. The Gemini were boosted by a modified Titan II launch vehicle from Complex 19. The target vehicles were boosted by Atlas Agena vehicles launched from Complex 14, the same complex that was the site of the orbital Mercury launches. On 14 April 1964, less than a year after the last Mercury launch, Gemini 1, an unmanned spacecraft, was launched successfully into orbit. On 19 January 1965, a suborbital mission called Gemini 2 was also successful. Between March and August of that year, three manned flights were successfully carried out in which the number of orbits was increased from three to 120 and the apogee was increased from 121 to 188 nautical miles. The next mission was to demonstrate actual rendezvous and docking with the target vehicle, but the Agena malfunctioned and did not achieve orbit. An alternate mission involving rendezvous of two Gemini spacecraft was substituted, and the program continued while the Agena problems were addressed and solved. The program, which ran through November 1966, ultimately achieved rendezvous on that mission and on five additional missions and achieved docking with the target vehicle on four. There were difficulties with the Gemini spacecraft itself on one mission and both the target vehicle and a substitute on another, but the final three missions were all successful in rendezvous and docking and included some extravehicular activity (EVA) on all three (4).

The Eastern Range Facilities

Cape Canaveral Air Station. The heart of the ER and its predecessors is, of course, the launching area itself; without it there would be no requirement for the remainder of the ER, but it would not carry out its mission without the rest of the ER. In its own history, it has undergone a number of name changes. Originally designated as Operating Sub-Division 1, it was redesignated as Cape Canaveral Auxiliary Air Force Base in 1951, Cape Canaveral Missile Test Annex in 1955, Cape Kennedy Air Force Station in 1964, Cape Canaveral Air Force Station in 1974, and Cape Canaveral Air Station (CCAS) in 1990. Throughout all of the nomenclature machinations, the basic mission did not change, and the area was familiarly known as “The Cape.”

Launch Complexes. If the *raison d'être* for the ETR is the Cape, then the reason for the existence of the CCAS is the collection of the launch complexes located there. Typically, a launch complex consists of a launch pad, a service structure, an umbilical mast or structure, and a launch control center.

The launch pad is the platform on which the missile rests during launch preparations and from which it is actually launched. This platform contains a multiplicity of connections to the vehicle. Fluid connections and the necessary controls are included to load propellants into the vehicle and to unload in case of a launch delay or at the conclusion of a servicing or “tanking” test. Pneumatic connections are included to allow loading gases used as pressurants or in small control devices. There are also electrical connections that allow controlling vehicle functions remotely during launch preparations and instrumentation connections for monitoring the state of the vehicle and pad systems.

The service structure, variously and familiarly known as a gantry or a tower, gives workers access to the vehicle during launch preparations and can be of assistance in positioning and assembling the vehicle on the launch pad. Typically this structure has a number of platforms that allow circumferential and vertical access to the assembled vehicle. Necessarily, the service structure must be removed to a safe distance for the actual launch, so many of these platforms must either fold or retract to allow movement of the structure. Most service structures are mounted on railroad type wheels that allow movement to the retired positions on permanent tracks. Some projects have used service structures that can be rotated from the vertical to the horizontal to the vertical for assembling the vehicle, serve as a series of work platforms for prelaunch activities, and then rotate from the vertical to the horizontal before final launch preparations.

Some functions, which for reasons of accessibility cannot be routed through the launch platform, must be maintained even after the service structure has been retired or rotated away from the vehicle. These are typically accomplished by a connection on a mast that remains near the vehicle even after the service structure is withdrawn. These are generally referred to as “umbilical” masts or towers. The connections are severed either by movement of the vehicle at liftoff or by a mechanism on the mast itself, which senses liftoff and initiates disconnect. Originally, umbilical masts were rather flimsily constructed and had to be replaced after each launch. Recent improvement in materials and design have made possible permanent umbilical towers that require minimum refurbishment after each launch.

The launch control center, commonly called the blockhouse, was generally a heavily reinforced structure from which most prelaunch launch operations were supervised and from which the launch crew directed the actual launch. It provided a safe environment for the launch crew to direct operations during final launch and during other hazardous operations.

Other installations on a launch complex might include propellant tanks, both cryogenic, such as liquid oxygen and liquid hydrogen, which must be stored at high pressure to maintain the liquid state; so-called storable propellants, such as hydrazine and nitric acid, that can be kept at ambient temperatures; the necessary fluid lines and controls to load and unload the vehicle; and pressurant tanks that typically contain liquid or gaseous nitrogen for maintaining so-called blanket pressures in tankage when empty.

The following is a listing of the launch complexes at the Cape and a description of the projects which used them, some of the majors events associated with them, and their current status. Complexes were given numerical designations, 1, 2, 3, etc. Generally, if a complex has two launch pads they were designated A and B although there were some exceptions to this practice. Some complexes were planned but never built. This accounts for the fact that some numbers are not listed. Most of the complexes that are still active or play a noteworthy role other than for launching are mentioned specifically.

Complexes 1 and 2 were constructed for the Snark winged missile program and also supported some launches of the Matador, another aerodynamic missile. These complexes remained active until 1960.

Complexes 3 and 4 were designed to support the interceptor missile Bomarc. Complex 3, however, did support the Cape's first launches—those of the Bumpers in April 1950. It was later used by other projects, including the X-17 used to test reentry nose cones, some early Redstones, and some Polaris operations.

Complex 5 and Complex 6 were used for the Redstone project, an Army ballistic missile whose range was approximately 200 miles. There were two launch pads with a common blockhouse, and the facility was usually called Complex 5/6 or simply 56. The complex is best known as the site of all six Mercury Redstone missions, including that of America's first man in space, Alan Shepard, and the subsequent flight of Virgil (Gus) Grissom. It was also used for several early Explorer and Pioneer missions, including the first successful American lunar flyby mission by Pioneer 4 launched by a Juno 11 on 3 March 1959.

Complexes 9 and 10 were used for the long-range, rocket-booted, ram jet powered aerodynamic missile Navaho.

Complex 11 was used for the Atlas ICBM. It was also the site of the first orbital use of the Atlas. On 18 December 1958, almost the entire Atlas, minus jettisoned booster section, was placed into orbit as Project SCORE. The vehicle was equipped with communications equipment which was used to broadcast President Eisenhower's Christmas greeting to the world from space.

Complex 12 was used for the numerous Atlas ICBM launches and for two unsuccessful launches of multistage Atlas Able vehicles on projected lunar missions in 1960. NASA's flights of the Ranger Program, designed to take a series of television views of the Moon before impact, were launched from here as were

several Mariner missions that flew by Venus and Mars. The first Orbiting Astronomical Observatory (OAO) and two Orbiting Geophysical Observatories (OGO) were launched from Complex 12. Some OGOS were launched from the Western Test Range into near circular polar orbits; they were nicknamed POGO for Polar Orbiting Geophysical Observatory to distinguish them from the ETR launched OGOS which were nicknamed EGO for Eccentric Orbiting Observatory. The first three Applications Technology Satellites were also launched from here.

Complex 13 was used by both the USAF and NASA for their Atlas Agena launches. The USAF launches were usually classified missions; NASA missions launched from Complex 13 included one OGO/EGO and five Lunar Orbiter missions that provided photographic coverage of most of the Moon's surface in support of the Apollo Program.

Complex 14 was used for the Atlas ICBM project and for the NASA Atlas Mercury Project. It was also used for an unsuccessful launch of a lunar mission by the Atlas Able vehicle in November 1959. The Atlas Agena target vehicles for the Gemini Program were launched from here.

Complexes 15 and 16 were used for the Titan ICBM program. Complex 16 was also used for the Pershing solid propellant missile.

Complex 17 was designed for the Thor Intermediate Range Ballistic Missile. It has also been used for the Thor-Able, Thor Able Star and Delta launches by the USAF, NASA, and Boeing (formerly McDonnell Douglas). The Boeing usage is for commercial and government contracted launches. Current vehicles still being launched at Complex 17 include both Delta 2 and Delta 3 vehicles. Complex 17 stands ahead of all other complexes on the Cape in the number of missile and space launches. From the first Thor launch in January 1957 through the end of 1998, the complex supported 276 launches. The number of first and spectacular missions is so large that only a few can be mentioned, with the obvious danger of omitting some equally outstanding in some opinions. From a technological point of view, the first restart of an upper stage flight in flight, that of the Able Star second stage on the launch of the Transit 1B Navy's navigation satellite on 13 April 1960, is important. TIROS 1 (for Television Infrared Observation Satellite), America's first weather observation satellite, was launched by a Thor Able on 1 April 1960. The active communications satellite Telestar 1, the world's first privately owned satellite was launched on a Delta on 10 July 1962. SYNCOMs 2 and 3 and Intelsat 1 are important milestones in the development of geosynchronous satellites. The Mars Pathfinder mission, with the Rover Sojourner, launched on 4 December 1996, is a more recent accomplishment. A 1991 aerial view of Complex 17 is shown in Fig. 2. This photo was taken from the east (Atlantic Ocean) side and shows the two service towers around two Delta vehicles being prepared for launch. The solid propellant strap-on motors are clearly visible on the vehicle on Pad 17B, to the viewer's left.

Complex 18, a two-pad complex, was built for the Thor IRBM program. When the Navy's Vanguard Earth Satellite project for the International Geophysical Year was established with a short lead time until its first launch in 1956, arrangements were made with the Air Force for the new program to share Complex 18. All 14 Vanguards were launched from Pad 18A, Thors were launched from 18B, and the blockhouse and other facilities were shared. The Air

Figure 2. Complex 17, which is still active, is shown in the 1991 photograph, taken from the east. Note the Delta vehicle on the left pad, 17B. Even though the service structure surrounds the vehicle, the thrust augmenting boosters are visible. The wedge-shaped blockhouse is located at the intersection of the covered cable trenches running west from each pad (USAF photo). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Force later used the complex for launches of the Blue Scout, a version of NASA's four-stage solid propellant launch vehicle.

Complexes 19 and 20 were built for the Titan ICBM projects. Complex 19 was also the launch site of the NASA Gemini two-person spacecraft. Complex 20 was modified to accommodate the Titan IIIA, which consisted of the two liquid stages of the upcoming heavy-lift IIIC space launch vehicle. Four successful launches of the Titan IIIA were successfully conducted by May 1965, after which the complex was deactivated.

Complexes 21 and 22 were built for the USAF Bull Goose decoy missile program and were also used by the Matador follow-on program called MACE.

Complexes 25 and 29 were built for the Navy's Fleet Ballistic Missile Program. Launches of Polaris, Poseidon, and Trident I took place here.

Complex 26, a two-pad complex, was built for the Army's Jupiter IBM and Army/NASA Juno space programs. It was the site of the launch of the first U.S. Earth satellite, Explorer I, on 31 January 1958. The successful flight and recovery of the two space monkeys, Able and Miss Baker began from Complex 26 on 29 May 1959 (5). Complex 26 was declared a national historic landmark in 1964.

Complex 30 was a dual launch pad used for the Army's solid propellant Pershing missile program.

Complexes 31 and 32 were built for the USAF solid propellant multistage Minuteman ICBM. They included both surface and below ground (silo) launch capability.

Complexes 34 and 37 were built for NASA's Saturn 1 and 1B heavy-lift space vehicles. They were the sites of five vehicle development launches of these vehicles, some of which carried payloads as secondary objectives. Complex 34 was the site of two suborbital launches of Apollo hardware, as well as the launch Apollo 7, the first manned orbital flight in the program. It also has the undeniable distinction of being the site of the fatal spacecraft fire that took the lives of Astronauts Grissom, White, and Chaffee. Complex 37 saw the orbital launches of five unmanned tests of Apollo hardware. Complex 37 has been assigned to Boeing under the Air Force contract for its Evolved Expendable Launch Vehicle (EELV).

Complex 36, built for the Atlas Centaur space vehicle, has two pads, 36A and 36B. The first stage of the rocket is a modified Atlas, and the second stage (Centaur) is the first successful cryogenic (hydrogen/oxygen) upper stage. It has been used by NASA for a number of space launches, including lunar and planetary missions. It is still in regular use for USAF missions and by the Lockheed Martin Corporation (formerly General Dynamics) for commercial launches and for NASA contracted launches. The Surveyor soft landing missions to the Moon in the early 1960s; the interplanetary Pioneer 10 and 11 missions to Jupiter, Saturn, and eventually out of the solar system; Mariner missions to Mercury, Venus, and Mars, as well as a number of commercial and government communications satellites were among the many launches from Complex 36.

Complex 39 is at the Kennedy Space Center. It was designed for the Apollo program's Saturn V lunar launch vehicle and was also used for the Saturn 1B vehicles used in the Skylab and Apollo-Soyuz Test Program launches. It has been modified for Space Shuttle requirements and is still in regular use. It will be discussed further in the section of this article called The Kennedy Space Center.

Complexes 40 and 41 were built for the USAF's Titan IIIC space vehicle program; construction was completed in 1965. This approach, sometimes called ITL, for Integrate, Transfer, and Launch, was a new concept for the Cape. The core vehicle consisting of two Titan stages and upper stages were assembled and prepared in the Vertical Integration Building (VIB) on a platform on wheels that also served as the launch vehicle and launch umbilical tower. This part of the whole assembly was then transported by locomotives to the Solid Motor Assembly Building (SMAB) where the two large solid motor boosters, already checked out in the SMAB, were attached to the core. This assembly was further transported on the rails to the launch pad itself where the launch platform was secured in place. A service structure was provided at the pad to facilitate payload installation and final preparations for launch. The VIB was located several miles from both the SMAB and the launch pad, so it could be used as laboratory and office space without the personnel constraints of the traditional blockhouses or launch control centers. Complex 41 was modified to accept NASA's Centaur upper stage for the NASA Titan Centaur Viking Mars lander/orbiter program and Voyager outer planets program and the joint Germany/US Helios solar research program in the 1970s. Complexes 40 and 41 have been further modified to accept the larger USAF Titan 4 vehicle that can accommodate either a Centaur upper stage or the solid propellant Inertial Upper Stage (IUS) or can accomplish certain

missions without an upper stage above the Titan IV core vehicle. They are still used by the USAF for military missions and by Lockheed Martin for either commercial launches or for NASA spacecraft launches. Complex 41 will be used by Lockheed Martin under the Air Force contract for its Evolved Expendable Launch Vehicle (EELV) after the Air Force's need for the complex for Titan IV launches. Some other facilities in the ITL and elsewhere on the Cape have been assigned to either Lockheed Martin or to Boeing for their EELV programs.

Complex 46 was built between 1984 and 1986 to support the Navy's Trident II ballistic missile program. Between January 1987 and 1989, 19 Trident II launches were conducted from this complex. With no new Trident requirements for the complex forthcoming, Spaceport Florida Authority (SFA), with the aid of an Air Force grant, redesigned the complex to accommodate small commercial space launch operations. The completed complex has been used by Lockheed Martin for launches of variants of its Athena space launch vehicles for such missions as NASA's Lunar Prospector and the commercial/international ROCSAT for the Republic of China Satellite (6).

Industrial Area and Missile Assembly Buildings (Hangars). The launch complexes are the heart of the launch base, but they could not exist without a myriad of other functions and facilities at Cape Canaveral. Many of the functions are provided in the Industrial Area, which is located a safe distance from the launch complexes. These include such prosaic things as cafeterias, dispensaries, office buildings, distribution of utilities such as water, electricity, communications and sewage, maintenance of roads and grounds, security, fire protection, and janitorial services to give a few examples. Less prosaic features of the Industrial Area are the Missile Assembly Buildings as well as spacecraft and space payload preparation buildings.

An obvious need exists for a facility to receive the launch vehicle from the factory, inspect and refurbish it, and prepare it for transfer to the launch complex for launch, as well as to store missiles not yet ready for flight or awaiting a pad assignment. These functions are accomplished in Missile Assembly Buildings commonly referred to simply as hangars. In the early hurry-up days of the missile programs, a standardized structure, essentially an aircraft hangar, was provided by the Range to incoming projects. The use of a standardized building expedited the availability of the hangars for the new projects which were typically operating under high priority and accelerated schedules. The typical hangar had an area of about 41,000 square feet. A high bay area with a number of cranes was included along with large sliding doors at both ends of the hangar. On each side of the high bay was a two-story concrete block structure. This could be used by the project for offices, guidance laboratories, telemetry and data labs, etc. The office and lab spaces were generally air conditioned because of the hot and moist coastal Florida climate; the high bay areas themselves were not air conditioned; environmental control for the high bay consisted of opening and closing the large doors.

Propellant Storage and Explosion Proof Areas. There are functions that are neither compatible with the industrial area nor is it feasible to locate them near the complexes where their work may be interrupted by launch activity. Such facilities include propellant storage areas and explosion proof areas. Those launch complexes using propellants such as RP-1, a kerosene-like substance used

as a fuel in many launch vehicles; liquid oxygen, a cryogenic oxidizer used in conjunction with RP-1; liquid hydrogen, a cryogenic fuel used in some space vehicle stages; and other commodities such as liquid and gaseous nitrogen and liquid helium maintained storage vessels in the complexes for direct servicing of the vehicle during countdown. It is, however, the responsibility of the ETR to maintain sufficient quantities of these commodities to keep the storage tanks at operational levels. At one time, the ETR actually operated a LOX (familiar name for liquid oxygen) and LIN (familiar name for liquid nitrogen) manufacturing plant on Cape Canaveral. They are now supplied commercially, but the ETR is responsible for maintaining supplies and facilities to fill project needs.

Other projects use storable, that is, noncryogenic, liquid propellants sometimes as either the principal propellants for the missile stages or as the propellants for upper stages or spacecraft. The principal fuel of this type is a hydrazine variety, and the usual oxidizer is a form of nitric acid. For some projects, these propellants can be loaded into the vehicle well in advance of the actual launch countdown, so that there is no need for last minute loading capability at the complex as that for cryogenic propellants. Other projects prefer to load these propellants during the launch countdown and maintain on-pad facilities to maintain strict temperature control and to measure the load precisely. The ETR maintains storage facilities for the commodities and delivers them to the complexes as needed.

Solid propellant launch vehicles such as Minuteman and Pershing included storage facilities for these motors in their launch complexes. However, the need in space vehicles for solid propellant upper stages for actual spacecraft injection into orbit dictates that a facility for storing such motors be provided until the motors enter the actual processing flow which is normally when the solid motor is mated to the spacecraft. The use of solid propellant strap-on motors in the first stages of space launch vehicles to increase performance has resulted in the need for storage facilities for many such items until they enter the launch preparation flow. The ETR operates such storage facilities for the various Range users.

The advent of sophisticated satellites that have their own propulsion and controls system dictated the need for explosion proof areas where satellites could be fueled and their control systems serviced. Other such facilities accommodated the mating of a spacecraft to a solid propellant upper stage and sometimes a dynamic balancing of a spin-stabilized upper stage/satellite combination. Safety concerns dictated locating such facilities in relatively remote areas of the Cape.

Range Control Center. As the blockhouse or launch control center is the focal point for the actual launches, so is the Range Control Center the focal point for all of the functions that the ETR performs to support a project, as well as the center of its own mission of providing Range Safety. Here, all the information is gathered that is necessary for the ETR to ascertain that it is ready to perform its functions for a launch. Ground safety and security must verify that the launch danger area is clear; instrumentation coordinators must ascertain that the necessary radars, telemetry sites, and other instrumentation necessary for either the project requirements and safety monitoring are ready; and range safety officers must verify that there are no ships or aircraft in the prohibited areas and that the instrumentation required for the range safety function is operational.

These operations are coordinated by such officials as the Superintendent of Range Operations (SRO), Range Control Officer (RCO), and the Range Safety Officer (RSO). In earlier days, this building was in the heart of the industrial area, but it has been replaced by a new facility near the south end of the Cape.

A historical footnote to the reporting of status by instrumentation sites involves the famous expression "AOK" which is now generally attributed to the manned space program. Actually, this term has been in use at least at the ETR for many years before the manned space programs. When asked for readiness to support over communications circuits from remote sites, the operators at the sites had a choice of three replies. AOK meant that the site was operational and that it would support its requirements. CNY meant that the site was not operational and did not expect to be operational for the operation: BEX meant that the site could not meet its requirements at the time of the report but that it anticipated that it would be operational by the time its support was scheduled. The use of three letters for each readiness condition was intended to assist in recognizing the status signal over potentially noisy communications circuits.

Skid Strip. The landing strip is another prominent feature of the Cape. It was built in the early 1950s for the Navaho X-10 test vehicle. It was used in the mid 1950s as a landing area for Snark missiles which might be reused after successfully landing. The Snarks were equipped with landing skids instead of wheels; hence the name skid strip. Originally a 10,000 × 200 foot configuration, it has since been widened to 300 feet, resurfaced, and expanded to include a taxiway and a parking apron (7). It is frequently used for cargo aircraft delivering launch vehicles and spacecraft to the launch site. The skid strip has also been used by passenger aircraft bringing distinguished visitors to the USAF and NASA areas for tours or for observing important launches. The skid strip can be seen clearly in Fig. 3, an aerial view of the Cape.

Downrange and Tracking Stations. As early as 1954, the Eastern Test Range had three tracking sites equipped with tracking, telemetry, or photographic instrumentation. There was launch coverage instrumentation at the launch site at Cape Canaveral, and there were additional stations at Jupiter Auxiliary Air Force Base south of Cape Canaveral on the Florida mainland and at Grand Bahama Island in the Bahamas. Additional stations usually called Auxiliary Air Force bases were soon added on the islands of Eleuthera, San Salvador, Mayaguana, and Grand Turk in the British West Indies; in the Dominican Republic on the island of Hispaniola, and at Mayaguez in Puerto Rico. A submarine cable was incrementally constructed connecting all of the stations and was completed in December 1956. Some instrumentation was also located at Patrick Air Force Base to afford different viewing angles than was possible from the Cape itself during the launch phase.

The distance covered by these stations (about 1200 miles from the Cape to Mayaguez) was sufficient for the early programs. However, when the much longer range aerodynamic Snark and Navaho missile programs were approved, much longer distances had to be accommodated. Antigua and St. Lucia in the Lesser Antilles and Ascension Island, approximately 5000 miles from the Cape in the South Atlantic, were selected, and negotiations with the British governments ensued. A fourth at Fernando de Noronha, an island off the coast of Brazil, was also selected, and an agreement with the Brazilian government was negotiated.

Figure 3. A 1961 aerial photograph of the Cape, with North at the top, showing the Skid Strip in the center, the various launch pads generally along the coast of the Cape, and the Industrial Area to the left of the west end of the Skid Strip (NASA/USAF photo). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Antigua, St. Lucia, and Ascension were operational in 1958, and Fernando, as it was usually called, became operational in the summer of 1958. Even with the additional range stations, there were areas, where air breathing vehicles at relatively low altitudes, could not be tracked by land-based instrumentation. As

many as 12 small telemetry ships were positioned downrange to cover the gaps between the island-based instrumentation. As a matter of history, the ETR supported its first 5000-mile long mission (a Snark test flight) in October 1957 (8).

Although the Snark and Navaho programs were the impetus for extending the range, the new Intermediate Range Ballistic Missiles (IRBMs) such as the Army's Jupiter and the Air Force's Thor, as well as the Intercontinental Range Ballistic Missile (ICBMs) such as the Atlas, Titan, and Minuteman programs, after a slow start, eventually became major range users. A few years later, the new space vehicles became the largest users in terms of launches, and the Navy's Trident program remains a major user. Ballistic missiles and space launch vehicles that have higher trajectories than aerodynamic missiles could be tracked continuously from fewer stations, allowing the phase out of some downrange stations as the workload shifted from aerodynamics to ballistic and space launches. There have also been some notable additions to "downrange." Additional ships that have more sophisticated instrumentation were added and subtracted as workloads varied. Instrumented aircraft were also added that operated from bases in South Africa and Mahe in the Indian Ocean.

The downrange stations were usually officially designated as Auxiliary Air Force Bases, but there was frequently only one military person on site, usually an Air Force Officer, who held the title of Base Commander and among whose many duties was dealing as United States Government official with the local authorities. In the early days of Range operations, there was a Base Manager, an employee of the Range contractor (for many years Pan American World Airways) who ran the day-to-day operations of the station except for the instrumentation. A person called the Instrumentation Manager was an employee of Pan Am's instrumentation subcontractor, the Radio Corporation of America (RCA) Service Company. Most of the personnel at a downrange station were either from the Air Force, Pan Am, or RCA, although indigenous personnel were employed where feasible. For simplicity, the terms Pan Am and RCA are used here rather than trying to trace the various contracting and subcontracting schemes used during the history of the Range.

Range Instrumentation. The Range used a variety of instrumentation in its host responsibility of providing data to the Range users and in its own responsibility of ensuring that the launched vehicles did not pose a hazard to life or property. Trajectory information for both purposes was principally obtained by radars that tracked a transponder or beacon in the vehicle. These radars were also capable of echo or skin tracking, but the use of airborne beacons improved both the range to which something could be tracked and the accuracy of the data. There were other tracking devices used ranging from very complicated systems to such simple devices as optical gunsights and wire sky screens for close tracking, but precision tracking radars were the principal means for obtaining trajectory data. Telemetry antennas of varying sophistication were another important asset provided by the Range.

Command/control as used today is principally a method of either terminating the thrust of an errant vehicle or initiating an airborne destruct package in a vehicle if it has malfunctioned. This is the common conception of command/control, but there have been launch vehicle projects which have used this system to operate some vehicle systems usually as a backup to an airborne system.

Range Support and Safety. The preparation and launch of missiles, space launch vehicles, and spacecraft are potentially dangerous, so each participant in the process has a serious responsibility for safe conduct of such operations. The vehicle or spacecraft manufacturer or contractor, as well as the sponsoring agency, typically have safety organizations, but the Range as host has the overall responsibility for operations conducted on its facilities. To carry out this responsibility, the Range requires of its tenants detailed information about such hazardous items as pressure vessels, pyrotechnic devices, radioactive sources, and propellants that are used.

In the exercise of its responsibility to ensure flight safety, the Range requires each project to equip its vehicles with devices to assist real-time tracking by the Range, explosive or other means to either stop propellant flow (cutoff) or actually to destroy the vehicle (destruct), and receivers in the vehicle to accept cutoff and destruct radio-frequency signals from the ground and transmit these received signals to the appropriate devices. In perhaps overly simple terms, the Range Safety Officer (RSO) is presented with a plotting board display or display that shows the actual trajectory as measured by a tracking radar, for instance, and the predicted instantaneous impact point of a vehicle if thrust were terminated at a given instant. These are overlaid on a prepared chart showing such things as the nominal trajectory, the estimated normal deviation from the nominal, lines showing what areas are to be protected, and lines showing how far from the protected areas pieces of a destroyed vehicle might travel because of such factors as their size and density or human reaction time.

The RSO is also presented with other data, such as telemetry, indicating the performance of the vehicle. If the RSO determines that a flight is performing unsafely or that it will violate destruct criteria, the RSO can send appropriate signals to the vehicle which, when received by the command receivers aboard, will initiate cutoff and/or destruct (9).

Meteorological support is another important service of the Range. Even relatively routine information such as temperature, precipitation, and winds becomes vital when certain operations are scheduled. For instance, hoisting a spacecraft to the top of a launch vehicle by a crane cannot be done in high winds. The safety function of the Range itself demands certain ceiling and visibility minimums to allow optical tracking and observation of a launched vehicle early in flight. Weather balloon data on weather aloft is provided to the projects to allow determining whether such things as wind velocity and shear might compromise their control systems. Lightning data and prediction is important to both ground tasks and to launch operations. Activities on launch complexes are understandably restricted during thunderstorms. It is also necessary to know the state of the atmosphere aloft before a launch, so that a rising vehicle would not trigger lightning as it passed through dangerous levels.

In addition to the support given to launches from the ETR and KSC, the Range is called upon to support launches from ships and from submarines in the Navy's Polaris, Poseidon, and Trident ballistic missile programs. Support has also been rendered to United Kingdom submarine launches. Airborne launches of the Air Force's Hound Dog air-to-ground missile were a frequent customer between 1959 and 1965. Seventy-seven Hound Dogs were launched from B-52 aircraft over the Range in that period. Support was also given to Skybolt, the

proposed, but eventually canceled, successor to Hound Dog in the early 1960s. The Range has also given some support to the European Space Agency's Kourou launch site in French Guiana. Recently support has been given to the air-launched Pegasus space launch vehicle.

Kennedy Space Center

Introduction. The Kennedy Space Center (KSC) consists of almost 84,000 acres and an additional area of about 56,000 acres of submerged, formerly state-owned land. The location of the Kennedy Space Center with respect to Cape Canaveral is shown in Fig. 4.

Like the Eastern Test Range, KSC has undergone changes of name in both of its definitions. Organizationally, it was originally the Launch Operations Directorate (LOD) of the Marshall Space Flight Center (MSFC) in Huntsville, Alabama. MSFC was created in December 1958 when the Development Operations Division, including the Missile Firing Laboratory at Cape Canaveral, of the Army Ballistic Missile Agency at Redstone Arsenal in Alabama was transferred to NASA. In July 1962, LOD was raised to the status of an independent NASA Center and became the Launch Operations Center (LOC). After President Kennedy's death in 1963, the name was changed to the John F. Kennedy Space Center, NASA. This is usually shortened to Kennedy Space Center, or simply KSC. As a physical entity, the area was originally called the Merritt Island Launch Area (MILA); that eventually also became the Kennedy Space Center.

There were other NASA elements operating in the Cape Canaveral area in this period. The Navy's Vanguard Project was transferred to the Beltsville Space Flight Center (soon renamed Goddard Space Flight Center) of NASA when that new agency was created on 1 October 1958. The Cape-based Vanguard Operations Group (VOG) became the Field Projects Branch of GSFC and later the Goddard Launch Operations Division, which eventually assumed launch responsibility for Delta, Atlas Agena, and Atlas Centaur launches at the Cape, as well as for Thor Agena launches at Vandenberg Air Force Base in California.

The coming of the Mercury program to the Cape brought a detachment of the Space Task Group to Florida to support the Mercury Redstone and Mercury Atlas launches. This group eventually became the Florida Operations Group of the new Manned Spacecraft Center (MSC) in Houston. This was later renamed the Lyndon B. Johnson Space Center (JSC). This Florida Operations Group was transferred to the Kennedy Space Center in December 1964 after the conclusion of the Mercury program and before the first manned launch in the Gemini program.

The Atlantic Missile Range Operations Office which had been the official conduit for NASA's support requirements to the Range and the Range's commitment to support NASA was disbanded, and its functions were taken over by KSC's NASA Test Support Office at Patrick Air Force Base. The consolidation of NASA launch elements in Florida under KSC was finalized in October 1965 when the Goddard Launch Operations Division was transferred to KSC and became the Unmanned Launch Operations Directorate.

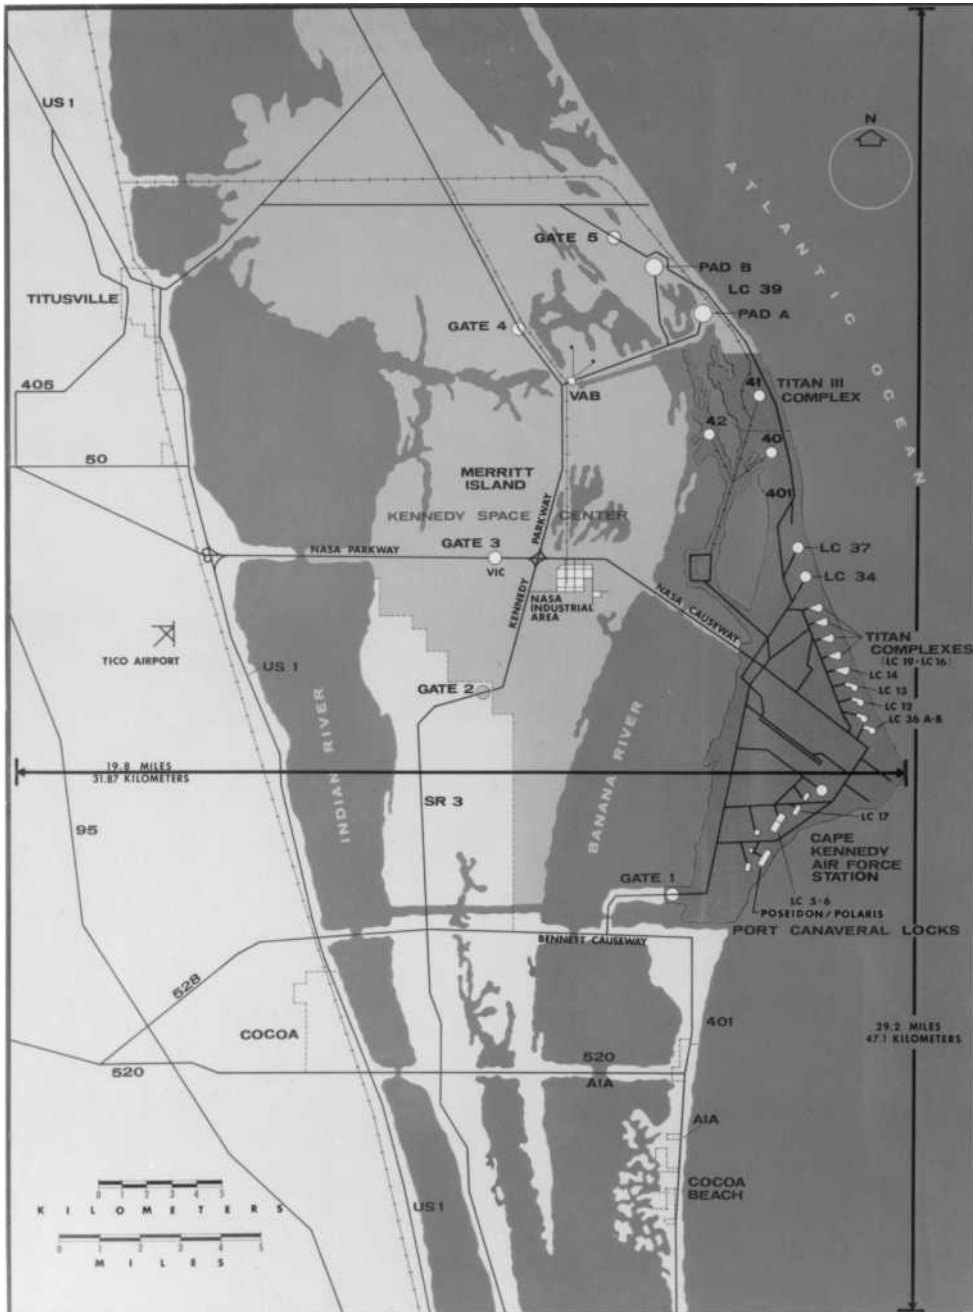

Figure 4. The geographical relationship of KSC, the Cape, and the surrounding communities in 1971. This drawing shows some facilities which had been planned but never built, such as Pad 42 (NASA photo). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

The Apollo Program. The Apollo program was NASA's implementation of President Kennedy's declaration of 25 May 1961 that America "should commit itself to achieving the goal, before this decade is out, of landing a man on the Moon and returning him safely to the earth." At this time, there was no launch vehicle of sufficient power to do this, no spacecraft to take astronauts to the surface of the Moon and get them back to Earth, and no facility from which to launch the vehicle and spacecraft. The launch vehicle task fell largely to MSFC, and the spacecraft portion was assigned to MSC/JSC. The task of establishing a base for preparing and launching these elements clearly belonged to KSC.

Even though the launch vehicle, which would emerge as the Saturn V, had not been finally designed, it was clear that its size would preclude the possibility of using an existing Cape complex or of building a new complex on the Cape. A joint DOD/NASA task group pondered the question locating the launch base, and, after considering alternatives, including sites in Hawaii, Texas, California, Georgia, and islands in the Caribbean, selected Merritt Island. Other sites offered some appealing characteristics, but Merritt Island offered the opportunity to use many of the existing capabilities of the Atlantic Missile Range (AMR), and it allowed LOC/KSC to continue operating on the Cape at the same time as the Merritt Island Launch Area (MILA) was being built.

Complex 39 and the Vehicle Assembly Building. It was decided that the vehicle and its launch platform would be integrated vertically in a "hangar" on MILA to minimize time on the pad. The Apollo spacecraft elements would be checked out in the MILA industrial area and mated with the launch vehicle before the entire combination of launch vehicle, spacecraft, and launcher would be transported to the pad in the vertical position. There would be the capability of returning the combination to the hangar in case of weather or technical problems. The hangar, which would be larger than any existing one to accommodate the eventual 363-foot launch vehicle, is now known as the Vehicle Assembly Building (VAB). Its dimensions are 716 feet in length, 518 feet in width, and 526 feet in height. The VAB consisted of a high bay containing four bays or checkout cells, each large enough to accommodate a mobile launcher carrying a fully assembled space vehicle; a transfer aisle between the pairs of checkout cells; considerable office space, and a low bay for work on individual stages and components. A multiplicity of lifting devices as large as the two 250-ton bridge cranes with hook heights of 462 feet were included. Upward telescoping doors on each cell allowed access from and to the outside of the building. Only three of the high bay cells in the VAB were activated.

Operations in the VAB and at each of the two launch pads were controlled by personnel in the Launch Control Center (LCC) constructed to the southeast of the VAB. Not to be confused with most launch control centers or blockhouses on the Cape, this was a four-level building whose function was to check out the vehicle during preparations both in the VAB and at the launch pad. It was about three and a half miles from the pads, so it was not in the danger area and could provide support, such as offices, labs, data stations, and even a cafeteria, in addition to the actual control rooms called firing rooms. There were four of these firing rooms provided but, like the cells in the VAB, only three were fully equipped. A cable way and a personnel access corridor were provided between the third level of the LCC and the VAB.

The launch pads themselves were a major construction feat. Because the selected area was marshy, as was much of MILA, the entire pad had to be elevated with the bottom of the flame trench at ground level. Beneath the surface of the elevated pad were four floors containing terminal connection rooms, high-pressure gas systems, and emergency egress rooms for the astronaut crew and the pad close-out crew. A water system to cool the flame from the rocket engines was also there. Propellant storage tanks and other facilities similar, except in size, to Cape complexes for liquid fueled projects were also included within the pad perimeter. Pads 39A and 39B are essentially identical; several identical pads were planned at one time but were never built.

Essential to the mobile concept of operations were the mobile launchers, transportable steel structures that moved the Saturn V launch vehicles from the VAB to the launch pad. Three identical mobile launchers were built, each 445 feet tall and weighing 12,600,000 pounds when carrying an unfueled Apollo Saturn stack. The launcher consisted of a two-level base whose area is about a half acre and an umbilical tower capped by a 25-ton hammerhead crane. The bases contained a computer linked to counterparts in the firing rooms. The umbilical tower provided work platforms; swing arms that were disconnected automatically at liftoff; and distribution lines for propellant, pneumatic, electrical, and instrumentation functions. The highest swing arm, Number 9, 320 feet above the base connected with the Apollo spacecraft and was used by the astronauts to enter the command module. The base also provided hold-down arms that precluded motion of the vehicle after engine ignition until it was determined that all engines were operating satisfactorily. A rectangular opening in the launcher base allowed exhaust from the first stage engines to vent into a flame trench at the pad.

The launcher and the vehicle had to be moved from the VAB to the pad. After such concepts as barge transport, a rail system, and even pneumatic tired transporters and air cushion devices were considered and discarded, the choice was made of a crawler rolling on eight tracks that had a propulsion system similar to some used in strip mining. Two of these were procured. In addition to its transporting function, the crawlers could lift the entire stack to disengage it from the 22-foot pedestals in the VAB and lower it to similar pedestals at the pad after transport. The combined mass of the crawler, launcher, and unfueled Apollo Saturn was about 18 million pounds.

The highway for the crawlers to transverse with their burdens is the crawlerway, a two-lane road with a grass median to be straddled by the crawler. This highway is not paved but constructed of materials that can bear the intended weight without permanent deformation. The actual surface is Alabama river rock that minimized friction on the crawler treads. About halfway between the VAB and Pad 39A, an extension of the crawlerway turns northeast and goes to PAD 39B.

Another major element was the Mobile Service Structure (MSS), a 410-foot, 10,500,000-pound structure designed to give 360° access to the space vehicle and outfitted with air conditioning, elevators, computers as well as television instrumentation, communications, and power systems. It was removed from the pad by the crawler about 7 hours before liftoff and placed at its park site along the crawlerway. It was mobile and was removed from the danger area before launch, so only one mobile service structure was built to service both pads.

The size of the Saturn V and Apollo components required a new look at delivering them to the launch site. Earlier programs delivered either by road or by transport aircraft. The first and second stages were transported by barge from MSFC in Huntsville, Alabama. The third stage, the instrument unit, and the Apollo spacecraft, were delivered in a specially modified aircraft, called the Guppy.

Air transported components landed at the Cape's Skid Strip and were transported overland to the VAB. The barge method required constructing, on MILA, a dock and turning basin near the VAB, inclusion of draw spans on bridges, constructing a lock between Port Canaveral on the Atlantic Ocean and the Banana River, and considerable dredging.

The KSC Industrial Area. In addition to the Complex 39A area, there was a need for an industrial area for much of the same purposes as the Cape industrial area. One important difference was that there were no hangars in the KSC industrial area; essentially all work on the vehicles themselves was done at Complex 39. There still remained the requirement for administration and data gathering facilities as well as for a Flight Crew Training Building and for a building to prepare the command, service, and lunar modules. The Operations and Checkout (O&C) Building, a multistoried structure with a high bay checkout area 100 feet high and 234 feet long and an adjacent low bay checkout area 251 feet long was constructed to fulfill this last requirement. Salient features in the high bay were two altitude chambers each 50 feet high and 30 meters in diameter, which allowed checking out the Apollo spacecraft in near vacuum. The O&C also had a large and more conventional portion separate from the checkout area but connected by above-ground access corridors. The north portion of the O&C contained offices, laboratories, a weather station, and astronaut quarters. The first NASA occupants of the KSC Industrial Area were members of the MSC's Florida Operations Group that moved much of its operation from Hangar S on the Cape to the O&C building in the fall of 1964, even before that group was part of KSC. Completion of other buildings in the industrial area, including the Headquarters Building, the Central Instrumentation Facility, a Training Auditorium and the Base Operations building, followed soon after.

Apollo Operations. Even while all this preparation for the eventual Moon landings was going on at KSC, work on the project was proceeding on the Cape at Complexes 34 and 37. Orbital launches of boiler plate or dummy Command and Service Modules (CSMs) were conducted as early as 1964 by Saturn 1 vehicles and continued through July 1965. Suborbital tests of CSMs were conducted using Saturn 1B vehicles in 1966. The success of all of these tests led up to preparations for the first manned launch of a CSM from Complex 34 using the Saturn 1B vehicle AS (for Apollo Saturn) 204 and CSM 012. The 27 January 1967 fire in the spacecraft during a simulated countdown took the lives of Astronauts Grisom, White, and Chaffee. Modifications of hardware and procedures were made, which culminated in a successful orbital launch of SA 205 carrying a redesigned CSM 101 with astronauts Schirra, Eisele, and Cunningham. This was the last manned launch from the Cape, and Complexes 34 and 37 were deactivated.

The history of the Apollo Program with its successes, especially the accomplishment of the first manned lunar landing within President Kennedy's schedule and its difficulties, including the disastrous AS-204 spacecraft fire and the harrowing flight of Apollo 13, is well known and is covered elsewhere (10). The

Figure 5. The launch of Apollo 11, the first lunar landing mission, on 16 July 1969 (NASA photo). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

launch of Apollo 11 on 16 July 1969, which culminated in the first manned lunar landing and successful return to Earth, is shown in Fig. 5.

Skylab. The next challenge for KSC was Skylab, a program that would demonstrate that humans can exist in space for long periods and carry out useful scientific and applications tasks. (See the article on Skylab elsewhere in this Encyclopedia.) The first launch would orbit the Skylab itself, and three succeeding launches would propel crews of three men to the orbiting workshop where they would transfer to Skylab and live and work there for periods increasing from 28 to 59 to 84 days, before returning in their command and service modules. KSC facilities were modified for checkout of the workshop which replaced the Saturn third stage in the stack. The flights to the workshop did not require the power of the Saturn V; a Saturn 1B would suffice. At one time, it was planned to make these launches at Complex 37 on the Cape which had already supported the Apollo 7 manned launch in 1967. However, an ingenious plan to launch these missions (and the subsequent Apollo-Soyuz Test Program (ASTP) mission) from Complex 39 was devised and allowed deactivating Complex 37 years earlier than once planned at a considerable saving in money and manpower.

The solution was the construction of a steel pedestal, humorously called the “milk stool,” 127 feet in height atop which the much shorter Saturn 1B would be placed on a mobile launcher allowing some of the Saturn V and Apollo access arms to be used. The mission concept called for the launch of Saturn V with the workshop on one day and the launch of the Saturn 1B with the first Skylab mission crew on the next. This of course required that launch crews at KSC would have to prepare two launch vehicles at the same time and operate two complexes simultaneously. Plans were made to do this, and KSC was ready to launch the crew on 15 May 1973, the day after the workshop was launched. The experience in rendezvous and docking first demonstrated in Gemini and used extensively in Apollo also came into play here, as did the requirement for relatively short launch windows to accomplish rendezvous and docking. However, serious problems arose with the workshop during ascent, and it was necessary to delay the Saturn 1B launch while personnel at MSFC and JSC worked on ways to salvage the mission. These were quickly accomplished, and the Saturn 1B with the first crew of three in their CSM was launched on 25 May 1973 on a 28-day mission.

Figure 6 shows the Skylab 2 stack atop the milk stool and mobile launcher on Pad 39B. The Mobile Service Structure, propelled by the crawler, is approaching the Saturn 1B vehicle. Skylab 3 was launched on 28 July on a 59-day flight. The program concluded with the third mission, launched on 16 November and splashdown occurred on 8 February 1974 after an 84-day flight.

Figure 6. The Skylab vehicle on the “milk stool” on Pad 39B on 11 January 1971. The work stands on the Mobile Service Structure are clearly seen as it is propelled to the prelaunch position by the crawler (NASA photo). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Apollo–Soyuz Test Program. KSC then turned its attention to the Apollo–Soyuz Test Program (ASTP) which was a joint program between the Soviet Union and the United States for rendezvous and docking of a Soyuz, which would be launched first, and an Apollo CSM and joint flight of the two docked spacecraft. This called for using another Saturn 1B and Apollo CSM. Liftoff of the Apollo with three astronauts aboard took place on 15 July 1975. The U.S. portion of the successful mission was terminated by splashdown of the Apollo command module on 24 July 1975 (11).

With the launch of ASTP, KSC entered a period of almost 8 years with no launches at Complex 39. Although there were no launches, it was a period of intense activity preparing the center for the Space Shuttle program.

Space Shuttle. The Space Shuttle program, which is described in detail elsewhere, featured a reusable Spacecraft called the Orbiter, boosted into space by three rocket engines in the Orbiter and by two large solid rocket boosters which would be jettisoned after burnout, recovered, and reused. After solid rocket separations, the Orbiter would continue on to orbit using its own engines which consumed liquid oxygen and liquid hydrogen from a huge external tank (ET) which would be jettisoned after engine burnout. The Orbiter would then continue to achieve the desired orbit by using its own onboard thrusters. After the mission was completed, the Orbiter would use thrusters to decelerate from orbital velocity and land like an airplane, although without any engines running.

The mobile launch concept was carried over to the Space Shuttle, so the mobile launcher crawlers, crawlerway VAB, LCC, and the two pads were destined to be used with the new program, even though some required considerable modification. Because the orbiters were to be reusable, a 15,000-foot landing strip, eventually called the Shuttle Landing Facility (SLF), was required. The Orbiters had to undergo considerable refurbishment after return to KSC, so a two-bay building called the Orbiter Processing Facility (OPF) was needed for the refurbishment and for necessary modifications for the next mission, as well as for the initial preparations of each Orbiter as it came on line. Some payloads for Shuttle missions were installed in the OPF. Figure 7 shows the SLF, the VAB, the LCC, the OPF, and part of the crawlerway.

An interesting change of nomenclature, emphasizing the Orbiter's reusability, had occurred with the advent of the Shuttle. Vehicles that were used only once, like the Delta, the Atlas Centaur, and the Titans, were now called "expendable," as opposed to the reusable Shuttle. Heretofore, all launch vehicles, even those used in the manned programs, were in fact expendable. Whether or not the fact that the terms "manned" and "unmanned" were now politically incorrect was involved in the name change is not clear. KSC, however, went to the extent of renaming its Unmanned Launch Operations Directorate the Expendable Launch Vehicles Directorate.

Modifications of the mobile launcher included removing the umbilical tower, reconfiguring the openings in the base to accommodate the different solid and liquid engine configurations, adding two tail service masts to handle connections between the launcher and the orbiter, and adding a hold-down/release mechanism to allow analyzing the liquid engine performance before igniting the solids. A number of modifications were made to the VAB; the most important was the

Figure 7. The Shuttle Landing Facility at the top of this 1983 photograph taken from the southeast. The VAB is prominent in the center, and the Launch Control Center can be seen nearer the bottom of the picture. The Orbiter Processing Facility is visible to the west of the VAB. The Mate/Demate Device is barely visible at the right of the apron between the SLF and the tow way to the OPF. The VAB displays the American flag and the U.S. Bicentennial symbol as a carryover of the Bicentennial “Third Century America” exposition held at KSC in 1976. The Bicentennial symbol has since been replaced by the traditional NASA “meatball” (NASA photo). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

modification of the low bay area to a checkout area for the solid rocket segments and nose cones to prepare them for stacking on the modified mobile launcher in the high bay cells.

The process of stacking started with transporting the mobile launcher into one of the high bay cells with the crawler. The two solid motors were then assembled segment by segment on the launcher. The external tank was then attached to the two solid motors. Last the Orbiter was rolled over to the VAB transfer aisle on its own landing gear, hoisted into position, and attached to the ET. After VAB operations were complete, the crawler returned and transported the entire stack of two SRBs, the ET, and the Orbiter to one of the two pads for final checkout and launch. (See the article on the U.S. Manned Spaceflight: Mercury to the Shuttle elsewhere in this Encyclopedia.) The fact that the SRBs were the basis of the stack, added to the presence of SRB segments in the VAB at almost all times, precluded the use of the office space in the VAB, as contrasted with the Apollo setup where ordnance was installed just before rollout.

At the pads, the modifications included changes in the flame bucket to match the penetrations of the mobile launcher necessitated by the new motor configuration. A fixed service structure (FSS) mounted on the pad surface

replaced the tower on the launchers. Among the features on the FSS are the Crew Access Arm, through which the crews enter and exit the Shuttle—ingress and egress in NASA parlance and the so called “Beanie Cap” which is positioned above the ET and draws off the vented gases from the cryogenic propellant tanks.

Attached to the FSS is the Rotating Service Structure (RSS) that rotates about a large hinge on the FSS allowing it to interface with the Orbiter when required and to rotate to the retired position as launch approached. The RSS provides some protection from the elements for the Orbiter and, more importantly, contains a Payload Changeout Room (PCR) that allows access to the payload bay and allows installing payloads at the pad rather than in the OPF much earlier in the preparation process. Eventually, most users opted to install payloads at the pad, allowing for shorter times in the field for spacecraft crews and less unattended times for the spacecraft.

Modifications were also necessary to facilities away from Complex 39. The O&C building in the industrial area was modified to check out payloads that would be flown repetitively and that would usually be installed in the OPF. These payloads were sometimes called horizontally processed payloads. The most prominent of these was Spacelab, a facility that fits into the Shuttle payload bay and was built in Europe by the European Space Agency (ESA). Although final assembly and checkout of Spacelab before delivery to KSC was accomplished in Bremen in the Federal Republic of Germany, many of the components were manufactured in plants located in other ESA member countries.

An interesting product of the Shuttle era at KSC was the acquisition of a NASA “navy.” As mentioned earlier, the solid rocket boosters were designed to be recovered, refurbished, and reused. After booster separation, parachutes were deployed, and the burnt out rockets descended to the ocean surface, where they would be located and towed back to a new dock behind Hangar AF on the Cape by two specially designed ships, the Liberty and Freedom leased by NASA. They were taken into the hangar, disassembled, and put into condition for rail shipment back to the factory for refurbishment for a subsequent flight.

Shuttle Operations at KSC. The first Orbiter named “Columbia” arrived at the KSC SLF on 24 March 1979. It had ridden piggyback from its California manufacturing plant atop a specially modified 747 aircraft called the Shuttle Carrier Aircraft (SCA). The two vehicles were then towed to another new KSC facility called the Mate/Demate Device (MDD) which was capable of lifting the Orbiter from the attach fittings on the 747 and, after the 747 had been moved away, of lowering it to the surface on its own landing gear. (The MDD can also reverse the process of lifting an Orbiter from the surface to the back of a 747, which has been done when Orbiters have been returned to the factory for major modifications and upgrades.) Columbia was then towed to the OPF to begin launch preparations. The other three original Orbiters were “Challenger,” “Discovery,” and “Atlantis,” all named for ships famous for exploration. An earlier model with no engines was named “Enterprise” and was used for approach and landing tests at Edwards, for vibration tests at MSFC, and as a pathfinder for the new facilities at KSC. After the Challenger was destroyed, an additional Orbiter called “Endeavour” joined the fleet.

Columbia arrived at KSC with considerably more factory style work yet to be accomplished, mostly in the installation of the thermal protection tiles on areas of the Orbiter that would be susceptible to extreme heating during reentry. The original estimate was that about 25% of the approximately 31,000 tiles still needed installation. New tests that raised concern about the capability of many already installed tiles resulted in the removal of thousands of these tiles. This situation severely increased the amount of work to be done at KSC and resulted in substantial delays. Indeed, a second bay of the OPF was turned into a virtual production facility for tiles.

Meanwhile, other components were arriving at KSC. A pathfinder ET had arrived by barge in March. The flight ET arrived on 6 July 1979, and the first of the three Orbiter engines arrived on 10 July. The first solid rocket motor segments arrived in September.

The Orbiter finally was towed from the OPF to the transfer aisle of the VAB on 24 November 1980 after some twenty months in the OPF. In the VAB, it was mated to the ET and the SRBs already on the launch platform. On 29 December 1980, the crawler picked up the stack, and by evening the first Space Shuttle was on its launch pad, ready for preflight operations of the first shuttle mission, called STS-1 (for Space Transportation System). Unlike all other U.S. manned spaceflight programs, whose early launches were accomplished without a human crew, the first launch of Columbia was to be piloted by two astronauts. John Young, veteran of two Gemini flights and two Apollo flights, was the commander, and Robert Crippen, who had no previous space experience, was the pilot. On 12 April 1981, after a 20-second flight readiness firing on 20 February and an aborted countdown on 10 April, the first Space Shuttle lifted off on a mission of 2 days and 6 hours, terminated by a successful landing on a dry lake bed runway at Dryden Flight Research Center at Edwards Air Force Base in California.

A 300-man crew from KSC was stationed at Edwards to service the Orbiter and prepare it for return to KSC aboard the SCA two weeks later. An MDD like that at KSC had been constructed at Edwards for use in the Approach and Landing Test of the Enterprise and to facilitate delivery of the Orbiters from their relatively nearby production facilities in Palmdale (12).

On its first flight Columbia carried no payload per se. It did, however, carry extensive instrumentation called Development Flight Instrumentation (DFI) to measure the Orbiter's environment and performance. The second, third, and fourth flights of Columbia were primarily additional flight tests, but each of the STS-2 and STS-3 missions included a payload for NASA, and the STS-4 mission included a payload for the Air Force.

STS-5, using Columbia, was the first operational mission. It successfully carried into low Earth orbit two commercial communications satellites each with two solid motors, one for achieving a geosynchronous transfer orbit after being separated from the orbiter bay and a smaller one for circularizing the orbit to geostationary. The launch of STS-5 took place on 11 November 1982.

STS-6, the first flight of the second Orbiter, Challenger, carried a larger communications satellite and a different solid motor. It, too, was successful.

On the tenth STS flight, Challenger concluded another commercial spacecraft delivery mission, and the first Orbiter landed at the SLF on 11 February

1984. (The NASA nomenclature system for designating missions was changed starting with this mission, which was called STS 41-B, rather than STS-10.)

Mission 41-D, the twelfth mission, marked the introduction of the third Orbiter, Discovery, into the fleet on a 6-day satellite delivery flight launched on 30 August 1984. The fourth Orbiter, Atlantis, made its first flight in October 1985 carrying a Department of Defense payload as Mission STS 51-J, the twenty-first launch.

By the end of 1985, the STS had successfully accomplished 23 missions with a variety of mission objectives. The launch rate had increased with the addition of new Orbiters, from two in 1981, to three in 1982, to four in 1983, to five in 1984, and to nine in 1985. One successful mission had been flown in early January 1986, when disaster and tragedy struck the program with the destruction of Challenger soon after launch as Mission 51-L on 28 January 1986.

The Challenger loss, and the actions NASA took as a result, caused a significant hiatus in the launch of shuttles. The launch of Discovery on the STS-26 satellite delivery mission occurred more than 32 months later on 29 September 1988. (The nomenclature of missions had reverted to the former system.) By the time flights were resumed, several important policy changes had been made. No shuttle launches would be made at Vandenberg, commercial spacecraft would not be flown on shuttles, and no new DoD missions would be manifested on the Shuttle.

As a result, after resumption of flight, the launch rate did not continue to increase as had been planned, and the mark of nine per year has not been exceeded, even though an additional Orbiter, Endeavour, joined the fleet and made its first flight as STS-49 in September 1992. Parenthetically, the designation as STS-49 does not mean that it was the forty-ninth flight; STS numbers were now assigned with the manifesting of the mission, and the flights did not necessarily occur in that order. For instance, STS-28 was flown after STS-29 and STS-30, all in 1989.

Shuttle Payload Processing. The Shuttle would carry two principal kinds of payloads reusable and attached like Spacelab and deployable, typified by communications satellites. Even that distinction is not absolute because the deployables require cradles, erection devices, and separation systems which were not deployed but remained in the payload bay and had to be removed before the next flight.

In the beginnings of the Shuttle program, the term “cargo” was frequently used to describe the complement of experiments, satellites, attached payloads, and airborne equipment used to elevate and separate deployable payloads carried on a given Shuttle flight. A payload could be either a part of the cargo or, in the case of Spacelab, possibly the entire cargo. Gradually, as the program matured, this distinction between cargo and payload became blurred and though there are still references to cargo, the terms tend to be essentially interchangeable, and the term payload is more common.

Spacelab, a so-called attached payload, was installed in the cargo bay and remained there throughout the mission. It could be flown in either a manned or unmanned configuration. In the manned configuration, it consisted of a pressurized module outfitted with experiments and connected with the crew compartment of the Orbiter by a tunnel. Once the Orbiter and Spacelab were in orbit, the mission and payload specialists could enter the Spacelab through the tunnel and perform the planned experiments; similarly when the flight was nearly complete, the Spacelab crew secured the experiments, left through the tunnel, and went

through deorbit, reentry, and landing in the crew compartment. The unmanned version consisted of a number of pallets containing experiments, which also stayed in the bay during flight, but which did not require hands-on attention. Any operation of the instruments could be accomplished from the aft flight deck of the Orbiter.

Most spacecraft that were intended to be deployed from the Orbiter are processed in some of the same facilities on KSC and on the Cape that had been used for the unmanned programs. One of these facilities, Building AO on Cape Canaveral, contains a large clean room that was used extensively to prepare planetary spacecraft. Most of these payloads were assembled into a cargo in the Vertical Processing Facility, a building that was originally constructed in 1964 as the Pyrotechnic Installation Building for Apollo spacecraft components. It had been previously used with the name Spacecraft Assembly and Encapsulation Facility 1 (SAEF-1) for planetary spacecraft and even housed the sterilization facility mandated to keep the Viking landers from contaminating Mars.

Payloads have historically been processed using two general philosophies. One is the host mode whereby the resident agency, usually the project providing the launch vehicle, provides facilities, services, and coordination functions with the Range and itself to a payload team that will be at the launch site for a relatively short time, sometimes called a launch campaign. The visiting project team will check out the payload for itself, depending on a coordinator and a team from the launch vehicle project, called the Launch Site Support Manager (LSSM) and the Launch Site Support Team (LSST), to see that its needs are fulfilled and, equally important, that it does not run afoul of Range and vehicle project rules and regulations, particularly in the area of safety. This host mode has been used by NASA's Unmanned Launch Operations Directorate (later renamed Expendable Vehicles Directorate) in the conduct of the Delta, Atlas Agena, Atlas Centaur, and Titan Centaur programs. It is appropriate for launch vehicle projects that launch a variety of spacecraft.

An alternate mode is more appropriate for a payload project that has a number of similar spacecraft. In this case, launch site personnel are delegated the task of performing the actual checkout, of course, subject to the requirements of the payload project. This method has been used on the Mercury, Gemini, and Apollo programs.

The Space Shuttle program has used both methods. Repetitive payload programs such as Spacelab were handled by resident NASA personnel. Generally deployable satellites that include a number of significantly different configurations are treated in the host mode. LSSMs were generally assigned in either case.

Payload processing was certainly not a new thing at either the Cape or at KSC, but the advent of the STS, its reusable delivery method, and the concept of reusable payloads brought about a new look to the process (13,14).

The International Space Station and KSC. The construction of the International Space Station (ISS) placed new requirements on KSC and resulted in the erection of a new facility at KSC, the Space Station Processing Facility (SSPF). The building contains processing bays, an airlock, control rooms, laboratories, logistics areas, office space, and a cafeteria. After the construction of the SSPF had begun, a decision was made to perform leak checks on pressurized modules of the International Space Station at KSC. One of the altitude

chambers in the O&C building which had been used in the Apollo, Skylab, and ASTP programs was refurbished and turned over to ISS operators in 1999 (15). These altitude chambers were deactivated after the ASTP mission in 1975, but they remained in the building unused because there was no requirement for them for Space Shuttle payloads and because removing them would have been very expensive and disruptive.

The new SSPF has been used for the prelaunch checkout of segments of the ISS and will continue to support the program with checkout of other segments of the ISS, experiments, and resupply items that will be transported on the Shuttle throughout the life of the ISS.

Accommodating the Public

NASA has been aware of the requirement in its charter to keep the public informed of its activities. From its beginning, it has given the press information about and access to launches and other major events. In addition, KSC and other centers operate Visitors Centers, where the public is allowed to view exhibits and actual space hardware. These are normally located outside the gates in areas for which no credentials or passes are required. One of the features at the KSC Visitor Center is the Rocket Garden, which includes full size replicas (in some cases actual surplus flight hardware) of space launch vehicles of the past. A full size replica of a shuttle orbiter can be toured, and full scale exhibits of the external tank and the solid rocket boosters can be viewed. Also at KSC, there is the additional feature of bus tours throughout the center that allow the public, for a fee, to ride through the center and to some NASA sites on Cape Canaveral with the option of stopping at certain sites, such as the SSPF observation gallery, an observation tower from which one can see the entire Complex 39, and a Saturn V Apollo building devoted to Apollo, Skylab and ASTP. Within this building is actual Saturn V and Apollo hardware displayed horizontally with the stages and spacecraft elements separated. The KSC Visitor Center, which is operated by a concessionaire, consistently ranks among the top tourist attractions in Florida.

The Air Force, which faces a different set of security concerns, has also accommodated the public with its Air Force Space and Missile Museum. The museum is located within the boundaries of the Cape at deactivated Complex 26, the complex from which America's first Earth satellite was launched. The blockhouse is used for a display area, and many missiles and space vehicles are erected on the grounds in a Rocket Garden similar to its namesake at the KSC Visitor Center. It includes early ballistic and aerodynamic missiles in addition to some space launch vehicles. Admission is free, but operational and safety concerns limit visiting hours. Adjacent to the Air Force Museum is the deactivated Complex 5/6, the site of the Mercury Redstone launches. A Mercury Redstone and a Jupiter C are displayed in their gantries and can be viewed on drive-through tours of this facility.

ELECTROMAGNETIC PROPULSION

Introduction

Sporadic attempts have been made for more than 150 years to use electrical energy to launch projectiles at high velocities. Throughout the world during the

last 20 years, most of the funding invested in electromagnetic (EM) launcher development has been for military applications. In most cases, the perceived advantage has been attaining higher velocities than can be achieved with propellant guns, leading to enhanced lethality. The elimination of gun propellants would also reduce vulnerability as well as allowing an increased number of stored rounds and enabling extended missions. The EM rail gun has been the preferred choice for this application because it has already repeatedly demonstrated muzzle velocities well above those of conventional guns—typically 2500 m/s versus 1750 m/s. The military challenge is to fit the electric pulsed power equipment into a battleworthy vehicle, especially if it needs to be compact. The main potential applications are direct fire tank guns, long-range artillery, and air and missile defense.

Several electrical or electromagnetic (EM) concepts have been suggested, as described later, but their potential for space applications is, as yet, limited. However, the technological bases are now being created on which future EM launch systems for space exploration could be based in the twenty-first century. Such systems could include launch to space from the surface of Earth, the Moon or asteroids, Maglev launch assist for large rocket systems and, possibly, EM thrusters for space transportation. Electrical ion engines have been used in space, and the Hall plasma thruster is under development for NASA.

The interest in electric launchers for military applications has led to improved understanding and advances in many technical areas. Most military applications for EM launchers require gigawatt power levels for pulse lengths of a few milliseconds to accelerate a useful projectile in a launcher of acceptable length. Coupled with the need for compact and robust equipment, this is a challenging goal for the pulsed power system. The desire to achieve muzzle velocities significantly greater than those of conventional guns—from 2–3 km/s—also requires developing the launcher and projectile. Recent progress in these areas could be the basis for future space applications.

History

There are isolated reports of efforts to develop EM propulsion technology in the nineteenth century, but the major developments were in the twentieth century. Pioneering efforts were undertaken in Norway in 1901–1903, in France during World War I, in the United States in the 1930s, and in Germany during World War II. In the second half of the twentieth century there were notable contributions from many countries, including Australia, Britain, China, France, Germany, Korea, Russia, the Ukraine, and especially the United States.

The first known scientific account of an EM launcher was provided by Prof. Page of the Colombian College, Washington, D.C., in 1845, only 10 years after Faraday's pioneering studies on electricity (1). Page's description of the electric launcher stated,

Another curious instrument is the galvanic or magnetic gun. Four or more (helical coils) arranged successively, constitute the barrel of the gun, which is mounted with a stock and breech. The (iron) bar slides freely through the (coils) and, by means of a wire attached to the end towards the breech of the gun, it makes and breaks the

connection with several coils in succession and acquires such a velocity as to be projected to the distance of forty or fifty feet.

The well-known Norwegian inventor, Birkeland, developed an EM launcher using multiple coils (2). He obtained the first patent for an electric gun, formed a company to exploit the technology, and successfully tested two 4-m long induction launchers in 1902. However, his widely advertised public demonstration in 1903 spectacularly failed to live up to the claims that the projectile would be launched without flash or noise, and within weeks, he moved on, in this case successfully, to a different technical career.

Seeking a different approach, Fauchon-Villeplee started studies on EM rail launchers in France during World War I (3). In 1917, he successfully constructed a small working model powered by batteries. The principles of his direct current (dc) electric rail gun were different from those of the coil, or solenoid, launchers. A cross section of the basic configuration taken from one of his patents is shown in Fig. 1. The structure of the gun was iron, and it had two pole pieces to concentrate the magnetic flux into the region where the projectile was located. The magnetic field was energized by copper windings that extended along the length of the barrel and used the same current as fed into the fins of the projectile through sliding contacts. The lightweight projectile was a plastic tube that had a wooden tail in which copper fins transferred current via a sliding contact with the rails. Fauchon-Villaplee proposed that an EM cannon could be built to launch a mass of 100 kg at 1600 m/s. This formidable gun, shown mounted on a railway bogie in Fig. 2, was supposed to have a muzzle energy of 128 MJ—an energy level that has still not been achieved. When World War I ended, these projects were abandoned, but the work did not go unnoticed. A 1923 report by Korol'kov of Russia (4) critiqued the physics and engineering calculations of Fauchon-Villeplee and commented positively and negatively on the claimed advantages of electric guns:

- Electric guns fire without smoke and with virtually no noise.
- Electric gun efficiencies are considerably higher than those of conventional guns.
- Electrical guns use fuels whose energy is greater than explosives and are less expensive.

Figure 1. Cross section of Fauchon-Villaplee's iron-cored rail gun barrel (ca. 1918).

Figure 2. Fauchon-Villaplee's long-range gun concept (ca. 1918).

- The force propelling the projectile is applied along the entire projectile, not just its base.
- The velocity and range of the projectile can be changed by varying the voltage without changing the angle of elevation of the barrel.
- There is no (powder) charge in electric guns, and there cannot be a premature explosion in the gun barrel.
- The power of electric guns...depends only on the instantaneous energy of the electrical source.

MacLaren's U.S. patent of 1921 described a traveling magnetic wave induction launcher powered by a high-frequency, three-phase generator (5). In this, the traveling magnetic wave induced currents in the projectile and provided the EM force that accelerated the projectile through the barrel. In the 1930s, Professor Northrop undertook experiments at Princeton University with similar launchers powered by motor-generators and capacitors. The work was described in a novel written by Northrop¹ (6) in which the theme was a journey to the Moon using an EM coil launcher in place of the conventional cannon proposed by Jules Verne. Northrop provided considerable detail on the engineering calculations, as well as several photographs illustrating the equipment needed—some of which were retouched to appear more impressive.

¹Using the pen name "Pseudoman."

During World War II, a group led by Hansler in Germany was involved in developing EM launchers (7). The experiments started with induction launchers but because little success was achieved, refocused on rail guns. Hansler's first rail launcher tests in September 1944 used an iron barrel similar to Fauchon-Villaplee's that was energized by windings to create a transverse magnetic field to give the $J \times B$ forces needed for accelerating a projectile (Fig. 3). A velocity of 1080 m/s was achieved using a spring-loaded arrangement to ensure good electrical contact between the projectile fins and the rails. To meet the wartime needs of defending against high-altitude bombing raids, the development of a 40-mm EM gun with a high velocity (2000 m/s) and rate of fire of 72 rounds/min. was proposed. The initial design had a 10-meter iron barrel with a 3-tesla magnetic field. However, Hänsler soon realized that the performance required could be achieved only with an air-cored barrel that had a much higher magnetic field, as shown in Fig. 4. This was designed, but not built, when the war ended. Modern EM rail-gun launchers are of this type, and operating currents are so high that pulsed magnetic fields > 20 T are generated, making the presence of iron irrelevant. Starting in May 1946, the Armour Research Foundation in the United States evaluated Hansler's work. A comprehensive document was created based on reports, blueprints, and equipment from Germany (8). After evaluating the material and performing calculations, the report concluded that the anti-aircraft EM rail gun was technically feasible.

Relatively few efforts were undertaken in the aftermath of World War II, with one or two exceptions (9,10), until rail-gun experiments were undertaken at the Australian National University in the early 1970s based on the concept of macroparticle acceleration to high velocities for meteorite impact studies (11). These experiments led to a growth of interest in the United States and also caused non-U.S. efforts to accelerate. Most of these efforts were for defense applications, but launch-to-space was studied by MIT and NASA.

The early pioneers of electric gun research would be impressed to see what has been accomplished in the last decade. Pulsed power supplies using capacitors and rotating generators have provided currents in excess of 3 MA to EM rail launchers. Velocities of more than 6 km/s have been achieved in rail guns using

Figure 3. Sketch of Hansler's iron-cored rail-gun (ca. 1944).

Figure 4. Hansler's air-cored rail-gun cross section.

projectiles of a few grams, and muzzle energies of 5–8 MJ have been achieved for larger masses at velocities up to ~ 4 km/s. Induction launcher technology has been demonstrated for low velocities (some 100's m/s), but the highest confirmed velocity is 1 km/s.

Electric Launcher Configurations

Rail Launcher Parameters. Rail launchers and coil launchers rely solely on electromagnetic (EM) forces to accelerate projectiles to high velocities. Most single-stage laboratory EM rail launchers operate at efficiencies of 30% or less, so that substantial energy is needed at the breech of the launcher for each shot. Modifications to improve launcher efficiency are described later. Some of these are more appropriate for launch-to-space than for ordnance applications.

Most experimental and theoretical studies of EM rail launchers during the last 20 years have used the simple air-cored rail-gun arrangement proposed by Hansler. In this, a short pulse of high-current electrical power is fed to the breech of a two-rail configuration in which the projectile is accelerated by the Lorentz ($J \times B$) force (Fig. 5). This configuration has operated successfully across a wide range of conditions.

Because the induced magnetic field in the air-cored launcher bore is created by the current I passing through the rails, the $J \times B$ accelerating force (F_{EM}) can be expressed as

$$F_{EM} = 0.5L'I^2, \quad (1)$$

where L' is the inductance gradient ($=dL/dx$) of the rails in the vicinity of the projectile. L' is a relatively invariant quantity that depends on rail-gun bore geometry, more accurately, the relative fraction of the bore cross section occupied by the rails: a typical value is $\sim 0.5 \mu\text{H/m}$. L' is small, so a large current is required to accelerate a significant mass m to a high velocity because

$$F_{EM} = 0.5L'I^2 = ma. \quad (2)$$

Figure 5. The two-rail, breech-fed rail-gun arrangement. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Currents of several megamperes have been successfully used in 90-mm bore rail guns in laboratory experiments.

Because the accelerating force depends on I^2 , it is independent of current direction and, in principle, an alternating current (ac) could be used. Some early systems were of this type, but shorter barrels and a better acceleration profile can be achieved by using a unipolar (dc) current pulse. Modern rail launchers use a current pulse that has a fast rise to a constant current for the majority of the acceleration, followed by a decrease in current near the muzzle exit to minimize muzzle flash. This “flattopped” pulse shape can be achieved using several short pulses in sequence from each section of a subdivided energy store or generator. Using this approach, the subpulses must be correctly timed and overlapped to achieve the desired total pulse shape (12).

One major source of inefficiency in the simple rail launcher is the magnetic energy remaining in the barrel at the instant of projectile launch. For an idealized constant current pulse, the inductive energy left in the barrel at launch equals the projectile muzzle energy so that the launcher efficiency², even without other losses, cannot exceed 50%. Reducing the current at the muzzle exit decreases the magnetic energy stored in the barrel but increases the barrel length. The need for compact power supplies has led to the invention of alternative launcher configurations that may have higher efficiency, as described later. None of these has yet been widely studied, and further research is required to determine whether the advantages of these concepts outweigh their disadvantages.

Numerical models are used for the detailed design of EM rail launchers, but simple expressions can illustrate the fundamental principles and provide approximate engineering parameters, as shown here.

When the fundamental definitions of acceleration a and velocity v are integrated for the condition of constant acceleration \bar{a} , they yield the well-known result that: “*work done (or energy) equals force times distance.*” For an EM

²The efficiency is the kinetic energy of the projectile at the muzzle exit divided by the electrical energy supplied to the breech of the launcher.

launcher this can be written as

$$E_{\text{muz}} = 0.5mv_{\text{muz}}^2 = \overline{F_{\text{EM}}}s, \quad (3)$$

in which s is the launcher barrel length and \overline{F} is the average EM force. Assuming that the force is constant across the cross-sectional area A of the barrel, the accelerating force is also

$$F_{\text{EM}} = pA. \quad (4)$$

In EM launchers, as in propellant guns, the accelerating pressure p does not remain constant during the launch process, unless special design approaches are taken. The measure of how close the acceleration is to the ideal is the piezometric efficiency, η_P

$$\eta_P = p_{\text{max}}/p_{\text{ave}}. \quad (5)$$

For a propellant gun, $\eta_P > 2$, but simple rail launchers have operated with $\eta_P \sim 1.5$, and operation to 1.3 or lower may be possible. Even lower values may be feasible with the “distributed” EM launchers described later.

From Equations 3–5,

$$E_{\text{muz}} = p_{\text{max}}As/\eta_P, \quad (6)$$

showing that, for a given barrel length and area, the muzzle energy is determined only by the average pressure \bar{p} , or by the maximum pressure, p_{max} and the piezometric ratio.

Using $I^* = I/h$ as a measure of the linear current density on the inner surface of the rails that carry current (where h is the height of the rail at the inner bore from one insulator to the other), Equation 2 can be written as

$$F_{\text{EM}} = 0.5L'I^{*2}h^2. \quad (7)$$

Combining Equations 4 and 7 and using $A = h^2$ for a square barrel yields

$$p_{\text{sq}} = 0.5L'I^{*2}. \quad (8)$$

Typical values in this expression are $L' = 0.5 \mu\text{H/m}$ and, for a copper rail, $I^* \sim 40 \text{ kA/mm}$, to give $(p_{\text{sq}})_{\text{max}} = 400 \text{ MPa}$. This is the highest pressure that a simple EM rail launcher can achieve. Substituting $(p_{\text{sq}})_{\text{max}}$ in Equation 6 allows rail launcher parameters to be estimated.

For simplicity, the above analysis assumed a square rail launcher bore. Other geometries (e.g., rectangular or circular) have been investigated experimentally and analytically. Calculating L' is complicated in complex barrel cross-sections and requires knowledge of the variation of current density and temperature around the periphery of the rail (13).

The maximum acceleration pressure achievable in a simple rail launcher is lower than the peak values achieved in powder guns, but useful performance levels can be still achieved with a rail launcher, even within these pressure constraints, as shown in Table 1.

Table 1. Maximum Launch Energy (MJ) Achievable in a Simple Square Bore Rail Launcher

Barrel length, m	Bore height, mm			
	80	100	120	140
4	7.9	12.3	17.7	24.1
5	9.8	15.4	22.2	30.2
6	11.8	18.5	26.6	36.2
8	15.8	24.6	35.4	48.2
10	19.7	30.8	44.3	60.3

Some techniques for increasing the achievable pressure have been sought, as described later, but they are still limited by Equation 8. Increasing I^* requires different rail materials, but the potential benefits of using high-temperature materials is largely offset by their poorer electrical and thermal properties, as can be seen from Table 2.

For example, although tungsten, has a melting point three times higher than copper, it will reach surface melting when $I^* = 56 \text{ kA/mm}$, which is only a 37% improvement over copper. In the absence of fundamental material improvements, it may be necessary to use other rail launcher configurations that have higher L' values, as described later.

Augmented Rail Launcher. In early concepts, external magnets—either superconducting (14) or permanent (15)—were proposed to provide a steady magnetic field that would permeate the entire launcher bore volume to add to the induced magnetic field produced by the applied current. However, such fields are generally small compared with the pulsed field resulting from the main current in large bore launchers, and this technique has now been replaced by additional rails close to the main launcher rails to enhance the magnetic field in the launcher bore. The augmenting rails may be energized either by (1) using all of the current that goes through the main rails, (2) using a separate supply, or (3) taking part of the main current and diverting it through the augmenting rails. The first option has generally been used experimentally because it is simple and only one power supply is needed.

Table 2. Limiting Rail Currents for Several Materials

Rail material	I_{max}^* , MA/m
Copper	40.9
Aluminum	25.3
Silver	32.8
Tungsten	56.2
Graphite	35.0
Stainless steel	32.7
Molybdenum	45.5
Elkonite (67% W, 33% Cu)	65.5

The advantage of augmentation is that the current in the main rails and armature is reduced for a given accelerating force, thereby decreasing bore erosion and easing the task of the armature designer. In addition, the power supply can operate at lower current³. For single augmentation (one augmenting turn in addition to the rails in the barrel bore), $L' \sim 1 \mu\text{H/m}$; double augmentation yields $L' \sim 1.2$ to $1.3 \mu\text{H/m}$. Singly and doubly augmented barrels have been successfully demonstrated with small-bore rail guns (16,17). Augmentation has not been widely considered for military applications because the launcher is larger and heavier than a simple barrel, complicated breech and muzzle current connections are needed, and additional magnetic energy is stored inductively in the barrel at the muzzle exit. However, this may not be a concern for a fixed launcher, as for a launch into space.

DES Rail Launcher. A second alternative to the simple rail gun is the distributed energy store (DES) launcher. In this, multiple power-feed points are located along the rails so that energy can be fed from several independent energy sources (18,19). This allows the maximum current to the projectile armature to be provided at just the right time in the acceleration process to maximize the EM force on the launch package.

To supply this launcher, the energy source⁴ needs to be segmented into separate sections that are energized sequentially as the projectile passes. The magnetic energy is switched into each stage of the launcher exactly when the projectile reaches that stage and is switched off after the projectile leaves. Therefore, the amount of inductive energy left in the barrel when the projectile leaves the muzzle is only that from the last one or two sections. If there are n sections, only $\sim 1/n^{\text{th}}$ of the usual amount of inductive energy remains in the barrel, so that the overall launch efficiency is much improved. This concept may be especially advantageous for a long static system, such as for launch to space. For a military system in which it is necessary to slew the barrel rapidly, the need for multiple power leads to transfer current to each stage from many independent power supplies is a significant disadvantage.

Multirail Launcher. The third alternative version of the simple rail gun is the multiple rail arrangement (20). In this concept, the rails of the simple rail gun are subdivided, so that one- n^{th} of the normal current passes through each rail. The rails are electrically insulated from each other and are electrically in series so that a low-current, high-voltage source can be used. The current required from the power supply is divided by the number of rails, but there is a corresponding increase in the applied voltage. Electrical shorting prevents this technique from being applied with plasma armatures, but it can be used with solid armatures if arcing contact between adjacent rails can be prevented. The concept has been demonstrated experimentally (21,22) but has received relatively little attention because of the concern about the ability to *always* prevent arcing. If arcing occurs between the rails or within the armature, the power supply could be electrically shorted out with disastrous consequences, unless precautions were taken.

Staged Transiently Augmented Rail (STAR) Launcher. The STAR concept (23) combines the features of an augmenting magnetic field and the DES

³Although at the expense of an increased voltage.

⁴And, in some configurations, the barrel rails.

Figure 6. STAR—staged transiently augmented rail gun—module, showing the rails (1), insulator (2), containment (3), and pulsed augmenting magnet coils (4).

power feed. The augmenting field is provided by a series of independent coils that are energized only when the projectile is nearby. Figure 6 illustrates a three-section version of such a launcher; many such sections would be arranged in series for an Earth-to-space launcher. The energy used in these coils (less losses) is then transferred from coil-to-coil as the projectile accelerates along the barrel. The energy required for augmentation is therefore much less than in the usual augmentation concept. This arrangement allows the main rail current to be reduced, which is beneficial for the power supply and the barrel. The total launcher efficiency will also be better than that of the simple rail launcher because the augmentation is transferred forward with the projectile, rather than permeating the entire barrel structure. Although STAR is merely a concept at present, high-field pulsed magnets have been tested at magnetic fields up to 68 tesla (24)—a level that is significantly higher than that used in present EM launchers. The STAR concept is most appropriate for a long static system and is a possible candidate for launch to space.

EM Induction Launchers. In principle, having no direct sliding contacts and operating with relatively low currents, EM induction launchers promise high efficiencies and contactless launch. Operating velocities of a few 100 m/s have been achieved by several groups, but there have only been two reports of velocities near or above 1000 m/s (25,26). As a consequence, there has been little funding for research on high-velocity launch applications, and this technology lags that of rail launchers. However, the approach may be useful for lower velocities and could replace the first stage of a rocket system.

Several induction launcher approaches have been studied (27). The barrel-type launcher consists of two parts—a stationary array of drive coils and a moving conductive projectile. The stationary coils generate a rapidly varying magnetic field that induces currents in the projectile. The interaction between the applied magnetic field and the induced magnetic field creates an axial propelling force and, in some configurations, a radial centering force that eliminates

the need for a contacting guide rail system. The geometry can be coaxial or flat channel, and the induction can be pulsed or traveling-wave. The flat arrangement could be applied to the wings of a projectile in a toroidal configuration.

The single-stage pulsed induction launcher consists of a coaxial, single, fixed, drive coil and movable conduction ring. When the drive coil is pulsed with current i_1 , an induced current i_2 is created in the conduction ring that generates a magnetic field in the direction opposite to that in the drive coil. The mutual repulsion between these two coils causes acceleration of the ring. The EM accelerating force is

$$F = i_1 i_2 \frac{dM}{dx}, \quad (9)$$

where M is the mutual inductance and x the distance between the coils. High velocities and extremely high accelerations were reported with close-coupled, single-stage repulsion launchers of this type (28). A modified arrangement uses a smaller movable ring that can be nested inside the drive coil. This can be further modified by adding additional drive coils to create the barrel of a launcher that can be operated either synchronously or asynchronously. In the synchronous mode, only one drive coil is energized at a time and is synchronized by a feedback switching control system to match the movement of the accelerated coil or cylinder. The pulsed magnetic field from the driving coils induces an azimuthal magnetic field in the rear of the inner coil or cylinder in a direction that opposes the applied field, so that the inner coil is accelerated along the launcher. To maintain a unidirectional azimuthally induced current in the projectile, the current in all of the drive coils must be in the same direction. In strictly synchronous operation, the dc component of the current induced in the projectile decays with time, so that the direction of induced current flow has to be reversed.

Another system is the traveling wave induction launcher in which alternating currents are separately fed to a number of the drive coils across a region that is longer than the projectile being accelerated. This creates a traveling magnetic field that travels with a velocity v :

$$v = 2\tau f, \quad (10)$$

where 2τ is the wavelength of the magnetic wave and f is the frequency of the current in the drive coils. The traveling wave induces azimuthal currents in the projectile and an associated magnetic field pattern that is similar to that generated by the drive coils. However, the induced magnetic field pattern is displaced relative to the driving field pattern, and the projectile is "dragged" along the barrel at a velocity close to that given by Equation 10. The advantages of this arrangement are that the propelling force acts more uniformly across the entire body of the projectile, a radial centering force acts to keep the projectile centered in the barrel, and the need for exact synchronization between the projectile and the drive coils is eliminated. Disadvantages include the need to divide the barrel into several sections that are fed with different frequencies so that the slip velocity and thermal losses can be minimized.

Energy Storage and Pulsed Power

Energy Requirements and Options. From the earliest days of electric launcher research, it has been understood that supplying the required high-power pulses of electricity is a critical issue. Conventional guns and rockets have reached high level of capability after hundreds of years of development in which very energetic propellants have been created. Energy densities in propellants are impressively high—several MJ/kg. Achieving similar energy densities in a system that stores and transfers electrical energy is not yet possible, as can be seen from Table 3. Some of the other benefits of electrical systems such as higher velocities and improved safety due to the absence of propellants offset this disadvantage. In many situations, the capability to easily control the electric launcher to provide the required muzzle energy offers a benefit that is not available from conventional propellants.

The energy needed for an EM launcher is determined by the mission requirements. A notional set of input energy requirements for several launcher technologies for a muzzle energy of 20 MJ is given in Table 4. Other applications, such as an EM catapult for aircraft launch or launch to space, may require much more energy.

It is necessary to provide *average* power to the electrical system at a rate that matches the launch rate. The prime mover⁵ is typically coupled to a generator and operates through a transformer/rectifier to provide electrical power to the energy storage system. The availability of stored energy in a flywheel or battery pack can permit a few launches to occur quickly without energizing the main prime mover power system for certain applications. The design of this subsystem depends on the type of launcher and the firing rates required. For high firing rates or continuous operation, it is necessary to cool the components.

Capacitor Banks. Most early electric launcher experiments used capacitor banks because they are inexpensive in small sizes and the components are widely

Table 3. Electrical Energy Storage Options

Device	Storage mechanism	Defining equation	Assumption	Limiting values	Energy density, MJ/m ³
Capacitor	Electrostatic	$E = \frac{CV^2}{2}$	High-energy-density plastic film	$E_{op} = 400$ $V/\mu m \quad \epsilon_r = 10$	7
Rotor	Inertial	$E = \frac{I_m \omega^2}{2}$	High-speed composite/conductor rotor	$\rho = 1500$ kg/m^3 $v_{periph.} = 600$ m/s	135
Inductor	Magnetic	$E = \frac{B^2}{2\mu_r \mu_0}$	High-field air-cored inductor	$\mu_r = 1 \quad B = 40$ T	640
Battery	Electro-chemical		Li ion	3.5 volts	4000
Propellant or explosive	Chemical		High-energy-density materials	Few eV per bond	5000–10,000
Diesel fuel	Chemical		“Free” oxygen from atmosphere	More exothermic bonds	40,000

Table 4. Input Energies Needed for 20-MJ Muzzle Energy

Electric launcher type	Energy input per shot, MJ	Peak current, kA	Peak voltage, kV	Pulse length, ms	Minimum average instantaneous power, GW
EM railgun	40	4000	10	6	7
ETC gun	4	150	16	4	1
ETC igniter	0.4	50	10	1	0.4

available. Early experiments used banks with an oscillating output current whose characteristic time period was matched to the transit time of the projectile through the rail gun. Because this results in substantial current variation and very nonuniform acceleration, it is generally not preferred. In some cases, a high-frequency, rapidly ringing bank was used, and the averaged fluctuating current was accepted as an inexpensive way to undertake experiments. A better arrangement is to “crowbar” the circuit after the current has reached its peak value, which extends the high-current portion of the output pulse. To achieve this, a closing switch connects the current to the gun, and a diode is used in the crowbar leg with another closing switch.

Even when a single capacitor bank is “crowbarred,” current droop can cause inefficient energy transfer for a launch time that is longer than the characteristic decay time of the bank. The solution is to subdivide the capacitor bank into separate modules that can be independently triggered but are connected together at the current feed point into the launcher breech.⁶ A practical benefit of the modular approach is that repair and maintenance can be carried out on some modules while the remaining units continue to operate. The design of individual modules and the way in which they are connected depends on the type of gun and the duty required. A flat-topped current pulse can be created for a rail gun by triggering several modules sequentially to match the transit time of the projectile through the barrel. To get the desired high initial acceleration, a high-energy module is fired initially, followed by subsequent discharge of smaller modules. Because the projectile is traveling at higher velocity further down the barrel, later modules have smaller inductors in series with the capacitor modules to achieve faster rise times (12).

To ensure high efficiency, the output switches that connect the modules to a single load connection (the launcher breech) must prevent current from later modules from being routed back into modules that discharged earlier (29,30). If this is not done, considerable stored energy may be lost resistively, as it transfers from one module to another without ever reaching the launcher. Capacitor voltages are generally in the range of 10–15 kV, but values of 22, 44 kV, and higher have been used for some experiments. Such values necessitate close attention to insulation integrity and component locations to prevent electrical breakdown.

⁵Usually this is a gas turbine or internal combustion engine.

⁶For a single point breech-fed simple rail gun.

Table 5. Plastic Film Dielectrics

Material	Dielectric constant	Breakdown voltage, V/ μ m	Stored energy Density, MJ/cum
Polypropylene	2.1	200	0.37
Polyethylene	3.25	300	1.3
Polyvinylidene fluoride	10	400	7
Siloxane	9.3	~ 400	$\sim 2.5^a$

^aMeasured with composite materials that had siloxane on a kraft paper backing for strength.

The capacitors in which energy is stored are the single largest contributor to the size and mass of the total system. The energy stored in a dielectric is proportional to the dielectric constant ϵ_r and to the square of the operating electric field strength E_{op}^2 , which is chosen as near as possible to the breakdown strength of the dielectric material while ensuring a low probability of spurious breakdown. Capacitors that use paper dielectric with foil electrodes were standard for many years. Plastic films such as polyethylene (PE), polypropylene (PP), and polyvinylidene fluoride (PVDF) provide better performance (see Table 5).

The performance of PE and PP capacitors is well characterized, and capacitors made from these materials are widely available. Units made from PVDF have been developed in the last decade. Although offering high energy density, this nonlinear material is more difficult to characterize, less efficient in operation, and more difficult to integrate into a complete system (31). As a result of these disadvantages, there is much to be gained if new dielectric materials could either be discovered or created. Recent small-scale experiments have been performed using siloxane-based materials with promising results (32). However, substantial investments are needed to bring a new capacitor material to reliable large-scale manufacture, and few sponsors have yet been found.

It is important to consider the entire capacitor system when component development is planned. If extremely high-energy-density dielectric materials were to become available, the volume of the system would then be dominated by other components, such as switches or inductors. Therefore, these components also need to be developed to reduce their size and weight. Integrated systems, in which component functions are combined, rather than by being individually optimized, may have significant benefits (33).

Rotating Machines—Homopolar Generators. Laboratory studies of electric launchers were undertaken in the 1970s and 1980s using homopolar generators (HPGs) which operated as electrified flywheels to deliver a low-voltage but high-current output (34). The HPG voltage, typically 100–200 V for an iron-cored machine, is much less than that required to drive an electric gun directly. Therefore, it is necessary to add a pulse compression stage in which energy is transferred into an inductor where it is temporarily stored as magnetic energy before delivery to the launcher at a higher voltage. Getting the energy into the inductor is relatively simple, but getting the energy out of the inductor to the gun can be difficult. An opening switch is needed that can carry a current of megamperes during inductor charging, but which can open quickly when transfer of

the current into the gun is required. Such switches are not readily available, although laboratory versions have been developed. The need for the opening switch and storage inductor has caused the HPG to go out of fashion during the last few years in favor of other rotating machines.

Pulsed Alternators. Synchronous ac generators of very large sizes (>1400 MW) operate successfully for many years for electric utilities delivering voltages greater than required for most electric launchers. A short-circuit fault near the terminals of such a generator could cause a substantial overcurrent to flow and would damage the machine. To prevent this, utility generators are deliberately designed so that the resistance seen by such a fault (the “subtransient reactance”) is high enough to limit the current to a value that does not cause serious damage. However, such machines can be modified to deliver a limited number of higher than normal current pulses. For example, in 1963, a 3-GVA machine was used for testing circuit breakers with asymmetrical currents of 300 kA at 16.5 kV (35).

A pulsed alternator deliberately designed with a low subtransient reactance to deliver safely a high current is an alternative to the HPG for an electric launcher. Instantaneous power of several GW is typically needed for electric launchers, usually for subsecond pulse durations. Such a machine has to operate under conditions so extreme that they would be acceptable only once or twice in the lifetime of a utility machine.

Pulsed iron-cored machines are too heavy for many electric launcher applications. Therefore, during the last few years, the United States has invested in the development of pulsed alternators that have disk (36) and drum topologies (37,38). These machines can be driven up to full speed in seconds to minutes and then discharged into the electric launcher. Multipolar geometries are used to ensure compactness so that the ac output current has to be rectified for launchers that require dc. The rectifier and switching assembly can be a significant part of the total system mass, volume, and cost. High rotational speeds enable small machine sizes to be achieved but necessitate the use of lightweight, high-strength rotor materials in which the conductors necessary to carry current are embedded. Carbon fiber composites are the modern structural choice. At high rotational speeds, aerodynamic losses become important, and it may be necessary to partially evacuate the machine interior to minimize heating.

One feature shared by all rotating machines is their capability to store more energy inertially in the rotor than required for each shot. The voltage, power, and energy storage requirements need to be evaluated for each particular launcher type and mission to give the optimum design. In some cases, the machine size and geometry may be determined by the electrical design (required output voltage or power), but in other cases the stored energy is the dominant feature. Decoupling the design for electrical power production from the energy storage design may be possible by using flywheels that are separate from the power generator.

Linear Magnetic Flux Compressors. Linear flux compressors have been suggested as an alternative to rotating machines and capacitors for driving electric launchers (39). By using large quantities of high explosives to drive conductors together to compress a magnetic field, current pulses greater than 250 MA have been achieved in microsecond pulses at low efficiencies (<1 to 10%).

Neither of these conditions is ideal for an electric launcher that might require pulses of a few milliseconds, especially because the use of explosives implies single-shot operation. Replacing explosives with a fuel/air combustion system has been suggested for multi-shot systems (40,41) but has not been tested. Flux compressor efficiencies are likely to fall to low levels as pulse lengths are extended, as a result of diffusion of the magnetic field into the conductors and correspondingly increased resistive losses.

Magnetohydrodynamic Generators. In a magnetohydrodynamic (MHD) generator, the flow of an electrically conducting gas (a “plasma”) through a magnetic field generates a voltage which, when extracted through electrodes in a generator channel, can transfer current to an external load without the intervention of any rotating element, such as a turbine or generator. A practical device consists of a plasma source and a channel, through which the plasma flows following acceleration in a supersonic nozzle, together with a magnet and electrodes embedded in the channel. The plasma is produced by reacting fuel and oxidant, together with “seeding” by a material of low ionization potential, such as a potassium or cesium compound. Early electric utility concepts also considered high-temperature, gas-cooled nuclear reactors cooled with cesium-seeded helium as the heat source. It is possible that a future space system could employ a similar Brayton or Rankine-cycle arrangement.

Considerable research was undertaken in the 1960s and 1970s on MHD devices for long-duration, low-current, utility power generation, but relatively little research has been done for pulse lengths of a few milliseconds. Repetitive, low-current (kA) pulses at a frequency of ~ 2 Hz and rise/fall times of tens of milliseconds were generated for pulses of a few seconds during operation of a liquid oxidizer/solid fuel rocket-driven generator (42). Currents as low as this would need to be transformed up for most electric launcher applications. Explosively driven, highly ionized argon systems have produced extremely high power ($> \text{GW}$) and high current ($> \text{MA}$) for tens of microseconds (43).

The claimed advantage of MHD generators is the relative simplicity of their “direct conversion” of thermal to electrical energy. However, the relatively low conductivity of most partially ionized plasmas limits the current that can be obtained from MHD generators to 10's kA, rather than MA desired for large electric launchers. One experiment to power a low-current rail gun with a MHD generator via energy storage in an inductive current transformer has been reported (44).

Inductors. Pulsed inductors have been used for intermediate energy storage and as a pulse compression component in HPG-powered rail-gun systems (11,45,46). Any low-voltage source including batteries, can be used to provide current for the inductor. The inductor can be regarded as a pressure vessel for mechanical design purposes; the stored magnetic energy is given by

$$E = B^2 / 2 \mu_0, \quad (11)$$

where B is the magnetic field strength (teslas) and $\mu_0 = 4\pi \times 10^{-7} \text{ H/m}$. A toroidal inductor is ideal for minimizing EM interference with external circuits caused by fringing magnetic fields. Shielded solenoids are a less expensive alternative that can also have low fringing fields.

For large EM launchers, the need to store and deliver tens of MJ at a few MA necessitates inductances L of a few μH . Using high currents, it is difficult to achieve system resistances R less than tens of $\mu\Omega$ with room temperature conductors, so that characteristic current decay times ($\tau = L/R$) are typically < 0.1 s. This requires discharging the inductor very quickly after charging, otherwise substantial current decay and losses occur. It is helpful to cool the inductor to cryogenic or even superconducting temperatures, so that R is reduced and τ increased. Cooling copper to liquid nitrogen temperatures (77 K) is beneficial in reducing resistance. Liquid hydrogen (20 K) with high purity (99.999% purity) aluminum is even better but requires careful handling. At liquid helium temperatures (4 K), many materials become truly superconducting, and large inductors have been made with NbTi and NbSn₃ conductors for nuclear fusion experiments. Liquid helium is unlikely to be acceptable on cost or logistic grounds for military applications but could be attractive for static ground-based systems that operate for long times with low losses.

The last decade has seen spectacular progress in high temperature superconductors based on copper oxide compounds: superconductivity has been demonstrated at temperatures well into the liquid N₂ range (over 130 K). So far, critical current densities are low, and present conductors are not yet candidates for high-field inductors. Nevertheless, there are promising developments in the development of high current density ($> 1 \text{ MA/cm}^2$), YBaCuO films on flexible substrates that could be used for inductors, and further improvements seem likely (47).

Batteries and Flywheels. The two options usually considered for energy storage are chemical batteries and flywheels. Batteries store large amounts of energy very compactly (a standard lead-acid automobile battery may contain 50 MJ) but cannot deliver high-power pulses. The recent international interest in developing electric vehicles for the consumer market is likely to lead to battery improvements. Unfortunately, electric vehicle requirements do not match the energy or pulse length needs of electric launchers. Modified batteries for high-power delivery generally use bipolar geometry, but even these are not well matched to most electric launcher requirements unless coupled with a multi-stage inductor (48). Lithium-ion battery technology has recently progressed rapidly, but other candidates are also possible. In all cases, batteries (and a similar system, the ultracapacitor) are based on electrochemical reactions that have characteristic voltages of 2–4 volts, so that multicell units are necessary to get voltages of 100–500 V. The voltages needed for electric launchers require multiple series/parallel strings or, more likely, electronic inverters to transform the battery dc output to high voltage dc.

Flywheel energy storage is another alternative. Very high energy storage densities can be achieved, especially at high peripheral rotor speeds. Oak Ridge National Laboratory has achieved peripheral speeds > 1400 m/s using carbon fiber composites (49). Less highly stressed versions of such flywheels are now in service commercially on a limited scale for passenger buses in Europe. There are significant differences between long-term energy storage and discharge for commercial applications versus the short pulses needed for electric launchers. The flywheel requires support subsystems for bearings, lubrication, and vacuum housing and needs to be coupled to a generator with a transformer/rectifier to produce high-voltage dc for launchers.

Auxiliaries. All of the power delivery and energy storage devices described here require auxiliary components. For example, switches are required to connect the pulsed power source to the electric launcher. These need to transfer high currents and to hold off high voltages. Options include solid-state devices, spark-gap switches, vacuum switches, and plasma-filled devices. Other auxiliaries depend on the specific power technology. For example, high-speed rotating generators require brushes and slip rings, vacuum enclosures, and cabling to connect the components together and to the gun breech. Operation of the entire launcher system requires a control system that includes the diagnostics necessary to monitor the total system health. This control system must integrate inputs from the prime power, pulsed energy and power system, launcher control system, and an overall mission control system.

Space Applications

First Stage/Orbiter Launch. A natural progression from the early work of Birkeland and Northrop was for low-velocity applications of launcher technology to merge with the development of linear induction motors. Linear motors are usually considered for continuous applications such as “people movers” in transit systems or for intercity trains where magnetic levitation can be employed in “maglev” systems. These motors operate continuously. A class of applications that has arisen recently is linear motors in amusement park rides in which short-term “launches” of a few seconds provide passengers the “thrill” of a high (or low)-g ride. An extension of this is to the launch of aircraft or other military equipment.

During World War II, a full-scale EM catapult called the “Electropult” was developed and built by the Westinghouse Corporation for the assisted launch of U.S. bombers from short runways on small mid-ocean atolls in the Pacific (50). Although successful, the project was finished too late to enter the war and was not pursued further. Similar efforts have been restarted in the last few years by the U.S. Navy to develop an EM Aircraft Launcher System (EMALS) to replace the steam catapult on an aircraft carrier (51). Depending on the results during the next few years, it is possible that future aircraft catapults could be of this type. The masses launched in these systems are 5–50 tons, and the required velocity is usually 25–100 m/s, so that launch energies of 50–100 MJ are typical. The challenge in this case is to accomplish the launch in the limited distance onboard the aircraft carrier, which is about 100 meters. The aircraft is therefore subjected to an acceleration of about 3 gs. The most important system concern is reliability; failure rates need to be less than 1 in 10 million to be acceptable for naval aviation.

The NASA Space Flight Center in Huntsville is currently testing a small-scale system of this type that could form the basis for a future replacement of the first stage for an Earth-to-space orbiter launch system (52). This could eliminate the first stage of a multistage missile system by boosting the orbiter to the speed at which the later stages can be ignited for further propulsion. A system of this type, known as *Maglifter*, was proposed in 1994 (53). A similar proposal, made recently by the Russians, suggested the use of MHD generators to power the

launcher (54). Based on the technical success of experimental maglev trains in Japan and Germany, the successful development of such a system seems quite feasible.

Direct Launch to Space. It is remarkable that one application that was apparently considered by the early developers of EM technology was that of launching manned or unmanned objects directly into space.⁷ The interest was based on the idea that, in principle, EM forces can act at very high speeds, so that there should not be any *fundamental* physical barriers to their operation. Though this is largely true, some physical effects have been encountered at speeds in excess of 3 km/s that are not yet fully understood, and the velocities required for a direct Earth-to-space launch have not yet been reached except with gram-sized projectiles.⁸

Two concepts have been studied—the coil-based inductive system and the rail-gun system. The earliest versions of coil launchers, referred to as “mass drivers,” were studied at Princeton University by O’Neill and his colleagues (55,56) and at MIT in the late 1970s and early 1980s. Only relatively low velocities of (<100 m/s) were achieved, but because O’Neill’s suggestion was to use the mass drivers for escape from the Moon or to move objects from one orbit to another, very high velocities were not necessary. What was important was the use of renewable energy—so that solar panels were proposed. Scientists at the Sandia National Laboratories, where velocities up to 1 km/s have been achieved with a coil system (25), have suggested launch-to-space using a coil gun (57), but the required muzzle velocity of 6 km/s has not been achieved. Rail guns have been much more successful in demonstrating high velocities (up to 4.3 km/s with 0.6 kg and ~ 7 km/s with gram-sized projectiles) and high energies (up to 9 MJ), and this has led to a number of detailed studies of possible space launch (58–65).

Very high energies and power levels are required to accelerate large masses into space. Launching a 1000-kg aeroshell of the type illustrated in Fig. 7 requires an armature and sabot system that may make the total mass 1250 kg (see Fig. 8). At a launch velocity of 7.5 km/s, this represents a muzzle energy of 35 GJ. One suggested approach would use a staged transiently augmented rail-gun (STAR) launcher of the type illustrated in Fig. 6 (65).

This concept offers very high efficiency because the energy needed for the launch is transferred from section to section along the launcher during acceleration. With a launcher efficiency of 80%, the energy input for the launch of this package would be 44 GJ. The cost of the electricity for such a launch would be negligible—less than \$1000. A substantial capital investment would be required to build, install, and operate such a facility, including a dedicated power supply or link to the utility network. For a moderate peak acceleration (by gun standards) of 30,000 g’s, the launcher would be some 230 meters long while for 2000 g’s,

⁷There is a report that the Russian, Rynin, stated in 1929 that “the Austrian, Heft, in 1895 proposed a solenoid gun for launching interplanetary spaceships at speeds exceeding the 11.8 km/s needed to reach interplanetary space.”

⁸Launch from the Moon or from an asteroid would require a much lower velocity and may be within the reach of present laboratory velocities. However, there is no requirement now for a system with such capabilities.

Figure 7. A flight body concept. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

it would be about 1 mile long.⁹ One recent estimate of the cost of such a system is about \$1.4B (65) (see Table 6). A proposal for an induction launcher system also estimated a capital cost of \$1–\$2B. These costs are competitive with conventional launch methods and are similar to the cost of a single Shuttle-Orbiter vehicle.

System needs have not yet been fully evaluated. One of the most important issues (for an Earth-based system) is the “inverse reentry” problem of getting a gun-launched projectile up through the atmosphere without substantial ablation. Techniques for dealing with this, such as sacrificial ablative coatings or gas/vapor nose-tip cooling, appear feasible at first analysis. A mitigating factor is that the projectile should transit the atmosphere in only a few seconds. Launching from an equatorial site at high altitudes, as shown conceptually in Fig. 9 (66), would be doubly beneficial because the atmospheric density would be lower and there is about a 400 m/s velocity contribution from Earth’s rotation.

Part of the total mass to be launched will be a rocket motor that is needed to circularize the orbit after reaching apogee (see Fig. 8). In addition, some divert capability may also be needed to ensure that the payload can reach a collection point in space, such as the International Space Station. As a result, only 20 to 30% of the aeroshell mass will be useful payload. Hence, if tens or hundreds of tons of supplies were to be launched in this way, many launches would be required. For example, to supply 100 tons of materiel into orbit in payload packages of 250 kg would require 400 launches per year, which is equivalent to two per day for 200 working days. Launching does not seem an impossible task (a power station of only about 10 MWe would be required), but management of the packages in orbit will require an infrastructure that does not presently exist.

EM Spacecraft Propulsion. To reduce the mass of fuel that has to be carried by a rocket, it is beneficial to increase the exhaust velocity of the propellant. Chemical rockets generally operate with a specific impulse (I_{SP}) in the range from about 250 to 400 seconds. To increase this, other techniques need to be developed. These include ion thrusters which have an $I_{SP} \sim 2000$ to 3000 s,

⁹Of course, only rugged materials such as fuel, water, food, or engineering supplies could be launched at such accelerations.

Figure 8. The launch package concept. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

plasma thrusters, and even EM launchers. All of these are applicable only for use in space, not for launch into space from the surface of a planet.

Two studies of EM launchers for spacecraft propulsion were published in the early 1980s. Snow, et al. evaluated an induction launcher (known as the “mass driver”) as a reaction engine for LEO to GEO orbit transfers (67). The goal was an I_{SP} of 500–1000 s, which requires an exhaust velocity of 5 to 10 km/s. As discussed earlier, induction launcher performance is far from this at present. Bauer et al. (68) proposed to use a rail gun that launched pellets of an unspecified material at velocities of 5 to 20 km/s, corresponding to an I_{SP} of 500–2000 s. Apart from the failure of induction or rail launchers to reach the required velocities, a major concern with these concepts is the hazard created for other spacecraft, such as commercial satellites in near-Earth orbits, from ejecting high-velocity projectiles. In principle, these techniques could be considered for other missions, but there are competing technologies that are likely to be more attractive.

U.S. and International Programs

The best resources to consult for a review of EM launcher developments are the *Proceedings of the EM Launcher Symposia* that have been held every 2 or 3 years since 1982. These conferences have been published in archival form in special editions of the *IEEE Transactions on Magnetics* (69–78). Some papers can also

Table 6. Capital Cost Estimate for an Earth to Space EM Launcher

Component	Cost per unit	No. units	Total component cost
Ac generators	\$3 M	100	\$300 M
Switching	\$3 M	100	\$300 M
Barrel	\$0.3 M/m	1600 m	\$480 M
Busbars and structure			\$100 M
Civil engineering			\$250 M
Total			\$1410 M

Figure 9. The preferred launch site layout.

be found in the nonarchival, but widely circulated, *Proceedings of the Pulsed Power Conference*, which is also now sponsored by the IEEE (79). Proceedings of specialized journal issues or conference in different countries are also available occasionally (80). Because of the defense-related nature of much of this work, as well as the desire of industrial companies to protect their proprietary concepts, it seems likely that much R&D has occurred that has not been openly published. This overview is based on information from open sources.

United States. Although one or two isolated studies were undertaken in the late 1950s and 1960s, it was not until the mid-1970s that significant efforts began to develop in the United States. Following the approach pioneered at the Australian National University, several of these programs used homopolar generators as the energy and power source. These include facilities at Picatinny Arsenal (30 MJ), the University of Texas (60 MJ), and Eglin Air Force base (13 MJ). Large facilities were built with capacitors at Picatinny Arsenal (52 MJ) and Westinghouse (32 MJ). One facility installed by the USAF at Eglin used thousands of automotive batteries to charge an inductor that powered a rail gun. A larger number of small facilities were also used for R&D, based mostly on capacitors in independent modular arrangements. The largest rail guns used were 90-mm bore diameter and up to 8 meters long. Muzzle energies achieved with these rail guns were close to 9 MJ. In the last few years, financial strictures have forced rationalization of these facilities, and most have been dismantled or “mothballed.” Coil-gun research has been more sporadic; the last remaining organization that has interest in this area is Sandia National Laboratories, although this effort is now not active.

Europe. Efforts on EM launchers and related technology developments are being, or have been, undertaken in recent years in Britain, Germany, France, Italy, Sweden, Israel, the Netherlands, and Switzerland. Experimental facilities have been established in several locations; the largest are at Kirkcudbright in Scotland (33 MJ), Unterluss in Germany (30 MJ), and St. Louis in France (10 MJ). Smaller facilities are available in the other countries. Several of these facilities use power supplies based on capacitors that were supplied by U.S. manufacturers¹⁰. TNO in the Netherlands also used a refurbished U.S. homopolar generator, and Magnet Motor GmbH in Germany is developing flywheel

¹⁰In some cases, through cooperative arrangements with the U.S. Department of Defense.

systems with permanent magnet generators that can serve as MW power sources to charge superconducting, inductive, pulsed GW systems. Research in Britain and France has been on rail guns and electro thermal chemical (ETC) guns. Germany, Israel, and Sweden have concentrated solely on ETC gun technology. **The Former Soviet Union.** During the latter years of the Soviet Union, considerable R&D was undertaken on EM launchers for military applications, although relatively little was published in the West. Russia and the Ukraine were the primary developers, and several significant systems were built. Perhaps because capacitor technology is less well advanced in these countries, greater use seems to have been made of rotating machines. One notable Ukrainian system that was installed in a transportable trailer used four homopolar generators, powered by helicopter gas turbines, that had 60 MJ stored energy. Other rotating machine system designs were for even larger energies. Based on published reports, there appears to have been more emphasis on achieving very high velocities in Russian research than in the United States, with several reports of 6 or 7 km/s with small pellets of a few grams (81) and possibly up to 10 km/s with milligram masses.

East. One of the early efforts in developing rail guns was undertaken at the Ministry of Defense in Australia in the mid-1960s. The availability of a very large (550 MJ) homopolar generator at the Australian National University (ANU) and interest in the effects of micrometeorite damage on spacecraft led to a larger effort at ANU in the early 1970s. Experiments were undertaken at velocities close to 6 km/s with gram-sized projectiles. This work ended after the two main researchers moved to the United States in the late 1970s.

During the late 1980s and early 1990s, several programs on EM launchers were funded at a modest level by industrial companies in Japan. In most cases, capacitor banks were used that were purchased from U.S. companies. Several innovative solutions were developed with modest investments. In the related area of high-speed transport, Japan, like Germany, has strong research programs and a national commitment to improved high-speed transit technology. This could form a good foundation for induction launcher research for higher velocities.

Serious Chinese studies started in the late 1980s, but publication occurred only in Western conferences and journals in the mid-1990s. A wide range of technical interests and level of technical sophistication are evident in recent publications, that show interest in both EM and ETC technology. The work builds on what has been undertaken in the West but with its own variations. Summaries of Western work have been prepared by Chinese authors and are available as a foundation for further research (82).

South Korea began to take an interest in this technology in the mid-1990s, and there are now several technical organizations involved with their Ministry of Defense in this research, especially on ETC guns. A Korean Conference on this technology was held in 1997.

Future Possibilities

Despite the many potential advantages of EM propulsion enumerated by Fauchon-Villeplee more than 80 years ago, military applications of rail guns are not

yet guaranteed. Further developments during the next few years will be important in showing what can be accomplished and where this technology should be best applied.

Much has been done in projectile, barrel, and power supply development for rail guns; velocities of 2000 to 3000 m/s are routinely reached with kilogram-sized projectiles and up to 7000 m/s with gram-sized masses. It seems likely that a research program on the technical challenges of rail guns for very high velocity applications, such as launch-to-space, would be most interesting and rewarding.

In contrast, much more has yet to be demonstrated before inductive launchers are likely to prove useful for high-velocity applications; the maximum velocity achieved so far is about 1000 m/s. The first use of induction technology seems likely to be for low-velocity applications; such as an EM catapult for the Navy. It is feasible that this could be followed by the replacement of the first stage of a launch system for an orbiter vehicle using the Maglifter (58) or a similar concept.

EVOLUTION OF U.S. EXPENDABLE LAUNCH VEHICLES

Beginnings

Robert H. Goddard was a Professor of Physics at Clark University in Worcester, Massachusetts, a post he held for 26 years from 1919 until his death in 1945.

During these years, Goddard performed a classic series of experiments in which he, almost single-handedly, worked out the basic elements of liquid-fueled rocket technology. Goddard was interested in using rockets for space flight from the very beginning. He felt that for this purpose, liquid fuels, specifically, kerosene or gasoline and liquid oxygen would be best. This fuel would be more efficient, that is, it has a higher specific impulse, and it has the advantage that by closing and opening valves, the rocket engine could be stopped and restarted. This latter point was especially important because it gave liquid-fueled rockets a truly decisive advantage over those that operated with solid fuel. In solid-fueled rockets, once the motor is started, the rocket is committed, and the engine cannot be turned off.

In 1919, Goddard published a paper titled "A Method for Reaching Extreme Altitudes" in the *Journal of the Smithsonian Institution* in which he outlined his plans (1). These came to fruition on 16 March 1926, when a liquid-fueled rocket built by Goddard performed the first successful liftoff and flight and reached an altitude of about 80 feet (Fig. 1). This experiment was carried out in an open field on a farm near Auburn, Massachusetts. Goddard realized that this was not the best place for these experiments. He took advantage of an offer from Daniel Guggenheim, the heir to a huge mining fortune and an enthusiastic supporter of American aviation, to support the continuation of his experiments and to set him up on a large ranch near Roswell, New Mexico. It was here that Goddard built and flew the first gyroscopically stabilized liquid-fueled rocket on 31 May 1935; it reached an altitude of more than 7000 feet.

Goddard's remarkable success was unfortunately not pursued. Because of the depression, Guggenheim could no longer support Goddard's work, and eventually, the work at the Roswell ranch was abandoned. The U.S. military showed no interest in Goddard's work. When the Second World War started, the military did initiate a vigorous effort to develop solid-fueled rockets for use as airborne and ground-based weapons, in which Goddard participated. Goddard's untimely death in 1945 precluded his participation in the rapid development of large liquid-fueled rockets in the United States following World War II.

While all of this was happening in the United States, a group of Germans was also interested in developing liquid-fueled rockets for the same reasons that motivated Goddard. The intellectual leader of this group was Professor Hermann Oberth, a Romanian-German, who wrote the first book on planetary exploration that was published in 1923, "Die Rakete zu den Planetenraumen" (2). He advocated using rocket propulsion. In this book, he worked out the necessary mathematics to accomplish this objective and also elaborated on the infrastructure that would have to be built. (Both Goddard and Oberth were unaware of the work of Konstantin E. Tsiolkovski, a Russian mathematics professor who had worked out the rocket equation and had speculated on the use of rockets for space travel 20 years before Goddard and Oberth wrote about their work.) Oberth's book attracted the attention of a small group of German scientists and engineers who had a great interest in space travel and rockets. Along with Oberth, these included Rudolf Nebel, Klaus Riedel, Willy Ley, and Max Valier. On 5 July 1927, these people and a few others founded the "Verein für Raumschiffahrt," the "Society for Space Travel." By 1929, the Society had almost 900 members, one was a 17-year-old high school senior named Wernher von Braun. Von Braun was a

Figure 1. Robert Goddard with the liquid-fueled rocket that first flew on March 16 1926, (photo courtesy NASA Goddard Space Flight Center). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

member of a prominent and affluent Prussian family. His father served as Minister of Agriculture and also as Minister of Education under the democratic German Weimar Republic.

The Society acquired a small tract of land a few miles north of Berlin that was a German army ammunition storage depot and could be used for rocket flight experiments. The area was named the "Rocket Flight Area" (Raketenflugplatz, in German), and the Society began to conduct flight experiments. The technical leaders of the Society were convinced—as was Goddard—that only liquid-fueled rockets were practical for space travel. They knew about Goddard's work, and they began to build and test liquid-fueled rockets. The first test models were called "Mirak" which stood for the German "Minimum Rakete." They were small test rockets designed only for static tests. They also built flight models called "Repulsors" which looked very much like Goddard's first rocket. One of these flew for the first time on 10 May 1931 and reached an altitude of 18 meters. The rockets following this event were somewhat more sophisticated, but none reached the technical complexity of Goddard's gyrostabilized rocket.

Both Oberth and Nebel had talked and written about military applications of rockets. There was interest in rockets in Germany because the Versailles Treaty that ended World War I contained provisions that seriously limited German artillery development. In 1929, the Army Ordnance Department established a small group to study the possible military applications of rockets. A year later, a young German artillery captain, Walter Dornberger, was named to head this group. Dornberger was aware of the experiments conducted by Oberth, Nebel, and the others at the Raketenflugplatz. He decided to help the group by providing modest financial support. He also quickly came to the conclusion that the Raketenflugplatz site was not adequate, and he offered the facilities of the German artillery range at Kummersdorf for the rocket experiments. These moves accelerated technical progress, but they also weakened the Society because several of the people who worked on the Society's rockets joined Dornberger's group. Wernher von Braun, one of them, started to work at Kummersdorf on 1 October, 1932.

When Adolf Hitler and the Nazi party came to power in January 1933, things changed drastically. The civilian organizations interested in rocketry disappeared, and the work on military rockets was substantially accelerated. During the mid-1930s, the Germans developed a well-organized, systematic research program on liquid-fueled rockets. The first of these rockets, called the A-2, was successfully launched in December 1934 and reached an altitude of 2000 meters, about 6000 feet. It was not as sophisticated as Goddard's gyrostabilized rocket that was launched a few months later, but the A-2 did work. Wernher von Braun had acquired a Ph.D. and was the technical director of the Kummersdorf enterprise reporting directly to Dornberger. In any event, the Germans had now roughly caught up to where Goddard was when he was forced to quit.

By the mid-1930s, the Germans had made enough progress that they decided to develop a test site which would make it possible for them to test large rocket vehicles. They chose an isolated region on the north German Baltic coast where the River Peene reached the sea. The place was called Peenemünde and by 1939, test operations were started there. The A-2 was followed by the A-3 and the A-4, the latter was successfully flown on 3 October, 1942, almost a decade to the

day that von Braun joined Dornberger's unit. The A-4 was the prototype of the V-2, the first long-range weapon based on rocket technology (Fig. 2). It could throw a payload of 1 metric ton about 250 miles. The rocket engine of the A-4 developed a thrust of 60,000 pounds. The rocket burned ethanol as a fuel and used liquid oxygen as an oxidizer. Due to the success of the A-4 launch and the loss of the Battle of Britain in 1941, Hitler decided, on 7 July 1943, to put the development and production of the V-2 missiles at the highest level of priority.

Because of good air reconnaissance and brilliant photo interpretation, the British were aware that new and dangerous weapons were being developed and tested at Peenemunde. They mounted a massive air raid on the test site, which was partially successful. The Germans realized that they would have to disperse their test and production facilities because more allied air raids attacking the Peenemunde complex were inevitable. The Germans built a massive underground facility in central Germany called the "Mittlewerk" for producing V-2 missiles. They also built a test site in Poland which was out of range of long range bombers based in England. A little more than 6,250 V-2s were produced. About 3700 were fired at targets in Great Britain and on the continent, of which about 700 failed! About 2000 were in storage at the end of the war, 300 were expended in tests, and 250 were taken to the United States at the end of the war. Although

Figure 2. A V-2 missile taking off from the launch pad (photo courtesy NASA Marshall Space Flight Center). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

the outcome of the war was not influenced by the use of large numbers of V-2 rockets, the creation of the V-2 missile and its successful operation was still a technical achievement of the first rank. It has been said that if the Manhattan Project to produce nuclear weapons was the technical “tour de force” of the United States during World War II, then the development of the V-2 played the same role in Germany.

The End of World War II

The V-2 rocket team that Wernher von Braun organized at Peenemunde was dispersed at the end of World War II. Wernher von Braun and most of the 100 or so senior technical people were housed in the small mountain village of Oberjoch on the Austrian-German border. They wanted to surrender to the U.S. Army, which had some units in the neighborhood, but they did not know how to make contact. At the same time, in 1945, the U.S. Army realized that it would be important to capture the Germans who had the knowledge to develop and build long-range missiles. An operation dubbed “Paperclip” was initiated to locate and detain the people who had this expertise. It was headed by U.S. Army Colonel Holger N. Toftoy. Eventually, the von Braun group surrendered to a U.S. Army unit and was taken into custody. Other veterans of the V-2 program wound up as prisoners of the Soviets. There were a few who actually volunteered to go to work for the Soviets.

Wernher von Braun, Walter Dornberger, and other leaders of the V-2 program arrived at Newcastle Air Base in Wilmington, Delaware on 19 September 1945. They were now under contract to the U.S. Army and were going to work on missile development. They were taken to Fort Bliss near El Paso, Texas, the U.S. Army’s Center for Anti Aircraft Artillery. Fort Bliss is located at the southern end of the White Sands Missile Test Range in New Mexico. It would be the job of von Braun and his colleagues to launch some of the V-2s brought over from Germany, to perform research, and to train Americans in the art and science of rocketry. In doing so, a large number of V-2 rockets was used; some were modified to measure the upper atmosphere and to photograph Earth, the Sun, and other astronomical objects. All of these activities were very important to the future of U.S. ballistic missile and space flight programs (3).

At the same time that the Germans were working for the U.S. Army, a group at Douglas Aircraft Company in Santa Monica, California, published a far-reaching document in 1946. The group was led by some outstanding scientists and engineers including Francis Clauser, David Griggs, and Louis Ridenour among others; they later left Douglas to form the RAND Corporation. The title of their work was “Preliminary Design of an Earth-Orbiting Spaceship” (4). The group anticipated that large rockets, based on extensions of the V-2 designs, would be developed both by the United States and the Soviet Union to carry nuclear weapons at ranges from 8,000 to 10,000 miles. Such rockets could be modified to place significant payloads into Earth orbit and to other places in the solar system. Thus, the means to realize the early ideas of Tsiolkovski, Goddard, and Oberth would soon be available, and therefore, it was time to make some detailed calculations about spaceflight. The remarkable thing about

“Preliminary Design of an Earth-Orbiting Spaceship” is that it was a serious engineering study—about 250 pages long—that predicted nearly all of what has happened in spaceflight since 1946. Weather observations, intelligence gathering, communications, and other things now being done by Earth orbiting vehicles were treated. In addition, there were estimates of what it would take to put people in space. Thus, the stage was set for humanity’s first steps into space.

The Development of U.S. Space Launch Vehicles

As the authors of the 1946 report anticipated, the United States embarked on a vigorous program to develop and then build large liquid-fueled rockets for military reasons. Two military services, the U.S. Army and the U.S. Air Force, were charged with the responsibility for creating the missiles that would carry nuclear weapons. In 1950, the Army reached the decision that the Germans had finished their work at White Sands and that they would be moved to the Redstone Arsenal near Huntsville, Alabama, to initiate the development of new ballistic missiles.

The U.S. Army Rocket Development Program. Wernher von Braun, the leader of the German rocket engineers, arrived in Huntsville on 15 April 1950. It is safe to say that the town has not been the same since. The Army’s attitude toward long-range rockets was that they were an extension of artillery. Thus, in the beginning, the objective was to develop a second-generation V-2 missile. The military requirements, written in early 1951, called for a rocket that had a range of about 200 miles but had a substantially increased payload capability to carry the nuclear weapons then being developed. The rocket was named the Redstone and there were some important differences between the Redstone and the V-2. One was that the payload was designed to separate from the rocket, so that the entire vehicle would not have to reenter the atmosphere. This made it possible to build the rocket from aluminum rather than steel, as was the case for the V-2. The Redstone’s engine had a thrust of 80,000 lb, rather than the 60,000 lb of the V-2. The first Redstone was launched on 20 August 1953, from the new launch site on the east coast of central Florida at Cape Canaveral. The flight was a failure, but subsequent flights proved that the Redstone design was sound. The Chrysler Corporation was given the contract to produce the Redstone in quantity.

Wernher von Braun and his German colleagues never lost their interest in spaceflight. In 1952, von Braun, along with Fred Whipple, the Harvard astronomer, and Joseph Kaplan, a distinguished atmospheric scientist at UCLA, were the leading authors of a series of articles published between 1952 and 1954 in *Collier’s* magazine entitled “Man Will Conquer Space Soon”(5). There were articles about what became the space shuttle, space stations, and journeys to the Moon and the planets. The articles attracted considerable attention and encouraged von Braun and his colleagues to press for an upgrade of the Redstone so that a man-made satellite could be put into Earth orbit. On 15 September 1954, von Braun submitted a proposal to Colonel Toftoy—who by now was chief of the rocket branch at the Redstone Arsenal—to upgrade a Redstone rocket with suitable upper stages so that a small satellite could be put into Earth orbit. This was technically feasible, but the proposal was rejected for political reasons.

The Eisenhower Administration was anxious to keep the effort to create an Earth orbiting satellite as a civilian project. The scientific community had designated 1957 as the first "International Geophysical Year," and orbiting a satellite would be part of the program of research. The satellite would be launched by a Vanguard rocket that would be developed by the Martin Company for this purpose. Even though people from the U.S. Naval Research Laboratory were involved in developing the Vanguard, the program would be managed by a civilian organization.

In spite of this edict, the Redstone was upgraded. The first of these modifications was called the Jupiter A, which was used as a rocket test vehicle. The second, Jupiter C, which had three solid-fueled upper stages, was used in developing heat-resistant materials for ballistic reentry vehicles that would carry nuclear warheads. The first Jupiter C was launched on 20 September 1956 carrying a one-third scale warhead. It reached an altitude of 682 miles and flew a distance of 3,335 miles, a record that stood until the first intercontinental missiles were tested. It was only a short step from the Jupiter C to a rocket that could orbit a satellite. Von Braun secured permission to continue studies to achieve this objective in spite of the fact that his Army superiors were under strict orders not to develop orbital vehicles. Finally, an extended version of the Redstone was used to develop the Jupiter MRBM (medium range ballistic missile) that had a total takeoff thrust of 150,000 lbs.

The Soviets were not bound by the rules imposed on the U.S. Army's group at Huntsville. On 4 October 1957, using a military rocket, the Soviets placed the first man-made object, Sputnik I, into an orbit around Earth. (How this was done is described in an article elsewhere in this *Encyclopedia*.) The Soviet spacecraft created a sensation and caused great consternation in the United States. To add insult to injury, the Soviets launched a much larger satellite, Sputnik II that carried a dog named "Laika" and weighed 1100 lbs, a month later on 3 November. The final embarrassment came on 6 December 1957 when the first Vanguard was launched and then fell back to Earth two seconds later. At this point, the decision was finally made to ask von Braun's group to use the Jupiter C to orbit an American satellite. The Huntsville group recruited William Pickering, the Director of the Jet Propulsion Laboratory at the California Institute of Technology, then funded by the Army, to build a fourth stage for the Jupiter C. Professor James A. Van Allen was recruited to build a payload for Pickering's fourth stage so that if it went into Earth orbit, some scientific results would be obtained. Von Braun's team estimated that they could put a satellite into Earth orbit within sixty days.

The modified Jupiter C, now called the Juno I, blasted off from Cape Canaveral on 31 January 1958 and put Explorer I, the first American satellite into Earth orbit. It was launched 56 days after the Huntsville group was given the job to go ahead. Professor Van Allen's scientific payload was the first to measure the radiation fields above the Earth's atmosphere. This led to the discovery of permanent "belts" of radiation surrounding the Earth, now called the "Van Allen Belts." Juno I was used to launch two more satellites, Explorers 3 and 4, and was then replaced by further upgrades of the Redstone, Juno II, and the Mercury Redstone. Juno II, was used to launch a series of "Pioneer" satellites that explored the newly discovered radiation belts. Finally, the Mercury-Redstone was

used to launch Alan Shepard on a suborbital flight on 5 May 1961 followed by an identical flight by Gus Grissom on 21 July. Both of these flights were carried out after Yuri Gagarin achieved the first orbital flight by a human being on 12 April 1961. (See the article *First Flight of Man in Space* by Klimuk and Vorobyev on Gagarin's flight elsewhere in this *Encyclopedia*.) Thus, the United States was still substantially behind the Soviet Union in spaceflight technology.

The flights of Shepard and Grissom were the last to use the Redstone as the core of the launch vehicle. Thus, the period of playing catchup with the Soviet Union would not be over until launch vehicles more powerful than the Redstone were available.

The U.S. Air Force Rocket Development Program. The U.S. Air Force, unlike the Army, was given a broader mission in rocket development. In addition to short- and intermediate-range missiles, the Air Force would also develop rockets with intercontinental ranges. Another difference between the Army and the Air Force rocket programs was that the leaders of the Air Force program were Americans rather than people from Germany who had been captured at the end of the Second World War. Although a number of members of the German rocket team went to work for contractors who built the rockets, none of them went to work in the Air Force management organization, the Western Development Division in Los Angeles. Walter Dornberger, who had risen to the rank of Major General in the German Army before the end of World War II, went to work at Bell Aircraft, and he was soon joined by Krafft Ehrlicke. Ehrlicke later joined Convair to work on the Air Force Atlas rocket development. Dr. Hans Friedrich also joined Convair to work on the Atlas. Dr. Adolf K. Thiel joined Ramo/Woolridge, later TRW, and Dr. Martin Schilling became a vice president of Raytheon Corporation.

Wernher von Braun and the rocket team that remained with him in Huntsville eventually were transferred to NASA when part of the Redstone Arsenal was turned over to the new civilian space agency in 1960. The new organization was called the George C. Marshall Space Flight Center. There they developed the Saturn V launch vehicle that eventually put humans on the Moon in 1969. (See the article on *U.S. Manned Spaceflight: Mercury to the Shuttle* elsewhere in this *Encyclopedia*.)

The rocket development program that the Air Force eventually adopted grew out of a careful study conducted by the Air Force Strategic Missiles Evaluation Committee. This group was headed by Professor John von Neumann of Princeton University who played a major role in the development of nuclear weapons during World War II. Von Neumann first broached the idea of putting nuclear warheads on top of large rockets, which he called "intercontinental artillery." In 1954, the Missile Evaluation Committee urged the development of relatively small intercontinental ballistic missiles (ICBMs) that were able to carry the advanced "second-generation" nuclear and thermonuclear weapons then being developed. Von Neumann's detailed familiarity with nuclear weapons development influenced the Evaluation Committee to make this judgment. He knew that nuclear explosives much smaller and more efficient than those used at Hiroshima and Nagasaki were being developed, and the rockets, therefore, would be tailored to carry the new weapons. Ironically, this was the reason, among others, that the Soviets gained a significant advantage over the United States

during the first years of orbital space operations. Their nuclear weapon technology was well behind that of the U.S. Accordingly, they had to develop larger and more powerful rockets to carry their heavier nuclear weapons.

To develop the new ICBMs, the Air Force established the Western Development Division at Los Angeles. This move was in accord with the recommendation of the von Neumann Committee to create an organization that would have full authority and responsibility for ICBM development. The Western Development Division would have the technical support of a new organization, the Aerospace Corporation, which was a nonprofit organization created by the transfer to the Air Force of the Space Technology Laboratory of the Ramo-Woolridge Corporation. The first commander of the Western Development Division was a brilliant young Air Force Brigadier General, Bernard A. Schriever. He later achieved four-star rank as the leader of the U.S. Air Force Systems Command. The basic organization described here is still in existence, although the Western Development Division has undergone periodic name changes. Today, it is the Air Force Space and Missiles Division. This organization still receives technical support from the Aerospace Corporation just as it did half a century ago.

The Western Development Division was given the job of developing three missile systems, two ICBMs, the Atlas and the Titan, and one intermediate range ballistic missile (IRBM), the Thor.

The Thor Missile and the Delta Space Launcher. The Thor first stage is a missile that has roughly the same performance characteristics as the Army's Redstone missile. The decision to go ahead with the Thor was controversial because of the apparent duplication of effort. Eventually, the Joint Chiefs of Staff approved the proposal to go ahead with both missiles. In December 1955, the Douglas Aircraft Company was given the contract to develop the missile. The first successful flight of the Thor was carried out on 20 September 1957, and the first operational missiles carrying warheads were deployed in the United Kingdom in 1958, 3 years after the contract was given to Douglas. This remarkably rapid development cycle was due to General Schriever's push for "concurrency." This means essentially that calculated risks are taken in the development process to speed the schedule and, in this case, the adoption of "concurrency" succeeded.

Both the Thor and the Jupiter MRBM had pressurized, regeneratively cooled rocket motors that developed thrusts of about 150,000 lb. Unlike the Redstone, which burned ethanol and liquid oxygen, the Thor burned a kerosene liquid oxygen mixture. It was also designed to be very rugged, and this is the feature that has led to the large number of versions of the Thor, so that it has been called, justifiably, the workhorse of space launchers. It is truly remarkable that space launch vehicles based on the Thor started in the late 1950s with the capability of placing a few hundred pounds in near Earth orbit and now can place a payload of more than 8000 lb. into a geostationary transfer orbit.

The Thor has carried a number of upper stage vehicles. One is the Agena, built originally by the Bell Aerospace Company and later by the Lockheed Corporation. It will be described later. The most important booster stage was the "Delta" solid-fueled rocket built by Aerojet General Corporation that had a thrust level of 8,000 to 10,000 lb depending on the version used. The Delta stage was used so frequently with the Thor that the combination is now called the "Delta."

The second important thrust augmentation for the Thor is the Castor rocket built by Thiokol Corporation. These are powerful solid-fueled rockets that are strapped to the bottom skirt of the Thor rocket. Each unit has a thrust level of 50,000 lbs, and they can be strapped on in numbers between three and nine. The Castor rocket capability adds both power and flexibility to the Delta space launch vehicle system. More than 200 successful Delta rocket launches have been conducted since the first Thor was launched in 1957.

The Delta launch family originated in 1959 when the NASA Goddard Space Flight Center awarded a contract to Douglas Aircraft Company to produce and integrate 12 launch vehicles. Using components from the U.S. Air Force Thor intermediate range ballistic missile (IRBM) program and the U.S. Navy Vanguard launch program, the Delta rocket was available 18 months after the award. On 13 May 1960, the first Delta was launched from Cape Canaveral Air Force Station, Florida, carrying a 178-pound Echo I passive communication satellite. Although the first flight was a failure, the ensuing series of successful launches established Delta as one of the most reliable of all U.S. boosters.

The Delta II Space Launcher. For more than 40 years, the Delta system has consistently demonstrated its robust design, launch flexibility, and value to launch service customers. A second generation, the Delta II launch system, was developed to include multiple configurations to suit the needs of the U.S. Air Force, the National Aeronautics and Space Administration (NASA), and to accommodate the emerging commercial satellite market.

From 1985 through 1987, the space industry was impacted by an unprecedented string of failures of various launch systems, which seriously impeded U.S. space launch capability. In one of several steps to revitalize assured access to space, the U.S. Air Force held a competition for a medium launch vehicle that primarily would launch Global Positioning Satellites (GPS). The contract was awarded to McDonnell Douglas (now Boeing) for its Delta II series vehicles. With a 98.1% mission success rate since its inception in 1989 the Delta II has become the industry workhorse for deploying remote sensing satellites for U.S. government and commercial applications, GPS, commercial satellite systems/constellations, and numerous planetary missions for NASA.

In addition to the demonstrated reliability of the Delta II launch system, Delta vehicles provide incremental performance capability with three, four or nine Castor solid rocket motor (SRM) configurations. These configurations provide a broad range of performance, from 2000 to 4000 pounds to geosynchronous transfer orbit (GTO), using the highly reliable Rocketdyne RS-27A main engine, and two- and three-stage configurations. The latest version, which is designated Delta II Heavy, integrates the solid rocket motors (SRMs) used on Delta III with the Delta II standard upper stage, resulting in approximately a 12% increase in payload lift performance from the standard nine SRM configuration to more than 4700 pounds to GTO (Fig. 3) (6).

The Delta II launch system payload accommodations provide various mechanical interfaces, separation systems, and deployment systems that are designed for compatibility with launch industry standard interfaces. Payload accommodations enable deploying single, dual, or multiple satellites in a single Delta II launch. The multiple manifest, spacecraft dispensers have successfully

Figure 3. Delta II and III space launch vehicles. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

deployed 55 Iridium spacecraft, five per launch on eleven launches, and 24 Globalstar spacecraft, four per launch on six launches.

The Delta II is launched in the United States from three launch pads, two on the East Coast at Cape Canaveral Air Force Station that has a capacity of 12 launches and one on the West Coast at Vandenberg Air Force Base, California, that has a potential of nine launches per year. Launch sites on both coasts enable the Delta II launch system to launch to virtually any orbit and provides customers with launch schedule assurance.

The demand for Delta II launches increased significantly in the mid- and late 1990s and has continued to maintain a steady backlog of government and commercial customers. In addition to continuing GPS deployment missions, Delta II has been selected for numerous NASA payloads because of NASA's focus on smaller, less expensive spacecraft and its demand for proven reliable launch systems. NASA remains a critical customer for Delta launches, Delta II has assigned and planned missions through 2009.

Building on the success of the Delta II launch system, McDonnell-Douglas developed the two-stage Delta III in the mid- to late 1990s to address the trend toward increasing mass of commercial satellites. The Delta III nearly doubled the payload lift capability of the Delta II launch system by deploying an 8400-pound payload to GTO. Delta III evolved from the highly reliable Delta II by maximizing the use of common components and infrastructure. Both launch systems use the same Rocketdyne RS-27 main engine, first stage LO₂ tank, flight avionics, and launch operations infrastructure. Most notable of Delta III's evolved features are a 13-foot diameter cryogenic second stage, 13-foot diameter composite biconic payload fairing and nine, larger, more powerful SRMs (46-inch dia.). The second stage uses a single RL10B-2 engine fueled by LH₂ and LO₂ that incorporates an extendable nozzle.

The Delta III established itself as an operational launch system in August 2000 by launching a 9460-pound demonstration payload to a planned subsynchronous GTO. The mission was successful; all of the systems and subsystems performed as planned. Intended to be a transition vehicle to the Delta IV, the Delta III has enabled demonstration and flight qualification of several critical components that would be used on the Delta IV.

The Atlas Intercontinental Ballistic Missile (ICBM) and Space Launcher. Concurrently with the development of the Thor, the U.S. Air Force also undertook to develop the first large truly intercontinental missile—the Atlas. This missile included a number of innovative design features. The first and most important of these was that the body of the rocket vehicle was also the wall of the pressurized fuel and oxidizer tanks, and unlike the Thor and Redstone, both of which had conventional braced aluminum air frames, the Atlas skin was manufactured from a thin sheet of stainless steel. The Atlas could only stand on a launch pad if the tanks were pressurized; if they were not, the vehicle would collapse. The pressurized steel tank thus assumes some of the structural burden. This design saves enough weight, so that the Atlas dry weight fraction was the smallest of any large rocket yet built.

The propulsion system of the Atlas was also unique. It consisted of three engines, one mounted on the centerline of the vehicle and the other two fitted on a skirt and placed on either side of the center engine. At launch, all three Rocketdyne MA5 engines would be running, generating a total thrust of 370,000 lb. The skirt, called the “booster section,” could be jettisoned at an appropriate time, and the center engine, called the “sustainer,” would continue to run, generating 60,000 pounds of thrust until the propellant is consumed. This concept is called “stage and a half” because no fuel is carried in the booster section, so that no fuel tank is dropped. The engines burned RP-1 (kerosene) using liquid oxygen as the oxidizer. The engines were gimballed for thrust vector control, as was the Vanguard rocket mentioned earlier.

The Atlas program was initiated in 1951, and the contract to develop the rocket was given to Convair/General Dynamics Corp. The first successful flight of an Atlas ICBM occurred in December 1957, and the first employment as a space vehicle launcher occurred in December 1958 when it was used to put an active communications satellite that weighed about 200 pounds into Earth orbit.

Since these first flights, the Atlas, in combination with a number of different upper stages, has been a very successful space launch vehicle. Perhaps the most important launch of an Atlas booster was John Glenn’s first flight in the Mercury program. The Mercury spacecraft, “Freedom Seven,” was placed into Earth orbit by a modified Atlas D ICBM on 20 February 1962 (Fig. 4). The Atlas has also been used very effectively with Agena, Centaur, Delta, and Burner upper stages. (The technical details of these upper stages will be discussed more thoroughly later.) The Atlas/Agena combination was used for some of the first Mariner Missions (Mariner 4) that returned the first pictures from a Mars flyby in July 1965. The Atlas/Agena was also used to send a Ranger spacecraft to the Moon for a hard landing, and it placed the Lunar Orbiter around the Moon as well. The latter spacecraft was particularly important because the high resolution pictures it obtained were used to select the landing sites for the Apollo landings. The Atlas/Centaur combination is a more capable launch vehicle that was used to put

Figure 4. Launch of John Glenn's Mercury "Freedom Seven" spacecraft by an Atlas space launch vehicle. (photo courtesy NASA). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

the first soft landing spacecraft, the Surveyors, on the Moon. These spacecraft were also very important precursors for the Apollo missions because they determined the mechanical properties of the lunar surface.

The most interesting application of the Atlas/Centaur was launching the Pioneer 10 spacecraft on 3 March 1972, as well as its sister ship, Pioneer 11, 13 months later. Pioneer 10 was the first spacecraft to pass beyond the orbit of Mars,

to fly through the asteroid belt, to fly past Jupiter, and finally, it became the first human artifact to leave the solar system. Pioneer 11 repeated this performance a year later, and, in addition, it became the first spacecraft to fly by Saturn.

The Atlas II family was developed in the mid-1980s to address the growing demand for large commercial geosynchronous satellites. The Atlas II family has a 100% success rate and 56 consecutive launches, a reliability record unmatched in the industry. During the past decade, the Atlas II vehicle has been continually stretched and upgraded to improve payload performance. The Atlas IIAS is the most powerful and has the highest lift capability of the Atlas II family. Other configurations include the Atlas IIA and the Atlas II, which was retired in March 1998. Currently, Atlas II vehicles are being flown from both U.S. ranges.

Four solid fuel rockets are used to augment payload performance of the Atlas IIAS. All three MA-5 engines are ignited prior to liftoff. Approximately 180 seconds into first-stage ascent, the two larger MA-5 booster engines are shut down and jettisoned, reducing weight and improving payload performance. The center MA-5 sustainer engine burns for an additional 100 seconds up to main engine cutoff and staging. The Centaur second stage uses two RL-10A-4 engines to place up to 6700 lb (Atlas IIA) and 7950 lbs (Atlas IIAS) into a GTO orbit.

In the early 1990s, General Dynamics (now a part of Lockheed Martin) decided to upgrade the Atlas first-stage propulsion system. The prime modification was replacing the two MA-5 first-stage and single MA-5 sustainer engines with a single Russian NPO Energomash RD-180. Furthermore, Lockheed Martin simplified vehicle construction by drastically reducing the total part count. The reengineered vehicle, known as the Atlas IIAR, has since been renamed the Atlas III. The maiden flight of the Atlas III launch vehicle, the replacement for the Atlas II, occurred on 24 May 2000.

Two versions of the Atlas III are currently available. The Atlas IIIA has a single RL-10A-4-2 engine powering the Centaur upper stage, whereas the Atlas IIIB has two RL-10A-4-2 engines and a stretched Centaur upper stage to increase GTO performance to just under 10,000 lb (Fig. 5) (7).

The Titan ICBM and Space Launch Vehicle. One of the limitations of the Redstone, the Thor, and the Atlas as military missiles was that they could not be kept on "instant alert." This meant that they could not be launched on very short notice because the liquid oxidizer (liquid oxygen) is a liquid only at 210°C below room temperature so that it cannot be stored on the missile itself. Special cryogenic storage facilities had to be built at each of the military launch sites, and upon the order to launch the missile, the liquid oxygen had to be transferred from the storage tank to the missile. Such operations take, at best, something of the order of half an hour, which means that an instant "launch on alert" is not possible.

The Titan missile actually started as a replacement for the Atlas because the fragility of the Atlas was deemed undesirable for deployed military rockets. The Titan was thus designed using the more rugged monocoque technique in which an appropriately braced aluminum "fuselage" took the stresses of the launch. Originally, the first version of this missile, the Titan I, was designed for conventional fuels and would be placed in hardened underground shelters. A successful test was conducted in February 1959, and the Titan I system became

Figure 5. The Atlas space launch vehicle family. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

operational in 1962. In spite of this, the system was awkward to operate, and the Air Force decided to convert the Titan I to a missile that could use storable fuels so that it could be maintained on instant alert. The implementation of this idea led to the Titan II ICBM.

The Titan I ICBM was somewhat more capable in range and payload than the Atlas. The Titan II had to be substantially more capable. The storable fuel

chosen for the Titan II was a mixture of nitrous oxide (N_2O_4) and “Aerozine,” a hydrazine-based fuel. These two substances are liquids at room temperature, and they ignite when they come into contact, that is, they are hypergolic. Thus, with appropriate care, they can be stored on the missile itself. However, the hypergolic fuel mixture does not have the same high specific impulse of the liquid oxygen/hydrocarbon fuels, so that the rocket is not as effective as a launch vehicle. Thus, the Titan II ICBM was designed from the very beginning as a two-stage system, which gave it substantially better performance than the Atlas. The Titan II second-stage motor was also fueled by a hypergolic mixture, so that the entire vehicle could be stored at room temperature.

The first successful test of the Titan II was carried out on 16 March 1962, and the first operational missile was installed in its hardened underground bunker in December 1962. Ultimately, 51 Titan II missiles were deployed at three sites near Wichita, Kansas; Tucson, Arizona; and Little Rock, Arkansas. The Titan II was a formidable part of the U.S. nuclear deterrent force; it carried a multimegaton warhead that could reach targets 8000 to 10,000 miles away. In September 1980, a technician at one of the Titan II missile sites in Arkansas dropped a wrench down the silo and it punctured the fuel and oxidizer tanks as it fell. Eventually, the two liquids mixed, ignited, and the resulting conflagration destroyed the missile and silo. Fortunately, the nuclear warhead, which had a hardened design, survived the accident unharmed. Partly as a result, all of the deployed Titan II ICBMs were decommissioned by 1987.

Like the Thor and the Atlas, the Titan II ICBM was also converted into a very flexible and capable space launch system. The first of these, fielded in 1964, was called the Titan IIIA; it consisted of the Titan II two-stage ICBM plus a third stage called “Transtage” that could put payloads of more than 3000 pounds into low Earth orbit. This was followed quickly by the Titan IIIB/Agena in 1966 that could put 8500-pound payloads into near Earth orbit. This was accomplished by increasing the thrust of the first stage from 430,000 to 463,000 pounds and using the somewhat more capable Agena rather than the Transtage. All of these modifications were carried out by the Martin Company.

The Titan II space launch vehicle is a two-stage liquid-fueled booster designed to provide small-to-medium weight class capability. It can lift approximately 4200 pounds into a polar, low Earth circular orbit. Titan IIs were also flown in NASA’s Gemini manned space program in the mid-1960s. Deactivated Titan II missiles are in storage at Davis-Monthan Air Force Base in Tucson, Arizona. Lockheed Martin was awarded a contract in January 1986 to refurbish, integrate, and launch 14 Titan II ICBMs for government space launch requirements.

Tasks involved in converting the Titan II ICBMs into space launch vehicles included modifying the forward structure of the second stage to accommodate a payload; manufacturing a new 10-ft diameter payload fairing with variable lengths plus payload adapters; refurbishing the Titan’s liquid rocket engines; upgrading the inertial guidance system; developing command, destruct, and telemetry systems; modifying Vandenberg Air Force Base Space Launch Complex 4 West to conduct the launches; and performing payload integration. Six Titan II Space Launch Vehicles have been launched from Vandenberg Air Force Base, California, since 5 September 1988.

The major modification of the Titan III could be made because of the sturdy monocoque construction of the original Titan II missile. This was the addition of two very large solid-fueled strap-on rockets on opposite sides of the Titan II core vehicle. These rockets have a thrust of just over 1,000,000 pounds each, which raises the takeoff thrust of the entire vehicle in the launch configuration to about 3,000,000 pounds. This configuration of the launch vehicle is called Titan IIIC, and with a Transtage, it can place about 30,000 pounds in low Earth orbit. It can place a payload of about 3600 pounds in a geosynchronous orbit by using the appropriate upper stages. Another important variation is the Titan IIID, which has no upper stages but can put a 13,000-pound payload into near Earth polar orbits. This is the launch vehicle that, when launched from the West Coast at Vandenberg Air Force Base, puts most of the U.S. highly capable reconnaissance satellites in orbit. The Titan IIID was declared operational in 1971.

In 1977, the Titan IIIE/Centaur was fielded. This is the most capable expendable space launch vehicle in the current American inventory. The addition of the Centaur upper stage makes the difference (Note: The upper stage will be described in more detail later.) The Titan IIIE/Centaur has launched a whole galaxy of spacecraft to explore everything from the outer planets using exquisitely designed cameras to putting very sophisticated payloads into the atmosphere of Jupiter. This would include Helios, Galileo Jupiter with the probe, the two Voyagers, the two Vikings, and a substantial number of others. A related version of the Titan IIIE is the Titan 34D which, instead of carrying the Centaur, carries a solid-fueled upper stage called the "inertial upper stage" or IUS. This stage was developed by the Air Force to put large military and intelligence gathering satellites into polar orbits.

Titan IV consists of two solid-propellant, stage-zero motors, a liquid propellant two-stage core and a 16.7-ft diameter payload fairing. Upgraded three-segment solid rocket motors increase the vehicle's payload capability by approximately 25% (Fig. 6) (7). In 1985, the U.S. Air Force selected the Martin Marietta Astronautics division (now Lockheed Martin) in Denver to build and launch 10 Titan IVs. In 1986, the contract was increased to 23 vehicles, and, in November 1989, the contract was extended to 41. Titan IV has been used exclusively to launch U.S. government satellite missions. It provides primary access to space for critical national security and civil payloads.

The operating success rate of Titan launch systems is better than 95%. It can place 47,800 lb into low Earth orbit or more than 12,700 lb into geosynchronous orbit.

Titan IV is launched from Launch Complex 40 at Cape Canaveral Air Force Station, Florida, and from Space Launch Complex 4E at Vandenberg Air Force Base, California. The first Titan IV B was successfully flown from Cape Canaveral Air Force Station on 23 February 1997. This configuration improves reliability and operability and increases lift capability by 25%. Advancements also include improved electronics and guidance. The Titan IV B has standardized vehicle interfaces that increase the efficiency of vehicle processing. Additionally, the more efficient programmable aerospace ground equipment is used to monitor and control vehicle countdown and launch.

Upper Stages. In describing the evolution of military missiles to become space launchers, we mentioned a number of upper stages used in combination

Figure 6. The Titan IV space launcher. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

with the military rockets to place spacecraft into Earth orbit and beyond. In this section, we will provide brief descriptions of the most important.

The Centaur, developed and built by Convair/General Dynamics, is the most capable of these vehicles. The Centaur uses liquid oxygen to burn hydrogen fuel. This mixture is the most potent of all chemical rocket fuel combinations

because it provides the highest specific impulse to the rocket. Thus, rockets using this combination have the highest propulsive efficiency. The Centaur can be shut down and restarted in space, which is most important because it permits executing complex space maneuvers. However, because the fuels are cryogenic, these maneuvers have to be carried out shortly after launch, so that the fuel and oxidizer are not lost by evaporation. The Centaur has two Pratt and Whitney RL-10 engines that develop a total thrust of 30,000 pounds. The first Centaur was flown in 1962, and since then, Centaur upper stages have been used on top of Atlas and Titan boosters.

The Agena is the second important liquid-fueled upper stage. The Agena also uses a hypergolic fuel/oxidizer mixture of (N_2O_4) and unsymmetrical dimethyl hydrazine (UDMH) to provide a thrust of about 15,000 pounds. The Agena also has shutdown and restart capability like the Centaur. The difference is that the fuel/oxidizer mixture can be stored at ambient temperature, so that the Agena vehicle can stay in orbit in a dormant condition much longer than the Centaur. The Agena has been used on Thor, Atlas, and Titan rockets and has proven to be the most ubiquitous of the high-performance liquid upper stage vehicles. The Agena was originally designed and built by the Bell Aerospace Company for the Atlas and was later taken over by the Lockheed Missiles and Space Company (now called Lockheed Martin Co.). It was flown for the first time in 1960 on an Atlas booster.

Solid-fueled rockets have been used extensively as upper stages for space launch vehicles ever since the first orbital flights. The Juno I launcher, which placed Explorer I in Earth orbit in January 1958, had three solid-fueled upper stages, including a small solid booster on the Explorer I satellite itself. Solid-fueled rockets have the advantage that they are safely storable and also extremely versatile. They have ranged from the small rockets already mentioned that might develop tens of pounds of thrust to the huge strap-on rockets of the Titan IIIC that develop thrust levels of more than a million pounds. The primary disadvantage of solid-fueled rocket boosters is that, except in certain cases, such as the two-grain systems used in antimissile applications, they cannot be turned off once they are lit. Another disadvantage is that failure of solid-fueled rocket is usually catastrophic—which was unfortunately graphically illustrated in 1986 by the failures of a solid rocket booster in January that caused the loss of “Challenger” and then again in April that caused the loss of a Titan 34D flight.

There are too many solid-fueled upper stages to list here. Probably the most important and capable solid-fueled upper stage is the inertial upper stage (IUS) that was built by the Air Force for use with the Space Shuttle and the Titan 34D system.

The Evolved Expendable Launch Vehicle Program (EELV)¹

The EELV Concept. The Evolved Expendable Launch Vehicle program, born of studies conducted in the late 1980s and 1990s, represents a commitment to

¹Excerpts from input by James Simpson, The Boeing Company

reducing significantly the cost of access to space. An industry/government partnership has developed two competing EELV systems to meet space transportation needs during the next 20 years (8).

Conceived as a "system of systems" to improve operability and reduce recurring and infrastructural costs, EELV is using streamlined manufacturing and improved mission assurance processes. Its facilities and operations are designed to lower costs.

Requirements call for a 25–50% reduction in recurring operational cost compared to current systems and for improving system reliability and availability. The U.S. Air Force interest is that EELV will replace the Titan, Atlas, and Delta vehicles and their launch infrastructures supported by DOD. The program implements DOD acquisition excellence goals by streamlining the government's role and replacing its oversight of contractors with less intrusive "insight." The objective is to enhance U.S. launch industry competitiveness in the international market by reducing costs across the entire system.

In October 1998, the government awarded \$500 million contracts each to Boeing and Lockheed Martin. Development costs are shared between the contractors and the government, resulting in a national, dual-use launch service. The government program office has virtually unlimited access to all but some highly sensitive and proprietary cost and pricing data. The Air Force simultaneously awarded initial launch service contracts to both firms.

The strategy enabled two further benefits: competition and assured access to space. Having two competitors throughout the life cycle of the program is key to achieving price competitive procurement. Two providers using a standard payload interface maintain payload interchangeability between Delta IV and Atlas V and enhance assured access to space.

Each delivery order for a launch service has a standard 24-month period for performance. Individual launch service plans, however, are highly flexible and can be tailored to spacecraft customer needs.

EELV will support U.S. military intelligence, civil, and commercial mission requirements using contractor-provided commercial launch services. The two are the Boeing Delta IV and Lockheed Martin Atlas V, both designed to meet the full range of government launch requirements.

The EELV program has three key performance parameters: specific payload mass-to-orbit requirements; vehicle design reliability of 0.98 (threshold) at a 50% confidence level; and standardization, including standard payload interface for each class of vehicle and standard launch pads that can accommodate all configurations in an EELV family (9).

Delta IV. Delta IV was developed under a U.S. Air Force EELV contract. The Delta IV launch vehicle uses a new liquid oxygen/liquid hydrogen 16.7-foot diameter common booster core (CBC) powered by the new Boeing-Rocketdyne RS-68 main engine. This is the first large liquid-fueled engine to be developed in the United States since the SSME (Space Shuttle main engine). The RS-68 is a gas generator liquid oxygen/hydrogen booster engine. The bell-nozzle RS-68 develops 650,000 pounds of sea level thrust and uses a simple design approach that has drastically reduced the total part count compared to engines of equivalent size

or performance. The vehicle's cryogenic upper stage, which uses the Pratt & Whitney RL10B-2 engine, is substantially similar to that flown on the Delta III (6,9,10).

There are several variants of the Delta IV launch vehicle. The Delta IV-M (medium) is a single-core variant that combines the CBC with a version of the Delta III liquid oxygen/hydrogen second stage and a stretched 4-meter fairing that provides 9200 pounds to GTO. The Delta IV-M + variants augment the single core with two or four solid rocket strap-on Alliant Techsystems graphite epoxy motors (GEMs) and provide two variations of upper stages and payload accommodations, the 13-foot Delta III derivative and the 16.7-foot version that has greater fuel capacity and greater payload volume. The M + variants enable payload deployment of 14,700 pounds to GTO. The Delta IV vehicle family will have a GTO lift capability of up to 29,500 pounds and is available in three major variants. The largest variant, the Delta IV-Heavy, combines three CBCs with the 16.7-foot upper stage. The payload accommodations include either a 16.7-foot isogrid aluminum fairing based on the existing Titan IV or a newly developed composite fairing based on the Delta II and Delta III designs. The 13-foot fairing is the existing Delta III composite fairing lengthened by 3 ft (Fig. 7) (6).

Improvements include the new CBC, the newly developed and simplified main cryogenic engine, the focused factory facility, and simplified launch-processing operations.

Parts for the medium-plus and heavy CBCs are, respectively, 88% and 93% common relative to the medium CBC. All are manufactured using a common factory production list. CBC innovations include friction stir-welded tanks, spun-formed domes, and the use of composite structures. The RS-68 has reduced operating pressure, 80% lower part count, 95% less labor, uses cast versus welded parts, and has no special coatings. However, more than 85% of the upper stage part count is a Delta III heritage, and much of the avionics are from Delta II and III.

Full integration, assembly, and checkout testing take place before each vehicle leaves the factory. Delta IV's horizontal booster processing flow and vehicle stage mating in the horizontal integration facility allow parallel integration, reduced hazardous lifting operations, and decreased pad time. Total vehicle time at the launch base is less than 1 month and only 8–11 days on the pad. Delta IV features launch sites on both the East Coast (Cape Canaveral Air Force Station, Florida) and West Coast (Vandenberg Air Force Base, California). Each pad can launch all configurations, and launch pads are virtually standard between the Cape Canaveral SLC-37 and Vandenberg SLC-6 launch sites.

Atlas V. The Atlas V vehicle family, developed under the U.S. Air Force EELV contract, builds on the improvements made for the Atlas III. The Atlas V family of vehicles incorporates a reinforced first-stage structure, as well as increased propellant load in the first stage, called the common core booster (CCB) powered by the Russian RD-180 engine. The RD-180 is produced by RD AM-ROSS, a joint venture between Pratt & Whitney and Russian's NPO Energomash. The engine develops 860,000 pounds of thrust at sea level, uses liquid oxygen/RP-1 propellants, and is the only high-thrust, staged-combustion engine in production. It has

Figure 7. Evolved Delta. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

been tested extensively and was flight proven on the first Atlas IIIA mission in May 2000 (Fig. 8) (7).

Lockheed Martin has proposed variants of the Atlas V that incorporate different arrangements of solid strap-on boosters to increase the payload performance of the single common core variant up to 18,000 lb to GTO. To differentiate the various Atlas V configurations, Lockheed Martin devised a secondary numbering system. The first number identifies the fairing diameter in meters (3,4, or 5-meter fairing). The second number identifies the number of solid strap-on boosters (0 through 5). The final number identifies the number of second stage RL-10 engines (either 1 or 2). As an example, an Atlas 5 532 has a 5-meter fairing, three solid strap-on boosters, and two second-stage RL-10 engines. A single engine RL-10 second stage is used for high altitude (MEO and GTO) missions, whereas the two-engine variant is used for LEO missions.

Atlas V's several configurations have the flexibility to meet varied performance requirements for missions from LEO to GTO. Options include the addition

WSC October, 2002

1

Figure 8. Evolved Atlas. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

of one to five Gencorp Aerojet strap-on solid rocket motors for intermediate lift capability or the use of three CCBs for heavy payloads. The Atlas 400 series has a 13-foot payload fairing and a single CCB; the 500 series has a composite 16.7-foot payload fairing, a single CCB, and up to five Aerojet solid rocket boosters; and the heavy launcher has three CCBs and a composite 18-foot payload fairing. All three series use a common Centaur upper stage with Pratt & Whitney RL10A-4-2 engines(s).

These modifications, combined with the stretched Atlas IIIB Centaur upper stage, allow the Atlas V to place more than 10,000 lb in a geosynchronous transfer orbit with the single CCB. The heaviest variant of the family currently planned for production will incorporate an arrangement of five solid strap-on boosters to increase the payload performance of the single common core variant up to 18,000 pounds to GTO. Lockheed Martin has designed a three common booster variant capable of placing more than 13,000 lb directly into a geostationary orbit that is currently not being marketed commercially (8,10).

Atlas V, which uses the same Centaur upper stage as the Atlas IIIB, can be configured with either one or two RL10A-4-2 engines. A hydrazine attitude control system provides precise in-orbit maneuvering. The 18-foot payload fairing is a new design derived from the Ariane V fairing manufactured by Contraves Space of Switzerland. It will be offered in two lengths, one optimized for communications satellites and the other for accommodating large-volume spacecraft missions. The 13-foot payload fairing is the same one used on Atlas II and III. Among Atlas V's innovations is the RD-180 engine capability for continuous throttle between 47 and 100% of nominal thrust, which allows substantial control over launch vehicle and payload environments. Others include reduced manufacturing cycle time and simplified launch processing. Atlas V also includes

the Air Force EELV standard payload interface that allows payload interchangeability with Delta IV (8).

Atlas V incorporates efficient launch site processing, including use of an off-pad vertical integration facility (VIF) for the vehicle and parallel processing of the encapsulated payload in separate installations. Launch site processing has been reduced from 28–38 days for Atlas II to just 18–26 days. The encapsulated payload will be transported to the VIF and mated to the launch vehicle. After combined systems testing, the fully integrated Atlas V/encapsulated payload will be transported to the nearby “clean launch pad.” All vehicle configurations use common processing procedures and can be launched from the same clean pad. On-pad time has been reduced to less than 1 day.

Current Status. The Lockheed Martin-built Atlas 5 401 (single CCB, no solids, and single engine Centaur) booster launched flawlessly on 21 August 2002 deploying the Hot Bird 6, a communications satellite for Eutelsat.

The 12.5-foot diameter rocket was the largest to launch from Cape Canaveral since the Saturn 5 sent Apollo astronauts to the Moon. This flight gives the Atlas family a string of 61 consecutive successful launches during 9 years using the Atlas II, Atlas III, and Atlas V vehicle configurations.

On 20 November 2002 the Delta IV-M + 4,2 carried the W5 communications satellite for Eutelsat to a precise geostationary transfer orbit.

The Department of Defense and related agencies (e.g., NASA), as well as the commercial sector, will be major customers for both vehicles. The Pentagon has scheduled 29 launches aboard the rockets to date.

Conclusions

It is truly remarkable that from Goddard's first liquid-fueled rocket flight to the landing on the Moon was a mere 43 years—well within the lifetimes of many people living today. The spurs for this achievement were clearly the Second World War (1939–1945) and later, the Cold War (1948–1991). In both cases, the technology of rocket propulsion was considered critical by all concerned to prevailing in the conflicts. However, this is only half the story. The other half is that a group of unusually talented and motivated people from many nations contributed to the successes that we have described. The principal technical conclusion that can be drawn from what has been said here is that the technology of chemically fueled rockets is mature. For the past 40 plus years, since the development of the ICBMs in the early 1960s, no new propulsion technology has been developed and applied. What has happened is that the proliferation of liquid- and solid-fueled chemical rockets has made it possible to develop a very large number of launch vehicle combinations tailored to meet a great many different requirements for expendable space launchers. This, of course, is what is meant by the term “evolution” in the title of this article. For the foreseeable future, this evolution will continue and will be made possible by advances in guidance and control systems, more accurate timing and navigation, and other auxiliary technologies. It is a tribute to the designers of the early ICBM rockets that their products are still in our front line expendable space launchers.

What of the future? We believe that there are now signs on the horizon that new technologies for space launch systems will be required. We are on the threshold of initiating human exploration of the solar system. The International Space Station will be the staging base for this new phase of space exploration. We believe that both electric propulsion systems and nuclear rockets will be assembled at the space station and will eventually take people and equipment on journeys around the solar system. Hopefully, the designers and builders of these new propulsion systems will display the same skill and virtuosity as the people who created the space launchers described in this article.

EXPLORATION OF MARS BY THE USSR

Introduction

Mars research began long before the Space Age. Ground-based astronomical observations using photometry (I.K. Koval', N.P. Barbashev, et al.), polarimetry (A.V. Morozhenko et al.), and infrared spectrometry (V.I. Moroz) were performed in the Soviet Union throughout the 1950s and 1960s. G.A. Tikhov attempted to find evidence of life on Mars using spectroscopic techniques. Theoretical models for the internal structure of the planet began to be developed (V.N. Zharkov et al.). An overview of this period may be found in Ref. 1.

Early Soviet planetary spacecraft were developed by Special Design Bureau 1 (OKB-1, now NPO Energia) under the leadership of Chief Designer S.P. Korolev (1907–1966). B.E. Chertok has brilliantly described this period of history in his books (2–4). One of the primary motivations for the development of long-term Martian research programs was a desire to find life on the planet. It was generally understood that this project had to begin elsewhere—learning more about the planet Mars itself. Nevertheless, early Soviet spacecraft carried a spectrophotometer for observations of the so-called Sinton bands, which were, at that time, presumed to indicate the presence of organic material on Mars.

Eight attempts were made to launch a spacecraft to Mars, starting in 1962. Only the fourth spacecraft, the Mars-1 (1962) executed a flyby, but communications were lost prior to the flyby. Jet Propulsion Laboratory made two attempts (1964) during this period, one of which was successful: Mariner-4 performed a Mars flyby and transmitted an image of the planet.

In 1965, S.P. Korolev transferred all unmanned interplanetary space flight projects to another facility, the Design Bureau and Plant named after S.A. Lavochkin. The Design Bureau ("KB") was managed by Chief Designer G.N. Babakin (1914–1971). Later (1974) this facility was re-named to Nauchno-Proizvodstvennoe Obyedinenie imeni S.A. Lavochkina (NPO Lavochkin or NPOL), in translation Research-Industrial Association S.A. Lavochkin. For simplicity we will use the designation "NPO Lavochkin" for all periods covered below.

Many successful missions were carried out by NPO Lavochkin to the Moon, Venus, and eventually to Halley's Comet, but, the USSR's development of Mars projects was unsuccessful. Between 1969 and 1973, six Soviet spacecraft were launched, two in 1971 and four in 1973; however, virtually all of the new knowledge about Mars obtained by the early 1980s came from the NASA Mariner 9 and Viking missions. The Soviet contribution to research concerning the planet itself turned out to be quite meager, except for various issues relating to the interaction of the planet and its plasma sphere with the solar wind, where the Soviet Mars-3, Mars-5, and Phobos-2 spacecraft provided the basic results. It should also be noted that the Soviet Union was responsible for the first successful landing on Mars (Mars-2) and the first direct measurements performed in the Martian atmosphere (Mars-6). A NASA-published history of the NPO Lavochkin Mars efforts may be found in Ref. 5. The first papers discussing the scientific results of

the 1973 Soviet missions were published in a special volume of the journal *Kosmicheskie Issledovaniya* [*Space Research*] (6). A description of the major scientific research results related to the Martian atmosphere and surface obtained during both Soviet and American missions of that era may be found in Ref. 7.

Mars-2 and Mars-3 Spacecraft

The Mars-2 and Mars-3 unmanned interplanetary spacecraft were launched on 19 and 28 May 1971. Each spacecraft included an orbiter and a lander (Figs. 1 and 2). Upon arrival at Mars (on 27 November and 2 December 1971, respectively), the landers separated from the Mars-2 and Mars-3 spacecraft and reached the surface of the planet, thereby becoming the first spacecraft to attempt a landing on the surface of Mars. Each 1000-kg lander carried a pennant with the seal of the Soviet Union, a camera, and scientific instrumentation for studying soil samples. These were the first items made on Earth to land on Mars. The Mars-2 lander broke up at coordinates 44.2°S 313.2°W because of inaccurate targeting, which led to an error in the entry angle and caused the lander to impact on the surface before the parachute opened. The Mars-3 lander successfully landed on the surface at coordinates 45°S 158°W. The Mars-2 and Mars-3 orbiters (each weighing 2265 kg) were inserted into Mars orbit and performed a research program on the composition of the Martian atmosphere, surface photometry and IR radiometry, the magnetic field of Mars, and the interaction between the solar wind and the Martian plasma environment for more than 8 months. Both orbiters had cameras but no scientifically important images were transmitted. A global dust storm prevented imaging during first months after orbit insertion, and cameras failed by the time when dust dissipated. The Mars-2 and Mars-3 orbiters ceased operations in August 1972.

Mars-4 and Mars-5 Spacecraft

The Mars-4 and Mars-5 spacecraft for planetary studies of Mars from Mars orbit were launched on 21 and 25 July 1973 (Fig. 3). Mars-4 reached Mars on 10

February 1974 and passed within 2200 km of the planet's surface without entering Mars orbit; however, it did transmit photographs of the planet to Earth. The Mars-5 spacecraft entered Mars orbit on 12 February 1974 (the orbiter had a mass of 2200 kg). The spacecraft continued operating once it reached Mars orbit; data were obtained on the atmosphere and surface temperature patterns, and approximately 120 surface photographs and panoramas of the Martian Southern Hemisphere were transmitted to Earth.

Mars-6 and Mars-7 Spacecraft

The Mars-6 and Mars-7 Mars spacecraft were launched on 5 and 9 August 1973. (Figs. 4 and 5). Mars-6 reached the planet on 12 March 1974. The descent module separated from the orbiter, landed on the surface of Mars, and performed direct measurements of the Martian atmosphere during its descent. Mars-7 reached the planet on 9 March 1974. The descent module separated from the spacecraft and performed a flyby 1300 km above the Martian surface.

After 1973, there were no USSR flights to Mars for many years. At that time, it would have been difficult to mount a standard mission (e.g., with a satellite and several lander modules) that could have obtained new scientific results at a level higher than that already achieved by the United States. There was a desire to undertake a project that would be more significant on a

Figure 3. Mars-4 and Mars-5 orbiter. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

fundamental level. The project that was eventually selected involved the return of a sample of Martian material to Earth. NPO Lavochkin worked on this mission for several years, but the project turned out to be too risky and was eventually cancelled (5).

During this period, the USSR successfully continued its flights to Venus. A new direction for research was pioneered by R.Z. Sagdeev. These were research projects related to two solar-system bodies, Phobos and Halley's Comet.

Phobos-1 and Phobos-2 Spacecraft

The primary purpose of the Phobos spacecraft was to study not Mars itself, but Phobos (8). However, this mission was the next major post-Viking step in Mars research and marked the first mapping of the planet in the thermal infrared (the spatial resolution was approximately 1 km at a wavelength of approximately 10 μm). Approximately 40,000 near-infrared (1–3 μm) images were obtained using a mapping spectrometer. At that time, no instruments of this type had yet been used, even in remote sensing observations of Earth. This mission also marked the first spectroscopic remote sensing of the Martian atmosphere via measurements of the solar spectrum at various altitudes above the limb in several wavelength bands; these data were used to determine the vertical water vapor and aerosol distributions. The first measurements of the dissipative flux in the upper atmosphere of Mars were made. Several interesting new results were also obtained for Phobos. Precise mass and density values were determined, and brightness was measured as a function of wavelength. The brightness as a function of wavelength did not conform to previously held views regarding the composition of Phobos. A large amount of unique data was obtained on the plasma environment of Mars and its interaction with the solar wind (9). Papers describing the scientific results of the Phobos mission were published in the journals

Figure 4. Mars-6/Mars-7 spacecraft. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

Nature (10), *Geophysical Research Letters* (11), and *Planetary and Space Science* (12). Despite the fact that Phobos-1,2 was a short-term mission (transmitted data from orbit for approximately 2 months), the resulting scientific data exceeded the scope and quality of that obtained in all of the other Soviet Mars expeditions taken together.

The Phobos-1 and Phobos-2 new-generation spacecraft (Table 1) were launched on 7 and 12 July 1988, respectively (13) (Figs. 6 and 7). These spacecraft performed research on Phobos, Mars, and outer space (Fig. 8). Thirteen countries, plus the European Space Agency (ESA), were involved in developing the scientific instrumentation (Table 2).

Snyder and Moroz (14) provide information on the scientific instrumentation for all Mars missions (including Soviet), as well as a review of the major scientific results.

Figure 5. Mars-6/Mars-7 descent module. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

After the end of the mission of the two Phobos spacecraft, an intense controversy erupted over whether another mission of the same type or a new mission should be developed whose primary goal would be to study the planet Mars itself. The latter point of view won out and led to approval of a very complicated project with the following five elements: a satellite in Mars orbit, small stations (landers), penetrators, a Mars rover, and an aerostat. The science experiments were largely developed within the framework of an international cooperative effort involving 20 countries. Launch was scheduled for 1994 but was then rescheduled for 1996. The situation was dramatic: Work on the project had begun in one country—the Soviet Union—and was continued and finally completed in another—the Russian Federation. The Russian Space Agency was established during this period, and Mars-96 became its first large scientific project. It soon became clear that it needed to be simplified. The Mars rover and aerostat were eliminated. However, there was a lack of funding, the project was continuously delayed, and the infrastructure crumbled. For the first time ever, the two-launch scheme had to be abandoned due to lack of funding.

Mars-96 was launched on 17 November 1996 but was unable to enter the transfer orbit because of a failure in the Block D stage. This was a catastrophe of a magnitude different from previous disasters. Many were convinced that this meant an end to the overall space-science research strategy inherited from the Soviet Union, with virtually unlimited funding, use of expensive launch vehicles, etc. However, it would have been very difficult for this strategy to continue, even

Table 1. Basic Specifications for Phobos-2 Spacecraft

had the Mars-96 launch been successful. Basic data on the Mars-94/96 spacecraft and its scientific instrumentation may be found in two *Institute for Space Research* preprints (15,16).

While work on the Mars-96 project was under way, an attempt was made to organize bilateral cooperation between the United States and Russia in space-science research; this attempt was initiated by W. Huntress, who at that time was NASA Deputy Administrator for Space Science. The Cold War was now over, and it was logical to combine efforts in Mars research, as well as several other areas. Several options were generated for a joint flight to Mars under the title "Together to Mars": A Russian launch vehicle, an American orbiter, and a Russian descent module. For various reasons, this effort never proceeded beyond the preliminary discussion phase. This cooperative effort eventually merely amounted to participation of Russian scientists in three American Mars missions. Two of

them (Mars Climate Orbiter and Mars Polar Lander) failed but the third (Mars Odyssey 2001) was successful. Important observations of ice in the subsurface ground layer were made by Mars Odyssey with the gamma-spectrometer package that includes a Russian instrument (high energy neutron detector HEND).

Despite all of the lack of success in Mars research, Mars and its satellite, Phobos, remain highly attractive targets for the current Russian planetary program.

EXPLORATION OF THE MOON BY SOVIET SPACECRAFT

Launches of Soviet spacecraft to the Moon started on 2 January 1959, only 15 months after the launch of the first Sputnik. The full list of missions to the Moon is given in Table 1. It includes all officially declared Soviet lunar missions. According to some sources there were also several failed Soviet attempts to send spacecraft to the Moon, when for various reasons, spacecraft stayed in Earth orbit or failed even earlier (1). They have never been officially recognized by the Soviet Union as lunar missions, and this is why they are not mentioned here. As a source for Table 1, we used the Soviet Encyclopedia of Cosmonautics (2). In total, there were 29 Soviet missions to the Moon. Of them, 20 were successful, one was partly successful, and eight missions failed. Twenty-four missions were named Luna (the Moon, in Russian); five missions were named Zond (probe, in Russian). All Soviet missions to the Moon were robotic, although there was a program of Soviet manned flights to the Moon, which was canceled in the late 1960s because of failures of the heavy booster rocket necessary for those flights (3).

It is necessary to mention that in the 1960s–1970s, when the Soviet Union sent spacecraft to the Moon, the space activity of both the Soviet Union and the United States was strongly politically motivated. The Soviet Union, by sending numerous lunar missions, wanted to demonstrate the superiority of its political system. The Apollo mission to the Moon, the backbone of the U.S. space program of that time, was a response to the challenge of Soviet space activity.

The first Soviet mission to the Moon, Luna 1, although it missed by 6000 km, was partly successful. It made geophysical measurements in near-Moon space and showed that the Moon does not have a significant magnetic field. Eight months later, Luna 2 reached the Moon and made scientific measurements until the spacecraft hit the surface. Data taken by magnetometer showed that the magnetic moment of the Moon could not be larger than 1/10,000 of the magnetic moment of Earth (4). The next Soviet lunar mission, Luna 3, October 1959, flew by the Moon sending back to Earth images of the far (invisible from the Earth) hemisphere of the Moon. Although the image quality was rather poor, it was discovered that the lunar farside, in comparison to the nearside, has much

Table 1. Soviet Missions to the Moon

Luna 1	Probe	2 Jan 1959
First attempt to reach the Moon. Missed it by 6000 km. Showed absence of lunar magnetic field. Sped up by lunar gravity and became the first artificial satellite of the Sun.		
Luna 2	Probe	12 Sept 1959
Successfully reached the Moon at 1° W, 30° N (435 km from the Moon's visible center), confirmed absence of lunar magnetic field.		
Luna 3	Probe	4 Oct 1959
Flew by the Moon and made first images of the farside of the Moon, invisible from Earth. The pictures were developed onboard and then sent back to Earth. Deficit of maria on lunar farside was discovered.		
Luna 4	Lander ?	2 Apr 1963
Mission failed: spacecraft missed the Moon by 8500 km.		
Luna 5	Lander	9 May 1965
Mission failed: spacecraft reached the Moon but due to a retrorocket failure crashed in Mare Nubium.		
Luna 6	Lander	8 Jun 1965
Mission failed: due to midcourse correction error, spacecraft missed the Moon by 160,000 km.		
Zond 3	Probe	18 Jul 1965
Flew by the Moon and made images of the farside and partly nearside of the Moon. The pictures were developed onboard and then sent back to Earth. Deficit of maria on lunar farside was confirmed.		
Luna 7	Lander	4 Oct 1965
Mission failed: spacecraft reached the Moon but due to a retrorocket failure crashed in Oceanus Procellarum.		
Luna 8	Lander	3 Dec 1965
Mission failed: spacecraft reached the Moon but due to a retrorocket failure crashed in Oceanus Procellarum.		
Luna 9	Lander	31 Jan 1966
First soft landing on the Moon (Oceanus Procellarum, 7.13°N, 64.37°W). First TV panoramas with close-up view of lunar surface were sent back to Earth.		
Luna 10	Orbiter	31 Mar 1966
First lunar satellite. Solar plasma sensors, magnetometer, micrometeorite sensors, gamma-ray spectrometer to measure surface composition of lunar surface.		
Luna 11	Orbiter	24 Aug 1966
Micrometeorite sensors, plasma sensors, gamma- and X-ray sensors to determine the Moon's chemical composition, tracking to measure lunar gravity field.		

Table 1. (Continued)

Luna 12 Onboard TV camera.	Orbiter	22 Oct 1966
Luna 13 Soft landing on the Moon (Oceanus Procellarum, 18.87°N, 62.05°W); TV panoramas sent to Earth; soil mechanics measured.	Lander	21 Dec 1966
Luna 14 Plasma and particle sensors; tracking to measure lunar gravity field.	Orbiter	7 Apr 1968
Zond 5 First lunar flyby with Earth return test; flight for Soviet manned expedition to the Moon, later canceled; a biological payload was included in the flight.	Flyby	14 Sept 1968
Zond 6 Lunar flyby with Earth return; continuation of test flight for Soviet manned expedition, micrometeorite and cosmic ray measurements, in-orbit photography, and biological payload.	Flyby	10 Nov 1968
Luna 15 Attempt of sample return from Mare Crisium; soft landing failed.	Lander	13 Jul 1969
Zond 7 Lunar flyby with Earth return; in-orbit photography of the Moon.	Flyby	7 Aug 1969
Luna 16 First successful robotic sample return; spacecraft landed in Mare Fecunditatis (0.68°S, 56.3°E).	Lander	12 Sep 1970
Zond 8 Lunar flyby with Earth return; in-orbit photography of the Moon.	Flyby	20 Oct 1970
Luna 17/Lunokhod 1 Soft landed in Mare Imbrium (38.17°N, 35°W); deployed the first robotic lunar rover which functioned for almost a year.	Lander	10 Nov 1970
Luna 18 Failed attempt of robotic sample return from lunar highland region in between Mare Fecunditatis and Mare Crisium.	Lander	2 Sep 1971
Luna 19 Micrometeorite, plasma and particle sensors, magnetometer, TV camera, tracking to measure lunar gravity field.	Orbiter	28 Sep 1971
Luna 20 Robotic sample return from lunar highland region in between Mare Fecunditatis and Mare Crisium (3.53°N, 56.55°E).	Lander	14 Feb 1972
Luna 21/Lunokhod 2 Soft landed in crater Le Monier at the eastern edge of Mare Serenitatis (25.85°N, 30.45°E); deployed robotic lunar rover which functioned for 4 months.	Lander	8 Jan 1973

less dark plains, called *maria* by astronomers. Now, this is, like the absence of a lunar magnetic field, common knowledge.

Then, the 3-year period of mission failures (Luna 4 to 8) in 1963 started, when the Soviet Union tried to soft land spacecraft on the Moon. This period was partly interrupted by the success of Zond 3, which flew by the Moon and sent back to Earth higher quality images of the lunar farside and part of the nearside, confirming the farside deficit in maria and providing knowledge of the photometric properties of the farside (5,6). Finally, in January 1966, Luna 9, successfully made a soft landing, 4 months before it was done by the U.S. Surveyor 1, and sent back to Earth TV panoramas of the close vicinity of the landing point (Fig. 1). This mission provided the first close-up view of the lunar surface (centimeter-size features were clearly seen). The successful landing had proved that the lunar surface is strong enough to withstand a load of this and future landers, a conclusion very important for exploration of the Moon (7).

Next, still in 1966, there was a series of three orbiters: Luna 10, 11, and 12. Luna 10 and 11 measured the micrometeorite and plasma environment in near-lunar space as well as gamma-ray radiation from the lunar surface. The latter is indicative of the chemical composition of the surface material. It was found that the surface material resembles basaltic lavas of Earth (8). At that time, these were the only measurements of the chemistry of the lunar surface. Luna 12 provided TV images of several areas of the lunar surface, some with a resolution as high as 15–20 m per pixel. Photogeologic analysis of these images led to a morphological classification of small (<1 km) lunar craters later used in the analysis of other images of the lunar surface. This series of successes was continued with the soft landing of Luna 13, December 1966, and the orbiter of Luna 14, April 1968. Luna 13, in its general design and presence of a panoramic TV camera was a repetition of Luna 9, but in addition, it had a mechanical penetrometer, dynamograph, and radiation densitometer to study lunar soil mechanics. It was found, in particular, that the surface material (at least 5 cm thick) consists of fine grains and its bulk density is $\sim 0.8 \text{ g/cm}^3$ (9). Luna 14 was making measurements of the micrometeorite and plasma environment, and its radio tracking (as well as tracking of Luna 10 to 12) was used to study the structure of the lunar gravity field that was required for better ballistic control of future lunar missions.

Then there was the flight of Zond 5, and a month later, Zond 6. Zond 5 was launched on 14 September 1968. Four days later it flew by the Moon and safely

Figure 1. Luna 9 lander after opening its petals; 1-petal antennae; 2-rod antennae; 3-photometric standard; 4-two-edge mirrors. The lander mass 99 kg. A similar petal design, which guarantees that despite spacecraft orientation on landing it would take the correct (antennae up) orientation, was used in the U.S. Mars Pathfinder, which successfully landed 30 years later than Luna 9.

returned to Earth on 21 September. These were test flights of circumlunar modules of the Soviet manned mission to the Moon (at that time still in preparation). The science payload included micrometeorite and cosmic ray measurements, important for the safety of future crews, as well as in-orbit photography and a biological payload. The latter included turtles, wine flies, and other creatures that were the first living earthlings brought close to the Moon.

On 13 July, Luna 15 was launched, its mission was the first robotic return of lunar samples to Earth. It was a race with the Apollo 11 mission, which started on 16 July and landed American astronauts on the Moon on 20 July. Unfortunately, on 21 July, trying to land, Luna 15 crashed. The first successful robotic sample return was accomplished in September 1970, when Luna 16 landed in Mare Fecunditatis and brought back to Earth 101 g of lunar soil. In a year, after another failed attempt (Luna 18), Luna 20 successfully landed in the highland area between Mare Fecunditatis and Mare Crisium and brought back to Earth 55 g of lunar soil (Fig. 2). Then, again after a failed attempt (Luna 23), the last Soviet mission to the Moon, Luna 24, August 1976, successfully landed, drilled deep into the surface and brought the sample (a 1.7-m long drill core with 170 g total mass) back to Earth.

The returned lunar samples were thoroughly studied in Soviet and many other laboratories of the world and were partly exchanged with the samples brought by six Apollo expeditions. Thus, the Luna 16, 20, and 24 samples, despite

Figure 2. Returned capsule of Luna 20 with lunar samples inside landed in snows of Western Siberia. The two extended features in the top part of the capsule are inflated antennae sending signals to the recovery teams.

their relatively small mass, became an essential part of the research bank of lunar materials available for international scientific research that resulted in many publications (see e.g., (10–13)). Study of the Luna samples helped to construct a more complete picture of the distribution of different types of lunar materials along the visible part of the Moon. It was found, in particular, that the three Luna sites, all at the eastern equatorial part of the Moon, form a geologic province for which the presence of basalts, rich in aluminum and depleted in titanium and alkalis, was typical. It is necessary to add that studies of the Luna samples (and the Apollo samples as well) are still ongoing and produce more and more details in our understanding of our natural satellite.

The series of robotic sample returns was interrupted from time to time by other missions. The last two Zond missions were in August 1969 and October 1970 (7,8). They continued in-orbit photography of the Moon, covering, in particular, some areas of the farside not covered in necessary detail by the U.S. Lunar Orbiter and Apollo missions (14). There were also Luna 19 and 22 missions whose major goal was the study of the structure of the lunar gravity field. And finally, there were two more successful landings, Luna 17 and Luna 21, which brought to the lunar surface the research rovers, Lunokhod (in Russian: Moonwalker) 1 and 2.

Luna 17 brought Lunokhod 1 to the northwest part of Mare Imbrium. It had traveled 10,540 m, sent to Earth more than 50,000 pictures from the navigation TV cameras and more than 200 TV panoramas, conducted more than 500 lunar soil tests, and made numerous measurements of the chemical composition of the soil by the X-ray fluorescence technique. Lunokhod 1 also had a French-made laser retro reflector for high-precision measurements of the distances between the Moon and Earth. Luna 21 brought Lunokhod 2 to the mare-like surface of the floor of the large crater Le Monier at the eastern edge of Mare Serenitatis (Fig. 3). It had traveled 37,450 m, partly along the mare-like surface, partly intruding into hilly terrain of the highland type, and studying the edges of a 15-km long linear trough named Fossa Recta. It sent to Earth more than 80,000 pictures from the navigation TV cameras and 86 TV panoramas and conducted

Figure 3. Lunokhod 2. General scheme; 1-magnetometer; 2-low-gain antenna; 3-high-gain antenna; 4-mechanism of antenna steering; 5-solar battery; 6-the cap (closed at nights); 7-panoramic TV cameras for vertical and horizontal scanning; 8-radioisotope heater; 9-instrument for soil-mechanics measurements; 10-rod antenna; 11-wheel with motor; 12-sealed instrument container; 13-X-ray fluorescence spectrometer; 14-stereo-scopic navigation cameras; 15-laser retroreflector; 16-upper navigation camera.

more than 150 lunar soil tests and numerous chemical analyses. In addition to that of Lunokhod 1, the Lunokhod 2 payload included a magnetometer, a photometric standard in the field of view of the panoramic TV cameras, and a special up-looking photometer to study the brightness of the night sky of the Moon.

The analysis of TV images taken by Lunokhod 1 and 2 led to a better understanding of the geologic processes responsible for the formation of the lunar soil and small-scale (centimeters to hundred meters) features of lunar topography (Fig. 4). In particular, it was found that surface regardening by meteorite

Figure 4. Fragment of Lunokhod 2 panorama showing rocky surface of the western edge of Fossa Recta trough and its opposite slope.

impacts was accompanied by a variety of down-slope gravity controlled mass-wasting phenomena (15–17). Joint consideration of local geology, the along the route measurements of the soil chemical composition (18) and soil optical reflectivity (19) led to conclusions on the mechanisms and scales of lateral and vertical mixing of lunar mare and highland materials. Measurements of the magnetic fields along the route and on the observation stations led to the discovery of local sites of residual magnetization associated with small impact craters and probably formed by the impacts (20,21). Analysis of variations of the interplanetary magnetic field registered by the Lunokhod 2 magnetometer led to estimates of the large-scale (hundreds of kilometers) structure of the Moon's interior (22). Lunokhod 1 and 2 measurements formed a very large database of lunar soil mechanics (23). Its analysis showed, in particular, that the soil is more cohesive on horizontal surfaces and less cohesive on steep slopes. Photometric observations of the lunar sky led to the discovery of a significant concentration of dust particles above the lunar surface (24).

As mentioned before, both Soviet and American lunar space programs were politically motivated. For about a decade, from January 1959 until December 1968, in the Soviet–American race to the Moon, there was approximate parity and several cases when “firsts” in key observations and discoveries were made by the Soviet Union. Since the Apollo program started its flights to the Moon, the U.S. role became dominant and some important achievements made by Soviet spacecraft lost importance because similar things had been done earlier and better by Apollo missions. The situation started to change after the last Apollo mission was completed (Apollo 17, 7–19 December, 1972). Meanwhile the Soviet studies of the Moon continued (Luna 21 to Luna 24), and it became obvious that the robotic approach to lunar studies could be very effective. The experience gained showed that Lunokhod type rovers could effectively study the Moon with a variety of instruments. Using the robotic arm, they could collect samples in places geologically interesting, but risky for landing, and reload them into the returning spacecraft of the Luna 16–24 type at sites safe for landing. The obvious advantage of this approach was that, compared to manned flights, it was much cheaper and could accept a much higher probability of risk. The Soviet lunar science community and space industry were actively discussing these possibilities, and even the Lunokhod 3 vehicle had been manufactured. But the Soviet leadership, which lost political interest in lunar studies, canceled all of these plans, and that was the end of Soviet missions to the Moon.

EXTRATERRESTRIAL LIFE, SEARCHING FOR

Introduction

Since at least the beginning of recorded history, humans have looked up at the sky and wondered whether or not we are alone. Traditionally, we have consulted philosophers and religious figures for guidance in answering this question. In every age and in every culture, these leaders have responded according to the particular belief system that they embraced at the time. Today, we live in a very special time. Beginning at the end of the twentieth century, humans acquired the knowledge and technological capability to try to answer this old and important question by doing experiments. As we begin the twenty-first century, scientists and the engineers may, in the near future, be able to present us with the first examples of life off planet Earth. At one extreme, we may be able to discern at a distance only some very suggestive biomarkers, without knowing whether they reveal the presence of microbes or minds. At the other extreme, it may be possible to discover another technologically advanced civilization and engage in some form of communication with it. In the middle ground, we may be able to acquire actual samples of biology from another world within our solar system and by returning them to our labs, unambiguously determine whether they represent an independent genesis of life. Or, to the contrary, whether all life on Earth can be traced to a distant place of origin.

Within this century, perhaps within our own lifetimes, we may know whether the laws of physics and chemistry, operating throughout the universe, routinely produce biology. Christian DeDuke has proclaimed that “life is a cosmic imperative” (1); we are poised to test that hypothesis.

Searching for Life Elsewhere in Our Solar System

Other Habitable Worlds. Liquid water is the key to all life as we know it. Water chauvinism will inevitably guide (and even bias) our search for habitable domains and life off Earth. This may represent an enormous failure of imagination, but it is the only practical approach to developing technologies and search strategies for life (and biology) as we do not yet know it. On the scale of previous human exploration, our own solar system is vast and continuously surprising; we cannot search everywhere at once. Choices need to be made and priorities established. For the next few decades at least, searches for extinct or extant life within our solar system will be a case of “follow the water.” During the exploration of those environmental niches where water exists or once existed, it will also be necessary to have a working definition of life so that we will know it if we find it. There is no perfect definition of life, but one that is used frequently is due to Gerry Joyce (2): “life is a self-sustained chemical system capable of undergoing Darwinian evolution.” Such a definition does not lend itself to exploration of our solar system by robotic surrogates. Instead, we will rely on evidence of liquid water, the presence of biogenic elements (C, H, O, N, S, P), and a

plausible source of free energy. If we can detect and document macroorganisms, the conclusions will be more straightforward. However, the expectation is that most of our searching will deal with microorganisms. At this small scale, even on Earth, the distinction between living and nonliving is not always clear.

More Than the Goldilocks Story. The concept of habitability, first introduced in Dole's *Habitable Planets for Man* (3), has been expanded into the habitable zone for life. This zone is the time-dependent volume surrounding the host star(s) over which liquid water could exist on the surface of a planet (4). Our own solar system makes it abundantly clear that in addition to stellar insolation, the atmospheric composition (the greenhouse gas components and the albedo) of the planets is another very important factor in enabling surface liquid water. Only recently have we begun to appreciate some of the other significant contributors to the Venus (too hot), Mars (too cold), and Earth (just right) Goldilocks story. The D/H ratio measured in the Venusian atmosphere and the dendritic channels photographed on the surface of Mars have convinced most scientists that 4 billion years ago, Venus and Mars boasted liquid water on their surfaces, as did Earth. As the primitive Sun evolved and brightened, Venus accumulated increasing concentrations of CO₂ in its atmosphere and underwent a runaway greenhouse that boiled away its water. Lightweight Mars lacked enough radioactive material in its interior to continue to keep it warm, and lost its surface water as runaway glaciation froze out its CO₂ atmosphere. On Earth, tectonic activity plays a crucial part in controlling terrestrial atmospheric CO₂ through the carbonate-silicate rock cycle (5). Breaking the cycle on Venus (dehydrated rocks became too brittle for subduction) and Mars (loss of energy source to drive plate motion) destroyed the stabilizing negative feedback loops. Subsurface liquid aquifers may still exist on Mars today and provide niches for the survival of life that originated and evolved during more clement times.

In 1996, the potential for life on early Mars was brought into sharp focus by claims that the ALH 84001 meteorite (a piece of rock ejected from Mars 16 million years ago and deposited on the Antarctic ice sheet 13,000 thousand years ago) contained fossil evidence for microbial life (6). Since that time, the debate has raged whether the material in question is of mineralogical or biological origin. The most recent assertion that tiny grains of aligned magnetite must have been produced by the analogs of magnetotactic bacteria (7) (because no abiological production mechanism is now known) has fueled the flames of this controversy, rather than settling the question. The rather recent realization that on Earth we have collected 16 samples of Mars (the so-called SNC meteorites) has reminded us that the terrestrial planets were not necessarily biologically isolated at the time when all three bodies were wetter and more conducive to the origination of life. If the answer for ALH 84001 turns out to be biology, the next question will be whether that biology is independent of, or related to, terrestrial biology. Might we be Martians?

Other Oceans under Ice. Images and data from spacecraft flying through or orbiting the Jovian system have caused us to expand the possibilities for the solar system habitable zone. Liquid water cannot survive on the surfaces of Jupiter's moons Europa, Callisto and Ganymede, but vast oceans may exist beneath their icy carapaces. The water would be kept liquid by the frictional heating produced from tidal distortions of the moons (alternately compressed and

stretched) as Jupiter and the other moons wage a gravitational tug of war throughout their orbits. This same energy source drives the extreme volcanism seen on the surface of Io. The evidence for these oceans is still indirect and consists of images of the fractured crusts that resemble familiar terrestrial ice fields floating over oceans (8), and magnetic field measurements that argue for a briny, conducting ocean beneath the ice of Europa (9). Spectral data provide evidence of organic structures on the surfaces of Callisto and Ganymede (and perhaps Europa) (10). Organics and liquid water have led scientists to begin speculating on free energy sources on Europa (and the other moons) capable of supporting metabolism for some form of life under the ice (11).

On Earth, we have been surprised by the deep, hot biosphere (12) beneath our feet, where microorganisms appear to exist in abundance, at depths up to 3 kilometers, independent of surface photosynthesis. Though life can apparently thrive at depth, we do not know whether life can evolve at depth. European oceans should prove to be a very interesting test case.

Missions of Exploration. The Taylor and McKee (2000) report on *Astronomy and Astrophysics in the New Millennium* (13) identified “Is there life elsewhere in the universe?” as one of five fundamental questions setting the scientific agenda for the decade to come. The committee further argued that within this millenium astronomers must “Search for life outside of Earth, and if it is found, determine its nature and distribution in the galaxy.” Thus in the United States, NASA has a clear mandate to undertake missions of exploration in search of life elsewhere. The Cornerstone missions of ESA reflect this same priority.

Although the Viking Landers found no trace of biology on the Martian surface, there has been growing interest in returning there to look for fossils or perhaps even extant life in any subsurface aquifers (14). Recently, the Mars Global Surveyor provided possible evidence for the existence of liquid water quite near the surface in the not so distant past (15). Previous mission failures have delayed, but not deterred, the continuing exploration of this close neighbor. Another orbiter, Mars Odyssey will be launched in 2001. Two surface rovers will be launched in 2003 along with ESA’s Mars Express. Placeholders exist for launches in the Mars Surveyor program in 2005 and 2007, and many planetary scientists are pushing for a sample return mission.

Europa will be the destination of an orbiter, originally scheduled for launch in 2003, whose goal is establishing whether a liquid water ocean does indeed exist beneath the surface ice. An affirmative answer will bolster the case for a lander to explore the ice in regions where water has recently reached the surface (and perhaps some form of hydrobot to probe the underlying ocean itself) for signs of life. It would be hard to overestimate the difficulty of this task. If life is distributed throughout the ocean and not strongly concentrated near the (presumed nutrient-rich) ice/water interface (11), the number of cells of microorganisms could be far less than 1 cm^{-3} .

The Cassini mission will drop its Huygens probe into Saturn’s moon Titan in 2004 to sample the organic chemistry there and perhaps provide valuable information about early Earth and chemical pathways to life. Bepi Colombo will be launched in 2009 to study the planet Mercury. While not directly relevant to biology, it will help us to understand better the conditions that lead to the formation of terrestrial planets.

The smaller bodies of the solar system will also get their share of attention. Radar observations from the newly upgraded Arecibo Observatory will explore the properties of nearby asteroids and their companions. NEAR Shoemaker has just ended its mission with a spectacular landing onto the surface of the asteroid Eros. This spacecraft has provided a wealth of data to help understand the conditions in the early solar system, but it has also posed surprising new questions. Very recently, the Pluto/Kuiper Express (planned to fly by Pluto in 2012 and go on to make a close approach to primitive Kuiper Belt objects) has been canceled. A more cost-effective substitute mission is now under study with the objective of reaching Pluto before 2020. Rosetta will be launched in 2003 to study the nucleus of comet Wirtanen. The Stardust Mission is on its way to collect interstellar dust and then return samples from the vicinity of Comet Temple II in 2006. As for a sample return from Mars, new analytical tools will be required to tease out any biological signatures from micro- and nano samples. As yet, there are no unambiguous methodologies for distinguishing terrestrial biology from an independent origin and evolution of life, but this challenge will be enthusiastically embraced should the sample returns demand it.

These missions are all subject to modification from fiscal pressures, equipment malfunction, and new scientific discoveries. The most reliable source of current mission planning can be found on NASA's Solar System Exploration Division web site at <http://solarsystem.nasa.gov/missions/mission.html> and on the ESA mission sites <http://sci.esa.int/home/missionsinprogress/index.cfm> and <http://sci.esa.int/home/futuremissions/index.cfm>.

Searching for Life Beyond Our Solar System

Other Habitable Planets. Life as we know it is a planetary phenomenon. The origin and evolution of terrestrial life were shaped by planetary circumstances, and life in turn has profoundly changed the planet on which we live. We are now extending our exploration for life within our solar system to the oceans of giant moons, and it is reasonable to reach farther and to search for life in the vicinity of other stars. To do so, we should begin by looking for habitable planets.

Searching for Planets. Planets shine in reflected starlight and are extraordinarily weak compared to their host stars. At optical wavelengths, the Sun outshines Earth by a factor of a billion to one. In the infrared at 10 microns, the contrast ratio is improved to about a million to one. Therefore, in principle, given an angular resolution that is sufficient to separate an image of the planet from an image of the star and methods for dealing with the extreme contrast ratio—adaptive optics, speckles, and nulling interferometers—any planets that may orbit the nearest stars could be directly imaged. That feat lies in our technological future. The methods of extrasolar planetary detection currently in use are all indirect.

It is possible to measure the reflex motion of a star about its planetary system's center of mass due to the gravitational pull of unseen orbiting planets. Astrometry measures this motion across the plane of the sky, and radial velocities measure the reflex along the line of sight to the star. Given a favorable alignment, one can also measure the diminution of stellar luminosity as a planet

transits in front of the star. Fortuitous alignment can also lead to magnification of the light of a distant star by a planet (sitting near the Einstein ring surrounding a foreground parent star) creating a short-lived gravitational microlensing event.

Measurements of reflex motions and direct imaging techniques will work best on nearby stars. The techniques also work best for massive planets and low-mass stars. Transits and microlensing events are transient and unpredictable and require long-term monitoring of large populations of stars. These techniques can provide planetary statistics and demographics for distant stars. The instrumental precision required for all these detection methods is extremely challenging (16), and in some cases require orbital platforms and new technological developments that will take one or more decades to achieve. In other cases, such as radial velocity studies, we have already achieved the required limiting precision, but we have not had the instruments on telescopes for the decade or more needed to detect planets in long-period orbits comparable to those of our own outer solar system. Recently Marcy et al. (42) reported the detection of a Jovian analog orbiting the star 55 Cancri.

Now, there are 99 reported extrasolar planets that orbit 86 stars and two pulsars (17). None of these is likely to be a habitable world. If the terrestrial mass planets that orbit the pulsar PSR 1257 + 12 ever were habitable, it is hard to conceive how they could have remained so during the supernova event that turned their host star into a pulsar. If the planets accreted after the event, they now exist in a hostile radiative environment without central warmth. As for the planets discovered orbiting normal stars, they are gas giants, often far more massive than Jupiter, and in surprisingly short-period orbits close to their host stars. These orbits are often very eccentric, and though the planets spend some time within the habitable zone of their stars, they also have extreme excursions from it. There is abundant scientific speculation whether these massive gas giants might have massive moons wrapped in thick atmospheres that might render them habitable. Testing this speculation about moons will be even more difficult than finding potentially habitable planets.

To date, we have found no analogs of our own solar system that have small terrestrial planets in short-period, circular orbits, and gas giants much farther out, in long-period orbits. We think that this is an observational bias. Observational tools currently lack the precision to detect terrestrial planets [except for transits that occur in eclipsing binary systems (18)], and we have not yet accumulated data long enough to detect the giant planets in wide orbits reliably. That will change within the decade. The radial velocity studies responsible for detecting the greatest number of planets have now achieved the 2 m/s precision required to yield an accurate measurement of planetary eccentricity (19). Therefore, it will be possible to detect any Jupiter analogs at orbital distances of ~ 5 AU and also to determine whether they actually travel in circular orbits. These will become the systems of choice for more intensive exploration for habitable planets.

What follows is a laundry list of projects and missions (now being implemented or planned for the future) that have potential for finding terrestrial-sized planets within the habitable zones of their stars. In general, no timelines are given because many of the spacecraft require very significant technological

development programs before they can be enabled. References to specific missions have been omitted, but they can be found (along with updated information on the projects) on two excellent websites in the United States and Europe: <http://exoplanets.org/> and <http://www.obspm.fr/encycl/encycl.html>.

Direct Imaging. Ground-based: nothing. Adaptive optics for the Kecks, Very Large Telescope (VLT), and other large aperture telescopes will permit imaging massive Jupiters, but cannot provide the contrast ratios needed for Earths.

Space-based: High resolution correction on the Next Generation Space Telescope (NGST) should allow detecting Earth-like planets around a nearest dozen stars within decade. The Planet Finder and Darwin will be free-flying nulling interferometers that work in the infrared and are being scaled to find Earth-like planets around the nearest 100 stars within two decades.

Astrometry. Ground-based: nothing. Narrowfield astrometry on the Kecks will yield 10 microarc second precision; good enough for Uranus, but not Earth (at a distance of 5 pc).

Space-based: GAIA should be able to detect 10-Earth-mass planets around the nearest 100 stars, and SIM promises a limit of 2-Earth-mass planets for the nearest 50 stars and 10-Earth-mass planets for another 200 stars. Both will provide finding lists for Terrestrial Planet Finder (TPF) and Darwin.

Radial Velocity. Ground-based: nothing. Both the HIRES and CORALIE spectrometers in time will be able to discover true solar system analogs by finding Jupiter-mass planets in large circular orbits. The other search techniques will then surely focus on trying to find any inner terrestrial planets in those systems.

Space-based: nothing. The fundamental limitation to the precision of this technique is set by the intrinsic fluctuations in the light from the star, so there is little to be gained by observing from above Earth's atmosphere.

Transits. Ground-based: The Transits of Extrasolar Planets (TEP) network of modest telescopes has achieved the precision to find 2-Earth-radii planets around a handful of nearby eclipsing binary stars. For these systems, it is assumed that the planetary orbits will be aligned with the stellar orbital plane, and therefore planetary transits are more probable. A network of dedicated telescopes is being proposed for detecting the gravitational micro lensing events caused by planets like Earth.

Space-based: Kepler will stare at 100,000 distant stars continuously for 4 years. It should achieve a photometric precision of 8×10^{-5} and detect Earth-sized planets in orbital periods of a year or less. It will also detect giant planets in short-period orbits. The mission expects to detect hundreds of terrestrial planets, but follow-up will be difficult because the population of stars is so far away. COROT will also spend one-half of its time in similar observations looking for planets in orbits of less than 0.5 AU.

Figure 1 illustrates the discovery space for extrasolar planets and the different observational techniques mentioned before, using some specific missions as examples.

Searching for Biomarkers. Compared to the other planets in our solar system, what most distinguishes Earth's atmosphere is its extraordinary disequilibrium chemical state. CH_4 coexists with O_2 . In equilibrium, these gases would

Figure 1. Observational Precision for Extrasolar Planet Searching Techniques (courtesy of Kepler website). This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

quickly convert to CO_2 and H_2O . That conversion takes place in our atmosphere as well, but a continuous biological source function replenishes the trace gases; photosynthetic plants produce oxygen, and microbes in the guts of termites and bovine flatulence renew methane. In theory, an extremely sensitive, distant spectrometer working near 7 microns would be able to see the fingerprints of life as it viewed the absorption spectrum imposed upon the reflected sunlight by our atmosphere. This is a tremendous technical challenge. No spacecraft mission now on the books will have the required sensitivity to discover the trace levels of these two gases on any terrestrial planets that circle nearby stars. Our first attempts will be cruder and should also be less specific because life on other planets may more closely resemble early terrestrial methanogens before the invention of photosynthesis. Transits of short-period hot Jupiters offer the first opportunity to study potential biological markers in distant atmospheres. The CRIRES instrument on the VLT should be able to see CO , CH_4 , and H_2O in absorption during a transit, and NGST may be able to find the signature of chlorophyll absorption from 400–700 nm. Biology is not expected on gas giants themselves, but it will be most useful to know that organic materials are available in other planetary systems. When TPF and Darwin fly, they will attempt a spectral assay of any terrestrial planets they find. Predicted spectral sensitivity should be good enough to detect the broad absorption feature of ozone. If reasonable arguments can be made for the presence of liquid water on the planet's surface (so that the silicate–carbonate cycle would be functioning), then there is currently no known abiological process that could produce detectable amounts of ozone. If this all transpires several decades hence, it will be a circuitous way of

saying that evidence for some sort of biology had been found. What kind is another question.

Other Inhabited Planets. Perhaps the easiest way to detect other habitable planets will be by having the inhabitants themselves assist us. The field of SETI (search for extraterrestrial intelligence) does precisely that. SETI searches for various manifestations of another extraterrestrial technology. That technology might be used deliberately to announce the presence of an advanced civilization or for its own internal purposes. For more than a half century, Earth has been unintentionally announcing that we can broadcast radio and television signals. We are a very young technology in a very old galaxy (10 billion years old), so it is plausible to assume that there may be others. We do not know. We may never know. On the other hand, searches of increasing capability are now operating on about a dozen telescopes and could succeed between the time this article is written and published.

Searching for Technology. How can we possibly detect a distant technology? This question has been vigorously debated since the first paper was published by Cocconi and Morrison in 1959 (20), and Drake was preparing to conduct the first search in 1960 (21). A recent compendium (22) lists 99 searches published in the literature during the past four decades. The vast majority are searches for signals, and most of those have been at radio frequencies. It is possible to conceive of searches for physical artifacts, or miniaturized probes within our solar system, for enormous astroengineering projects detectable across interstellar distances, or indirect (remotely sensed) evidence that results from warfare on planetwide or planetary-system scales. It is harder to envision *systematic* search strategies for these types of evidence and harder still to devise experimental search protocols from which a negative result would be significant. These are the primary reasons that researchers have concentrated on looking for signals. Searches for the other types evidence are best left to serendipitous detection by an active observational program of astronomy at all wavelengths. However, this requires a willingness to consider technological explanations for newly detected phenomena that do not easily yield to astrophysical explanations.

Even searching for signals is a daunting task. The search space consists of at least nine dimensions: three space, one time, one frequency, two polarizations, one signal strength, and one modulation scheme. Figure 2 is a decision tree representing the various choices that must be taken to arrive at a particular search strategy. The shaded path represents the selections made by the Cyclops Report (23). Sponsored by NASA in 1971, Cyclops was the first engineering design study of ways to conduct a SETI program. Once the decision to search for electromagnetic signals has been made, it is necessary to select the frequency range; to decide whether to transmit and wait for a reply or to passively listen for signals already enroute; to decide whether to structure the search to look for some sort of leakage radiation or deliberate beacons; to decide whether to seek a signal continuously radiated toward Earth or one that will have some intrinsic duty cycle less than 100%; to decide whether to conduct the search with a single antenna or an array of elements; to decide whether to phase up the array or use the antennas independently; and to decide whether to use the antenna (or array) to study a single beam on the sky or to create multiple, simultaneous beams (in the extreme case, imaging the entire available primary field of view); to decide

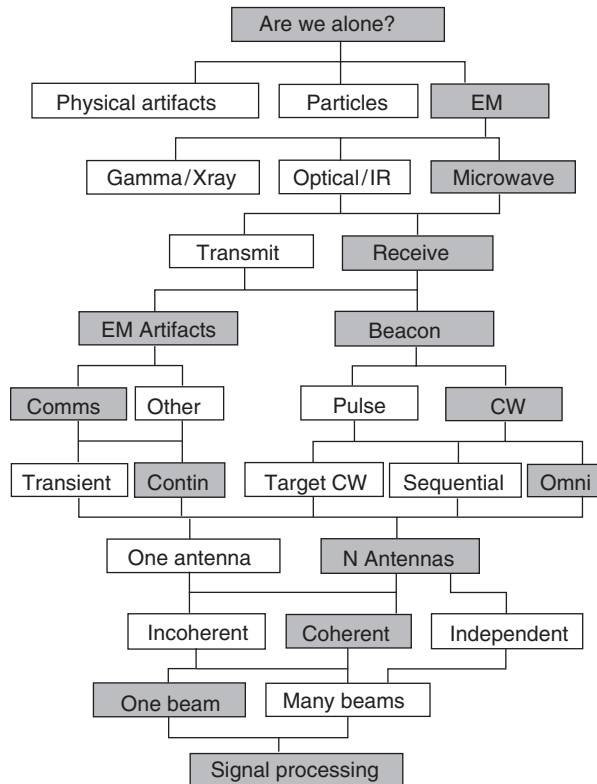

Figure 2. Decision tree for arriving at SETI signal search strategy.

whether to target individual stars or perform a sky survey; and finally, to decide what type of signal processing equipment needs to be acquired or invented to search for putative signals, given the other choices made at each level of the tree.

The signal processing step is the key to distinguishing technological from astrophysical signals. After many years of discussion, the basic criterion has remained unchanged. As far as we know, only technologies can produce a signal whose time-bandwidth product is close to unity ($B\tau \approx 1$), the limit set by the uncertainty principle. Because astrophysical emission processes are the result of very large collections of atoms, ions, or molecules, natural emitters will exceed this lower limit by many orders of magnitude (even in the case of intrinsically coherent processes such as masers). So search strategies and signal processing equipment have been developed to look for narrowband signals (continuous wave or long-duration pulses), and very short duration broadband pulses. Searches for CW and narrowband pulses at radio frequencies require extremely fine spectral resolution (resolving power $\sim 10^9$ – 10^{11}). Propagation through ionized interstellar medium disperses shorter radio pulses, eliminating the $B\tau \approx 1$ signature. At optical wavelengths, dispersion is not an issue, but absorption by interstellar dust becomes a limiting factor for distances beyond a kiloparsec. SETI searches for optical pulses require detectors that have time resolutions from nanoseconds to femtoseconds. Such devices have only recently become very affordable, and as a

result, searches at optical (though not yet infrared) wavelengths are beginning to offset the historical bias for radio wavelengths.

All searches must contend with both astrophysical and human-caused backgrounds. Much of the searching to date has been shaped by background considerations. To hear someone whispering in your ear, you would not choose to stand next to a waterfall but instead would listen in the quietest place in the forest. There are also waterfalls to be avoided in the sky. Figure 3 represents the natural astrophysical background radiation that any technologist within the Milky Way galaxy would encounter. Figure 3 assumes that the receiver is in space, without spectral, spatial, or temporal filtering. To date, almost every search has been done from the ground and each search has applied one or more types of filters. For a ground-based search, the atmospheric noise contributions and absorption from oxygen and water vapor need to be added to Fig. 3 at frequencies higher than 10 GHz.

Because we currently lack the spatial resolution to separate the emission from a transmitter on or near a planet orbiting another star from the stellar emission, any artificial signals must outshine the star to be detectable. At microwave frequencies this is an easy task. A star like our Sun is a weak radio source that produces only 1 kW/Hz. Thus, radio astronomy can be, and is, routinely conducted 24 hours per day, and at certain frequencies, our primitive technology handily outshines the Sun. The narrowband carrier waves embedded within broadcast FM and TV transmissions are factors of 10^6 to 10^9 brighter than the quiet Sun. Because stars like the Sun have a peak output at optical frequencies of $\sim 4 \times 10^{11}$ W/Hz, the power requirements are more severe for a continuous narrowband transmitter at those frequencies. Note that during a long

Figure 3. Background radiation from astrophysical sources.

observation, where integration is possible and the noise can be averaged down, the signal need only be detectable above the stellar fluctuations (rather than the total power). Rather (24) has argued that the transmitter power requirement is manageable for sufficiently narrow optical lines broadcast in the depths of the Fraunhofer absorption bands of the stellar spectrum.

SETI Today

Today, searches for fast optical pulses and CW signals as well as microwave searches for CW and narrowband pulses are all being conducted, using a variety of search strategies. Table 1. lists the currently active SETI searches that have committed to a regular program of observations. The search strategies, frequency coverage, sensitivity, and time on the air vary by many orders of magnitude within this table. Each of these projects maintains an active web site, and the reader is directed there for more details.

It is very difficult to compare the phase space searched by the various strategies represented in Table 1 and their relative effectiveness. Dreher and Cullers (25) attempted to define a figure of merit that will work for all SETI searches. They use the unknown transmitter power (continuous for CW signals and peak for pulses) as an explicit parameter. For each search strategy, they calculate the detection limit for an assumed transmitter power P_T and then they calculate the number of stars N_{stars} (foreground and background) that the search will explore. A logarithmic factor for the range of frequencies covered (from F_{lo} to F_{hi}) facilitates comparing optical and microwave searches on the same scale and yet favors the large frequency coverage of the former. A factor η_{pol} represents how thoroughly the signal polarization space is explored ($\eta_{\text{pol}} = 1$ for dual circular, 0.5 for single circular, and 1 for single linear with a corresponding reduction in the sensitivity by 0.5). The last factor is N_{looks} , the average number of times a star is observed in the course of the search program. A SETI figure of merit can then be given by

$$\text{FoM}(P_T) = N_{\text{stars}}(P_T) \times \ln(F_{\text{hi}}/F_{\text{lo}}) \times \eta_{\text{pol}} \times N_{\text{looks}}. \quad (1)$$

The exact form for the figure of merit is often debated; different emphases are placed on one or more of the terms. Figure 4 has been drawn assuming the preceding definition. It clearly indicates that targeted searches excel in finding faint nearby signals and sky surveys are superior in finding more powerful, distant transmitters. For sufficiently powerful transmitters, all sources become sky surveys seeing every star in the fraction of the galaxy that they cover. For more powerful sources still, these curves could be extended to include the neighboring galaxies and the Virgo supercluster. Whether such extraordinarily powerful transmitters exist is unknown. Figure 4 has been truncated within the Milky Way simply because there are insufficient data about the various search protocols to permit reliable predictions of their actual extragalactic coverage.

The 13 searches in Table 1 and Fig. 4 represent a higher level of global activity in SETI than at any time in the past four decades. This is surprising because all of the funding for these activities is now raised from private

COMMENTS:	Dedicated telescopes built for SETI. Uses high time resoution photodiodes in coincidence to search for laser pulses, soon to use two telescopes in coincidence and to be teamed with microwave search of same objects.

Figure 4. Exploration of the Milky Way Galaxy with current SETI programs. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

(nongovernmental) sources. From the mid-1970s to 1 October, 1993, NASA managed a SETI program named (finally) the High Resolution Microwave Survey (HRMS). This project consisted of two complementary search strategies: a targeted search from 1–3 GHz that examined 1000 nearby solar-type stars using large radio telescopes that belonged to the global scientific community and an all sky survey from 1–10 GHz enabled by the multiple 34-m antennas of the NASA Deep Space Network. Although there was some SETI activity in other countries, the NASA project and the United States were the primary players. Since Congressional termination of the HRMS, the level of private funds raised from philanthropic sources has (of necessity) grown dramatically. The largest project is the SETI Institute's Project Phoenix that uses modified equipment derived from NASA's HRMS to continue the targeted search. Jointly, the Planetary Society and the SETI Institute funded expansion of the SERENDIP project to survey one-third of the sky using the Arecibo Observatory across a reduced frequency range (compared to HRMS). Australia and Italy have now created privately funded support organizations to move SETI forward in those countries and have active search projects running commensally on large radio astronomy facilities and dedicated optical telescopes. By far, the most impressive indication of global interest in SETI is the success of the SETI@home experiment in distributed computing. More than 3.8 million people in more than 226 countries have downloaded this screen saver to assist in SETI data processing. The SETI League Project Argus hopes to establish a global organization of 5000 amateurs using small antennas to cover the sky at all times, looking for powerful transient sources. To date, 105 stations are operating in 19 countries.

SETI Tomorrow

Against this backdrop of global interest and reliance on philanthropic funding, the SETI Institute convened a series of workshops (from 1997–1999) to develop a road map for the next two decades, trying to predict what would be technologically feasible and affordable. The SETI 2020 Report (26) from those workshops recommends three projects:

1. An large array of small antennas that have 10^4 square meters of collecting area, that cover a factor of 20 in microwave frequencies, and can conduct SETI and traditional radio astronomy simultaneously by multibeaming and imaging. They called this the One Hectare Telescope or 1hT.
2. Initiating optical SETI searches for nanosecond pulses, using two high-time-resolution photodiodes in coincidence to reduce the false alarm rate from photons generated in the optics and detectors. It was envisioned that the first searches would take place on modest telescopes in the university community, to move down in frequency into the IR when detectors became available (to avoid extinction due to interstellar dust), and to migrate onto larger collecting areas as the field matured.
3. An omnidirectional SETI system (OSS) for the lower portion of the microwave window, following the early ideas for a radio camera first suggested for SETI by Dixon (27). The OSS is intended to enable searches for strong but transient signals (such as might be expected from a phased array beacon sequentially illuminating a large list of targets) or emission from sporadic astrophysical sources. The computational requirements for this equivalent of a radio-fly's eye are extreme because it must form all possible beams on the sky from horizon to horizon and provide high spectral resolution to search for signals. For an array of 4096 dipole elements, an estimated 10^{16} operations per second would be required. Although not available today at any price, this real-time computing capacity should be affordable in approximately 15 years. The workshop recommended a plan starting with an array of 4×4 elements and 4 MHz of bandwidth, growing exponentially as Moore's law improvements permit.

As the entries in Table 1 attest, optical SETI (OSETI) was enthusiastically embraced. Programs were operating on telescopes at UC Berkeley and Harvard, using target lists of several thousand stars, before the workshops concluded. Since then, OSETI projects have been started at Princeton (to work in coincidence with Harvard), at Lick Observatory, and at a newly constructed facility in Australia. Ground has been broken for an innovative optical sky survey telescope at Harvard that can survey the 80% of the sky visible from that site in about 150 clear nights. This survey will eventually cover the million stars within 1000 light-years and the space between, looking for strong signals. Initial discussions have begun to find ways that OSETI experiments can be piggybacked onto new Cherenkov detection arrays that consist of large light buckets and focal plane arrays of photodiodes (or other suitable experiments) to increase OSETI sensitivity in the most cost-effective way. OSETI detectors on 1-m-class telescopes

today could detect a nanosecond petawatt-pulse (1 megajoule) focused by a 10-m telescope from a distance of 200 light-years.

The concept of the 1hT has also been adopted. In partnership with the Radio Astronomy Laboratory at UC Berkeley, the SETI Institute is conducting the technology development for an array to be built in northern California at the Hat Creek Observatory. The Paul G. Allen Foundation has provided the development funding for what is now called the Allen Telescope Array (ATA), and Nathan Myhrvold has funded the electronics laboratory for the facility. The array consists of 350 offset-Gregorian antennas, each 6 m in diameter, with a 2.4-m subreflector, that are manufactured by the same hydroforming process used to mass-produce TVRO antennas. Construction should begin in 2003, following two preliminary prototyping stages necessary to validate the performance of the emerging consumer technologies now being adapted to provide unprecedented wideband performance and low cost. The array should commence operation in 2005 using three independent, synthesized beams on the sky, 100 MHz of processing bandwidth at frequencies tunable from 0.5–11 GHz, and an imaging processor of comparable bandwidth for the large field of view of the ATA (28). If funding can be found, the ATA will begin to expand antennas, beams, and bandwidth immediately. In so doing, the ATA will increase its sensitivity and serve as a proof-of-concept for the construction of an array that has 100 times the ATA initial collecting area—the Square Kilometer Array (SKA). This international project has as its goal 100 steerable beams on the sky, a frequency range from 150 MHz to 20 GHz, nanoJansky-level sensitivity, and a million-to-one imaging dynamic range. At present, five different concepts are being studied for the SKA in 10 different countries (29). To achieve the ambitious straw-man science requirements, a hybrid approach based on two or more of the current concepts will probably be required. However it is constructed, the SKA will improve the current sensitivity of microwave SETI searches [that can now detect strong terrestrial radars (10^{12} watts EIRP) at 150 light-years] by two orders of magnitude and open the door for searches of weaker “leakage” radiation from the vicinity of the nearest stars.

SETI 2020 made it clear that it would be more than a decade before the OSS becomes affordable. Nevertheless, a small-scale prototype array for the OSS is currently being developed at Ohio State University in collaboration with the SETI Institute. The Argus telescope, as it is called, will permit development of beam-forming, signal processing, and radio frequency interference excision algorithms, even though its sensitivity will remain low until the number of array elements (and thus the real-time computational loads) can be increased significantly.

All of these new searches have to contend with artificially high false alarm rates. At optical wavelengths, high-energy particles and coronal discharges in the detectors themselves are the problem, requiring coincidence detection schemes. Even using two photodiodes in coincidence, the spurious detection rate has remained unacceptably high (~ 1 per night); additional efforts are required. At Lick Observatory, three photodiodes have recently been used in coincidence to beat down the false alarm rate to nearly zero. The groups at Harvard and Princeton have collaborated to operate those two telescopes (each with two photodiodes) in coincidence, using GPS to synchronize the systems to 20 microseconds across the 1.6-millisecond path difference between the sites (30). To date, there are no

human-produced flashes of nanosecond light on the sky, but this could change in the future and would place high-time-resolution optical astronomy and SETI in the same situation that now disrupts microwave searches.

At microwave frequencies, the spurious detections result from our own use of the spectrum for all manner of communications. Even though microwave transmitters may be operating within their allocated frequency bands, from the view point of a comprehensive microwave SETI search, such signals represent undesirable radio-frequency interference (RFI). This is a worsening problem for all of the passive services as the number of satellite constellations increases. In addition, profit incentives often result in inadequate filtering and thus enhanced out-of-band and spurious emissions throughout the spectrum. Geographical isolation is no longer adequate to avoid RFI. The Phoenix project routinely conducts its targeted search in real time using two widely separated antennas (currently the 1000-foot Arecibo Observatory in Puerto Rico and the 250-foot Lovell telescope in the U.K.). Demanding detection of a narrowband signal at both sites with the correct differential Doppler signatures (31) significantly decreases the occurrence of false positives by discriminating against signals local to one site, as well as overflying or orbital platforms whose footprint encompasses both sites. The ATA will elaborate on this basic scheme by using the natural decorrelation of the signals across the extended array, by actively steering null beams of the array pattern to follow individual satellites, and by using one or more of the individual dishes within the array to observe the interfering transmitter with sufficient interference-to-noise ratio to permit accurate subtraction from the output of the array.

Before the SKA can be successfully implemented, serious consideration must be given to establishing an international radio quiet zone (IRQZ) that encompasses at least its central concentration of elements. No such zones exist today, nor is there any precedent for establishing such a zone internationally. Nevertheless, if the SKA can be sited in an area of sufficiently low population density (where the potential market is small), it may be possible to negotiate agreements with service providers so that they modify or turn off their transmitter beams when overhead. If this fails, some frequencies will be permanently unavailable to SETI and radio astronomy for some, or all, of the time. The only alternative would then be to construct observatories within the "Shielded Zone of the Moon" defined by the international ITU treaty in 1979 (32). Compared to the costs of doing business on the lunar farside, extensive investment in active strategies for RFI mitigation, alternate service delivery systems for affected populations, and even negotiations for provider compensation are likely to be cheaper.

What If the Searches Succeed?

The detection of microbial life beyond Earth would be spectacular. If it represents an independent origin and evolution, then it will revolutionize biology in all of its forms. We will begin to distinguish the necessary properties of life from the merely contingent. If we discover intelligent life elsewhere, it may be possible to shortcut the period of our technological infancy and understand our Universe and our place therein more rapidly than we would have done in isolation. In either case, positive results carry with them significant challenges.

Sample Return and Planetary Protection. On 15 January 2006, a capsule from the Stardust mission will parachute down over Utah returning samples of dust from the coma of Comet Wild 2. This is the first time since the Apollo Moon landings that extraterrestrial material samples will have been returned to Earth by spacecraft. However, because a billion dust particles from comets and asteroids fall to Earth every second, it is hardly the first time cometary dust has arrived here. The sample will contain about 1000 intact particles that were slowed, captured, and spike-heated in aerogel, and millions more fragments totaling only a few micrograms in mass. Although science fiction has considered the possibility of life within a liquid water reservoir deep inside a comet, the Planetary Protection Task Group of the National Research Council has concluded that there is no possibility that life forms will be returned in the Stardust cometary dust samples (33) and no hazard protection is required. The same cannot be said for a sample return from Mars, likely to occur in the second decade of the twenty-first century. In that case, the Task Group on Issues in Sample Return (34) recommended treating the returned samples as potentially hazardous, until proven otherwise, and curating them in a special sample-receiving facility. Given the desire to avoid both false positives and any alteration of the Martian environment, the Task Group also considered the problems of forward contamination from Earth to Mars and the levels of sterilization required for any spacecraft. These latter concerns will also be relevant to any future mission to sample probable liquid oceans beneath the ice crusts of Jupiter's large moons Europa, Callisto, and Ganymede. NASA's Planetary Protection Officer coordinates with the Planetary Protection Panel of COSPAR to internationalize standards and mission plans. Certainly, the global resources of the scientific community will be required to tease out the subtle distinctions between life versus nonlife and life-as-we-know-it versus exobiological life from the micrograms or nanograms of any future sample returns.

Our First Trip to the Stars. Interstellar travel is not possible now, and it is likely to remain uneconomic except for miniaturized robotic probes for the foreseeable future. Advanced propulsion systems are being actively studied by NASA at JPL (35) and MSFC (36) and at comparable facilities within ESA. For near-term interstellar precursor missions, solar sails and high-powered electric propulsion are being developed. Direct detection of terrestrial planets around stars within tens of light-years from Earth by TPF or Darwin and particularly, the remote sensing of biomarkers in the planetary atmospheres will enhance our resolve to reach the stars. We will want to send our surrogates there to view the beachfront property and look for other signs of life, as the Galileo spacecraft observed Earth during its 1990 and 1992 flybys (37). Whether this will be enough of an incentive to overcome the financial hurdles inherent in developing the new propulsions systems and information technologies necessary for such missions remains to be seen.

Who Will Speak for Earth? What Will They Say?

Any technological civilization that we detect will be more advanced than we are—they could not be less advanced—or they would not possess any technology that could be recognized over interstellar distances. Because we are a

hundred-year-old technology in a ten-billion-year-old galaxy, the odds that they are at a comparable technological level are tiny. The Drake equation (38) (with all of its uncertainty) tells us that technological civilizations will not be close to us in both space and age. If they are nearby, they will be old, if they are very distant, they could be as young as we are. In the former case (they are nearby and old), our first encounter with them is unlikely to be their first contact. They will have done this all before. We can expect a deliberate signal whose message content is intended to be anti cryptographic; in time we might even understand it. This scenario (so popular in science fiction) has the potential for causing the greatest impact on human society in the shortest time. But whether the signal is decodable, unintelligible, or content-free (unmodulated CW), the mere act of detection creates a way to reply. Whereas the search leading to the detection had to cover significant volumes of phase space for success to occur, anyone knowing the characteristics of the signal (and this will be everyone, because public disclosure is the policy of all SETI programs today) can send an answer, just by transponding back the original signal. Though this requires access to a transmitter and antenna, it is far easier than the original search. Anyone can do it, but should anyone? The SETI Committee of the International Academy of Astronautics worked with the International Institute of Space Law to draft a "Declaration of Principles Concerning Activities Following the Detection of Evidence of Extraterrestrial Intelligence" (39) and more recently, the IAA Position Paper "A Decision Process for Examining the Possibility of Sending Communications to Extraterrestrial Civilizations" (40). The first document, signed by most groups that conduct SETI programs, states that no reply to a detected signal should be sent until a global consensus is achieved, and the second document suggests that the U.N. Committee on the Peaceful Uses of Outer Space may wish to consider (in advance of an actual detection) just how such a consensus might be reached. There are no means of enforcement. The purpose of these documents is simply to highlight the possibility that improving technologies for searching might yield a detection at any moment. The authors suggest that it would be wise to consider any possible reply from Earth while there is no time pressure. These ideas were provided as information to the UN COPOUS in June 2000. Given the press of other immediate items facing that body, substantive deliberations of these issues are not likely to take place any time soon. Should a signal from (or other evidence of) an extraterrestrial technology be discovered in the near future, we can expect that a cacophony of national, or even individual, replies will be broadcast, speaking many ideas in many languages. This is likely to be a far more accurate picture of early twenty-first century Earth, our lack of global governance, and human diversity than are the carefully selected sights and sounds of Earth carried by the Voyager 1 and 2 records (41).

FIRST FLIGHT OF MAN IN SPACE

The twentieth century was one of rampant technological development, of unprecedented flourishing of science, a century in which grandiose, fantastic ideas became reality, and when the dreams of many generations of people who lived and now live on Earth came true.

There were a great many ideas, discoveries, projects, and accomplishments in the century just past. But among all the numerous outstanding human achievements in the twentieth century that captured the contemporary imagination, the most thrilling were the launch of the first artificial satellite and, especially, the flight of the planet's first cosmonaut, Yuriy Alekseyevich Gagarin on the Vostok spacecraft.

The launch of the first artificial satellite into orbit around Earth took place on 4 October 1957 at 22:28 Moscow time marking the start of the Space Era in human history. Yuriy Gagarin's spaceflight, launched on 12 April 1961 at 09:07 Moscow time, lasted for 108 minutes, during which the spacecraft carrying the first cosmonaut completed a full orbit around Earth and then landed safely in the scheduled recovery area. This flight marked the start of the Era of Human Presence in Space.

These two events are directly linked; without the first, the second could never have occurred. The first became a momentous milestone in the history of technological progress; the second was the embodiment of a centuries-old dream of humankind, one dreamt both by ordinary people gazing at the starry sky and by the world's great science fiction writers, seers, and creators.

The Prehistory of the First Artificial Earth Satellite Vehicles and Orbital spacecraft

Manned spaceflight is part of the regular process of development in history and reflects the eternal human desire to learn the secrets of nature and to discover

new living environments. The idea of flying to the Moon and the stars arose many centuries ago, when people still did not know either the structure of the solar system; or that Earth is round, rotates on its axis, and revolves around the Sun; or that Moon is its satellite. Indeed they knew very little about the continents of Earth itself. This did not prevent them, though, from creating legends and tales about flights into the sky in which they proposed the most unlikely vehicles for such voyages. In these legends and tales, heroes flew on swans, eagles, flying carpets, winged horses, balloons, and other exotic vehicles. In more recent times, in association with the development of technology, somewhat more scientifically justified projects began to be proposed, for example, giant cannons. The famous science fiction writer Jules Verne sent his hero to the Moon in a missile shot from a cannon that had a barrel approximately 300 meters long. His book is even titled in Russian *To the Moon by Cannon*. As science and technology developed, science fiction writers kept proposing new types of interplanetary craft and materials from which they could be manufactured.

However, the actual means that later made spaceflights possible was only discovered in the nineteenth century. This was the use of rocket engines to propel a spacecraft. Rockets had been used even earlier, for many years before this, mainly for military purposes. As early as the Middle Ages, inventors had begun to propose various ways to use rockets for propelling loads (missiles) across long distances. Rockets were used in war in sieges and taking of forts. The military aspect of rocket use predominated in the majority of inventions associated with them.

In the nineteenth century, the building of rockets had already developed extensively. Rockets were invented that used powder as well as those with liquid-fuel engines. However, the use of rockets for military purposes was still less effective and extensive than the use of artillery tube systems. Nevertheless, enthusiasts, believing in the future of rockets, continued working to improve them.

The scientific principles underlying the use of rockets for spaceflight were developed in Russia through the work of an outstanding self-taught scientist, a schoolteacher from the provincial city of Kaluga, K.E. Tsiolkovskiy. In 1883, Tsiolkovskiy, in his manuscript *Free Space*, advanced the idea that it would be possible to use the principle of reaction propulsion for spaceflight and provided a sketch of a spacecraft that would take humans into space. In 1895, in another of his works, *Dreams of the Earth and the Sky and the Effects of Universal Gravitation*, he gave a rationale for the belief that it was possible to attain the velocity necessary to break away from Earth and demonstrated that it was theoretically possible to build an orbital spacecraft. In 1897, Tsiolkovskiy derived the basic equation for rocket velocity, which is widely known as "Tsiolkovskiy's formula."

Tsiolkovskiy's fundamental scientific work, *Space Exploration Using Reaction Propelled Vehicles*, was published in two parts in 1903 and 1912. In this work, he established the laws of motion for rockets as bodies of variable mass, defined the efficiency coefficient for a rocket, investigated the effects of air resistance on its motion, noted the advantages of rocket engines at high speeds, and provided a sketch of an interplanetary rocket, for which he pointed out the advantages of a liquid propellant. Considering the rocket as the only practical and acceptable means of spaceflight, Tsiolkovskiy did a great deal to define the rational path along which cosmonautics and rocket building had to develop. He published hundreds of scientific works on these problems. It was he who spoke

the prophetic words, "Human beings will not remain on Earth forever; in the pursuit of light and space, they will first timidly penetrate beyond the bounds of the atmosphere and then conquer the space within the solar system." Tsiolkovskiy's ideas were developed very intensively by his students and followers in the 1920s and 1930s. Work on rocket technology was also taking place in other countries. The most significant such work is associated with the names of Robert Goddard (U.S.A.), H. Oberth (Germany), and R. Esnault-Peterie (France). By this time, in the Soviet Union, the efforts of individual rocket building enthusiasts had been combined in the Group for the Study of Reaction Propulsion (GIRD). A special laboratory was also founded and subsequently named the Gas-Dynamics Laboratory (GDL). These organizations played a prominent role in developing various types of rockets, including launch rockets using smokeless powder and liquid rocket engines for aircraft and torpedoes.

In 1933, the Government decided to found the Reaction Propulsion Scientific Research Institute (RNII) to centralize the efforts of the country's rocket builders. The efforts of this institute were responsible for the development of many types of rockets, and liquid-fueled rocket engines for missiles and aircraft. Modified models and new types of rocket that they developed were subsequently used extensively as weapons at the fronts of the Great Patriotic War of 1941–1945 (World War II). Among these, the legendary Katyusha, whose crushing salvos sowed panic and destroyed enemy troops and weapons, was especially popular in the army.

Germany was highly successful in developing and using rocket technology for military purposes during World War II. These successes are associated with the name of Werner von Braun—the Project Director for building the V-1 and V-2 rockets, which were used to bomb London. After the defeat of Germany, technical documentation on these rockets, a few examples of the rockets themselves, and some components found their way to the United States and the Soviet Union. These were used by both countries in the postwar period to build improved military rockets. And von Braun himself went to America and directed work on rocket technology.

As a result of worsening international tensions and the threat that atomic weapons would be used, the Soviet Union resolved to build a powerful intercontinental ballistic missile capable of carrying a warhead many thousands of kilometers. In a short time, this task had been accomplished: on 27 August 1957, the Soviet Union successfully fired one of these rockets. During this period, work on creating multistage intercontinental ballistic missiles was directed by Academician S.P. Korolev, who had been working in the area of rockets since the end of the 1920s. Successful testing of these military rockets showed that spaceflight and the launch of orbital satellites was technically possible.

The First Artificial Earth Satellites—Practical Preparation for Manned Space Flight

On 5 January 1957, Korolev sent to the Government "Proposals for the First Artificial Satellites of the Earth Before the Start of the International Geophysical Year." These proposals were examined and the USSR Government tasked

scientists, leaders of industry, and the military to implement preparations for launching the first artificial satellite of Earth, in full accordance with the program of scientific research for the International Geophysical Year. Preparations for the conquest of space required setting up special scientific institutes and laboratories, industrial enterprises, a cosmodrome, and a network of ground-based tracking stations in the country and training highly qualified work forces. All this had to be done despite the lack of any previous experience anywhere in the world. Nevertheless, the work was completed on an accelerated schedule.

On 4 October 1957, the Soviet Union launched the first artificial satellite in the world into orbit around Earth. The date of that launch entered history as the start of the Space Era.

The first Soviet satellite was a sphere 0.58 meters in diameter and a mass of 83.6 kg. The satellite's two radio transmitters would make available new data about the atmosphere. The successful functioning of the first satellite confirmed the correctness of the theoretical calculations and design solutions underlying construction of the launch vehicle, the satellite itself, and all onboard systems.

After the first launch, other, heavier satellites carrying improved onboard equipment were put into orbit. Meanwhile, the ground-based components of the space infrastructure were undergoing parallel development. The research program implemented in the second satellite included unique experiments with the dog Layka—the first space voyager belonging to a higher animal species. Flights of dogs continued subsequently and made it possible to study the status of a living creature under conditions of weightlessness. A foundation was being laid for the decisive conquest of space through manned spaceflights.

The first U.S. artificial satellite, Explorer 1, was launched into orbit on 1 February 1958. The United States thus became the world's second space power.

In May 1959, the USSR Government adopted two resolutions, "On preparing Humans for Space Flight." Based on these resolutions, the Government conducted a series of experiments involving flights of satellites carrying dogs and human dummies. At the same time, a spacecraft in which a human could be sent into space was being developed. Spacecraft of this type were named Vostok; until the first manned flight, they were launched into space unmanned. Experiments with dogs were not conducted on them.

Orbital spacecraft were launched on

- 15 May 1960—with no living things on board;
- 19 August 1960—with the dogs, Belka and Strelka, on board (recovered safely);
- 1 December 1960—with the dogs Pchelka and Mushka (caught fire on re-entry, the dogs died);
- 22 December 1960—with the dogs, Zhemchuzhina and Zhulka (the capsule failed to go into orbit; the descent module was recovered after 2 days; the dogs survived);
- 9 March 1961—with the dog, Chernuskha, and a human dummy (recovered safely);
- 25 March 1961—with the dog, Zvezdochka, and a human dummy on board (recovered safely).

The missions of these launches were to refine development of the spacecraft design and systems, to conduct biomedical experiments with dogs and other biological subjects, to return the descent modules to Earth, and to implement ejection and parachute landing of a dummy simulating a suited cosmonaut. The generally successful accomplishment of this flight program confirmed spacecraft and onboard system reliability. The prerequisites for manned space flight had been attained in practice.

Preparing the First Cosmonauts for Flight

To prepare humans for the first and subsequent space flights, a team of 20 candidates for flight was selected. Fighter pilots, submariners, rocket builders, automobile racers, and many other young and healthy people dreamed of becoming cosmonaut candidates. The flight surgeons who had been assigned the task of selecting the first spaceflight candidates were well aware that, of members of all of the professions, fighter pilots were most suited to endure the effects of extreme environmental factors. During their training and actual flights, they experienced the effects of hypoxia, increased pressure, G-forces in different directions, ejection, and other factors. During the first phase of selection, it was considered expedient to select the young cosmonaut candidates from among fighter pilots. This idea was fully supported by Chief Spacecraft Designer, S.P. Korolev, who said, "For this enterprise, it would be best to use trained pilots, especially, jet fighter pilots. A fighter pilot is just the generalist that is needed. He flies in the stratosphere in a one-man high-speed aircraft. He is a pilot and navigator and radioman and flight engineer rolled into one...."

Candidate selection began in Air Force units in October 1959. During the initial selection process, documents for 3461 fighter pilots, aged up to 35 years, were examined. A total of 347 men was selected for the initial interview. Based on the results of the interviews and outpatient medical examinations, 206 pilots were selected to undergo further medical selection. These candidates underwent inpatient examination in the Military Clinical Aviation Hospital between October 1959 and March 1960. Of the 206 men, 72 dropped out of their own volition in the course of the examination process. An additional 105 failed to meet medical requirements. Of the 29 pilots who passed all phases of medical examination and met all medical requirements, 20 were finally selected as cosmonaut candidates.

In late 1959, a government decision was made to create within the Air Force a special Center to train candidates for manned space flight. This was done concurrently with selection of cosmonaut candidates. In March 1960, the Cosmonaut Training Center was established. At first, the Center was located in Moscow in the Central Aerodrome. Then, a site outside Moscow was selected. In the summer of 1960, the Cosmonaut Training Center began to operate in Zvezdnyy Gorodok, which had been specially constructed for this purpose.

In early March 1960, the first group of spaceflight candidates, which was still not up to full strength, came to the Center, and on 14 March, the first class in general space training was held for this group. This group was brought up to full strength of 20 by mid-July 1960. Later this first cosmonaut team was named the

Gagarin team. The names of the members of the Gagarin team were I.N. An-ikayev, P.I. Belyayev, V.V. Bondarenko, V.F. Bykovskiy, V.I. Filatyev, Yu.A. Gagarin, V.V. Gorbato, A.Ya. Kartashov, Ye.V. Khrunov, V.M. Komarov, A.A. Leonov, G.G. Nelyubov, A.G. Nikolayev, P.R. Popovich, M.Z. Rafikov, G.S. Shonin, G.S. Titov, V.S. Varlamov, B.V. Volynov, and D.A. Zaikin.

In August 1960, the "Regulation on USSR Cosmonauts" was adopted. This document defined the following Center staff positions: "cosmonaut cadet," "cosmonaut," "cosmonaut instructor," and "senior cosmonaut instructor." The phases of cosmonaut training for spaceflight were defined, as was the list of organizations tasked with conducting this training. Issues concerning the material and social welfare of cosmonauts and their families were also resolved.

A total of only 1 year was allocated to train the first cosmonaut candidates (at that time called cosmonaut cadets) for flight. However, the flight training program was extremely extensive. Training of the first cosmonaut candidates consisted of theoretical classes, training on various simulators, and fieldwork in the design bureau where spacecraft were being built. At the direction of Korolev, classes on rocket technology and celestial mechanics were taught by the most experienced staff members of the design bureau. From their very first days in the program, the cosmonaut candidates were given to understand that classes in these disciplines must form the basis for their future profession.

It was also understood that throughout the entire training period, the future cosmonauts had to be subject to strict and constant medical monitoring, without which it would have been impossible to readjust the demands that were being put on them during training in a timely fashion. The demands on the cosmonauts' health had to be commensurate with the goals and tasks of the future flight.

The instructional and training program for future cosmonauts involved simulating spaceflight factors and conditions. The most complex phases of the flight program used special ground-based facilities, simulators, training devices, mock-ups, and flights on mass-produced or specially modified aircraft. Korolev, who had been a glider pilot, was a vehement advocate of flight and parachute training. He believed that this type of training would polish and refine the cosmonauts' professional skills and would also give them a large infusion of will-power.

In addition to these other factors, the great significance attached to flight and parachute training stemmed from the fact that, on flights on the earliest spacecraft, a cosmonaut had to eject from the spacecraft cabin along with his seat and then, after he had separated from it, descend by parachute.

As a result of this, people from a wide variety of professions went to work to set up and conduct a unified training process for the "special contingent," as the future cosmonauts were then called. The word "cosmonaut" itself was kept secret until the first flight, and it was recommended that it not be used in conversation.

The training program for the first cosmonauts was developed on the basis of their primary mission—to define the limits of human potential to live and work in weightlessness. Gaps in knowledge at that time included the following: Could the cosmonaut "float" in the spacecraft cabin, or did he have to remain strapped to his seat throughout? Wouldn't there be severe psychological disruptions in

space that prevented the cosmonaut from acting responsibly and consciously? There were many other similar questions. For this reason, biomedical training of the student cosmonauts was one of the main types of flight preparation. It was conducted, using specially designed simulators, by leading experts in medicine and psychology, who had a great deal of experience in practical work with pilots on flight qualification and therapeutic and prophylactic problems.

S.P. Korolev considered that the major problem involved in preparing humans for the first spaceflight was ensuring their safety. Safety was considered everyone's responsibility—those who developed space technology, as well as cosmonaut training specialists. They were all focused on solving the following problems:

- ensuring that the cosmonauts were provided with the fullest possible preliminary familiarity (under laboratory conditions and during aircraft flights) with predicted spaceflight conditions, which were reproduced on the training simulators one by one or in combination;
- phased refinement of the flight mission, particularly with regard to using the spacecraft systems;
- development of the cosmonauts' confidence in their own strengths and knowledge and in their readiness to undergo the most severe ordeals.

Here, it would be worthwhile to describe the following very significant phase that occurred during training of the first cosmonauts. When spaceflights with dogs took place as part of the single-orbit flight program, the cosmonauts flew to the launch pad at the Baikonur cosmodrome. After launch, they traveled by aircraft to the reentry module landing site to familiarize them with results of the flight and landing. This was done to teach them about and provide them with direct observation of launch operations, as well as to dispel the excess stress that might be experienced before their upcoming flights.

An important aspect of the training program involved testing the cosmonauts under exposure to prolonged solitude in a "limited space" under various daily work–rest schedules. Initially, the duration of these tests was limited to 15 days. Such tests made it possible to study the individual's psychological reserves.

The professional training provided to the pilots of the earliest spacecraft used a single training simulator. During training on it, the cosmonauts developed the components of the skills and knowledge required to control the onboard systems of the spacecraft. The trainer used a primitive visual simulation system that reproduced the spaceflight environment and incompletely simulated the dynamic operations of spacecraft control. More complex training simulators were only designed and used in preparation for subsequent flights.

To compensate for the inadequacy of the training simulators and other equipment, the facilities of the industrial plants where space technology was developed and tested were used for practical cosmonaut training. The future cosmonauts were frequent visitors to the plants, to the assembly and test building, and to the development stands and facilities. They made themselves at home in a spacecraft cabin mounted on an assembly stand. Lessons at the facilities using actual technology were conducted by the most experienced developers,

designers, and testers of spacecraft and their onboard systems. Frequently, Korolev himself conducted the lessons. He taught the cosmonauts about the design features and possibilities of the first spacecraft and also about the advanced and improved spacecraft of the future.

This combination of all feasible types of cosmonaut training and the means and methods used to provide it ensured that the cosmonauts were trained to a rather high level in the very short period of time allotted (approximately 1 year). This in itself was a unique undertaking, considering that there was no backlog of experience with such matters.

The most important goal in training cosmonauts is to ensure that each one forms an image of the upcoming flight, called by psychologists a conceptual model. During the flight itself, including occurrences of unforeseen or contingency situations, this image functions as a standard of performance and behavior. And, as the cosmonauts reported later, after they had actually flown, the real flight conformed fully to the expectations that they had developed in the course of flight training.

The Manned Spacecraft Vostok

When the concept of the first human spaceflight was being considered, it was proposed that the program should start, not with orbital flight, but with flying a cosmonaut to a great height and returning him ballistically to Earth. This type of flight would have been technically easier, but it would have represented only a timid, momentary type of space exploration. After all, the weightless state lasts only a few minutes during ballistic flight, whereas a single pass in near Earth orbit involves an hour and a half of weightlessness.

Thus, the objective that was set entailed developing a manned satellite capable of functioning in near Earth orbit for several days and then of returning to Earth. All necessary conditions to support normal human vital activity would have to be provided on board this satellite.

This task was daring and difficult. A booster rocket, the satellite itself, and the life support and reentry systems, all possessing extremely high reliability characteristics, were required for the manned flight. Many of these challenges were being confronted for the first time in history. The problem of returning the cosmonaut from orbit to Earth was particularly difficult. The robotic spacecraft of that time were not capable of returning to Earth; yet this was the main prerequisite for a manned craft. Furthermore, not only did a safe landing need to be ensured, but the landing had to occur in a predetermined area. Special safety measures also had to be provided in cases of booster rocket malfunction at launch or during insertion into orbit.

A spacecraft flying at a velocity of 8 km/s (29 thousand km/h) has to be decelerated and landed safely on Earth—at the time, this objective seemed almost fantastic. At that time, aviation was still in the process of mastering supersonic velocities. And here people were talking about 25 times the speed of sound!

When a spacecraft enters the dense layers of the atmosphere at such speeds, a powerful impact wave develops in front of it, and the air in this wave is

transformed into red-hot plasma at a temperature of 6,000–10,000°C. This is higher than the temperature on the Sun's surface. What needed to be done to allow the spacecraft to remain intact throughout this process and to protect the cosmonauts from the heat?

It was proposed to solve this problem by using a design analogous to a walnut. The metal body would be concealed in a "husk," which would burn and evaporate in the course of the descent and prevent the spacecraft itself from getting too hot. A special material was developed for this "husk," but it proved to be relatively heavy. This gave rise to a new problem—how to minimize the total weight of the heat shield. How this problem was solved depended on what method was going to be used to return the spacecraft to Earth. After considering several possible versions, the one selected involved ballistic deceleration followed by parachute-aided descent during the last phase of landing. Calculations showed that this method was simple and technologically feasible.

However, if the entire spacecraft was to descend using this system, the mass of the heat shield it required and the dimensions of the parachute system would exceed reasonable limits. Thus the idea arose of subdividing the spacecraft into the reentry module, which would house the cosmonauts, and the instrument and equipment module, which would contain the retrorocket and propellant tanks, the control system and other technical auxiliary systems needed for orbital functioning. In this spacecraft design, only the reentry module would need heat shielding.

Of all the reentry module shapes considered, the sphere proved the most preferred. It has the minimal surface area for a given volume and thus required the minimum heat shielding mass. It was easy to provide a sphere with stability during reentry by weighting its frontal section. Landing precision was acceptable—plus or minus 300 km. However, the descent of this type of module could only be ballistic.

But could a cosmonaut endure the high deceleration that would inevitably occur during ballistic descent? Calculations showed that at a small atmospheric entry angle of 2–3°, deceleration would not exceed 9–10 G and would continue for only about a minute. According to data from aviation medicine, healthy individuals would be fully capable of enduring such a G-force.

In less than a year and a half, the Soviets succeeded in building and testing a spacecraft system based on a new principle, the most complex that had ever been created at that time. Before the launch of the spacecraft in manned mode, only five test-flights were conducted. But, in essence, all that Soviet cosmonautics had achieved before that time was part of the preparation for this flight. Each test-flight was meticulously analyzed, so that no ambiguities remained. Cosmonaut safety measures were thought out in great detail.

The spacecraft for the first manned spaceflight had been created. From the outside, it looked rather simple: a spherical craft—the cosmonaut cabin—and an instrument and equipment module that was docked with it. The two modules were held together with four metal straps, attached on the "crown" of the reentry module by a pyrotechnic bolt. Before entry into the atmosphere, the bolt exploded, the metal bands were ripped away, and the reentry module continued its movement toward Earth separately from the instrument and equipment module (Fig. 1).

Figure 1. The “Vostok” space vehicle.

The total mass of the spacecraft was 4.73 metric tons; the instrument-equipment module accounted for 2.33 tons of the total. The diameter of the reentry module was 2.3 m, and its mass was 2.4 metric tons. The walls of the reentry module contained heat-resistant windows and fast-opening airtight hatches. In the center of the cabin was an ejection seat for the cosmonaut, who would be wearing a spacesuit. The seat contained the spacesuit ventilation device, the cosmonaut parachute system, and an emergency kit containing everything necessary in case of a landing in an unscheduled region. Thanks to its thermal shielding, the reentry module, though surrounded by a red-hot cloud of plasma created by air resistance, could fly safely through the dense layers of the atmosphere, decreasing its speed from orbital velocity to 180–200 m/sec. At an altitude of 7–8 km, the cosmonaut could eject through the exploded hatch and land by parachute separate from the spacecraft and seat. This system also served as a cosmonaut escape system in case of a malfunction at the start of flight. Special rocket engines installed in the seat could carry it, along with the cosmonaut, from the danger zone and raise him to a height sufficient for safe

parachute landing. The spacecraft was fully automated, but the pilot could take control manually.

The attitude control system, consisting of gyroscopic and optical sensors, logic devices, and microengines running on compressed gas, made it possible to pilot the spacecraft manually. The cosmonaut could control the attitude of the spacecraft in order to turn on the retrorocket. There was a special instrument, called Vzor, that could be used for visual orientation. If the craft was correctly oriented, the cosmonaut could see "Earth passing below" through the central portion of this instrument, that is, the cosmonaut could control the heading. Through the annular mirror, the cosmonaut could see the horizon, which allowed controlling the spacecraft's pitch and roll. The spacecraft was given the name Vostok, which became world famous after its launch with a human on board. The final work on the spacecraft was completed in March 1961, at the same time the first team of cosmonaut candidates completed their training course.

Yuriy Gagarin—Planet Earth's First Cosmonaut

During the training of the first group of 20 men selected as candidates for spaceflight, a smaller six-man subgroup was identified for intensive training for the first flight. The remainder were trained on programs for future flights. The selected subgroup consisted of the following student cosmonauts: V.F. Bykovskiy, Y.A. Gagarin, G.G. Nelyubov, A.G. Nikolayev, P.R. Popovich, and G.S. Titov (Fig. 2).

All six of the candidates selected for the flight were qualified and capable of performing it. But it was necessary to select the best of the best with regard to professional training, health status, psychological traits, and many other qualities. For this reason, each person who had even a slight say in who would be the first cosmonaut carefully observed each of them during the training process as well as in the cosmonaut's free time. Chief Designer Korolev also observed these men carefully.

In the course of training and during various official and unofficial events and meetings, the preference of the majority converged on the same one of the six cosmonauts—Gagarin. He was a born leader. The following lists only a few of the traits he possessed: unshakable faith in the success of the flight, outstanding health, unquenchable optimism, a flexible mind, curiosity, boldness and decisiveness, precision, love of work, restraint, simplicity, modesty, and sociability. Everyone who spoke to him was charmed by his personality.

As had been decided earlier, the decision was made by a State Commission at the Cosmodrome, but it was already clear to many that the first to fly should be Yuriy Gagarin. Events later confirmed that this choice was the right one. Gagarin handled the world's first space flight to perfection, withstood the stresses of fame, and represented his nation with dignity on all the continents of this planet. But in those days of April 1961, to all participants in the project, he was simply the man who would be the first to test a complex technology based on a completely new principle. People had faith in him; people worried about him.

Who was this man, Yuriy Gagarin? He was born to a family of peasants on 9 March 1934 in the town of Gzhatsk in the Smolensk District. He spent his

Figure 2. S.P. Korolev and Yu.A. Gagarin with a group of cosmonauts from the first team.

early years in the village of Klushino not far from Gzhatsk. The Gagarins had four children; Yuriy was the third. In 1941 he started his education at the village school. But the war had already come to the Smolensk area. The village of Klushino, the town of Gzhatsk, and the whole Smolensk area were occupied by the German troops attacking Moscow. Young Gagarin had to live through difficult times. Despite this, he was a good student who displayed a love of learning. In 1949, when he was 15, he decided to leave high school to be able to start helping his parents sooner. His goal was clear—he would work at a plant. For this, he needed to master a trade. He entered a trade school in the town of Lyuberts not far from Moscow. In 1951, he graduated from this school with honors with training as a mold maker and caster; at the same time, he completed an academic school for young workers.

In this same year, he received authorization for further instruction in an industrial technical college in the city of Saratov. In 1955, Yuriy graduated with honors from this technical college and from the aeronautics club where he had also studied while he was a student at the former school. His attraction to flight prevailed, and he entered the First Chkalovskiy Military Aircraft Pilot Academy, from which he graduated in 1957 with a first class qualification. Then, Yuriy Gagarin was sent as a military fighter pilot to serve in the North in one of the naval aviation units of the Northern Fleet. After 2 years, certain young fighter

Figure 3. Yu.A. Gagarin and Mrs. V.U. Gagarin with their children.

pilots were detailed to master a new technology. And in 1960, Yuriy Gagarin found himself in the first team of cosmonauts and then the first candidate for the first spaceflight in history (Fig. 3).

“Let’s Go...”

On 30 March 1960, the nation’s highest leadership received an official memo signed by officials from the Government, Academy of Sciences, War Department, and Industry. The memo stated, “We hereby report that we have performed a large number of scientific research studies and tests on the ground as well as under flight conditions... The upshot of this work to construct a manned orbital spacecraft and a system for returning to Earth, and to provide cosmonaut training is that now we are in a position to implement the first manned spaceflight. Six cosmonauts have been trained to make this flight.” (The memo did not contain the names of these cosmonauts.)

On 3 April 1961, a government resolution was adopted “On the launch of a manned orbital satellite.” This resolution stated: “I approve the proposal for

launch of the Vostok manned orbital satellite with a cosmonaut on board..." On 6 April 1961, the results of the graduation examinations for the first cosmonaut team were ratified, and special certificates were issued to them. A set of instructions was developed, and the cosmonaut's flight mission was signed. This mission was defined as follows: a single-orbit flight around Earth at an altitude of 180–230 km; flight duration—1 hour 30 minutes; flight objective—to verify that it is possible for a human being to survive in space in a specially equipped spacecraft, to flight test the spacecraft and radio communications equipment, and to validate the reliability of the spacecraft and cosmonaut landing devices.

On 10 April 1961, the State Commission approved S.P. Korolev's proposal to implement the first manned space flight in the world on 12 April 1961 on the Vostok spacecraft. The Commission approved Yu.A. Gagarin as the first cosmonaut pilot, and G.S. Titov served as backup pilot.

On 12 April 12, 1961 at 09:07 Moscow time, the first manned spacecraft in the world, Vostok-1, was launched. Its pilot was Major Yuriy Alekseyevich Gagarin, a citizen of the Soviet Union. The flight continued for 108 minutes, during which the spacecraft carrying the cosmonaut made a complete orbit around the Earth. For his successful completion of the world's first space flight Major Yu.A. Gagarin was awarded the title of Hero of the Soviet Union, and also the honorary title of "USSR Cosmonaut-Pilot." The era of human space exploration on piloted spacecraft had dawned.

A government statement regarding the first manned space flight read: "We consider triumphs in space exploration not merely the achievement of our own nation, but of all humanity. We are pleased to place them at the service of all nationalities in the name of the progress, happiness and well-being of all the people on Earth." The world was stunned by the announcement of this event. People on all continents ecstatically greeted the man who had been the first to view our planet from space.

And this is how Gagarin's launch and flight took place. In the last minutes before the launch, everyone who was present felt extraordinary emotion, especially those in the command bunker. The launch commands were listened to with strained attention...

"Fire!"

"Lift-off!"

And then Gagarin's famous words:

"Let's go!"

The first seconds were especially tense for all those in the bunker. The rocket was still relatively low and there remained some risk if the cosmonaut had to eject due to a malfunction, because the rocket could fall relatively close to the ejecting cosmonaut. All listened tensely to the voice of the operator on the loudspeaker "Five... five...five.." This meant that all systems were working normally... The launch went off superbly.

During the flight Gagarin, according to his reports to Earth, monitored the functioning of the instruments, equipment, and spacecraft systems and maintained the requisite constant radio and telegraph contact, observed Earth and the stars, and took water and food, which was also part of his flight program. During the entire flight, the cosmonaut evaluated the effects of weightlessness on his feeling of well-being and his performance capacity.

Everyone impatiently awaited the message from the tracking station at the very south of the country, to which Vostok was to come close. Everyone knew that during reentry from orbit, when the spacecraft passed through the plasma cloud, the transmitter signal would be lost. This disruption of communication was to take place at a predetermined moment. And everyone waited; would it or wouldn't it happen?

"OK, the signal is lost!

And 20 minutes later, a message was received from the Saratov region:

"The cosmonaut is back on Earth. Everything is fine!"

There, on the banks of the Volga, the most thrilling around the world journey of the twentieth century had just been completed (Fig. 4).

Here is how Yuriy Gagarin himself described it: "... I entered the cabin, which smelled like the wind from the fields, they settled me into the seat, and the hatch door closed soundlessly... Now, I could maintain my contact with the outside world, the flight controllers, and my fellow cosmonauts, only by radio... My eyes fell on the clock. The hands showed 9:07 Moscow time. I heard a whistle and a roar that grew louder and louder, and felt the giant craft begin to shake all over and slowly, very slowly break away from the launch pad. The struggle between the rocket and the Earth's gravity began. The G-force began to increase. I felt as if an irresistible force was pushing me harder and harder into my seat. And although it was placed so as to minimize the effect of the enormous G-force on my body, I had trouble moving so much as a hand or foot. But I knew that this would only last a short time as the spacecraft, gathering speed, went into orbit. The G-force kept on increasing. When we got beyond the dense layers of the atmosphere, the nose cone dropped off automatically and flew off somewhere. Through the windows I could see the far off surface of the Earth. At that moment Vostok

Figure 4. Reentry module of the "Vostok" space vehicle after landing.

was flying over a wide Siberian river. I could distinctly see its islands and shores in the sunlight. The spacecraft went into orbit—on the broad highway of space. Weightlessness started... At first this sensation was strange, but I soon got used to it, adapted and continued to perform the assigned flight program. Vostok was traveling at a speed close to 28,000 km/h. Such a speed is difficult to imagine on the Earth... Then the final phase of the flight approached. This phase—return to Earth—is perhaps even more critical than insertion into orbit and orbiting. I began to prepare myself for it. What awaited me was a shift from weightlessness to a new, perhaps even stronger G-force, and the colossal heating of the exterior spacecraft shell as it entered the dense layers of the atmosphere. Until now everything on the space flight had occurred approximately the way we had worked it out during our training on Earth. But what would happen during the final, culminating phase of the flight? Were all the systems operating normally? Was there perhaps some unforeseen danger awaiting me? Automatic mechanisms are all very well, but I checked the spacecraft's location and got ready to take control into my own hands... At 10:25 the retrorocket fired automatically. It worked beautifully, exactly on time. The flight altitude began to drop. Convinced now that the spacecraft would reach Earth safely, I got ready for the landing. Ten thousand meters... Nine thousand... Eight... Seven... Below, the ribbon of the Volga shimmered. I immediately recognized the great Russian river and its banks..." (Fig. 5).

The excitement produced by Gagarin's flight was triumphal. People throughout the world were thrilled by his exploit. The newspapers of all nations featured articles about this epochal event as their main story under headlines such as: "108 Minutes that Shook the World," "A Fairy Tale Comes True," "Columbus of the Universe," "A New Era," etc. April 12 became the Day of Cosmonautics, a day dedicated to aviators and the conquerors of space, which is celebrated worldwide.

During those days, specialists in public opinion concluded that there was no more famous man in all the world than Gagarin. He was greeted by all the people of Earth, in all languages, as the hero of the twentieth century. He was honored by kings and presidents. He received the highest awards, and babies were named after him. Towns and villages, avenues and squares, seagoing vessels and educational institutions now bear the name Gagarin. There is a "Yuriy Gagarin" crater on the Moon. There are monuments to Gagarin in many cities of the world (Fig. 6).

Gagarin endured the ordeal of fame with dignity. He did not imagine that he was a superman. He remained the man he had been before: simple and human, with the same open-hearted character and the same warm smile. When he was asked whether his fame interfered with his life, he answered, "There is 'fame' and then there is 'Fame.'" The Fame that you feel should be written with a capital letter never was and never will be something that belongs only to you. It belongs primarily to the nation that brought you up and educated you. And such Fame doesn't turn your head. Such Fame makes you demand more of yourself, it is difficult, but reliable."

Surrounded by attention, Gagarin continued to seek new knowledge and new accomplishments. He continued training for new spaceflights and was the backup for cosmonaut V.M. Komarev, who, in April 1967, tested the first Soyuz

Figure 5. Yuriy Gagarin reports to the national leadership on the successful completion of his spaceflight.

spacecraft, which was based on a new principle (the cosmonaut died on landing as a result of failure of the spacecraft's parachute system). Never discontinuing his professional training, Gagarin studied in the Professor N.Ye. Zhukovskiy Academy of Military Aircraft Engineering and on 17 February 1968 successfully defended his thesis. He was awarded a diploma for graduating from this renowned educational institution.

Only 1 month and 10 days after this, on 27 March 1968, Yuriy Gagarin was killed, along with his instructor, while performing a training flight on a training aircraft. This tragedy was mourned by the entire nation. However, Gagarin's name and his exploit will remain in humanity's memory for centuries. The enterprise that Gagarin began continues. After the first Vostok, new spacecraft went into space. American astronauts performed two suborbital (ballistic) flights, and then the United States went on to orbital flights.

Figure 6. The first cosmonaut of planet Earth, Yuriy Gagarin. This figure is available in full color at <http://www.mrw.interscience.wiley.com/esst>.

There were six flights of Vostok series spacecraft in the Soviet Union. This vessel was replaced by the multiman Voskhod spacecraft, on which two crews, of three and two men, completed flights. Then Soyuz went into orbit in space. After a series of eight group and one-man flights on spacecraft of this type, they became the main transport vehicles for flights to the manned orbital stations, which began to be launched into space in 1971. Parallel Soyuz spacecraft performed autonomous targeted flights. The first Apollo–Soyuz international experimental program of 1975 used this spacecraft. The total number of flights of Soyuz (and subsequent Soyuz-T and Soyuz TM) series spacecraft, counting supply flights to orbital stations, performed by the Soviet Union and then Russia are Soyuz: 40; Soyuz T: 15; and Soyuz TM: 32.

Extensive programs of scientific studies and experiments were conducted on the Salyut-1, Salyut-3, and Salyut-4 orbital stations as part of a national

research program for the study of space. The research performed on Salyut-6 and Salyut-7 formed part of international collaboration (the Interkosmos program) as well as national programs. Visiting crews, including citizens of various countries, worked on these stations jointly with the prime crews. The most famous orbital station was the multimodular Mir, which functioned in orbit for 15 years (from 1986 to 2001). An extensive program of international collaboration (the Mir-Shuttle, Mir-NASA, and Euromir subprograms and others) took place on this station.

Experience with long duration flights on Mir and the construction and technological design solutions validated on it were used extensively in creating of the International Space Station. Experience gleaned in the United States during implementation of the national manned Mercury, Gemini, Apollo, Skylab, and Space Shuttle programs was also incorporated here. Several international space crews have already gone into orbit on the International Space Station using Russian transport vehicles of the Soyuz TM series and the U.S. recoverable Space Shuttles (Altantis, Endeavor, Discoverer). Information about the general nature of flights on orbital stations of the Salyut and Mir series and also the International Space Station is presented in the article by Yu.P. Semyonov and L. Gorshkov on Russian Space Stations elsewhere in this encyclopedia.

Space has become an arena for international collaboration for the benefit of people throughout the world. The road to this achievement was laid by Yuriy Gagarin, the first cosmonaut of planet Earth.

GLOBAL NAVIGATION SATELLITE SYSTEM

The Global Navigation Satellite System (Glonass) was designed to provide global real-time determination of the position and velocity of an unlimited number of moving objects at any point on the Earth's surface, in the air, and in space. This system was developed in response to an order from the USSR (Russian Federation) Ministry of Defense. By instruction of the Russian Federation's President, the Glonass system was put into operation on 24 September, 1993. A 7 March, 1995 decree of the RF Government put the system at the disposal of the world community in standard mode intended for civil, commercial, and scientific use without a user fee.

A RF Presidential decree of 18 February, 1999 designated the Glonass as a dual-purpose (military and civilian) space navigation system. The decree designated the Federal executive agencies responsible for its use, maintenance, and development as the Ministry of Defense and The Russian Aviation and Space Agency. Issues relating to developing and implementing the systems were to be coordinated by the Internavigatsiya Interagency Commission and an interagency task force set up in accordance with the Russian Federation government decree of 29 March, 1999.

Users are informed of system status by the Coordinating Scientific Information Center of the RF Ministry of Defense, as well as by the Information Analytic Center for the positional and time support of the Russian Aviation and Space Agency's flight control center.

The system makes it possible to obtain highly accurate navigation location information with a maximum error less than or equal to 50–70 meters for position and 15 cm per second for velocity from any point on the globe or in near-Earth space. Information is received in real time after a two to three minute pause, when the user's navigational system has just been turned on and

continuously thereafter. At the same time, the system provides the capability to link the user's timescale with the State unified timescale with an error of no more than one microsecond. If the user's equipment can implement special methods for processing navigational information or differential operating modes are used, the accuracy with which the user's position is determined may be improved significantly. Tests have shown that the maximum error in such cases does not exceed a few meters.

Concepts Involved in Positioning

Users of the system, who are in the continuous radio-navigation field created by the space navigation system, navigate by determining their position and velocity at any moment relative to the navigation satellites. Radio-navigational signals are continuously emitted by each navigation satellite in an orbital constellation. These signals are received by the user's equipment, without interrogation, and are used to determine the relative pseudorange and pseudovelocity (rate of change in pseudorange). Pseudorange is determined on the basis of the time delay it takes the signal to go from the navigation satellite to the user (on the basis of phase shift of the signal obtained from the satellite's relatively stable signal and the user equipment's generator frequency and time store) and pseudovelocity on the basis of the Doppler shift of the received signal frequency. Measured values of pseudorange and pseudovelocity can be used to solve the navigational problem and determine the user's position and speed. Because atomic standard clocks are used on each navigation satellite, the system synchronizes the radio-navigational signals emitted by the satellite with the ground-based highly stable atomic standard that functions as the system standard for frequency and time. Use of the ground-based frequency and time standard and the highly stable onboard frequency standard systems time is kept synchronized for each satellite.

The user's intrinsic time differs from the satellite system time. For this reason, initially, during receipt of signals from the satellites, the frequency of the user's generator is synchronized with the frequency of the signals received. The discrepancy between systems time and the user's clock time is determined at the same time as the coordinates and the components of the user's velocity vector when the navigational problem is solved.

Solution of the navigational problem requires, along with the measured values of pseudorange and pseudovelocity, the use of the satellite ephemeris. At each moment, they determine the satellite's radius vector and velocity vector components with high accuracy. The ephemerides, along with the frequency-time corrections of the onboard generator of each navigation satellite relative to the system frequency and time standard, are transmitted in the radio-navigation signal and received by users.

To solve the navigational problem (i.e., to determine the user position and velocity), the pseudorange and pseudovelocity to four or more navigation satellites must be measured. Using the measured values of pseudorange and pseudovelocity, with known satellite position and velocity (from the ephemeris information), the navigational equipment estimates values of the measured

parameters. As a result of comparing the measured and estimated values of the parameters, the navigational equipment determines the location, velocity, and displacement of its own timescale relative to the Glonass time-scale system.

The accuracy of the user's measurement of position and velocity are influenced by the error associated with the characteristics of the parameters measured by the user's receivers and the mathematical methods used to process them, that is, to solve the navigational problem.

The first group of errors results mainly from errors in the ephemerides and synchronization of each satellite's onboard generator relative to the central synchronizer, which is the ground-based system standard for frequency and time. These errors occur as a result of imperfections in the procedures for comparing the frequency of the onboard and ground-based generators and maintenance of the onboard timescale. For example, a time shift of 10 nanoseconds can lead to an error of 3 meters in measuring pseudorange. The ground-based measurement complex corrects the onboard timescale so that the standard deviation of the shift relative to the timescale of the central synchronizer does not exceed 10 nanoseconds.
