- redness or scaling of the hands or feet
- sore, swollen tongue
- skin rash or itching
- temporary thinning of hair (alopecia)
- bleeding at the site of the catheter
- infection from the catheter
- closing off of the catheter

Other, rare side effects of floxuridine include:

- blood in urine or stools
- hiccups
- hoarseness or coughing
- fever or chills
- sore throat
- difficulty swallowing
- blurred vision
- lower back or side pain
- painful or difficult urination
- small red skin spots
- difficulty walking
- bleeding or bruising
- yellow eyes or skin
- seizures
- depression

In addition to lowering the white blood cell count, increasing the risk of infection, floxuridine may reduce the level of blood platelets that are necessary for normal blood clotting. This can increase the risk of bleeding. The drug also may lead to abnormalities in liver function. Intraperitoneal floxuridine therapy has been associated with the development of fibrous masses in the abdomen.

KEY TERMS

Catheter—Tube used to inject medicine into the body.

Hepatic intra-arterial infusion—Injection of medicine into the artery to the liver.

Intraperitoneal—Within the abdominal cavity.

Metastasis—Spread of cancer from its point of origin to other parts of the body.

Interactions

Previous treatment with radiation or other anti-cancer drugs can increase the effects of floxuridine on the blood.

Drugs that may interact with floxuridine include:

- amphotericin B (Fungizone)
- antithyroid drugs that are used to treat an overactive thyroid
- azathioprine (Imuran)
- chloramphenicol (Chloromycetin)
- colchicine
- flucytosine (Ancobon)
- ganciclovir (Cytovene)
- interferon (Intron A, Roferon-A)
- plicamycin (Mithracin)
- zidovudine (AZT, Retrovir)

Margaret Alic, Ph.D.

Fluconazole *see* **Antifungal therapy**

Fludarabine

Definition

Fludarabine is a **chemotherapy** medicine used to treat certain types of cancer by destroying cancerous cells. It is known as the brand name Fludara. Fludarabine may also be referred to as Fludarabine phosphate, 2-fluoroadenine aribinoside 5-phosphate, and FAMP.

Purpose

Fludarabine is approved by the Food and Drug Administration (FDA) to treat refractory **chronic lymphocytic leukemia** (CLL). Patients must have a disease that did not respond to other treatment or a disease that became worse during other treatment. Fludarabine has also been used to treat Hodgkin's and non-Hodgkin's **lymphoma**, **cutaneous T-cell lymphoma**, macroglobulinemic lymphoma, **mycosis fungoides**, and **hairy cell leukemia**.

Description

Fludarabine has been available for use since the early 1990s, and is a member of the group of chemotherapy drugs known as antimetabolites. Antimetabolites interfere with the genetic material (DNA) inside the cancer cells and prevent them from further dividing and growing more cancer cells.

Recommended dosage

Fludarabine is a clear solution that is administered through a vein.

A fludarabine dose can be determined using a mathematical calculation that measures a person's body surface area (BSA). This number is dependent upon a patient's height and weight. The larger the person, the greater the body surface area. BSA is measured in the units known as square meter (m^2). The body surface area is calculated and then multiplied by the drug dosage in milligrams per square meter (mg/m^2). This calculates the actual dose a patient is to receive.

The approved dose for chronic lymphocytic leukemia is 25 milligrams per square meter per day for 5 days in a row. The fludarabine is given intravenously into a vein over a 30-minute to 2-hour time period. This 5-day cycle is repeated every 4 weeks.

The dose of fludarabine may need to be decreased in patients who have kidney problems.

Precautions

Blood counts will be monitored regularly while on fludarabine therapy. During a certain time period after receiving fludarabine, there is an increased risk of getting infections. Caution should be taken to avoid unnecessary exposure to crowds and people with infections.

Patients with a known previous allergic reaction to chemotherapy drugs should tell their doctor.

Patients who may be pregnant or are trying to become pregnant should tell their doctor before receiving fludarabine. Chemotherapy can cause men and women to be sterile, or unable to have children. It is unknown if fludarabine has this effect on humans.

Patients should check with their doctors before receiving live virus **vaccines** while on chemotherapy.

KEY TERMS

Anemia—A red blood cell count that is lower than normal.

Chemotherapy—Specific drugs used to treat cancer.

Deoxynucleic acid (DNA)—Genetic material inside of cells that carries the information to make proteins that are necessary to run the cells and keep the body functioning smoothly.

Electrolytes—Elements normally found in the body (sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate) that are important to maintain the many cellular functions and growth.

Food and Drug Administration (FDA)—The government agency that oversees public safety in relation to drugs and medical devices, and gives the approval to pharmaceutical companies for commercial marketing of their products.

Gout—A disease caused by the build up of uric acid in the joints causing swelling and pain.

Intravenous—To enter the body through a vein.

Neutropenia—A white blood cell count that is lower than normal.

Refractory—Cancer that no longer responds to treatment.

Side effects

The most common side effect expected from taking fludarabine is low blood counts (**myelosuppression**). When the white blood cell count is lower than normal (**neutropenia**), patients are at an increased risk of developing a **fever** and infections. Patients may need to be treated with **antibiotics** at this point. The platelet blood count can also be decreased due to fludarabine administration, but generally returns to normal within 2 weeks after the end of the infusion. Platelets are blood cells that cause clots to form to stop bleeding. When the platelet count is low, patients are at an increased risk for bruising and bleeding. Fludarabine causes low red blood cell counts (**anemia**). Low red counts make people feel tired and dizzy.

Fludarabine can cause the development of autoimmune **hemolytic anemia**, which occurs when the body begins to destroy its own red blood cells. It is an uncommon side effect, but very serious when it occurs.

Common side effects from fludarabine include **nausea and vomiting**. If nausea and vomiting are a problem, patients can be given **antiemetics** before receiving fludarabine. This medication helps prevent or decrease these side effects. Other common side effects include fever, chills, joint pain, fluid gain, fatigue, sleepiness, pain, muscle ache, weakness, and infection. Other less common side effects include loss of appetite (anorexia), **diarrhea**, abnormal touch sensation, cough, **pneumonia**, and shortness of breath.

Damage to the nerves and nervous system tissues can occur with fludarabine. Side effects due to this nerve damage include sleepiness, confusion, weakness, fatigue, irritability, numbness or tingling in the hands and feet, visual changes, and difficulty walking.

Infrequent side effects of fludarabine are skin rashes, pain, **itching**, fever, lung problems, insomnia, headache, muscle and joint aches, swelling, and decreased blood pressure.

Rare side effects of fludarabine include mouth sores, constipation and abdominal cramping, bleeding from the bladder, hair loss, hearing problems, and liver and kidney problems.

Fludarabine can cause the rapid breakdown of cancer cells. Patients who have large numbers of cancer cells in their bloodstream can develop a problem known as **tumor lysis syndrome**. The symptoms of this syndrome include pain in the lower back and blood in the urine. A patient can develop high or low levels of electrolytes and high levels of uric acid, which can lead to gout and kidney damage. The drug **allopurinol** may be given to patients prior to fludarabine treatment to prevent this from occurring. Drinking an increased amount of liquids also may help prevent the kidney damage.

All side effects a patient experiences should be reported to the doctor.

Interactions

Fludarabine should not be used in combination with the drug **pentostatin**. The combination causes severe lung damage.

Nancy J. Beaulieu, R.Ph., B.C.O.P.

Fluorouracil

Definition

Fluorouracil is a medication that kills cancer cells. It is also known as 5-FU or 5-fluourouracil, and as the brand name Adrucil.

Purpose

5-FU may be used in combination with other **chemotherapy** agents to treat cancers of the breast, stomach, colon, rectum, and pancreas.

Description

5-FU is a cytotoxic drug. This means that it kills cancer cells. 5-FU kills cells by interfering with the activities of DNA and RNA, which are molecules in the cells important in expressing genetic material.

Recommended dosage

Most frequently, 5-FU is given as an injection into the vein (intravaneous injection or IV). Many different doses and regimens are used depending on the cancer diagnosis, and patients should discuss with their physician the dose based on the individual protocol used. A sample dose is 500 to 1,000 mg per square meter of body surface area given as a 24-hour infusion for four to five days every three weeks. A dose of 425 mg per square meter of body surface area per day for five days given along with the drug **leucovorin** is also common.

Precautions

Patients with allergic reaction to 5-FU should not be administered this drug. It is also inadvisable for pregnant women. 5-FU should be administered with caution to patients with impaired liver or kidney function, or in patients with a history of heart problems.

Side effects

The amount of drug given and the duration of which it is given during a single session greatly influences the side effects seen. For example, when given as a 24-hour continuous infusion, the most common side effects are **diarrhea** and mouth ulcers. If 5-FU is given as a bolus infusion (a high quantity of the drug all at once), the most common side effect is bone marrow suppression; this results in a decrease of the white blood cells responsible for fighting infections, the platelets responsible for blood clotting, and the red blood cells responsible for providing oxygen to the cells of the body.

The severity of the side effects is increased when 5-FU is given with the drug leucovorin. Vomiting, diarrhea, nausea, and loss of appetite (anorexia) may occur regardless of how 5-FU is administered. The diarrhea side effect may be severe in some patients, and it is important for them to alert their doctor immediately so that appropriate medications for the diarrhea can be prescribed.

5-FU may cause rashes, increased sensitivity to sunlight, changes in skin color, changes to the fingernails, and

KEY TERMS

Cytotoxic drug—A medicine that kills (cancer) cells.

DNA—A molecule found in all living cells that contains tiny bits of genetic information.

Infusion therapy—Administration of a medication as a liquid through an intravenous (IV) device.

RNA—A molecule found in all living cells that plays a role in transmitting information from the DNA to the protein-forming system of the cell.

redness and swelling in the palms of the hands and soles of the feet. Patients who have had heart disease before starting therapy with 5-FU may have problems with blood flow to the heart. Rarely, 5-FU may cause an allergic reaction, dry eyes, sleepiness, confusion, headache, changes in walking gait, involuntary rapid movement of the eyes, and difficulty speaking. When 5-FU is applied directly on the skin, there are usually no side effects except for those to the skin itself. These may include burning sensations, pain, and darkening of the skin color.

Some authorities recommend discontinuation of 5-FU therapy as soon as mild side effects are observed as a way of reducing the extent of injury to the digestive tract. Administration may then be restarted at a lower dose after the side effects have stopped.

Interactions

People taking fluorouracil should consult their doctor before taking any other prescription drug, over-the-counter drug, or herbal remedy.

Bob Kirsch

Fluoxymesterone

Definition

Fluoxymesterone is a synthetic male hormone used to treat women with hormone-dependent **breast cancer**, and may also be used as a **testosterone** replacement for men. Fluoxymesterone is sold as Halotestin, Android-F, and Ora-Testryl.

Purpose

Fluoxymesterone is used to manage metastatic breast cancer in menopausal women who have hormone receptor–positive tumors. It may also be used as a supplement to **chemotherapy** for metastatic breast cancer, or as a hormone replacement for men. Additionally, it is sometimes used to treat **anemia**.

Description

Fluoxymesterone is a synthetic androgen, or male hormone, similar in action to testosterone. Fluoxymesterone works by attaching itself to androgen receptors; this causes it to interact with the parts of the cell involved in the making of proteins. It may cause an increase in the synthesis of some proteins or a decrease in the synthesis of others. These proteins have a variety of effects, including blocking the growth of some types of breast cancer cells, stimulating cells that cause male sexual characteristics, and stimulating the production of red blood cells.

When used as a breast cancer treatment, this drug blocks the growth of tumor cells that are dependent on female hormones to grow. It can only be used on female breast cancer patients who have reached menopause one to five years earlier, or as a result of surgery. It may be used in addition to other chemotherapeutic drugs, such as **tamoxifen** or **cyclophosphamide**, **doxorubicin**, and **fluorouracil**.

Fluoxymesterone may be used to treat men; it replaces male hormones which are not being released in the body as a result of tumors, radiation, or surgery affecting the pituitary or hypothalamus.

Recommended dosage

The recommended dosage will depend on the age, sex, and diagnosis of the patient, as well as the response to treatment and occurrence of side effects. Treatment is usually with a full therapeutic dose initially, then adjusted to the individual needs of the patient.

Women being treated for breast cancer usually take 10 to 40 mg per day orally, divided into several doses. Up to three months may be required for a response to treatment.

Androgen replacement therapy for men is usually started at 5 to 20 mg per day, taken orally in divided doses.

If a dose is missed, it should be taken as soon as it is remembered, unless it is more than two hours late. If it is more than two hours late, the patient should skip that dose and continue to follow the normal dosing schedule.

Precautions

Fluoxymesterone may be taken with food if it causes stomach upset. Patients taking this medication should

ensure that they see their physician regularly during treatment and receive appropriate laboratory tests. Liver function should be monitored and cholesterol and red blood cell levels may need to be examined during treatment. Female breast cancer patients should have their serum and urine calcium levels checked. Prepubescent males will require x rays to determine the rate of their bone maturation. Diabetics should be aware that this medication may affect blood sugar levels.

Fluoxymesterone should not be taken by pregnant women as it will affect the sexual development of the fetus. The hormone may also pass into the milk of nursing mothers, affecting sexual development of the infant. Fluoxymesterone should not be taken by people with liver, kidney, heart or blood vessel disease, prostate problems, or sensitivity to the dye tartrazine. Patients with migraines or epilepsy should discuss these conditions with their physician before using the drug. Elderly male patients using fluoxymesterone have an increased risk of prostate enlargement.

Patients should consult their physician before discontinuing the drug.

Side effects

Patients who use fluoxymesterone have an increased risk of developing liver disease, and should report symptoms such as yellowing of the eyes and skin to their physicians immediately. Women being treated for breast cancer and patients who are immobilized may develop **hypercalcemia**. Other side effects which may occur include the following:

- fluid retention
- nausea and vomiting
- diarrhea
- anxiety
- depression
- changes in sex drive
- dizziness
- suppression of blood clotting factors II, V, VII, and X
- headache
- itching
- reduction in number of white blood cells
- increase in number of red blood cells

Women who take this medication may also experience menstrual irregularities, acne, enlarged clitoris, and masculine characteristics such as deepening of the voice, increased hair growth, and male pattern baldness. Some of these changes may go away if the medication is stopped, while others may remain.

KEY TERMS

Androgen—a male hormone

Hypercalcemia—high levels of calcium in the blood

Men taking fluoxymesterone may experience breast growth, erections of excessive frequency and duration, impotence, decreased ejaculatory volume, and bladder irritation.

Interactions

A large number of medications may cause interactions with fluoxymesterone, including acetaminophen, anabolic steroids, anticoagulants, antidiabetic agents, and many others. Patients should notify their physicians of any medications they are taking before using fluoxymesterone.

Racquel Baert, M.Sc.

Flutamide *see* **Antiandrogens**

Folic acid

Definition

Folic acid is a water-soluble B vitamin essential in the human diet. It is an important cofactor in the synthesis of DNA and RNA of dividing cells, particularly during pregnancy and infancy when there is an increase in cell division and growth.

Purpose

Folic acid is important to the field of oncology in two ways. First, prior to neoplasm formation, folic acid is important in the synthesis of DNA and RNA and the repair of damaged DNA. Second, after a tumor develops, a form of folic acid is used to counter the side effects of **methotrexate** and 5-fluorouracil (also called fluorouracil or 5-FU).

Description

Prior to tumor formation

Since folic acid is a cofactor in DNA replication and biosynthesis of purines and also in DNA repair, there is an increasing amount of research (epidemiological, clinical, and experimental) that suggests a folic acid deficiency might be a factor that predisposes the formation

of tumors in normal epithelial tissue. There is an inverse relationship associated with low folate diets and an increase in DNA breakage and mutation that is unable to be effectively repaired. The preventative influence of dietary folic acid on the formation of **colon cancer** is currently under heavy research. Although a correlation is observed, it has not yet been proven to show cause and effect. However, there is enough evidence to encourage consuming minimal daily dietary requirements of folic acid to potentially reduce the risk. When choosing supplements, other names for folic acid that may be encountered are folate and folacin.

After tumors form

Once a neoplasm forms, folic acid levels need to be decreased. In neoplasms, DNA replication and cell division are both occurring in an uncontrolled manner. Folate, which assists in this process, needs to be inhibited, causing an interruption in DNA synthesis and slowing the growth of the tumor. Chemotherapeutic agents called antimetabolites, or folic acid antagonists, such as methotrexate and 5-fluorouracil (5-FU), inhibit the enzymatic pathways for biosynthesis of nucleic acids by substituting for folic acid and sabotaging the reaction. Unfortunately, drugs that inhibit the biosynthesis of cancer cells also inhibit the biosynthesis of normal cells, resulting in extremely toxic side effects. To counter the side effects, a drug called **leucovorin** (a form of folate also known as Wellcovorin, Citrovorum and folinic acid) opposes the toxic effects of methotrexate on normal tissue. Leucovorin also increases the anticancer effect of 5-FU.

Recommended dosage

Non-cancer individuals supplementing their diet with folic acid may reduce the risk of cancer. Supplemental folic acid can be purchased over the counter and is also fortified in breakfast cereals and whole grain products produced in the United States. The recommended intake for adults is 400 micrograms (mcg) each day. While the risk of upper limit toxicity is low, adult men and women should not exceed the advised upper limit of 1,000 mcg per day. It is especially important that individuals diagnosed with cancer seek the advice of medical professionals before commencing or continuing supplemental folic acid use because it may interact with **chemotherapy**.

Cancer patients treated with methotrexate may be given leucovorin as a "rescue" treatment approximately 24 hours later to counteract the toxic side effects on normal tissues of the gastrointestinal system and bone marrow. Leucovorin is only available by prescription. It is a systemic drug available in oral form (tablets) or via injections. The dosage varies from person to person and is based on body size.

KEY TERMS

Folic acid antagonist—a drug that interferes with the action of folic acid

Neoplasm—abnormal tissue growth that is not controlled by normal stimuli and lacks normal structural organization

Purines—a substance that is part of the structure of guanine and adenine, molecules that combine to form DNA

Precautions

Patients should inform their physician of the following conditions before they begin to take leucovorin:

- Pregnancy or breast-feeding.
- Pernicious anemia.
- Allergies to leucovorin or any other drugs.
- Vitamin B_{12} deficiency. Folic acid may mask hematologic signs of B_{12} deficiency while neurologic damage progresses.

Side effects

Folic acid in general and specifically leucovorin are usually well-tolerated. However, there are some uncommon side effects that include skin rashes, **itching**, vomiting, nausea, **diarrhea**, and difficulty breathing. Although extremely rare, seizures have occurred in some patients taking leucovorin. Since leucovorin is taken with chemotherapeutic drugs, some side effects may be due to drug interaction.

Interactions

Supplemental folic acid can interact with anti-convulsant medications such as dilantin, **phenytoin**, and primidone. It also complicates the effects of metformin (used in individuals with type 2 diabetes), sulfasalazine (used in individuals with Crohn's disease), and triamterene (a diuretic).

Leucovorin enhances the effects of 5-FU and antagonizes the effects of methotrexate. It additionally interacts with barbiturate medications that may be taken by people with sleep disorders.

Sally C. McFarlane-Parrott

Foscarnet *see* **Antiviral therapy**

G

Gabapentin

Definition

Gabapentin is indicated to be used in combination with other anti-seizure (anticonvulsant) drugs for the management of partial seizure types. Gabapentin should not be used alone for the treatment of seizures unless the patient cannot tolerate other anticonvulsant drugs. This medication can also be used for the treatment of certain syndromes associated with nerve (neuropathic) pain (diabetic **neuropathy**, postherpetic neuralgia), pain associated with multiple sclerosis, neuropathic cancer pain, trigeminal neuralgia, and bipolar mood disorder. Gabapentin is also known as Neurontin.

Description

Gabapentin was introduced in 1994 as an anticonvulsant medication. Other medications in the anticonvulsant class include **phenytoin**, **carbamazepine**, phenobarbital, valproic acid, topiramate, and lamotrigine. Gabapentin's structure is similar to that of gamma-aminobutiric acid (GABA), which is a chemical found in the central nervous system (brain and spinal cord) that decreases firing of neurons leading to a decrease in seizure activity. Despite this structural similarity, gabapentin does not interact with GABA receptors and its exact mechanism of action for either epilepsy or pain is not known.

Gabapentin is a relatively recent addition to the arsenal of drugs used in the treatment of neuropathic pain. Traditionally, tricyclic antidepressants (**amitriptyline**, nortriptyline, desipramine) have been used as first-line agents. It takes one to three weeks for either gabapentin or tricyclic antidepressants (TCAs) to provide relief of pain after starting treatment. Gabapentin appears to be a safer agent to use than TCAs, especially in elderly patients and patients on multiple other medications. One of the disadvantages of gabapentin over TCAs is its higher cost.

Recommended dosage

Adults and children over 12 years of age

MANAGEMENT OF PARTIAL SEIZURE TYPES Therapy should be started at a dose of 300 mg, three times daily. The dose can be increased to 1,800 mg/day in three divided doses. Some patients may need even higher doses to control their seizures. Doses up to 3,600 mg per day have been well tolerated in research studies.

TREATMENT OF NEUROPATHIC PAIN Dosages of 300-3,600 mg/day have been effective in research studies. However, optimal dosage appears to be 1,200-2,400 mg/day divided in three doses.

TREATMENT OF BIPOLAR DISORDER Optimal dose has not been well established. Doses up to 4,800 mg/day have been used.

Children less than 12 years of age

Dosage varies due to the child's size, weight, and extent of condition. Parents should ask their physician about appropriate dosage levels for their child.

Administration

To minimize side effects, the first dose should be taken at bedtime. Capsules should not be chewed or crushed. Patients should avoid taking antacids (Mylanta, Maalox) at the same time as gabapentin. Doses should be taken at even intervals, and if a dose is missed, it should be taken as soon as remembered. However, double-doses can be hazardous and should be avoided.

Precautions

Gabapentin should be used with caution by breast-feeding mothers, children under 12 years of age (because of a lack of safety and efficacy studies in this population), and patients with impaired kidney function.

Gabapentin has resulted in fetal abnormalities in mice, rats, and rabbit offsprings. There are no current

KEY TERMS

Bipolar disorder—Recurrent mood disorder equally common among men and women, in which patients have extreme mood alterations between depression and mania or a mix of both. During manic episodes patients may have elevated mood, decreased need for sleep, rapid speech, extreme involvement in pleasurable activities, and may be easily distracted. The drugs commonly used in treatment of bipolar disorder include lithium, carbamazepine, valproic acid, and antidepressants.

Diabetic neuropathy—A chronic complication of diabetes that can take two forms, peripheral and autonomic. Patients with peripheral neuropathy experience dullness of sensation of pain, temperature, and pressure, especially in lower legs and feet. Autonomic neuropathy can cause alteration in bowel habits, impotence, and decreased heart function. The peripheral type can be treated with medications such as amitriptyline or gabapentin, while the autonomic type is more resistant to treatment.

Multiple sclerosis—A disorder of central nervous system, causing patches of plaques in brain and spinal cord and usually affecting young adults. Patients may experience visual changes, weakness, numbing or tingling of the hands or feet, changes in bladder and mood patterns.

Postherpetic neuralgia—Severe stabbing or throbbing pain associated with herpes zoster infection (shingles), resulting from the inflammation of nerve endings where the herpes vesicles erupt.

Trigeminal neuralgia—Severe, sudden bursts of throbbing and stabbing pain in one of the branches of trigeminal nerve located on the face. The pain can affect any area of the face, teeth, or tongue, and is often caused by some trigger points around the mouth.

studies on gabapentin use in pregnant women. This drug should only be used during pregnancy if potential benefits justify the risk to the baby.

This medication should not be discontinued suddenly because of the possibility of increased frequency of seizures. Gabapentin doses should be decreased gradually over a period of at least one week.

Gabapentin may cause drowsiness and dizziness. Alcoholic beverages may intensify these effects and their intake should be limited. Patients should use caution when driving, operating dangerous machinery, or performing activities requiring alertness.

A patient experiencing any of the following should contact their physician or pharmacist immediately:

- mental or mood changes
- tingling or numbness of hands or feet
- swelling of ankles
- vision problems
- fever or unusual bleeding

Side effects

This medication is usually well tolerated. Nervous system side effects are the most common, including drowsiness, dizziness, unsteadiness when walking, **fatigue**, and vision changes (double-vision, blurred vision). These side effects appear to be dose-related, and some patients may develop tolerance to these effects after the first several weeks of therapy. If these side effects persist or worsen, a physician should be notified. Other side effects that occur less frequently are irritability, dyspepsia, mood changes, memory loss, difficulty concentrating, slurred speech, and impotence. Elderly patients may be more sensitive to the side effects of gabapentin.

Interactions

One of the advantages of gabapentin is that it is not broken down in the body and does not have a lot of drug interaction. Antacids may interfere with the absorption of this medication in the body; they should be taken at least two hours apart. Gabapentin does not effect other commonly used anticonvulsants (for example, phenytoin, carbamazepine, valproic acid, and phenobarbital).

Olga Bessmertny, Pharm.D.

Gallbladder cancer

Definition

Cancer of the gallbladder is cancer of the pear-shaped organ that lies on the undersurface of the liver.

Description

Bile from the liver is funneled into the gallbladder by way of the cystic duct. Between meals, the

gallbladder stores a large amount of bile. To do this, it must absorb much of the water and electrolytes from the bile. In fact, the inner surface of the gallbladder is the most absorptive surface in the body. After a meal, the gallbladder's muscular walls contract to deliver the bile back through the cystic duct and eventually into the small intestine, where the bile can help digest food.

Demographics

About 5,000 people are diagnosed with gallbladder cancer each year in the United States, making it the fifth most common gastrointestinal cancer. It is more common in females than males and most patients are elderly. Southwest American Indians have a particularly high incidence—six times that of the general population.

Causes and symptoms

Gallstones are the most significant risk factor for the development of gallbladder cancer. Roughly 75 to 90 percent of patients with gallbladder cancer also have gallstones. Larger gallstones are associated with a higher chance of developing gallbladder cancer. Chronic inflammation of the gallbladder from infection also increases the risk for gallbladder cancer.

Unfortunately, sometimes cancer of the gallbladder does not produce symptoms until late in the disease. When symptoms are evident, the most common is pain in the upper right portion of the abdomen, underneath the right ribcage. Patients with gallbladder cancer may also report symptoms such as nausea, vomiting, weakness, jaundice, skin **itching**, **fever**, chills, poor appetite, and **weight loss**.

Diagnosis

Gallbladder cancer is often misdiagnosed because it mimics other more common conditions, such as gallstones, cholecystitis, and pancreatitis. But the imaging tests that are utilized to evaluate these other conditions can also detect gallbladder cancer. For example, ultrasound is a quick, noninvasive imaging test that reliably diagnoses gallstones and cholecystitis. It can also detect the presence of gallbladder cancer as well as show how far the cancer has spread. If cancer is suspected, a **computed tomography** scan is useful in confirming the presence of an abnormal mass and further demonstrating the size and extent of the tumor. Cholangiography, usually performed to evaluate a patient with jaundice, can also detect gallbladder cancer.

There are no specific laboratory tests for gallbladder cancer. Tumors can obstruct the normal flow of bile from the liver to the small intestine. Bilirubin, a component of bile, builds up within the liver and is absorbed into the bloodstream in excess amounts. This can be detected in a blood test, but it can also manifest clinically as jaundice. Elevated bilirubin levels and clinical jaundice can also occur with other conditions, such as gallstones.

On occasion, gallbladder cancer is diagnosed incidentally. About one percent of all patients who have their gallbladder removed for symptomatic gallstones are found to have gallbladder cancer. The cancer is found either by the surgeon or by the pathologist who inspects the gallbladder with a microscope.

Treatment team

The main member of the treatment team is the surgeon, since surgical removal of the cancer is the only measure that offers a significant chance of cure. Sometimes the cancer is too advanced such that surgery would be of no benefit. But the patient might suffer from jaundice or blockage of the stomach. In this case, the gastroenterologist or interventional radiologist may be able to provide non-surgical alternatives to address these complications. In limited scenarios, the oncologist or radiation therapist may treat the patient with **chemotherapy** or radiation therapy.

Clinical staging, treatments, and prognosis

Staging of gallbladder cancer is determined by the how far the cancer has spread. The effectiveness of treatment declines as the stage progresses. Stage I cancer is confined to the wall of the gallbladder. Approximately 25% of cancers are at this stage at the time of diagnosis. Stage II cancer has penetrated the full thickness of the wall, but has not spread to nearby lymph nodes or invaded adjacent organs. Stage III cancer has spread to nearby lymph nodes or has invaded the liver, stomach, colon, small intestine, or large intestine. Stage IV disease has invaded very deeply into two or more adjacent organs or has spread to distant lymph nodes or organs by way of **metastasis**.

Early Stage I cancers involving only the innermost layer of the gallbladder wall can be cured by simple removal of the gallbladder. Cancers at this stage are sometimes found incidentally when the gallbladder is removed in the treatment of gallstones or cholecystitis. The majority of patients have good survival rates. Late Stage I cancers, which involve the outer muscular layers of the gallbladder wall, are generally treated in the same way as Stage II or III cancers. Removal of the gallbladder is not sufficient for these stages. The surgeon also removes nearby lymph nodes as well as a portion of the adjacent liver (radical surgery). Survival rates for these patients are considerably worse than for those with early Stage I disease. Patients with early Stage IV disease may

KEY TERMS

Cholangiography—Radiographic examination of the bile ducts after injection with a special dye

Cholecystitis—Inflammation of the gallbladder, usually due to infection

Computed tomography—A radiology test by which images of cross-sectional planes of the body are obtained

Jaundice—Yellowish staining of the skin and eyes due to excess bilirubin in the bloodstream

Metastasis—The spread of tumor cells from one part of the body to another through blood vessels or lymphatic vessels

Pancreatitis—Inflammation of the pancreas

Stent—Slender hollow catheter or rod placed within a vessel or duct to provide support or maintain patency

Ultrasound—A radiology test utilizing high frequency sound waves

benefit from radical surgery, but the issue is controversial. Late Stage IV cancer has spread too extensively to allow complete excision. Surgery is not an option for these patients.

Other therapies

When long-term survival is not likely, the focus of therapy shifts to improving quality of life. Jaundice and blockage of the stomach are two problems faced by patients with advanced cancer of the gallbladder. These can be treated with surgery, or alternatively, by special interventional techniques employed by the gastroenterologist or radiologist. A stent can be placed across the bile ducts in order to re-establish the flow of bile and relieve jaundice. A small feeding tube can be placed in the small intestine to allow feeding when the stomach is blocked. Pain may be treated with conventional pain medicines or a celiac ganglion nerve block.

Current chemotherapy or **radiation therapy** cannot cure gallbladder cancer, but they may offer some benefit in certain patients. For cancer that is too advanced for surgical cure, treatment with chemotherapeutic agents such as fluorouracil (5-FU) may lengthen survival for a few months. The limited benefit of chemotherapy must be weighed carefully against its side effects. Radiation therapy is sometimes used after attempted surgical resection of the cancer to extend survival for a few months or relieve jaundice.

Coping with cancer treatment

After cancer treatment, many patients find that good nutrition, and a strong support system (which may include a support group) improve their quality of life. Treatment team members or hospital social workers can often recommend local resources that can be of assistance to the patient.

Clinical trials

More **clinical trials** are needed to define the role of chemotherapy and radiation therapy after attempted surgical resection of Stage II and III cancer. Some investigators are conducting trials to assess whether extremely radical surgery is beneficial in early Stage IV disease.

Special concerns

After the removal of the gallbladder, patients may experience a temporary change in bowel habits. The bowel movements may be more frequent or more liquid than before surgery. This situation usually resolves within about six months.

Gallium nitrate

Definition

Gallium nitrate is a drug that is used to treat **hypercalcemia**, or too much calcium in the blood. This condition may occur when individuals develop various types of cancer. Gallium nitrate is also known by the common brand name Ganite.

Purpose

The purpose of gallium nitrate is to reduce the level of calcium in a patient's blood. It is a liquid medication that is injected into a person's vein.

Description

Due to the fact that hypercalcemia is a serious condition that can be fatal, it is very important that it is effectively treated. Hypercalcemia is a common complication of cancer, affecting approximately 10–20% of all cancer patients. This condition can affect many systems of the body and has various signs and symptoms. Sometimes, these symptoms may be thought to be associated with the cancer, and therefore the hypercalcemia itself may go undiagnosed.

Symptoms of hypercalcemia include frequent urination, thirst, dizziness, constipation, nausea, vomiting, and disruptions in cardiac rhythm. If severe, this complication can lead to seizure, cardiac arrest, coma, or death.

Hypercalcemia should first be treated with fluids. Doctors should make sure that their patients are properly hydrated, meaning that they have enough fluid in their body. However, fluid treatment alone is usually not effective to treat this condition. Therefore, some physicians may recommend that their patients take gallium nitrate to establish a normal balance of calcium in the blood.

Recommended dosage

The recommended dosage of gallium nitrate differs depending on the patient, and should be determined by a physician. For adults and teenagers, the dosage of this medication is based on body weight/size, and must be calculated by a doctor. The medication is injected into a patient's vein at a slow pace for 24 hours over a period of five days. If a patient's calcium level is still too high, this process can be repeated in two to four weeks. For younger children, up to the age of 12, there are no specific studies to determine the effects of gallium nitrate. Therefore, use and dosage of this medication must be determined by the young cancer patient's personal physician.

While undergoing treatment with gallium nitrate, patients' doctors should check calcium levels at regular intervals. Even if a patient's condition has improved, he or she may still need to be followed closely to make sure that they do not develop hypercalcemia again.

Precautions

Before taking gallium nitrate, there are specific precautions that should be taken to avoid potential complications. Patients should let their physician know if they are allergic to any foods, preservatives or dyes. In addition, patients with certain medical problems, specifically kidney disease, should make sure that their prescribing physician is aware of this, as use of gallium nitrate can exacerbate this condition. Adequate hydration may minimize toxic effects on the kidney.

In addition, use of gallium nitrate has not been studied in pregnant animals or humans. It is not recommended for women who are pregnant or breast-feeding, as it may cause negative side effects.

With regard to children, as stated, there are no studies of gallium nitrate in younger populations. There are also no studies of this medication in the elderly. However, it is not thought that the use of gallium nitrate would cause very different side effects in older people versus younger adults.

Side effects

Individuals who are considering taking gallium nitrate should discuss its use in detail with their physician. This includes talking about the potential benefits versus any potential side effects. Some individuals may experience all, some, or none of these side effects. Some of these side effects may lessen as a person's body gets used to the medication. However, it is important to be aware of these potential side effects because some of them may require medical interventions.

More common side effects:

- blood in the urine
- pain in the bones
- change in urination frequency
- feeling thirsty
- loss of appetite (anorexia)
- weakness of muscles
- feeling nauseous
- diarrhea
- metallic taste in the mouth
- nausea and vomiting
- decrease of phosphate levels in the blood

Less common side effects:

- cramps in the abdomen
- a feeling of confusion
- muscle spasms

Rare side effects:

- excessive **fatigue** or weakness

KEY TERMS

Cancer—One cell that grows out of control in the body and subsequently invades nearby cells and tissue.

Ganite—The commonly used brand name for gallium nitrate.

Hypercalcemia—Excessive or increased calcium in the blood. Often a complication of cancer.

Interactions

Patients should tell their physician if they are taking any other medications on a regular basis, especially the ones listed below, as they could cause a negative interaction if taken with gallium nitrate.

- certain medications taken for infections
- cisplatin
- medications for pain that contain acetaminophen or aspirin
- cyclosporine
- deferoxamine
- some medications for treatment of arthritis
- lithium
- methotrexate
- pencillamine
- gentamicin
- amphotericin B
- "nephrotoxic agents"

Tiffani A. DeMarco, MS

Gallium scan

Definition

A gallium scan of the body is a nuclear medicine test that is conducted using a camera that detects gallium, a form of radionuclide, or radioactive chemical substance.

Purpose

Most gallium scans are ordered to detect cancerous tumors, infections, or areas of inflammation in the body. Gallium is known to accumulate in inflamed, infected, or cancerous tissues. The scans are used to determine whether a patient with an unexplained **fever** has an infection and the site of the infection, if present. Gallium scans also may be used to evaluate cancer following **chemotherapy** or **radiation therapy**.

Precautions

Children and women who are pregnant or breastfeeding are only given gallium scans if the potential diagnostic benefits will outweigh the risks.

Description

The patient will usually be asked to come to the testing facility 24–48 hours before the procedure to receive the injection of gallium. Sometimes, the injection will be given only four to six hours before the study or as long as 72 hours before the procedure. The timeframe is based on the area or organs of the body being studied.

For the study itself, the patient lies very still for approximately 30–60 minutes. A camera is moved across the patient's body to detect and capture images of concentrations of the gallium. The camera picks up signals from any accumulated areas of the radionuclide. In most cases, the patient is lying down throughout the procedure. Back (posterior) and front (anterior) views will usually be taken, and sometimes a side (lateral) view is used. The camera may occasionally touch the patient's skin, but will not cause any discomfort. A clicking noise may be heard throughout the procedure; this is only the sound of the scanner registering radiation.

Preparation

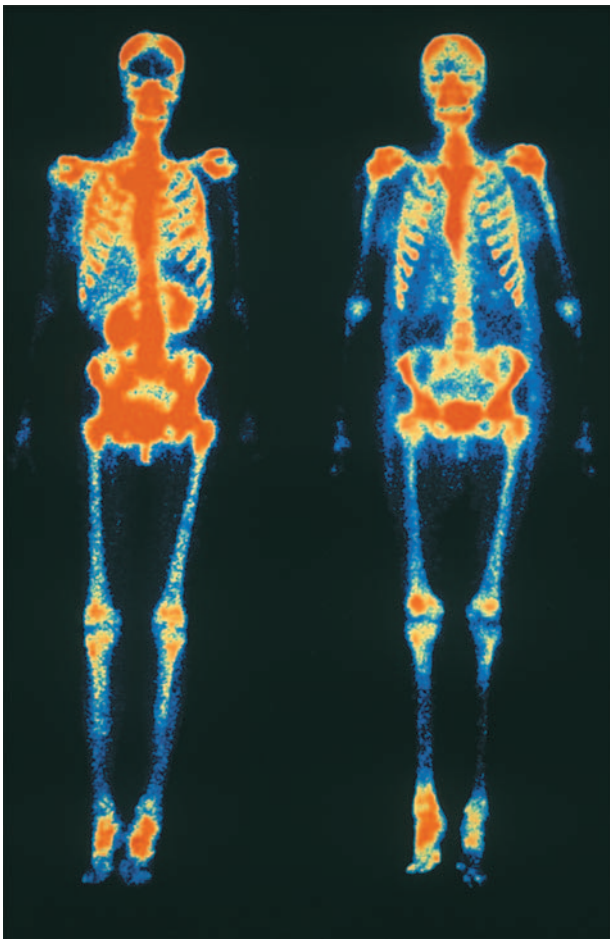
The intravenous injection of gallium is done in a separate appointment prior to the procedure. Generally, no special dietary requirements are necessary. Sometimes the physician will ask that the patient have light or clear meals within a day or less of the procedure. Many patients will be given **laxatives** or an enema prior to the scan to eliminate any residual gallium from the bowels.

Aftercare

There is generally no aftercare required following a gallium scan. However, women who are breastfeeding who have a scan will be cautioned against breastfeeding for four weeks following the exam.

Risks

There is a minimal risk of exposure to radiation from the gallium injection, but the exposure from one gallium scan is generally less than exposure from x rays.



Nuclear medicine scan of the skeleton. A radioisotope, like gallium, is used to produce this image. This scan reveals that lung cancer has spread to ribs and there is osteomyelitis in ankle. *(Copyright Scott Camazine and Sue Trainor, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

KEY TERMS

Benign—Not cancerous. Benign tumors are not considered immediate threats, but may still require some form of treatment.

Gallium—A form of radionuclide that is used to help locate tumors and inflammation (specifically referred to as GA67 citrate).

Malignant—This term, usually used to describe a tumor, means cancerous, becoming worse and possibly growing.

Nuclear medicine—A subspecialty of radiology used to show the function and anatomy of body organs. Very small amounts of radioactive substances, or tracers, are detected with a special camera as they accumulate in certain organs and tissues.

Radionuclide—A chemical substance, called an isotope, that exhibits radioactivity. A gamma camera, used in nuclear medicine procedures, will pick up the radioactive signals as the substance gathers in an organ or tissue. They are sometimes referred to as tracers.

Normal results

A radiologist trained in nuclear medicine or a nuclear medicine specialist will interpret the exam results and compare them to other diagnostic tests. It is normal for gallium to accumulate in the liver, spleen, bones, breast tissue, and large bowel.

Abnormal results

An abnormal concentration of gallium in areas other than those where it normally concentrates may indicate the presence of disease. Concentrations may be due to inflammation, infection, or the presence of tumor tissue. Often, additional tests are required to determine if the tumors are malignant (cancerous) or benign.

Even though gallium normally concentrates in organs such as the liver or spleen, abnormally high concentrations will suggest certain diseases and conditions. For example, Hodgkin's or non-Hodgkin's **lymphoma** may be diagnosed or staged if there is abnormal gallium activity in the lymph nodes. After a patient receives cancer treatment, such as radiation therapy or chemotherapy, a gallium scan may help to find new or recurring tumors or to record regression of a treated tumor. Physicians can narrow causes of liver problems by noting abnormal gallium activity in the liver. Gallium scans also may be used to diagnose lung diseases or a disease called sarcoidosis, in the chest.

Gastrointestinal cancers

Definition

Gastrointestinal (GI) cancers include cancer of the esophagus, stomach, small intestine, colon, rectum, and anus as well as cancers of the liver, pancreas, gallbladder, and biliary system.

Description

The GI tract, or digestive tract, starts from the oral cavity (mouth) and proceeds to the esophagus, the stomach, the duodenum, the small intestine, the large intestine (colon and rectum), and the anus. It processes all the food consumed. Along the way through the tract, food is digested, nutrients and water are extracted, and waste is eliminated from the body in the form of stool and urine. Cancer can affect any of the gastrointestinal organs. The National Cancer Institute estimates that 25% of all cancers are gastrointestinal, with the majority of these occurring in the colon and rectum (colorectal cancers). The next sites most commonly affected by GI cancers are the pancreas, stomach, liver, and esophagus. A brief overview of GI cancers follows; the reader should refer to other specific encyclopedia entries shown in bold for more comprehensive information on these cancers and their treatment. The reader should also note that the overview below does not discuss oral cavity cancers. Those cancers are also discussed in individual entries.

Types of cancers

Esophageal cancer

The esophagus is a muscular, hollow tube that carries food from the oropharynx (area behind mouth and soft palate) to the stomach. It consists of several layers. **Esophageal cancer** usually develops in the inner layer cells and grows outward. There are two major types of esophageal cancer. The first occurs in the cells found in the lining of the esophagus (squamous cells), and the cancer is called squamous cell carcinoma. It can develop anywhere along the entire length of the esophagus and represents approximately half of all reported esophageal cancers. The second type of cancer known to occur in the esophagus is an adenocarcinoma, which is cancer of the glandular cells that line the inside of organs. Adenocarcinoma occurs near the stomach entrance and may be associated with a condition known as **Barrett's esophagus**. This is a disorder in which the lining of the esophagus undergoes cellular changes as a result of chronic irritation and inflammation resulting from a backwash of acidic stomach gastric juices. Esophageal **adenocarcinomas** cannot develop unless squamous cells have been transformed by the acid reflux of the stomach juices. The American Cancer Society (ACS) predicted the occurrence of approximately 12,300 new cases of esophageal cancer in 2000 which will result in some 12,100 deaths in the United States.

Stomach cancer

Stomach cancer is also called gastric cancer. The stomach is located in the upper abdomen under the ribs. It is the most expandable organ of the digestive system. Food reaches the stomach from the esophagus and is broken down by gastric juices secreted by the stomach. After leaving the stomach, partially broken down food passes into the small intestine and afterwards into the colon (first part of the large intestine). In cancer of the stomach, cancerous cells are found in the tissues of the stomach and this cancer can develop anywhere in the organ. It may grow along the stomach wall into other organs such as the esophagus or small intestine. Or it may go through the stomach wall and invade the nearby lymph nodes or organs such as the liver, pancreas, and colon. And it may also spread to more distant organs, such as the lungs, the lymph nodes located above the collar bone, and the ovaries. The major type of stomach cancer is adenocarcinoma (90%). Approximately 24,000 new cases of stomach cancer are diagnosed per year in the US. The number of cases, as well as the death rate, have declined significantly over the past several decades, but it is still the seventh leading cause of cancer deaths. A cure is possible if the cancer is found before spreading to other organs. Unfortunately, the early symptoms are not very noticeable, and by the time stomach cancer is diagnosed, it has in many cases already metastasized.

Liver cancer

The liver is one of the largest organs in the body. In normal adults, it weighs about three pounds and is located in the upper right side of the abdomen, under the right lung and rib cage. It plays a major role in

Gastrointestinal cancers

Cancer	Types
Esophageal cancer	Squamous cell carcinoma
	Adenocarcinoma
Stomach cancer	Adenocarcinoma
Liver cancer	Angiosarcoma
	Hepatoblastoma
	Cholangiocarcinoma
	Hepatocellular carcinoma (hepatoma)
Gallbladder cancer	Adenocarcinoma
	Squamous cell carcinoma
	Carcinosarcoma
	Small cell (oat cell) carcinoma
Pancreatic cancer	Adenocarcinoma
	Insulinoma
	Gastrinoma
	Glucagonoma
	Vipoma
	Somatostinoma
	Acinar cell carcinoma
	Cystic tumors
	Papillary tumors
	Pancreatoblastoma
Colorectal cancer	Adenocarcinoma
	Carcinoid tumors
	Gastroinstestinal stromal tumors
	Lymphomas
Anal cancer	Squamous cell carcinoma
	Basal cell carcinoma
	elanoma
	Adenocarcinoma

digestion, in the transformation of food into energy and in filtering and storing blood. It is also responsible for processing nutrients and drugs, producing bile, controlling the level of glucose (sugar) in the blood, detoxifying blood, and regulating blood clotting. In cancer of the liver, cancerous cells are found in the tissues of the liver. Primary liver cancer is cancer that starts in the liver. As such, it is different from cancer that starts somewhere else and spreads to the liver. Liver cancer is a rare form of GI cancer in the United States with only about 15,000 new cases diagnosed in 2000. Primary cancers of the liver and of the bile ducts are far more common in Africa and Asia than in America, where they only represent 1.5% of all cancer cases. The highest occurrence rate is in Vietnamese men (41.8 per 100,000), probably a result of the high incidence of viral hepatitis infections in their country. Asian-American groups also have higher liver cancer incidence rates than the Caucasian population. Liver cancer mortality rates calculated for populations for which statistics are available are highest in China.

There are four main types of liver cancer: angiosarcoma, a rare type of cancer that starts in the blood vessels of the liver; hepatoblastoma, another rare type of liver cancer occurring chiefly in young children; cholangiocarcinoma, which starts in the bile ducts and accounts for approximately 13% of liver cancers; and finally, hepatocellular carcinoma, also known as hepatoma. The most common liver cancer is hepatocellular carcinoma which accounts for approximately 84% of liver cancers. As is the case with stomach cancer, liver cancer is hard to diagnose early because there are seldom any clear-cut symptoms.

However, some diseases have been identified as liable to increase a person's risk of getting liver cancer. They include: hepatitis B, hepatitis C, cirrhosis of the liver, exposure to certain chemicals such as aflatoxin (a substance made by a fungus in tropical regions and that can infect wheat, peanuts, soybeans, corn, and rice), vinyl chloride, thorium dioxide, anabolic steroids, arsenic, and birth control pills (of a type no longer prescribed).

Gallbladder cancer

The gallbladder is a pear-shaped organ located just under the liver in the upper abdomen. Its role in digestion is to store and release the bile produced by the liver into the stomach to help break down fat. In **gallbladder cancer**, the cancer cells develop in the tissues of the gallbladder. Several types of cancer can occur, such as adenocarcinoma, squamous cell carcinoma, carcinosarcoma and small cell (oat cell) carcinoma, all of them uncommon. Approximately 6,000 to 7,000 new cases are diagnosed per year in the U. S., affecting women twice as often as men and occurring mostly in the elderly.

Pancreatic cancer

The pancreas is a tongue-shaped glandular organ lying below and behind the stomach. It consists of two areas, the exocrine and endocrine regions. The endocrine pancreas secretes the hormones insulin and glucagon, which regulate blood sugar. The exocrine pancreas secretes pancreatic juice into the small intestine. The juice contains enzymes that break down fats and proteins so that the body can use them. In pancreatic cancer, the cancer can develop either in the cells that secrete the pancreatic juice (exocrine pancreatic cancer) or in the cells that release the hormones (endocrine pancreatic cancer). Exocrine pancreatic cancer is much more common than endocrine. Several types can develop, the majority being various types of carcinomas. The American Cancer Society predicted that, in 2000, about 28,300 people in the U. S. will be diagnosed with this type of cancer and that approximately 28,200 will die of the disease. Pancreatic cancer is the fourth leading cause of cancer death in men and women. Because the pancreas is located deep inside the body, it cannot be felt during a routine physical exam, and no tests are presently available to allow early detection.

Colorectal cancers

The colon, the first part of the large intestine, extends from the end of the small intestine to the rectum. The colon has four major divisions. The first is called the ascending colon, it starts where the small intestine attaches and extends upward on the right side of the abdomen. The second part is the transverse colon and it extends across the body to the left side where it joins the third section, called the descending colon, which continues downward on the left side. The fourth part of the colon is the sigmoid colon, which joins the rectum. The rectum joins the anus, where stool passes out of the body.

Each of the divisions of the colon and rectum has several layers of tissue. Colorectal cancers usually start in the innermost layer and can grow through some or all of the other layers. Colorectal cancers are common, and occur more frequently in people over the age of 50. The ACS estimated that in 2001 in the U. S., about 46,000 new cases of **colon cancer** will be diagnosed in men, and about 52,000 cases in women. For rectal cancers, the ACS estimates that about 21,000 men and 16,000 women will be diagnosed in 2001. The number of new colorectal cancer cases and reported deaths have declined in recent years due to improved screening and diagnostic methods. Colorectal cancers are highly treatable when detected early, but the symptoms are often not obvious in early stages.

Over 95% of colorectal cancers are adenocarcinomas. Other, less common types of colorectal cancers are: carcinoid tumors, which develop from the hormone-producing cells of the intestine, gastrointestinal stromal tumors, which start in the connective tissue and muscle layers located in the wall of the colon and rectum, and lymphomas, which are cancers of the immune system cells that usually occur in the lymph nodes but may also start in the colon.

Anal cancer

The anus has several types of tissues. Each type of tissue also contains several types of cells and cancer can develop in each of these kinds of tissues. Approximately half are squamous cell carcinomas. This type of cancer is found in the surface cells that line the anus and most of the anal canal. Another 15% of anal cancers consist of adenocarcinomas and usually start in glands found in the anus area. The remaining anal cancers are accounted for by basal cell carcinomas and malignant melanomas. **Anal cancer** is usually diagnosed in people over 50. People who have the human papillomavirus (HPV) also have a greater chance of developing anal cancer as well as men who practice anal sex. How treatable the cancer is depends partly on where it starts.

KEY TERMS

Abdomen—A part of the body which lies between the thorax and the pelvis. It contains a cavity (abdominal cavity) which holds organs such as the pancreas, stomach, intestines, liver, gallbladder. It is enclosed by the abdominal muscles and the vertebral column (backbone).

Bile—A greenish-yellow fluid produced by the liver and stored in the gallbladder.

Bile ducts—Passages external to the liver for the transport of bile.

Digestion—The conversion of food in the stomach and in the intestines into substances capable of being absorbed by the blood.

Digestive system—Organs and paths responsible for processing food in the body. These are the mouth, the esophagus, the stomach, the liver, the gallbladder, the pancreas, the small intestine, the colon, and the rectum.

Gastric juice—An acidic secretion of the stomach that breaks down the proteins contained in the ingested food, prior to digestion.

Gland—An organ that produces and releases substances for use in the body, such as fluids or hormones.

Lymph nodes—Small, bean-shaped organs surrounded by a capsule of connective tissue. Also called lymph glands. Lymph nodes are spread out along lymphatic vessels and store special cells (lymphocytes), which filter the lymphatic fluid (lymph).

Lymphatic system—The tissues and organs that produce, store, and carry white blood cells that fight infection. It includes the bone marrow, spleen, thymus, and lymph nodes as well as a network of thin vessels (lymphatic vessels) that carry lymph and white blood cells into all the tissues of the body.

Metastasis—The transfer of cancer from one location or organ to another one not directly related to it.

Ovary—One of two small oval-shaped organs located on either side of the uterus. They are female reproductive glands in which the ova (eggs) are formed.

Small intestine—The part of the digestive tract located between the stomach and the large intestine.

Squamous cells—Flat, thin cells, such as found on the outer layer of the skin.

Stage—The extent to which a cancer has spread from its original site to other parts of the body. A Stage 1 cancer is less advanced than a Stage 4 cancer.

Gastrointestinal complications

Description

Constipation, fecal impaction, bowel obstruction, and **diarrhea** are common gastrointestinal complications faced by cancer patients due to either their cancer or the treatment of it. The seriousness of these complications varies from mildly uncomfortable to life threatening.

Constipation is the slow and infrequent passage of small, dry bowel movements through the large intestine. Unpleasant and sometimes painful, constipation often causes people to strain while trying to have a bowel movement. However, constipation itself is generally not life threatening; however, fecal impaction can be.

Fecal impaction is the collection of hard, dry stool in the colon or rectum that can't be excreted. Patients with fecal impaction may or may not experience the typical gastrointestinal symptoms usually associated with constipation, such as cramping and pressure. For example, if the impaction is pressing on a nerve, there may be back pain. If the impaction is pressing on the urethra or bladder, there may be an increase or decrease in urination. There may be nausea and abdominal pain, as well as stool that leaks out when the patient coughs and explosive diarrhea, which is the result of stool moving around the impaction. When movement of the diaphragm is restricted due to abdominal distention (swelling of the abdomen), the patient may not be getting enough oxygen. Breathing, heart, and circulation problems may develop, such as dizziness, hypotension (low blood pressure), hypoxia (a lack of oxygen to the brain), and angina. If left untreated, fecal impaction can cause death.

Bowel obstruction, as defined by the National Cancer Institute, is "a partial or complete blockage of the small or large intestine by a process other than fecal impaction. Classified by type, cause, and location, bowel obstructions can be caused by tumors inside or outside of the bowel, as well as the development of scar tissue after surgery. Patients with colostomies have an increased risk of becoming constipated. Therefore, they need to be especially proactive and report any signs of constipation to their physicians in order to avoid developing bowel obstruction.

Diarrhea is loose, watery stool, which results in abdominal cramps and frequent trips to the bathroom. For cancer patients, diarrhea tends to be especially bothersome. It can affect their eating patterns, as well as cause them to become dehydrated and lose weight. Although it can usually be managed, it sometimes leads to life threatening problems.

Causes

Constipation and fecal impaction

Constipation can have many causes. It can be a symptom of cancer or the result of a growing tumor. It can be linked to certain cancer treatments as well. Sometimes the medications given to cancer patients, such as **opioids** for pain, diuretics, or **chemotherapy** drugs, can cause

constipation. Medications prescribed for anxiety and **depression**, not to mention the depression itself, can be the culprits, too. Patients may find it difficult or painful to move and may put off going to the bathroom. Physical illness, exacerbated by depression, can also alter eating habits, resulting in dietary changes that aren't healthy, such as drinking too little water or not eating enough. In addition, certain muscle and nerve damage, such as **spinal cord compression** from a tumor, can lead to a loss of muscle tone in the bowel, making it difficult for a patient to complete a bowel movement. Environmental factors can worsen constipation. For example, patients who are in unfamiliar surroundings, or need assistance getting to the bathroom, or use a bedpan may have difficulty relaxing and this may affect their ability to defecate. Treating cancer patients with dignity and allowing them as much privacy as possible can be very helpful in these situations.

The National Cancer Institute has identified five major factors that can lead to fecal impaction:

- Opioid pain medications
- Inactivity over a long period of time
- Changes in diet
- Mental illness
- Long-term use of **laxatives**

Oddly enough, using laxatives over a long period of time actually contributes to the development of constipation and fecal impaction, because the higher doses necessary to do the job "make the colon less able to signal the need to have a bowel movement," according to the National Cancer Institute. It may be difficult for cancer patients to avoid repeated bouts of constipation during their cancer treatment, especially if they are taking opioids for pain. However, patients should talk with their physicians about the specific preventative measures that would be the most suitable for them. Every effort should be made to avoid fecal impaction.

Bowel obstruction

According to the National Cancer Institute, "a bowel obstruction may be caused by a narrowing of the intestine from inflammation or damage of the bowel, tumors, scar tissue, hernias, twisting of the bowel, or pressure on the bowel from outside the intestinal tract." Most bowel obstructions, usually due to scar tissue and hernias, occur in the small intestine. Tumors, volvulus (twisting of the bowel), or diverticulitis account for most of the bowel obstructions in the large intestine. Cancers of the colon, stomach, and ovary are the ones that most frequently cause bowel obstructions. When lung and breast cancers spread to the abdomen, they too can cause bowel obstructions. Ripamonti and colleagues reported in the *Annals of Oncology* in 1993 that having abdominal surgery or abdominal radiation puts patients at a greater risk of developing a bowel obstruction.

Diarrhea

Most often when cancer patients have diarrhea, the cause is related to their cancer therapy (i.e., chemotherapy drugs, especially fluoropyrimidines or **irinotecan**, **radiation therapy**, or surgery). Intestinal surgery, for example, can cause diarrhea by negatively affecting the way the bowel functions. Chemotherapy drugs, which can alter the way food is broken down and absorbed in the small intestine, can cause indigestion and diarrhea. According to Tuchmann and Engelkind, the stress and anxiety associated with cancer diagnosis and treatment can also cause diarrhea. Unfortunately, antibiotic therapy to treat infection, as the National Cancer Institute points out, "can cause inflammation of the lining of the bowel, resulting in diarrhea that often does not respond to treatment." In other cases, the cause can be directly tied to the patient's diet or use of laxatives. Severe diarrhea may result from concurrent chemotherapy and radiation therapy.

Treatments

Constipation and fecal impaction

A physician can diagnosis the causes of constipation by performing a physical examination and reviewing a patient's medical history. The patient's stool can be tested for the presence of blood, which is done by asking the patient to provide a sample. In some cases, the physician might suspect that constipation has progressed to fecal impaction. In that case, an examination might include x-rays of the abdomen or chest, blood tests, and an electrocardiogram, which is a painless test that shows the activity of the heart. Another way to check for fecal impaction is to perform a rectal examination, which involves the physician inserting a lubricated, gloved finger into the rectum. If there is an impaction, there may be some discomfort; however, in general, the worst part of this examination is the embarrassment some people might feel.

A **colonoscopy** might be scheduled to see if cancer is present or to simply rule it out. A colonoscopy takes about thirty minutes to complete and is performed in a clinic or hospital setting. It is relatively painless, because patients are given a sedative and/or pain medicine. By inserting a flexible lighted tube into the patient's anus, the physician is able to see the entire large intestine all the way to the lower end of the small intestine.

Treatments options for patients with constipation may include a combination of preventative measures.

Patients will probably be advised to keep track of their bowel movements in a journal. If they are too ill to do so, their caregivers may be asked to perform the task on their behalf. When the patient is trying to defecate, caregivers should be careful to respect their privacy, allowing them enough time and space to encourage success. Some patients find it helpful to run water in the sink or tub; the sound relaxes them and creates a sound barrier. If it is not contraindicated, patients may be advised to add fiber to their diets. Patients may be referred to nutritionists who are familiar with addressing the needs of cancer patients and can create individualized meal plans based on a patient's medical profile.

Adequate fluid intake is critical for patients prone to developing constipation, as well as fecal impaction. Patients may be asked to reduce their use of laxatives. In addition, patients should seek the approval of their physicians before they take any over-the-counter medications. According to the National Institute of Cancer, "impactions are usually treated by moistening and softening the stool with an enema." However, a physician needs to be consulted before an enema is given, because too many enemas can damage the bowel. Nonstimulating bowel softeners may be needed. In some cases, it may be necessary for the fecal material to be manually removed by a physician, although it is understandable that many patients may dislike the thought of it.

Bowel obstruction

To make a diagnosis of bowel obstruction, the physician will need to perform a physical exam to determine if the patient has abdominal pain, gas, or stool in the bowel. The physician will most likely want to draw blood in order to check for infection and body chemistry imbalances. If an obstruction is diagnosed, a **barium enema** may need to be performed to ascertain its location.

Bowel obstruction can be classified into two categories: acute (short term) and chronic (long term). Patients with acute bowel obstruction must be monitored carefully. If their condition cannot be stabilized, it may necessary to insert a lubricated nasogastric tube through the patient's nose and esophagus until it reaches the stomach. Many patients find this procedure initially unpleasant, which is understandable. It is a brief procedure, but it causes many patients to gag and, in some cases, vomit. Some patients may respond better to a tube inserted in their rectum to relieve the pressure. The purpose of inserting the tube is to reduce the patient's swelling, gas, and excess fluid; however, surgery may be unavoidable, if the obstruction worsens and completely blocks the bowel. The insertion of a stent may be required in patients with advanced cancer, if the obstruction cannot be removed through surgical means.

A chronically ill patient may need to have a gastrostomy tube (or feeding tube) inserted through the wall of the abdomen into the stomach. This is done to help the patient eat and to alleviate painful symptoms. A gastroenterologist performs the procedure while the patient is under general anesthesia; therefore, it is completely painless. The tube may need to be temporary or permanent, depending on the patient's condition.

Diarrhea

Many factors can play a part in causing diarrhea, making its treatment challenging. Because severe diarrhea can be very upsetting and even life threatening, physicians will try to establish the cause of the problem as quickly as possible. Patients can expect to be asked a series of questions and to be physically examined. Their vital signs, such as blood pressure and pulse, will be taken and compared to previous readings. The patient may need to provide a stool sample so that it can be tested for the presence of blood or bacteria.

Dietary changes are likely to be suggested. The patient may be given a list of foods to avoid and a list of foods that are acceptable in small quantities. Patients with severe diarrhea may need to monitored closely by their caretakers or admitted to the hospital where intravenous fluids will be administered.

Alternative and complementary therapies

RELAXATION THERAPY Some patients find that relaxation therapy helps them cope with the anxiety associated with cancer treatments and their side effects. A well-established psychogenic modality, relaxation therapy has been said to help cancer patients alleviate pain. When patients are in pain, they tend to tense up. This increases the pain, which causes even more stress. Learning relaxation techniques can help reverse this negative cycle. For example, some patients have found that by utilizing progressive muscle relaxation techniques, they are better able to handle physical and emotional pain, such as constipation and anxiety.

COMFORT MEASURES Utilizing comfort measures to help patients heal is grounded in the belief that a patient should be seen as a whole person, not just someone with a disease and symptoms. Those who practice Eastern medicine have traditionally embraced this holistic approach, which considers the patient's mind, body, and spirit. Indeed, many Eastern philosophies have begun to greatly influence Western society. Some physicians have begun to change their personal philosophies to incorporate holistic concepts in their therapeutic handling of pain. For example, some cancer patients suffer not only from

KEY TERMS

Angina—Angina is chest pain that occurs when the heart muscle doesn't get enough blood.

Diverticulitis—Diverticulitis is inflammation of an abnormal pouch (diverticulum) in the intestinal wall.

physical pain, but they also feel anxious and show signs of depression. In an article published by the *New England Journal of Medicine*, Dr. Campion promotes comfort measures as a way to help alleviate depression, recognizing that a person's state of mind affects his or her physical health. Comfort measures that embrace dignity, such as showing the patient kindness and respect, go a long way to promote healing. Patients with diarrhea, for example, can benefit from comfort measures that include a bedside commode, frequently changed sheets, and adjustable beds.

ACUPUNCTURE Over 10,000 acupuncture and Oriental medicine practitioners currently practice in the United States. In a 1997 consensus statement issued by the National Institutes of Health, acupuncture was recognized as being an effective treatment for pain and nausea. It has also been used successfully to treat bowel obstructions. Developed by the Chinese as far back as 3000 B.C., acupuncture is thought to correct an imbalance of energy flow in the body. The technique involves inserting fine, sterile needles into a person's energy points, sometimes referred to as meridians. Some people fear acupuncture because they think the procedure will be painful, but in actuality it is not painful and tends to relax many people. Some people even fall asleep during the procedure.

Not everyone agrees on how acupuncture works, but research has shown that acupuncture increases the body's electromagnetic flow, which could cause the release of endorphins, the body's natural painkillers. Acupuncture is performed in a clinical setting. Patients interested in receiving acupuncture treatments should talk with their doctors to obtain suitable referrals to reputable, well-trained medical practitioners.

Gefitinib

Definition

Gefitinib, which is also known as Iressa, is an anticancer drug used to inhibit the growth of lung cancer cells and reduce the size of a cancerous tumor.

Purpose

Gefitinib is used as a single agent for the treatment of advanced **non-small cell lung cancer** that has advanced or failed to respond to other kinds of treatment. It is not suitable for use as an initial treatment, but may help to shrink tumors by as much as 10% when used as a third-line therapy in patients with advanced non-small lung cancer.

Description

In May 2003, gefitinib was approved for use in the United States under the U.S. Food and Drug Administration's (FDA) accelerated approval program. Generally speaking, before the FDA approves a drug for use, a great deal of data regarding the safety, efficacy, and quality of the drug is usually compiled. In fact, it is typical for the FDA to review thousands of pages of data about a medicine under consideration for approval. One of the reasons for this is the FDA's extremely strict approval process, an approval process that is, in fact,

among the strictest in the world. FDA approval means that the regulators have decided that the new drug's potential benefits outweigh its risks. When a drug is approved under the accelerated program it is done so because, as Mark B. McClellan, M.D. and FDA Commissioner states, the "FDA believes it is critical for patients to have many safe and effective treatment options available to them in their battles against disease."

In a 2004 article published in the *Pfizer Journal* entitled, "Enhancing Pharmaceutical Safety," Dr. Stephanie Crawford, a member of the FDA's Drug Safety and Risk Management Advisory Committee, said the following: "Approval of a drug as safe is not a blanket statement that it is without risk. It means that the risk is acceptable." Drawing on information provided by the FDA, it was further stated in the article that "the decision to approval a medicine involves consideration of the disease: a product to treat a life threatening condition may be approved even if it presents more of a certain risk, because its potential benefits are so great." In other words, the approval of a valuable cancer drug associated with an adverse side effect might be seen as more acceptable than the approval of an allergy medicine with the same side effect. As was further stated in the article, "The value of the medicine has to be seen in the context of its benefits, its known adverse effects, the severity and reversibility of these effects, and the availability of other medications for that person."

As the FDA cautiously stated in 2003, "The mechanism by which Iressa [gefitinib] exerts its clinical benefit is not fully understood. However, Iressa was developed to block growth stimulatory signals in cancer cells. These signals are mediated in part by enzymes called tyrosine kinases. Iressa blocks several of these tyrosine kinases, including the one associated with the Epidermal Growth Factor Receptor (EGFR)." Research has shown that the EGFR is sometimes found in abundance on the surface of cancer cells, causing them to divide excessively. Therefore, by blocking EGFR, it is thought that tumor growth can be thwarted.

However, gefitinib was approved by the FDA, as all drugs approved under the accelerated program, with the condition that further studies would be conducted to measure the drug's clinical benefit. According to the FDA, the drug's sponsor would be required to conduct three studies. One would evaluate gefitinib as a third-line therapy drug and evaluate if it prolonged survival as compared to the best supportive care available. Another study would compare gefitinib to **docetaxel**, which is another approved **chemotherapy** drug. And the third trial would analysis whether gefitinib is effective in reducing cancer symptoms in patients with lung cancer that are resistant to all available chemotherapy treatments. As Dr. McClellan indicated, "the studies are needed to confirm the clinical benefit, understand better which patients benefit, and evaluate long-term safety."

However, on March 4, 2005, Public Citizen in a letter to the FDA petitioned for gefitinib's removal from the market, stating that the study conducted to prove gefitinib's efficacy had failed and that the drug had already been removed from the market in Europe. Furthermore, the use of the drug has been tied to deaths in Japan. Therefore, it is possible that before long the FDA will reclassify gefitinib as an experimental drug.

Recommended dosage

Gefitinib is available in 250 mg tablets. Dosage levels may vary, depending on the needs of the patient. However, patients generally take one 250 mg tablet a day. The tablets should not be crushed or broken and the patient should be certain to drink plenty of fluids throughout the day.

Precautions

Women who are pregnant or may become pregnant should not use gefitinib. Patients receiving gefitinib should not breast-feed their babies during the treatment cycle and for a substantial time after the treatment.

Side effects

This drug has been associated with high toxicity in Japan. There have been reports indicating that using gefitinib caused severe side effects, such as inflammation of the lungs (interstitial **pneumonia**) and difficulty in breathing. Therefore, patients should report any side effects, whether they seem severe or not, to their physician. The most common side effects associated with taking 250 mg a day were:

- skin rash
- diarrhea
- acne
- dry skin
- nausea and vomiting

As reported in *Applied Therapeutics: The Clinical Use of Drugs* the most common side effects were skin related, which went away after the drug was discontinued. The symptoms were managed through the use of steroid creams, antihistamines, or topical or systemic **antibiotics**.

KEY TERM

Public Citizen—Public Citizen defines itself as " a national, nonprofit consumer advocacy organization founded in 1971 to represent consumer interests in Congress, the executive branch and the courts."

Interactions

Gefitinib increases the effect of metoprolol and may increase the risk of bleeding in patients taking **warfarin**. The following drugs may decrease gefitinib's effectiveness:

- cimetidine
- phenytoin
- rifampin
- ranitidine
- sodium bicarbonate

Gemcitabine

Definition

Gemcitabine is a drug that is used to treat advanced stages of pancreatic, lung, and other cancers. Its brand name is Gemzar.

Purpose

Gemcitabine is used to treat pancreatic cancer, particularly when it has metastasized, or spread to other parts of the body (Stage IVB). In combination with the drug **cisplatin**, gemcitabine is the first-line treatment for inoperable, metastasized non-small cell lung cancer. Sometimes it is used to treat cancers of the bladder or breast, or epithelial **ovarian cancer**.

Description

Gemcitabine is a relatively new anticancer drug. It is a type of medicine called a pyrimidine antimetabolite because it interferes with the metabolism and growth of cells. It does this by replacing the pyrimidine deoxycytidine in DNA, thereby preventing the DNA from being manufactured or repaired. As a result, cells cannot reproduce and eventually die.

Gemcitabine was approved by the U.S. Food and Drug Administration (FDA) to treat pancreatic cancer in 1998 and non-small cell lung cancer in 2002. Gemzar may relieve pain and other symptoms of advanced pancreatic cancer and increase survival time by several weeks to two months. Clinical studies of pancreatic cancer are comparing the effectiveness of combination treatments using gemcitabine with fluorouracil (5-FU), cisplatin, streptozocin, or **radiation therapy**. Gemcitabine has activity against metastatic **bladder cancer** and recurrent ovarian cancer, and further **clinical trials** are underway. Gemcitabine is being evaluated for its effectiveness in the treatment of uterine, stomach, laryngeal and hypopharyngeal, and colon and rectal cancers.

Recommended dosage

Gemcitabine is administered by injection over a period of 30 minutes. The dosage and number of administrations depend on a variety of factors, including the type of cancer, body size, the patient's sex, and other concurrent treatments.

Precautions

Gemcitabine may temporarily reduce the number of white blood cells, particularly during the first 10–14 days after administration. A low white blood cell count

reduces the body's ability to fight infection. Thus, it is very important to avoid exposure to infections and to receive prompt medical treatment. Immunizations (vaccinations) should be avoided during or after treatment with gemcitabine. It also is important to avoid contact with individuals who have recently taken an oral polio vaccine. Treatment with gemcitabine may cause chicken pox or shingles (**herpes zoster**) to become very severe and spread to other parts of the body.

Gemcitabine also may lower the blood platelet count. Platelets are necessary for normal blood clotting. The risk of bleeding may be reduced by using caution when cleaning teeth, avoiding dental work, and avoiding cuts, bruises, or other injuries.

Gemcitabine can cause birth defects and fetal death in animals. Therefore, this drug should not be taken by pregnant women or by either the man or woman at the time of conception. Women usually are advised against breast-feeding while taking this drug.

Side effects

Gemcitabine affects normal cells as well as cancer cells, resulting in various side effects. The most common side effects are related to reduction in red and white blood cells and blood platelets. These side effects may include symptoms of infection or unusual bleeding or bruising. Older patients are more likely to suffer from low blood cell counts after treatment.

Flu-like symptoms are common following the first treatment with gemcitabine. Other common side effects of gemcitabine may include:

- nausea
- vomiting
- chills and fever
- constipation
- diarrhea
- loss of appetite (anorexia)
- headache
- muscle pain
- weakness or fatigue
- shortness of breath
- blood in urine or stools
- skin rash
- swelling of the hands, feet, legs, or face
- insomnia

Less common side effects of gemcitabine may include:

KEY TERMS

Deoxycytidine—Component of DNA, the genetic material of a cell, that is similar in structure to gemcitabine.

Metastasis—Spread of cancer from its point of origin to other parts of the body.

Platelet—Blood component that aids in clotting.

Pyrimidine—Class of molecules that includes gemcitabine and deoxycytidine.

Vasculitis—Inflammation of a blood or lymph vessel.

- cough or hoarseness
- lower back or side pain
- painful or difficult urination
- chest, arm, or back pain
- difficulty with speech
- fast or irregular heartbeat
- high blood pressure
- pain or redness at the site of injection
- numbness or tingling in hands or feet
- sores or white spots on lips and in mouth
- hair loss (alopecia)
- **itching**

Some of these side effects may occur or continue after treatment with gemcitabine has ended. Itching, hives, swelling, or a skin rash, particularly if accompanied by breathing problems, may indicate an allergic reaction to gemcitabine. Some researchers have coined the term gemcitabine-induced severe pulmonary toxicity, or GISPT, to describe an inflammatory reaction in the lungs following treatment with gemcitabine. The incidence of GISPT is estimated to range between 0.5% and 5% of patients receiving the drug.

Additional side effects of gemcitabine may be symptoms associated with liver or kidney malfunction. Furthermore, kidney or liver disease may cause gemcitabine to be removed from the body at a slower rate, thus increasing the effects of the drug.

Another potentially fatal side effect of gemcitabine is vasculitis, or inflammation of blood or lymph vessels. A group of physicians in Iowa reported on two cases of women who died of necrotizing enterocolitis resulting from vasculitis associated with gemcitabine treatment for ovarian

cancer. A case of vasculitis in a male patient treated with gemcitabine for bladder cancer was reported in Turkey.

Interactions

Previous treatment with radiation or other anti-cancer drugs can increase the risk of very low blood counts with gemcitabine. Serious problems may develop in areas previously treated with radiation.

Drugs that may interact with gemcitabine, or that may increase the risk of infections while being treated with gemcitabine, include live **vaccines** and **warfarin**. Because some other medications have a tendency to interact with gemcitabine, patients should alert their doctor to any drugs they are taking.

It is also important not to take any medicines containing aspirin during treatment with gemcitabine, since aspirin can increase the chances of excessive bleeding.

Gemtuzumab

Definition

Gemtuzumab ozogamicin is a humanized monoclonal antibody produced by recombinant DNA technology that binds specifically to CD33, a protein that is found on the cell surface of most leukemic blasts, the abnormal, cancerous cells in acute myeloid leukemia (also known as **acute myelocytic leukemia**, or AML). It is marketed in the United States under the brand name Mylotarg.

Purpose

Gemtuzumab is a monoclonal antibody used to treat AML that is characterized by expression of the CD33 protein on the cancerous cells, called leukemic blasts. The CD33 protein is found on the surface of the leukemic blasts of about 80% of AML patients. After the gemtuzumab antibody is produced in the laboratory, a chemical reaction is used to link it to an antitumor drug called calicheamicin. About half of the antibody succeeds in acquiring the antitumor drug.

When the antibody-calicheamicin molecule binds to the cancerous cells, both the antibody and the drug are taken into the cell. There the drug binds to the cell's genetic material (deoxyribose nucleic acid or DNA) inducing breaks in the molecule and killing it. Because the antibody carries and delivers the toxic drug to the leukemic blasts targets, gemtuzumab treatment is called antibody-targeted **chemotherapy**.

Gemtuzumab can also be used to induce remission (remove cancerous cells) in AML patients to prepare them for stem-cell transplantation. It is indicated for refractory AML (AML that does not readily yield to treatment). The use of antibody-targeted chemotherapy has been shown to have fewer side effects than traditional chemotherapy courses and does improve the disease-free survival time after transplantation.

Description

Gemtuzumab is a genetically engineered monoclonal antibody linked to an antitumor antibiotic. It was approved by the FDA in 2000 as a method of treating relapsed AML in older patients (over 60 years of age) that are not candidates for other cytotoxic chemotherapy. About 75% of all patients with AML experience a relapse after initial treatment. In **clinical trials** focusing on the treatment of older patients with relapsed AML, gemtuzumab had an overall response rate of 30%, with 16% having a complete response.

Most of the gemtuzumab sequence is derived from human sequences, while about 2% are from mice. The

human sequences were derived from the constant domains of human IgG4 (called "constant" because it is essentially the same for all IgG antibodies) and the variable framework regions of a human antibody. These areas do not bind to the CD33 protein. Using human sequences in this part of the antibody helps to reduce patient **immune response** to the antibody itself and is called humanization. The actual binding site of gemtuzumab to the CD33 protein is from a mouse anti-CD33 antibody. The antibiotic antitumor drug calcheamicin is linked to the antibody in a way that does not interfere with the ability of the antibody to bind CD33.

Gemtuzumab is not currently approved for use in combination with other chemotherapy drugs or treatments. However, clinical trials that combine the drug with **cytarabine**, **fludarabine**, total-body irradiation, as well as other cancer treatments, are ongoing.

Recommended dosage

Gemtuzumab is administered intravenously. In the pivotal clinical trial, the drug was given at a dose of 9 mg/m^2 for two doses that were fourteen days apart.

Precautions

Extreme caution should be used when using gemtuzumab to treat patients with existent liver problems. Animal studies showed that the drug can cause significant harm to the development of a fetus, so it is likely the drug should not be used during pregnancy, and women of childbearing age should avoid pregnancy while on the drug. Because of the adverse effects of calicheamicin on DNA, the drug greatly reduced fertility in animal studies for males, but not females.

Side effects

A severe side effect of gemtuzumab treatment is a depletion of various types of cells in the bone marrow, including those that make white and red blood cells, a condition known as myelosuppression. Because CD33 is expressed on a patient's normal bone marrow cells, as well as on the surface of the abnormal leukemic blasts, the treatment eliminates both normal and cancerous cells. This results in severe reduction of the circulating blood cells normally produced by the bone marrow, including red blood cells (**anemia**), white blood cells (**neutropenia**), and clotting cells (thrombocytopenia). These conditions are treated with blood transfusions. However, the population of all these cells will rebound after clearance of gemtuzumab because the precursor to cells of the bone marrow, called pluripotent hematopoietic stem cells, do not express CD33 and will restore the various cell populations.

Gemtuzumab can produce a postinfusion symptom complex of **fever** and chills, and less commonly, low blood pressure and labored breathing during the first 24 hours after administration. Some patients developed severe liver function abnormalities, which were generally transient and reversible. The most common side effects were fever, chills, nausea, vomiting, thrombocytopenia, neutropenia, asthenia (loss of strength or energy), **diarrhea**, abdominal pain, headache, and **stomatitis** (inflammation of the lining of the mouth).

KEY TERMS

Antibody—A protective protein made by the immune system in response to an antigen, also called an immunoglobulin.

Blasts—A type of immature cell that lacks some of the outward characteristics of the mature cell. In AML, the cancerous cells are leukemic blasts.

Calicheamicin—An anti-tumor drug that binds to DNA within the tumor cells, causing breaks in the strands and killing the cell.

IgG—Immunoglobulin type gamma, the most common type found in the blood and tissue fluids.

Humanization—Fusing the constant and variable framework region of one or more human immunoglobulins with the binding region of an animal immunoglobulin, done to reduce human reaction against the fusion antibody.

Monoclonal—Genetically engineered antibodies specific for one antigen.

Myelosuppression—Reduction in the number of the cells of the bone marrow, which leads to reduction of many other circulating blood cells that are produced by the marrow.

Interactions

There have been no formal drug interaction studies done for gemtuzumab.

See also Monoclonal antibodies.

Genetics of cancer *see* **Cancer genetics**

Genetic testing

Definition

Genetic testing is a process which involves examining individuals' genetic material for the presence of a change that indicates why they may have developed a disease or disorder. Genetic testing may also tell patients if they are at increased risk for developing a disease such as cancer in the future, but currently do not have any symptoms of that particular disease.

Description

Genetic testing is usually done by taking a sample of a person's blood. The changes in the genetic material that can be detected by this testing vary in size. Sometimes parts or even entire chromosomes may be altered or missing completely. Other times, a mutation is present on a gene that causes it to malfunction. One type of mutation is known as a hereditary mutation. Hereditary mutations may also be called germline mutations because they are found in all the cells of a person's body, including the reproductive or germ cells, the sperm for a male and the egg for a female. This is why hereditary mutations can be inherited, or passed from a parent to a child. Genetic testing often looks for the presence or absence of these types of mutations in genes.

Genes and cancer

Cancer is defined as one cell that grows out of control and subsequently invades nearby cells and tissue. There are several steps involved in the process that causes a normal cell to become malignant (cancerous). It is believed that different genes play a role in this specialized process. Oncogenes typically promote or encourage cell growth. However, if they are overexpressed or mutated, they may cause cancer to arise. Tumor-suppressor genes, when working properly, prevent cells from growing too quickly or out of control. They are often compared to brakes in a car. If these genes cannot perform their function because of the presence of a mutation, cells may grow out of control and become cancerous. Finally, cancer may also be caused by faulty DNA repair genes. These genes usually correct the common mistakes that are made by the body as the DNA copies itself, a normally occurring process. However, if these genes can't correct mistakes, the mistakes may accumulate and lead to cancer.

It is very important to remember that while all cancer is genetic, or caused by changes in genes, just a small amount of cancer is hereditary, or passed from parent to child. It is thought that only about 5-10% of cancer falls into this category. Therefore, the majority of cancer is not hereditary. Most cancer is due to other causes, such as environmental exposures. Usually it is very difficult to determine the exact cause of cancer that is not known to be the result of an altered gene.

Identifying at-risk individuals and families for hereditary cancer

Although scientists have identified genetic tests for common cancers, like breast and **colon cancer**, genetic testing is not an option that should be offered to all people with cancer, or even to those who may have cancer in their family. This is primarily due to the fact that most cancer does not run in families. Therefore, genetic testing will not be helpful for many people. In order to determine those who may benefit from undergoing genetic testing for cancer, health care providers need to be aware of certain aspects of an individual's personal and family history of cancer.

A person who is thinking about having a genetic test for cancer often meets with a genetic counselor, a specially trained health care provider. When a patient meets with a genetic counselor, the counselor will ask the patient about their personal and family history of cancer. The counselor will also draw a very detailed family tree, also known as a pedigree. The counselor will then examine the family tree to determine if there are certain ''clues'' that the cancer may be hereditary.

The clues that may be observed in a family tree are listed below, with **breast cancer** used as an example.

- Multiple relatives in more than one generation with the same type of cancer, or related cancers. For example, a grandmother, mother and daughter with breast cancer. Or, relatives with both breast and **ovarian cancer**.
- Cancer occurring in the family at younger ages than is typically observed in the general population. For example, breast cancer usually occurs in women as they get older, most commonly in their 60's to 70's. However, in families that may have an alteration in a gene increasing their risk for developing breast cancer, the disease may occur in women at much younger ages.
- Cancer that occurs in paired organs. For example, breast cancer that occurs in both of a woman's breasts. This is also called bilateral breast cancer.
- Development of more than one type of related cancer in the same person within a family. For example, a female relative with both breast and ovarian cancer diagnosed at young ages.
- Specific ethnic background. Mutations in certain cancer susceptibility genes may be more likely to occur in

individuals of specific ethnic backgrounds. For this reason, it is very important that a complete family tree includes the country where a person's relatives originally lived.

If a genetic counselor or other health care provider observes one or more of the above features in an individual's family tree, he or she may talk about the option of genetic testing with the patient. In the case of cancer genetic testing, it is only offered to a patient if there are options available to screen for the certain cancer and detect it early, or to possibly prevent it from occurring at all.

The process of genetic testing

The process of genetic testing for genes that may increase risk for cancer is different from other medical tests. Genes involved in cancer are called cancer susceptibility genes. If a mutation is identified in one of these genes, it does not reveal that a person has cancer, but rather whether an individual has an increased risk to develop cancer in the future. In addition, if the person undergoing genetic testing has already had cancer, genetic testing may tell them whether they are at increased risk for developing cancer again. However, the risk for developing cancer is not 100%. The likelihood that a person will develop cancer if they carry an altered gene is called penetrance. Penetrance may differ even among relatives in the same family, and the reasons are not well understood. For example, a mother with a mutation in a cancer susceptibility gene may never develop cancer, but may pass this mutation on to her daughter, who is then diagnosed with cancer at a young age.

For a family in which an inherited mutation has not been previously identified, it is best to begin genetic testing by obtaining a blood sample from a person who has had cancer at a young age. From this blood sample, scientists will be able to extract some DNA. There are a number of different ways that they can then look at the DNA to determine if a mutation is present. The most common is known as sequencing, whereby the chemical sequence of a patient's DNA is compared to DNA that is known to be normal. Scientists will look for any differences, such as missing or extra pieces of DNA in the patient's gene.

Testing can be very expensive and it may take several weeks or months to obtain results. Also, insurance companies will sometimes not cover the cost of testing. Some families are able to participate in research studies where genetic counseling and testing is offered at a lower cost or free of charge.

Categories of results

A positive result indicates the presence of a genetic mutation that is known to be associated with an increased risk for developing cancer. Once this kind of mutation has been found in an individual, it is possible to test this person's relatives, like their children, for the presence or absence of that particular mutation. This testing can be done in a relatively short period of time and provides results that are clearly positive or negative for a particular mutation.

If a relative in a family is tested for a mutation in a cancer susceptibility gene that was previously identified in their family, and they are not found to have this mutation, this type of test result is called a true negative. This means that they did not inherit the mutation in the gene that is the reason why their relative(s)developed cancer. If a person receives a true negative test result, their risk for developing cancer is generally considered to be reduced to that of someone in the general population. Also, because they did not inherit the mutation, they cannot pass it down to any of their children. The term true negative is used to distinguish this test result from a negative or indeterminate result, which is described below.

If the first person tested within a family is not found to have an alteration in a cancer susceptibility gene, this result is negative. However, this result is often called indeterminate. This is because a negative test result cannot completely rule out the possibility of hereditary cancer still being present within a family. The interpretation of this type of result can be very complex. For example, a negative result may mean that the method used to detect mutations may not be sensitive enough to identify all mutations in the gene, or perhaps the mutation is in a part of the gene that is difficult to analyze. It may also mean that a person has a mutation in another cancer susceptibility gene that has not yet been discovered or is very rare. Finally, a negative result could mean that the person tested does not have an increased risk for developing cancer because of a mutation in a single cancer susceptibility gene.

Finally, sometimes mutations are identified in cancer genes and scientists do not know what they mean. They do not know if these types of mutations affect the functioning of the gene and thereby increase a person's risk for cancer, or if they are normal changes in the DNA that just make one person's gene a little bit different from another person's. When this occurs, the genetic counselor may work with the laboratory to determine if future research can be done to find out the meaning of the patient's test result.

In general, a genetic counselor will help a patient to understand the meaning of his or her genetic test result, whether positive, negative, or indeterminate.

Benefits and limitations of undergoing genetic testing for cancer susceptibility genes

There are potential benefits for patients who undergo genetic testing, but there are also possible limitations and risks regarding the information that is obtained. A genetic counselor will discuss these issues in detail with a patient. Before undergoing genetic testing, a patient will also sign a consent form. This is a written agreement indicating that the patient understands the benefits and risks of genetic testing and has made an independent decision to undergo the testing. The informed consent process is a very important part of genetic counseling and testing. With the exception of FAP, where polyps and subsequently colon cancer can occur at young ages or in the teens, the cancers associated with carrying an altered breast or colon cancer susceptibility gene do not typically occur at very young ages. Therefore, genetic testing for mutations in these genes is usually only offered to those men and women who are 18 years of age or older. In addition, individuals who are 18 or older are considered legally able to provide informed consent.

Benefits of participating in genetic testing for alterations in cancer susceptibility genes:

- Results of genetic testing may provide additional information about the increased risk for developing cancer in the future. It may also provide relief from anxiety if a person learns that they do not carry an altered gene.
- If a person finds out that they are at increased risk for developing cancer, they may choose to be screened for this cancer at a younger age and more often than someone without an altered cancer susceptibility gene. Results may also help men and women decide about prophylactic surgery.
- Testing may provide information about cancer risks for children, brothers and sisters, and other relatives.
- Genetic testing may help a person understand why they and/or their family members developed cancer. This may relieve a person from the emotional burden surrounding their cancer diagnosis.

Limitations and risks of participating in genetic testing for cancer susceptibility genes:

- It is possible that the results of genetic testing may be difficult to interpret. Even if a patient receives a positive test result, this does not mean that he/she will definitely develop cancer.
- During the process of undergoing genetic testing, a person may learn information about themselves or their family members. For example, they may learn about an adoption or that an individual is not the biological father of a child. This kind of information may cause strained relationships among relatives.
- Some patients may become sad, angry or anxious if they learn that they have a mutation in a cancer susceptibility gene. If these feelings are very intense, psychological counseling may be helpful.
- Results of genetic testing may place a person at risk for discrimination by health or life insurers, or their employer. There are some laws in effect that provide limited protection to people who undergo genetic testing. The completion of the Human Genome Project, which has mapped all the genes in the human body, will increase the number of genetic tests that are available. Therefore, additional laws need to be passed to completely protect all people who undergo genetic testing from any type of discrimination.

Genes and cancer types

As of 2001,genes have been discovered that are associated with or responsible for several types of cancer, including **Chronic myelocytic leukemia**, **Burkitt's lymphoma**, **retinoblastoma**, **Wilms' tumor**, and breast and colon cancers. The remainder of this entry will focus only on genetic testing for two of the most common cancers, breast and colon cancer.

Breast cancer genetic testing

Breast and ovarian cancer statistics

All women have a risk for developing breast and ovarian cancer during their lifetime. While breast cancer is a common cancer among women in the United States, ovarian cancer is not. Most women are diagnosed with breast or ovarian cancer after the age of 50, and the great majority of cases are not hereditary. But, of the 5-10% of breast and ovarian cancer that does run in families, most is due to mutations in two genes, the BReast CAncer–1 gene (BRCA1) and the BReast CAncer–2 gene (BRCA2). The BRCA1 gene is located on chromosome 17, and was discovered in 1994. The BRCA2 gene is on chromosome 13, and was discovered in 1995.

BRCA1 and BRCA2 genes

BRCA1 and BRCA2 genes are tumor suppressor genes and are inherited in a dominant fashion. This means that children of a parent with a mutation in one of the breast cancer genes have a 50% chance to inherit this mutation. These mutations can be passed from either mother or father, and can be inherited by both males and females. The mutations may be detected by performing genetic testing on a patient's blood sample.

Mutations in these genes are more common in people who are Ashkenazi (Eastern or Central European) Jewish. While these mutations may be more common in this specific population, they can be identified in a person of any ethnic background.

Cancer risks

Females who inherit a mutation in the BRCA1 or the BRCA2 gene have an increased risk for developing breast and/or ovarian cancer over their lifetime. The lifetime risk for breast cancer may be as high as 85%, as compared to about 13% in the general population. The lifetime risk for developing ovarian cancer may be as high as 60%, as compared to 1.5% in the general population. Males who inherit a mutation in one of these genes are also at increased risk for developing certain cancers, including prostate, colon and breast cancer.

Men and women who inherit an alteration in the BRCA2 gene also have an increased risk to develop more rare cancers, such as pancreatic and **stomach cancer**. However, these risks are much lower than those observed for breast, ovarian, and **prostate cancer**.

Screening and prevention options

It is recommended that individuals who are at increased risk for developing breast cancer undergo increased surveillance. This means that they may choose to see their physicians for medical screening tests at an earlier age and more often than they would if they did not have an altered gene. For example, it is recommended that women with an altered BRCA1 or BRCA2 gene undergo mammograms at a younger age than is recommended in the general population. It is also recommended that these women see their doctors more often to do a breast exam and also perform breast self-exams regularly. Because women who have a mutation in BRCA1 or BRCA2 are also at increased risk for developing ovarian cancer, they may also choose to be screened closely for this cancer. This screening involves undergoing a test, called a CA-125, which looks for protein levels in a woman's blood. Women may also undergo a pelvic ultrasound to look at the size and shape of the ovaries to determine if cancer may be growing in that area. It is important to mention that ovarian cancer is a difficult cancer to detect, and these screening methods may not be able to find the cancer at an early stage when a woman can undergo successful treatment.

Men with an altered BRCA1 or BRCA2 gene may also choose to be screened earlier and more frequently for the cancers they are at increased risk to develop. Prostate screening consists of a test called prostate specific antigen (PSA) that looks for protein levels in a man's blood. Men may also undergo an examination by a physician. There are no standard screening recommendations for males who are at increased risk for breast cancer. It is usually recommended that they learn to do breast self-exams and talk with their doctors if they find any changes in their breast tissue.

Some women at increased risk for developing breast or ovarian cancer may decide to have prophylactic or preventive surgery. This means that they may choose to have their healthy breasts or ovaries removed before cancer develops. However, even the very best surgeon cannot remove all of the breast or ovarian tissue. Therefore, even if a woman has her breasts or ovaries removed preventively, she may still develop cancer in the remaining tissue, but this risk is believed to be small.

Finally, some healthy women who are at increased risk for breast or ovarian cancer may decide to take certain medications that have been shown to reduce risk. As some of these medications have been studied only in the general population, further research is underway to find out how effective these medications are for women with an inherited risk for developing cancer.

Colon cancer genetic testing

Colon cancer statistics

Males and females in the general population have a 6% risk for developing colon cancer over their lifetime, and the average individual is diagnosed in their 60s to

KEY TERMS

Cancer—The process by which cells grow out of control and subsequently invade nearby cells and tissue.

Cancer susceptibility gene—The type of genes involved in cancer. If a mutation is identified in this type of gene it does not reveal whether or not a person has cancer, but rather whether an individual has an increased risk (is susceptible) to develop cancer (or develop cancer again) in the future.

Colonoscopy—A screening test performed with a tube called a colonoscope that allows a doctor to view a patient's entire colon and rectum.

Chromosome—Structures found in the center of a human cell on which genes are located.

DNA repair genes—A type of gene that usually corrects the common mistakes that are made by the body as DNA copies itself. If these genes are mutated and cannot correct these mistakes they may accumulate and lead to cancer.

Gene—Packages of DNA that control the growth, development and normal function of the body.

Genetic counselor—A specially trained health care provider who helps individuals understand if a disease (such as cancer)is running in their family and their risk for inheriting this disease. Genetic counselors also discuss the benefits, risks and limitations of genetic testing with patients.

Hepatoblastoma—A cancerous tumor of the liver. Individuals with FAP have an increased risk for developing this type of tumor at a young age.

Mammogram—A screening test that uses X-rays to look at a woman's breasts for any abnormalities, such as cancer.

Mutation—An alteration in the number or order of the DNA sequence of a gene.

Oncogene—Genes that typically promote cell growth. If mutated, they may encourage cancer to develop.

Pedigree—A family tree. Often used by a genetic counselor to determine if a disease may be passed from a parent to a child.

Penetrance—The likelihood that a person will develop a disease (such as cancer), if they have a mutation in a gene that increases their risk for developing that disorder.

Polyp—A growth that may develop in the colon. These growths may be benign or cancerous.

Prophylactic surgery—The preventive removal of an organ or tissue before a disease such as cancer develops.

Sequencing—A method of performing genetic testing where the chemical order of a patient's DNA is compared to that of normal DNA.

Sigmoidoscopy—A screening test performed with a flexible scope called a sigmoidoscope, that allows a doctor to view a limited portion of a patient's colon or rectum for the presence of polyps.

Tumor suppressor gene—Genes that typically prevent cells from growing out of control and forming tumors that may be cancerous.

70s. Similar to breast and ovarian cancer, most colon cancer does not run in families. However, some colon cancer is hereditary, and may be due to a mutation in a colon cancer susceptibility gene. Three of the more common hereditary colon cancer syndromes are described below.

Familial Adenomatous Polyposis (FAP)

FAP is a syndrome in which individuals develop numerous polyps (growths) in their colon or rectum. This disorder may also be called familial polyposis or Gardner's syndrome. Males or females with FAP often have hundreds of precancerous polyps at young ages, such as when they are teenagers or young adults.

FAP is due to a mutation in a gene called APC. Mutations in this gene are dominantly inherited. In about 80% of families genetic testing performed on a blood sample can find the alteration in the APC gene that is causing this disorder. It is believed that 2/3 of the people with FAP have inherited a mutated gene from their parent. The other 1/3 of individuals with FAP are believed to be new (sporadic) mutations, meaning that the alteration in the APC gene was not inherited from a parent. Individuals with sporadic mutations can pass the mutation on to their children.

Cancer risks

Due to the fact that individuals with FAP develop so many polyps in their colon, there is a very high risk that these polyps, if not removed, will develop into colon cancer. Individuals with FAP may also develop precancerous

polyps in other organs, such as their stomach or small intestine. Young people with FAP may also be at increased risk for developing a tumor in the liver, known as a hepatoblastoma. They are also at increased risk for developing tumors in other parts of the body, such as the thyroid gland or pancreas. Males or females with FAP may also have other manifestations of the disease. For example, they may have cysts or bumps on their skin or on the bones of their legs or arms, or freckle-like spots in their eyes.

APC I1307K mutation

In 1997 scientists identified another mutation on the APC gene, known as I1307K. This mutation is found only in individuals who are of Ashkenazi Jewish descent. It is estimated that about 6% of individuals who are Jewish have this particular mutation. The I1307K mutation itself does not cause an increased risk for colon cancer, but rather makes the APC gene more likely to undergo other genetic changes. These other genetic changes increase a person's risk for developing colon cancer. Genetic testing can be performed on a blood sample to determine if an individual carries the I1307K mutation. A person with this mutation has a 50% chance of passing it on to his or her children.

Cancer risks

Individuals who carry the I1307K mutation have an 18%-30% risk for developing colon cancer over their lifetime. Research is ongoing to determine if individuals with this mutation may also be at risk for developing other types of cancer, such as breast cancer.

Hereditary Non-Polyposis Colorectal Cancer (HNPCC)

HNPCC, also known as Lynch Syndrome, is a condition in which individuals have an increased risk for developing colon cancer, even if there are very few or no polyps present in the colon. It is believed that mutations in one of five cancer susceptibility genes are associated with most cases of HNPCC. These genes are known as hMSH2, hPMS1, MSH6 (all on chromosome 2), hMLH1 (chromosome 1) and hPMS2 (chromosome 7). It is possible that other genes may be found which are also associated with HNPCC. Mutations in these genes are dominantly inherited, and may be able to be detected through genetic testing performed on a patient's blood sample.

Cancer risks

Individuals with an altered HNPCC gene have a much higher risk for developing colon cancer, often at a younger age (less than 50) than people in the general population. Those with an HNPCC mutation are at increased risk for developing other types of cancer, including stomach, urinary tract, bile duct, uterine and ovarian cancer. It is recommended that men and women also be screened closely for these cancers.

Screening and prevention options

It is recommended that all individuals who are at increased risk for developing colon cancer undergo screening for this cancer. Screening for colon cancer consists of two main types of tests. The first test is called a **sigmoidoscopy**. It is performed by inserting a flexible tube, called a sigmoidoscope into the anus to look at the rectum and the lower colon. The doctor can use the scope to see whether polyps may be present, but these growths can not be removed with this test. The second test is known as a **colonoscopy**. While it is very similar to a sigmoidoscopy, it allows a doctor to see the entire colon. Also, with the use of a colonoscope a polyp can be easily removed at the same time a person is undergoing the test. However, because a colonoscopy is a more invasive test, patients have to be sedated. For patients who are at

QUESTIONS TO ASK THE DOCTOR OR A GENETIC COUNSELOR

- What is the likelihood that the cancer in my family is due to a mutation in a cancer susceptibility gene?
- If the cancer in my family is hereditary, what is the chance that I carry a mutation in a cancer susceptibility gene?
- What are the benefits, limitations and risks of undergoing genetic testing?
- What is the cost of genetic testing and how long will it take to obtain results?
- If I undergo genetic testing, will my insurance company pay for testing? If so, will I want to share my results with them?
- What does a positive test result mean for me?
- What does a negative test result mean for me?
- If I test positive for a mutation in a cancer susceptibility gene, what are the best options available for screening and prevention? What research studies may I be eligible to participate in?
- What legislation is in effect to protect me against discrimination by my insurer or employer?

increased risk for developing colon cancer, it is recommended that they undergo this screening at younger ages and more often then individuals in the general population. For example, because cancer can occur at such young ages for individuals with FAP, it is recommended that they have a sigmoidoscopy beginning at age 11.

Finally, men and women with a mutation in a colon cancer susceptibility gene may take certain medications that have been approved for use in individuals with an increased risk for developing colon cancer.

The only way to prevent colon cancer from developing is to remove the colon entirely. If a person with FAP, HNPCC or the I1307K mutation develops colon cancer he/she may choose to have the colon removed. In addition, if an individual is very anxious about developing colon cancer he or she may choose to have the colon removed before cancer develops. There are several different procedures for removing the colon that allow a person to function normally. Women with an HNPCC mutation may also consider prophylactic removal of their ovaries and uterus.

Germ cell tumors

Definition

Germ cell tumors are tumors that begin in cells that, in a developing fetus, become sperm or egg cells. Because of the way a baby develops in the womb, these kinds of tumors are found in the ovaries and testes, and in other sites along the midline of the body, such as the brain, the center of the chest, and the center back wall of the abdominal cavity. They can also be found in the center parts of the pelvis, cervix, and uterus, in the vagina or prostate, in the oral or nasal cavities, or on the lips. These tumors are usually discovered either during the first few years of life, or shortly after puberty (when an increase in hormone levels may initiate cancer formation).

Description

Germ cell tumors are a diverse group of tumors that all begin in germ cells, the cells in the developing fetus that become sperm or egg cells. Incidence in the United States is 2–3 cases/million live births. They can occur in the ovaries or testes or outside the reproductive organs in many other locations along the middle of the body. Some are very malignant and some are almost always benign; most require surgery, although some kinds are also treated with additional radiation or **chemotherapy**. Some typically appear in infancy, others are more common in adolescents. The treatment and prognosis will depend on the kinds of tissues present in the tumor and on the location.

Germ cell tumors are divided into two types: germinomas, which contain only immature germ cells; and embryonic tumors, which contain some cells that have started to develop into other tissues (as would happen in normal development of a fetus). Embryonic types of tumor commonly include endodermal sinus tumors, embryonal **carcinoma**, choriocarcinoma and teratoma. Gonadoblastoma and polyembryoma are rare types of embryonic germ cell tumors. Many tumors are mixed, containing more than one cell type.

Generally, any kind of germ cell tumor can appear at any germ cell tumor site, although some types are significantly more common at some locations. For example, about 40% of all germ cell tumors are teratomas in the area of the tailbone, which are typically diagnosed in the first month or two of life. Germinomas and endodermal sinus tumors are most common in the ovaries. Embryonal carcinomas are most common in the testes, usually mixed with endodermal sinus tumors or choriocarcinoma.

Demographics

Like other features of this diverse group of tumors, demographics of this cancer vary with the site and type. The peak in incidence of germ cell tumors during the first few years of life is primarily due to the high numbers of teratomas in the tailbone area, which are about 4 times more common in girls than in boys. The second peak, however, in adolescents reflects a significant

number of testicular cancers in teenage and young adult males. Other common childhood germ cell tumors are tumors of the abdomen, vagina and testicles in infants, brain tumors in childhood, and ovarian tumors in early teens. Adult germ cell tumors in adults are usually in the testes or ovaries. Germ cell tumors are found in all populations of the world in approximately equal numbers.

Causes and symptoms

The causes of germ cell tumors are not well understood, although events at puberty—probably increases in certain hormone level—are thought to play a role in tumors of the ovaries and testicles that occur in adolescents or early teens. Some germ cell tumors have a high percentage of certain genetic sequences, thought to be a possible cause of those types of cancers, while some have a high frequency of abnormal chromosome numbers. Some types of germ cell tumors do tend to run in families. Since germ cell tumors are made up of several different types of cancers, there are probably at least several different causes.

The most common symptom of germ cell tumors is a mass along the midline of the body. This mass may be accompanied by abdominal pain or bloating. Other possible symptoms include:

- constipation
- enuresis (involuntary discharge of urine)
- early entry into puberty
- vaginal bleeding
- late onset of menstruation
- menstrual problems
- excessive hair growth
- weakness in legs
- need to urinate often
- shortness of breath, other breathing problems
- diabetes
- hormonal abnormalities
- stunted growth
- headaches or vision problems

Diagnosis

Most germ cell cancers are initially identified by the discovery of lump in the testicles or somewhere else along the midline of the body. When a lump is identified, often the person's physician will arrange for a **biopsy** of the lump. During a biopsy, a small piece of the lump is removed and cut into thin sections. A specialist examines these sections under a microscope, looking for abnormal kinds of cells. How much the biopsied tissue is different from healthy tissue is a good indication of how severe the disease will probably be, and the results of biopsies are used to give tumors a grade that indicates the patient's chances of survival.

Tests that give a doctor pictures of the tumor are also used, such as x rays, computed tomography (CT, or CAT) scans, or ultrasound. X rays can show the doctors where calcium deposits have occurred in normally soft tissues (an indication of disease). Ultrasound and CT scanning give more details with regard to a specific tumor, such as its site of origin, whether it is solid or cystic, and how well defined its borders are. Well-defined borders have a better chance of complete surgical removal.

Another type of useful test which is specific to germ cell tumors is the measurement of several **tumor markers**. Tumor markers are proteins, often identified in blood samples, that are produced by tumor cells. Two main tumor markers are commonly seen to suggest'a germ cell tumor, alpha-fetoprotein (AFP) and β-Human Chorionic Gonadotropin (β-HCG). Germ cell tumors which produce elevated levels of AFP include endodermal sinus tumors and teratoma, although high levels of AFP are also produced by normal infants. β-HCG is usually associated with tumors which contain elements of the choriocarinoma or embryonic carcinoma types of germ cell tumors. These markers are also used as a measure of the success of surgery or other therapies, and to monitor patients for a recurrence of the disease.

Treatment team

As the understanding of cancer grows and new treatment approach are developed, the complexity of cancer treatment also increases. Today, a multi-disciplinary approach to cancer treatment is considered necessary for effective patient care. People involved in the treatment of a germ cell cancer will typically include the referring physician (often a gynecologist or pediatrician), a gynecological oncologist, a pathologist, and a nurse. If **radiation therapy** is pursued, a radiation oncologist, radiation therapist, radiation nurse, radiation physicist, and a dosimetrist will also be involved. Treatment may also include a psychologist, nutritionist, social worker and chaplain.

Clinical staging, treatments, and prognosis

Staging

Staging and grading tumors is a way of predicting the severity of the disease. Tumor grades are based on the types of tissues present in the tumor; stages

indicate the cancer's spread. Separate staging systems exist for both adult and childhood ovarian cancers and adult and childhood testicular cancers. These are developed separately by groups of pediatric and adult oncologists.

OVARIAN CANCERS Pediatric ovarian cancers are usually graded according to the following scheme: Grade 0 contains only mature tissues (tissues which have already become specific kinds of tissues, rather than primitive developing cells. Grade 1 contains mostly mature tissues, with some immature cells present. Grade 2 contains a moderate amount of immature cells, and in Grade 3, numerous immature cells are present.

Adult **ovarian cancer** is usually staged, with Stage I being found only in the ovaries. Stage II in adult ovarian cancer means that the cancer has spread to the uterus or the fallopian tubes, or other structures in the pelvic area. Stage III tumors are those which have spread to the lymph nodes or outer parts of abdominal organs. Stage IV tumors have spread to the interior of abdominal organs such as the liver or the intestines.

TESTICULAR CANCERS Pediatric testicular cancers are typically staged in a manner similar to adult ovarian cancers: Stage I tumors are limited to the testes, with normal postoperative tumor markers. Stage II tumors have spread to the abdominal lymph nodes and have elevated tumor markers; Stage III have greater involvement of the abdominal lymph nodes. Stage IV tumors have spread to other organs such as the lung.

Adult testicular cancers are commonly staged according to a simplified TNM system. Stage T (with several levels described) indicates a tumor that is localized, N means a tumor that has spread to local lymph nodes, and M means a tumor that has spread to distant lymph nodes and organs.

Treatment

The treatment choice in any specific germ cell tumor depends mainly on the type of tumor and the stage at diagnosis, although the age of the patient and whether or not future childbearing is an issue will also influence treatment choices. Treatment of most germ cell tumors involves surgical removal of the tumor. Advanced cancers normally will be followed by chemotherapy. For some tumors, it may not be possible to completely remove the cancerous tissues. In those cancers, "debulking" surgery will be performed in order to reduce the size of the tumor in order for chemotherapy (or radiation) to be most effective.

Chemotherapy can be given through pills taken by mouth, by injections or through IVs. Chemotherapy works by killing cancerous cells, and can kill cancer cells that have traveled away from the initial site. Therefore, in more advanced stages of disease, chemotherapy will sometimes be the primary treatment. Possibly another surgery will be performed after radiation therapy or chemotherapy is finished. This surgery (second-look surgery) allows the doctor to confirm that cancerous tissues have been eradicated.

Chemotherapy usually involves a platinum-based drug such as **cisplatin** in combination with one or two other anti-cancer medications. These drugs are used in combination because, since they each have different side effects, high doses can be given without increasing the risk of a serious drug reaction. Using combinations also decreases the chance that a cancer will develop resistance to any particular drug. Different combinations of drugs are used to treat different types of tumors.

The treatment of some types of germ cell cancers may follow a slightly different pattern. Germinomas are especially sensitive to radiation. This may be the primary treatment mode for those kinds of tumors. Radiation is used to shrink the size of tumors, and even in ovarian cancers usually involves only external irradiation. The only type of germ cell tumor in children in which radiation is regularly used is germinomas occurring in the brain.

When first-line treatments fail, stronger combinations of drugs may be given, or different, sometimes experimental therapies may be tried. These kinds of therapies includes immune system products like interferons that have been shown to destroy cancerous cells and new drugs being developed that decrease blood flow to tumors. Therapies like immunotoxins, which include anti-cancer drugs attached to antibodies specific to tumor cells, and other ways of making drugs more specific for tumor cells, are also being investigated. Many **clinical trials** for germ cell cancers are evaluating a therapy called "peripheral stem cell rescue," in which the patient's red blood cells are removed before high-dose chemotherapy is given, then replaced after the chemotherapy is complete. This decreases the side effects of the medications and improves the patient's chances of successful treatment.

The prognosis for germ cell tumors depends greatly on the type of germ cell tumor involved and the location in which it is found. Generally, about 90% of patients diagnosed with only localized tumors survive, compared to 50–70% of those who are diagnosed with tumors which have already spread. There is wide variation in the cure rates, depending on the tumor types involved. Mature teratomas of the ovaries, which are by far the most common type of ovarian tumor, are almost always

benign, unless mixed with other, more malignant germ cell tumor types. Choriocarcinomas and embryonal carcinomas, on the other hand, are especially malignant, with an average survival time without treatment of only a few months. Since ovarian cancers are the most difficult to catch early, ovarian cancers of types more malignant than the mature teratoma have the worst prognosis among the germ cell tumors. With modern treatment methods, most often including chemotherapy after surgical removal, survival rates have greatly improved. If caught early, most germ cell tumors have good cure rates.

Alternative and complementary therapies

Alternative and complementary therapies are therapies which fall outside the scope of traditional, first-line therapies like surgery, chemotherapy and radiation. Complementary therapies are meant to supplement those traditional therapies with the objective of relieving symptoms. Alternative therapies are nontraditional, unproven attempts to cure the disease.

Common complementary therapies in germ cell disease include aromatherapy, art therapy, massage, meditation, music therapy, prayer, t'ai chi, yoga, and other forms of exercise. These therapies have the objective of reducing anxiety and increasing a patient's feeling of well-being.

Numerous alternative therapies exist in cancer treatment. Laetril, a product of apricot seeds, is probably one of the most well known. Laetril contains a form of cyanide that may be released by tumor enzymes and may act to kill cancerous cells. However, the product is not approved for use in the United States, and the National Cancer Institute sponsored two clinical trials for the drug in the late 1970s and early 1980s, and decided that no further investigation into the drug was necessary. **Vitamins** and other nutritional elements like vitamins A, C, and E, and selenium are thought to act as **antioxidants**. Vitamin E, melatonin, aloe vera, and a compound called beta-1,3-glucan are thought to stimulate the immune system. Natural substances like garlic, ginger, and shark cartilage are also commonly held to shrink tumors, with less defined modes of action. Antineoplastons are believed by some to be another alternative approach to a cancer cure. Antineoplastons are small proteins which may act as molecular messengers and which may be absent from the urine and blood of many cancer patients. Replacing these proteins may have beneficial effects. After some proposed clinical trials were not completed, the National Cancer Institute draws no definitive conclusions about the effectiveness of antineoplaston therapy. Patients should discuss any supplements with their treating physicians.

Coping with cancer treatment

The use of chemotherapy and radiation therapy in addition to surgery has greatly increased the numbers of germ cell tumor patients who survive; but both of these treatments unavoidably result in damage to some healthy tissues and other undesirable side effects. Some of the more common side effects of chemotherapy include:

- hair loss (**alopecia**)
- **fatigue** and weakness
- **nausea and vomiting**
- bed wetting

Hair loss is a very common side effect of many drugs used to treat cancer. Getting a sample of hair before hair loss begins is desirable in case a wig is desired after hair loss begins. The patient's hair color and texture could then be more closely matched. Hair may thin out gradually or it may come out in big clumps. To slow down the rate of hair loss, avoid any unnecessary sources of damage to the hair, like curling, blow-drying, or chemical treatments.

Hair loss is a difficult part of dealing with cancer for all patients past infancy, especially for teenage patients. Children should be given the right to choose their own way of coping and their choices should be supported. Children may choose to remain bald, or may want to choose hats or scarves instead of wigs. Schools may need to be persuaded to allow a child to wear some kind of head covering. It is important to assure the child that loss of hair is a sign that the medication is doing its job, and that hair loss is temporary.

Hair usually begins regrowth within a few months of the end of intensive chemotherapy, although it may begin to thin out again during the course of maintenance drugs. Sometimes hair comes in a different color or texture than the original hair. It may be a good idea to prepare a child for that possibility.

Fatigue and weakness are other common side effects of chemotherapy. Side effects of the chemotherapy medications, along with the natural depletion of the body's resources as it fights off the disease and normal psychological consequences of the disease such as **depression** combine to make fatigue a very significant part of coping with cancer treatment.

The best way to deal with these symptoms is to cut back on activities and allow plenty of time for resting to let the body heal. Patients should avoid as much extra stress as possible, limiting visitors if necessary in order to avoid being overtired. Children should not be forced into the role of invalid. Children must be allowed to pursue normal activities and hobbies as much as possible.

Parents can best manage this by helping to select those activities that the child considers most important, and by providing a backup plan for times when the child does become too fatigued, such as alternate means of mobility (for example, a stroller, wheel chair or other acceptable and safe vehicle). It is also important to make sure that a well-balanced diet is provided.

Nausea and vomiting are also fairly common side effects of many chemotherapy drugs. Radiation to the brain or the GI tract can also cause nause and vomiting. After a few courses of chemotherapy drugs, some patients will become nauseated just from the thought of an upcoming treatment, or from smelling certain odors that act as nausea triggers. Drugs that combat nausea and vomiting can be prescribed, but are often not effective for anticipatory nausea. There are self-help measures that can be tried. If nausea and vomiting are a problem, heavy, regular meals should be avoided in favor of small, frequent snacks made up of light but nourishing foods like soup. Avoiding food smells and other strong odors may help.

Desensitization, hypnosis, guided imagery, and relaxation techniques may be used if nausea and vomiting are severe. These techniques help to identify the causes which trigger the nausea and vomiting, decrease patient anxiety, and distract the patient from thinking about getting sick. In children, activities like playing video games can be offered as very effective means of distraction.

Bedwetting is another common side effect of anticancer drugs, and one which can be especially distressing for older children. A child who experiences this problem should be reassured that the problem is temporary and will go away when the drug treatment is over. Parents can help the child cope by keeping extra linens ready or covering the wet spot with towels kept handy and most of all, by conveying an attitude that wetting the bed is not a big deal. Children should never be punished. It may also help to limit drinks for a couple of hours before bedtime, or to wake the child at regular intervals overnight to use the bathroom.

The biggest problem for those undergoing radiation therapy is the development of dry, sore, ''burned'' skin in the area being treated. Radiation does not hurt during treatment and does not make the person radioactive. Skin in the treatment area will become red, get itchy and sore, and may blister and peel, becoming painful. Patients with fair skin, or those who have undergone previous chemotherapy have a greater risk of more serious reactions. Dry, itchy or sore skin is temporary; but affected skin may be more sensitive to sun exposure for the rest of the patient's lifetime, so a good sunscreen should be used whenever affected skin is exposed to sunlight.

KEY TERMS

Choriocarcinoma—A highly aggressive malignant germ cell tumor made up of tissue derived from the outer membrane which covers the fetus.

Embryonic carcinoma—A highly malignant germ cell tumor made up of tissues derived from the embryo.

Endodermal sinus tumor—A more aggressive germ cell tumor made up of tissue originating in the nutrient sac of the embryo.

Germinoma—A tumor that develops purely from primitive germ cells.

Gonadoblastoma—A rare and almost always benign form of cancer highly associated with abnormal development of reproductive organs.

Polyembryoma—A very rare, aggressive form of germ cell tumor usually found in the ovaries.

Fear and anxiety are major factors in coping with cancer, including cancer treatments. The feelings are completely normal. Some patients find that concentrating on restful, pleasurable activities like hobbies, prayer, or meditation is helpful in decreasing negative emotions. Support groups are another useful tool, since they provide an environment where fears can be freely expressed and understood.

Clinical trials

Nearly a hundred clinical trials testing new treatments for germ cell tumors are ongoing. New approaches being evaluated emphasize new combinations of existing chemotherapy drugs, peripheral stem cell therapies to supplement chemotherapy, alternative therapies like antineoplastons, and new drug delivery approaches such as immunotoxins.

Therapies being evaluated in clinical trials are usually considered experimental and some, like peripheral stem cell rescue, can be very expensive. Most insurance companies do not cover the costs of experimental therapies.

To find an ongoing clinical trial for a specific kind of germ cell tumor, call the National Cancer Institute at 1-800-4-CANCER.

Prevention

Since the causes of germ cell tumors are not well understood, few identified risk factors exist, thus pro-

QUESTIONS TO ASK THE DOCTOR

- Can you explain what kind of cancer I have?
- Is it a benign or aggressive form of germ cell tumor? Can you explain the grade and stage of my cancer? What are the chances that it will come back?
- How was this cancer diagnosed?
- What is my prognosis?
- What treatments are we going to pursue? What happens if these don't work?
- Do you have experience in treating this type of cancer?
- Is there anything I can do to optimize treatment? Are there any particular side effects I should expect?
- Are there complementary therapies that you would recommend? Any other things that would help me cope with the diagnosis or treatment?

viding little information on the possibility of preventing these kinds of cancers. However, there are ways of improving prognosis with regards to germ cell tumors. Ovarian cancers are difficult to catch in early stages; women who get regular gynecological checkups are more likely to have ovarian cancer diagnosed in more treatable stages. Males who have had **testicular cancer** can improve their chances of catching recurrences in early stages by doing regular self-exams.

Special concerns

A special concern in germ cell tumor patients, especially since most patients are children or young adults, is maintaining these patients' ability to bear children. Unfortunately, all of the common treatments can have a negative effect on future fertility. Radiation, especially, destroys fertility and is avoided in children except for germinomas of the brain. Patients whose reproductive organs must be removed suffer major psychological consequences of the loss of childbearing potential and often, as well, suffer from altered feelings of **sexuality**. The treatment team will attempt to choose treatment options that will preserve the patient's childbearing ability to the best of medical capabilities.

Gestational trophoblastic tumors

Definition

A gestational trophoblastic tumor (GTT) is a rare cancer that develops in tissues formed when a sperm fertilizes an egg but does not create a fetus.

Description

Also known as gestational trophoblastic neoplasms (GTN), these highly curable malignancies originate inside the uterus, in cells (trophoblasts) that make up one layer of the placenta. The most common types of GTT are hydatidiform mole (molar pregnancy) and choriocarcinoma. Placental-site trophoblastic tumor is an extremely rare type of GTT. It originates at the place where the placenta was attached to the wall of the uterus.

Hydatidiform mole

A hydatidiform mole forms when sperm and egg cells unite but do not create a fetus. Cells that form the placenta continue to grow until they look like drops of rain or clusters of grapes. Also known as molar pregnancy, a hydatidiform mole does not spread beyond the uterus.

Choriocarcinoma

Characterized by rapid growth and heavy bleeding, this aggressive, invasive tumor is considered a medical emergency and requires immediate medical attention. Although choriocarcinoma usually originates in a hydatidiform mole, it can also develop in tissue that remains in the uterus following a normal delivery, an abortion, or an ectopic pregnancy.

A malignancy of the trophoblastic cells that form the lining of the uterus (epithelium), choriocarcinoma can spread (metastasize) to any part of the body. **Metastasis** begins at an early stage of the disease and usually involves the lungs, vagina, pelvis, brain, and/or liver. Symptoms of lung metastasis include severe shortness of breath (respiratory insufficiency) and coughing up blood. Irregular, abnormal bleeding can indicate that choriocarcinoma has invaded the vagina. The central nervous system (CNS) is rarely affected unless the disease has spread to one or both lungs; a patient whose brain does become involved may experience headaches, seizures, and stroke-like symptoms. More rarely, choriocarcinoma may spread to the kidneys, spleen, and/or gastrointestinal tract.

Demographics

GTTs occur only in women of childbearing age. These tumors are most common:

- before the age of 16
- after the age of 40
- in women who have had them before
- among women who are poor

Accounting for only 1% of all gynecologic malignancies, GTTs are five times more common in Africa and Asia than in Europe and North America. In the United States, hydatidiform mole occurs in only one of every 1,500 to 2,000 pregnancies.

Causes and symptoms

The cause of GTTs is unknown. A woman's chance of developing a second GTT, while still very low, is about twice as great as her risk of developing a first one.

Symptoms of hydatidiform mole

The most common symptoms of hydatidiform mole are vaginal bleeding and severe morning sickness during the first trimester of pregnancy. Other symptoms that suggest a hydatidiform mole include:

- a uterus larger than expected at a particular stage of pregnancy
- a uterus enlarged on only one side
- a fetus not visible on a sonogram
- absence of fetal heart sounds
- passage of clots with the color and consistency of prune juice or of finger-like structures containing fetal blood cells (villi)
- toxemia
- ovarian cysts
- hyperthyroidism

Recurrent bleeding often causes iron deficiency **anemia** in women who have had a hydatidiform mole. Although molar pregnancy is almost always diagnosed during the first trimester, it is often difficult to distinguish this condition from the early stages of a normal pregnancy. A woman should see her doctor if she experiences abnormal bleeding or cannot feel her baby move when she should.

Symptoms of choriocarcinoma

This GTT occurs in 4% of women whose hydatidiform mole was surgically removed or treated with **radiation therapy**. Following term pregnancies or abortion, the incidence of choriocarcinoma is 1 in 40,000.

A doctor should always consider choriocarcinoma when vaginal bleeding persists after a woman has given birth. Other abnormalities commonly associated with choriocarcinoma are unusual and unexplained neurological symptoms in women of childbearing age and lesions that can be seen on a chest **x ray** but do not cause shortness of breath or other symptoms.

Diagnosis

The process of diagnosing GTT usually begins with an internal pelvic examination that allows the doctor to detect lumps or abnormalities in the size or shape of the uterus. **Imaging studies** such as **computed tomography** (CT) scans, **magnetic resonance imaging** (MRI), and ultrasound may be used to locate tumors. Blood and urine tests measure levels of beta human chorionic gonadotropin (HCG). This hormone is normally produced during pregnancy but is abnormally elevated in the blood and urine of a woman with GTT. HCG is a sensitive marker of the presence of GTT before, during, and after treatment.

After diagnosing GTT, the doctor will perform a regular blood test (every week), pelvic exam (every other week), and chest x ray (every four to six weeks) until the level of HCG in the patient's blood has returned to normal. Once the patient's HCG levels have normalized, medical monitoring includes blood tests with decreasing frequency for the next three years.

Treatment team

GTT is typically treated by a treatment team of gynecologists, gynecologic oncologists, and medical oncologists. A patient who has a poor prognosis should be treated at a specialized trophoblastic disease center by a doctor experienced in caring for high-risk GTT patients.

Clinical staging, treatments, and prognosis

A common system used in U.S. cancer centers to describe the extent (stage) of GTT classifies patients into different prognostic groups. These groups include:

- Nonmetastatic disease: Cancer cells have not invaded tissues outside of the uterus. Cancer found in the muscle of the uterus is called invasive mole or choriocarcinoma destruens.
- Metastatic disease, good prognosis: Cancer cells have invaded tissues outside of the uterus but have not spread to the liver or brain; levels of HCG in the blood are low and the last pregnancy was less than four months ago. No **chemotherapy** treatment has been initiated.
- Metastatic disease, poor prognosis: Cancer cells have invaded tissues outside of the uterus, including the liver or brain; levels of HCG in the blood are high and/or the last pregnancy was more than four months ago. Chemotherapy treatment has been given but was not successful.

Treatment options

Because GTT cells respond well to chemotherapy drugs and HCG blood tests are a reliable means of determining whether cancer cells are still present and if therapy should continue, this disease is one of the most curable cancers of the female reproductive system.

Doctors usually treat GTT with surgery to remove the tumor, followed by chemotherapy taken in pill form or administered intravenously to kill any cancer cells still present after surgery. Radiation therapy is sometimes used to treat GTT that has spread to other parts of the body. Radiation used to treat GTT may be provided by:

- machine (external-beam radiation)
- radiation-producing pellets (radioisotopes) inserted into the area of the body where cancer cells have been found

Choice of treatment is determined by the following factors:

- patient's age and general health
- tumor type
- stage of disease
- areas of the body to which GTT has spread
- HCG levels in the patient's blood
- how much time elapsed between conception and start of treatment
- prior pregnancy-related problems
- extent of treatment for prior pregnancy-related problems
- whether the patient wants to become pregnant in the future

HYDATIDIFORM MOLE Hydatidiform mole is 100% curable with surgery. If the patient wants to become pregnant in the future, the doctor performs **dilatation and curettage** (D&C) with suction evacuation. This procedure involves:

- stretching the opening of the uterus (cervix)
- using a small vacuum-like device to remove material from inside the uterus
- gently scraping the walls of the uterus to remove any remaining material. If the patient does not wish to become pregnant in the future, the doctor removes her uterus (hysterectomy).

Following either of these operations, the doctor carefully monitors the level of HCG in the patient's blood. Chemotherapy is initiated when:

- HCG levels continue to rise for a period of two weeks or remain constant for a period of three weeks
- HCG levels become elevated after having fallen to normal value
- analysis of tissue removed during surgery indicates the presence of invasive disease (choriocarcinoma)
- heavy, unexplained bleeding occurs after material has been evacuated from the uterus

PLACENTAL-SITE GTT Hysterectomy is usually performed to remove cancer cells that have developed where the placenta was attached to the wall of the uterus. Although placental-site GTTs do not generally spread to other parts of the body, they do not respond well to chemotherapy and can be fatal.

NONMETASTATIC DISEASE The most common form of GTT, nonmetastatic disease does not spread beyond the uterus, where its cells develop from tissue remaining after treatment for hydatidiform mole, normal delivery, or abortion. Treatment for nonmetastatic disease consists of single-agent chemotherapy. Hysterectomy is sometimes performed if the patient does not want to become pregnant in the future.

METASTATIC DISEASE, GOOD PROGNOSIS This type of GTT originates as nonmetastatic disease but spreads from the uterus to other parts of the body. The likelihood of cure (prognosis) is considered good if:

- less than four months has elapsed since the patient's previous pregnancy
- HCG blood levels are low
- cancer cells have not spread to the liver or brain
- the patient has not previously received chemotherapy

Doctors may treat metastatic disease with good prognosis with chemotherapy alone, hysterectomy followed by chemotherapy, or chemotherapy followed by hysterectomy. These patients must be carefully monitored. Almost all of these cases can be cured, but between 40% and 50% will develop resistance to the first chemotherapy drug used in treatment.

METASTATIC DISEASE, POOR PROGNOSIS The prognosis for metastatic disease is considered poor if:

- more than four months has elapsed since the patient's previous pregnancy
- HCG blood levels are high
- cancer cells have spread to the liver or brain
- previous chemotherapy treatments did not eradicate the patient's disease

Treatment for this type of GTT must be started immediately and should be performed in a specialized medical center or by a doctor experienced in treating this disease. Treatment usually consists of combination chemotherapy but may include surgery and radiation to parts of the body that cancer cells have invaded.

Metastatic GTT is can also be described as low-risk, medium-risk, or high-risk. This classification enables doctors to identify patients who should be treated with the strongest, most effective combination of chemotherapy drugs. Factors used to determine a woman's risk include:

- age
- prior pregnancy experience
- how much time elapsed between conception and start of treatment
- HGC levels in her blood
- the size of her largest tumor
- where and to how many locations the cancer has spread
- whether she has previously been treated with chemotherapy

RECURRENT DISEASE GTT that recurs after a woman has been treated may reappear in the uterus or in another part of her body. One study indicates that GTT recurs in:

- 2.5% of patients treated for nonmetastatic disease
- 3.7% of patients treated for metastatic disease, good prognosis
- 13% of patients treated for metastatic disease, poor prognosis All these recurrences happened within 36 months of the disappearance of symptoms of the initial disease (remission), while 85% occurred within 18 months of remission.

A woman who develops one or more new GTTs after having been treated with chemotherapy is considered to be a high-risk patient and is categorized as having a poor prognosis. She should subsequently be treated with aggressive chemotherapy. If surgery is not successful in eradicating the cancer, treatment with single-agent chemotherapy is usually indicated unless one or more risk factors indicate that she should receive multiple-drug therapy. When recurrent disease spreads to the central nervous system, whole brain radiation and systemic chemotherapy are given at the same time. About half (50% to 60%) of patients receiving this treatment experience sustained remission. Combination chemotherapy may also be used to treat a woman whose recurrent GTT has spread to the brain.

The prognosis is poor for a woman whose recurrent GTT has spread to her liver; in this case radiation does not improve survival and may make chemotherapy less effective. The prognosis is even poorer if both the liver and brain are affected. "Salvage" surgery is sometimes

KEY TERMS

Ectopic pregnancy—An abnormal pregnancy in which the fertilized egg becomes implanted outside the uterus.

Ovarian cyst—A fluid-filled or semi-solid sac that may be painful or malignant.

Placenta—The organ that develops in the uterus during pregnancy and connects the mother's blood supply with the baby.

Remission—Disappearance or lessening of symptoms.

Salvage surgery—An operation used to treat a patient who has not responded to any other therapy.

Systemic—Affecting the whole body.

Toxemia—An abnormal pregnancy-related condition characterized by high blood pressure, swelling and fluid retention, and proteins in the urine.

QUESTIONS TO ASK THE DOCTOR

- What should I do if I am not sure my pregnancy is proceeding normally?
- Why is it important for me to see my doctor as soon as I realize something might be wrong?
- Will GTT affect my ability to have other children?
- Why must I wait so long before becoming pregnant?

used to treat patients whose disease has not responded to any other available form of treatment.

Disease outcomes

Although very rare in North America, GTT is an important disease because of its life-threatening potential and high curability rates with early, specialized treatment. The probability of cure is high even when the disease has spread far from the uterus. About 70% of patients with high-risk disease go into remission, while the cure rates for properly managed molar pregnancy and vigorously treated nonmetastatic GTT are nearly 100%. About 80% of patients with widely metastasized disease are cured when treated with prompt, aggressive chemotherapy sometimes combined with surgery and radiation.

Combination chemotherapy achieves results in nearly three out of four patients (74%) who have not responded to other forms of treatment, and more than three out of four high-risk patients (76%) who have not previously been treated with chemotherapy. More than half of patients (57%) whose earlier treatment did not eradicate the disease also achieve good results with combination chemotherapy. The survival rate for patients treated with combination chemotherapy is 84%.

Clinical trials

Researchers throughout the United States are currently investigating the following concerns:

- How effective are certain chemotherapy drugs in treating GTT that has not responded to other therapies or that has recurred after treatment?
- At what dosages do specific chemotherapy drugs become toxic?
- How does the frequency of chemotherapy treatments affect a patient's prognosis?
- What is the relationship between the start of chemotherapy and an immediate drop in a patient's HCG levels?

Prevention

The cause of GTT is not known, but the risk is higher than normal for a woman who belongs to blood group A and whose partner belongs to blood group O.

Special concerns

Medical oncologists emphasize the importance of the following treatment factors:

- Chemotherapy should be started as early in the course of the disease as possible.
- Chemotherapy should be administered every 14 to 21 days until HCG blood levels drop to normal.
- High-risk patients should be treated with combination chemotherapy regardless of the stage of their disease.
- Monthly blood tests should be continued for one year after HCG levels drop to normal.
- A woman who has been treated for GTT should wait at least a year before becoming pregnant and see her doctor as soon as she becomes or thinks she might be pregnant.

Giant cell tumors

Definition

Giant cell tumor generally refers to a bone tumor and is typically found in the end of arm and leg bones.

Description

Giant cell tumor of the bone is also referred to as an osteoclastoma as it contains a large number of giant cells resembling a type of bone cells called osteoclasts. Half of all giant cell tumors occurs in the knee, at the lower end of femur (thigh bone) or upper tibia (one of the bones of the lower leg). The tumor is usually located eccentrically and often causes expansion of the bone end. The tumor destroys the bony structure and thus could lead to fractures, even in the absence of stress. Other giant cell tumors can occur in virtually any other bone, including the sacrum, pelvis, and small bones of hands and feet. The growth of this tumor is variable and unpredictable. It is considered to be benign, but can recur following surgical removal. It can also have pulmonary metastases that are mostly curable. Some of the giant cell tumors may change into malignant **sarcomas**, especially when they recur after high-dose radiation treatment.

Giant cell tumor of tendon sheath

Giant cell tumor of tendon sheath is also referred to a localized nodular tenosynovitis. It usually occurs as single, painless mass that grows slowly. It is mainly found in the wrist and fingers. These are benign growths that can be easily excised (surgically removed). This type is not discussed further in this entry.

Demographics

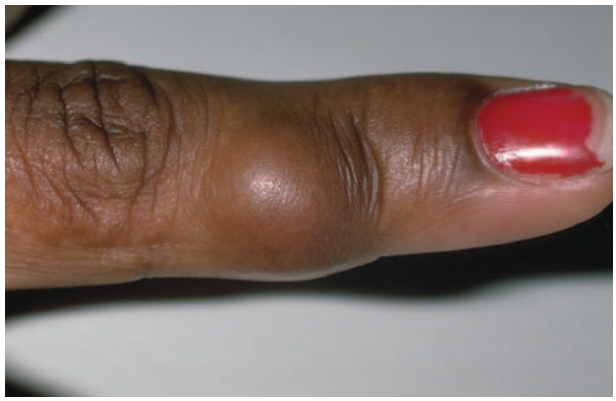
Giant cell tumor of bone is mostly seen in adults between the ages of 20 and 40 years. It is slightly more common among women than men and is seen in Asians more than other ethnic groups. It is very uncommon in children.

Causes and symptoms

The cause of giant cell tumors of bone is unknown.

The following symptoms may be seen in patients with giant cell tumors:

- Pain: As this tumors mainly occurs in the joints, arthritic pain is usually the first symptom.
- Swelling: Giant cell tumor causes enlargement of the bone and, as it grows, the patient may find a swelling at the site of the tumor.



Giant cell tumor of a tendon in a woman's finger. *(Custom Medical Stock Photo. Reproduced by permission.)*

- Fracture: Giant cell tumors destroy the surrounding bone and, unlike other bone cancers, fractures are common as the tumor grows. Initially the patient may have a sore or painful joint and the fracture could make it suddenly, severely painful.

Diagnosis

Typically the patient with giant cell tumor will go to the doctor because of pain. The doctor will perform routine physical tests and test the affected area for tenderness, swelling, warmth, redness, and mobility. An **x ray** of the affected area will be obtained. Certain other imaging tests could be done, including **magnetic resonance imaging** (MRI) and computed tomography (CT scan) to see extent of growth. CT scan of the chest will also be done to test for **metastasis** to the lungs. An isotope scan may be also done to test for extent of damage. These techniques are noninvasive and can be performed within a day. A surgical **biopsy** is always done either before or during surgical removal of the tumor. The biopsy determines whether the tumor is malignant and identifies the stage of the tumor. This may done under either local or general anesthesia, depending upon the location of the tumor and the condition and age of the patient.

Treatment team

The treatment team will consist primarily of radiation oncologist, orthopedic oncologist, and oncology nurse. Following surgical removal of the tumor, recovery may be aided by physical therapists.

Clinical staging, treatments, and prognosis

As of 2001 no satisfactory method for grading the tumor into either benign or malignant was available. Most giant cell tumors are initially classified as benign

KEY TERMS

Computed tomography—Commonly known as CT or CAT scan. It uses a rotating beam of x ray to get internal images of the body from different angles. During this test a harmless dye may be injected to increase contrast between normal and abnormal tissues.

Curettage—Surgical method in which a tumor is scraped away from the healthy tissue.

Magnetic resonance imaging—Also referred to as MRI. A procedure using a powerful magnetic field and radio waves to produce images of internal organs. MRI images can be used to look at soft tissues like muscle and fat.

Sarcoma—Uncommon, malignant tumors that begin in bones, or soft tissues such as muscle or fat.

QUESTIONS TO ASK THE DOCTOR

- What kind of surgery will need to be done for removal of the tumor?
- What will be the limitations after the removal of the tumor?
- Did you find any metastasis in the lungs?
- Is curettage instead of resection a possibility?

(grade 0). The tumor may progress in three stages. Stage 1, or latent stage, consists of a very slow growing tumor. It is well demarcated and there is little destruction of the outer surface of the bone. Stage 2, or the active stage, is the most commonly found stage. In this stage the tumor grows more steadily and the cortex (or outer layer of the bone) is lost. Stage 3 is the aggressive stage and accounts for about 20% of all giant cell tumors. In this stage the tumor grows rapidly and extends beyond the bone into the soft tissue. This stage is also associated more frequently with fractures.

Treatment of giant cell tumors is mainly surgical. Most stage 1 and 2 and some stage 3 tumors are treated by aggressive curettage, and the bone may be treated chemically and filled with cement. In some stage 2 and most stage 3 lesions the affected section of the bone may have to be removed (en bloc resection). In very rare cases the tumor may be so expanded that **amputation** may be necessary. Radiation is used to treat giant cell tumors in a location difficult to treat surgically. **Chemotherapy** has not been shown to be effective against giant cell tumors.

Prognosis following resection is excellent, with less than 5% chance of recurrence. When the tumor is removed by curettage followed by aggressive chemical treatment, there is a 5-10% chance of local recurrence. When the tumors recur locally it is usually within three years of surgical removal and the patient needs to be monitored closely during this time. A small percentage of giant cell tumors can metastasize to the lungs. The metastases can be removed surgically and most can be cured.

When a rare case of malignant sarcoma develops from a giant cell tumor, it is treated aggressively by surgery. In these cases, prognosis is poor and long-term survival rate is as low as 20-30%.

Alternative and complementary therapies

There are no alternative or complementary therapies available for giant cell tumors.

Coping with cancer treatment

As the treatment for giant cell tumors is mainly surgical, physical therapy with strengthening exercises to restore range of motion is extremely important. If amputation is required resulting psychological effects will also have to be addressed, especially as this disease occurs in adults who are physically and sexually active.

Clinical trials

As of 2001 there were no ongoing **clinical trials** by any major agencies specifically for treatment of giant cell tumors.

Prevention

As the cause of giant cell tumors is not known, there is no known method for prevention. When adults in the age group of 20-40 years notice pain and swelling in the joints, prompt radiological evaluation could identify giant cell tumors in early stages and lead to a complete cure.

Special concerns

Whenever a giant cell tumor is suspected, a chest CT scan should also be performed to check for metastasis to the lungs. During pregnancy the tumor can grow more rapidly, in which case it may be better to wait to perform surgery until the baby can be safely delivered by induction. If a patient with giant cell tumor suffers a fracture at the affected area, it may be best to wait until the fracture is healed before performing the surgery.

Glutamine

Definition

Glutamine is an amino acid that is used as a nutritional supplement in the treatment of a variety of diseases, including cancer.

Purpose

Glutamine is the most abundant free amino acid in the human body and, in addition to its role as a component of protein, serves a variety of functions in the body. It is a non-essential amino acid because it is made by body cells. In addition most dietary protein contains ample amounts of glutamine and healthy people usually obtain all the additional glutamine that they need in their diet.

Cancer and other diseases and injuries induce a state of physiologic stress that is characterized by glutamine deficiency. This deficiency is aggravated by **chemotherapy** and **radiation therapy** used to treat cancer. Therefore, glutamine is sometimes described as a conditionally essential amino acid that needs to be supplemented when the body is stressed.

Cancer-related glutamine deficiency can reduce the tolerance of normal tissues to cancer treatment, necessitating reduced doses and possibly diminishing the effects of treatment. Glutamine supplementation may help protect normal tissues from chemotherapy and radiation while sensitizing tumor cells to these agents.

Increasingly in the early 2000s, glutamine is considered an important component of both oral and parenteral (intravenous) nutrition (PN) therapy during high-dose chemotherapy and radiation treatment. It also is used as a nutritional supplement for bone marrow transplant (BMT) patients, particularly those with leukemia or **lymphoma** whose bone marrow has been destroyed with high-dose chemotherapy.

Glutamine supplementation appears to do the following:

- improve nitrogen retention
- decrease the incidence of infection
- decrease the length of hospitalization, saving thousands of dollars

Glutamine supplementation also appears to reduce the incidence of gastrointestinal, nervous system, and heart complications arising from cancer therapy. Oral glutamine may reduce **diarrhea** and the duration and severity of other gastrointestinal side effects of chemotherapy. In particular it appears to help prevent the intestinal toxicity of the cancer drug **fluorouracil**. Glutamine may reduce the incidence and severity of **mucositis**, a common, painful inflammation of the membranes of the oral cavity that can result from chemotherapy. Rinsing with a glutamine-containing mouthwash can help reduce mouth sores from radiation and chemotherapy treatments. Glutamine also appears to reduce the need for antifungal agents during chemotherapy.

Description

Glutamine (Gln) or L-glutamine is available by prescription as a powder called NutreStore. It is taken as an oral suspension for treating short bowel syndrome. It also is available in nutritional formulas and as an individual nutritional supplement. As an intravenous supplement it may be supplied in the form of alanyl-glutamine dipeptide or glycyl-glutamine dipeptide.

Metabolic effects

There is much speculation about why glutamine appears to be a beneficial adjunct for cancer treatment. Glutamine is required for numerous metabolic processes, including the following:

- Regulation of cell growth and function.
- Synthesis of proteins and nucleic acids (DNA and RNA).
- Movement of nitrogen in the body. Glutamine is the body's primary means of transferring ammonia in a nontoxic form.
- Gluconeogenesis—the formation of glucose from protein and fat.

- Maintenance of acid-base equilibrium in the body.
- As a major fuel for intestinal mucosal cells.
- Improved kidney cell function.

Tumors cause major disruptions in nitrogen and glutamine metabolism. The high rate of protein synthesis in rapidly growing tumors requires a continuous supply of amino acids. Tumors are referred to as nitrogen traps because they actively compete with normal tissues for nitrogen-containing compounds such as glutamine. Tumors also are referred to as glutamine traps because glutamine moves from normal tissues to tumors. Some evidence suggests that glutamine supplementation may diminish tumor growth, in part by improving overall protein metabolism.

Cancer cells generally move glutamine across their cell membranes at a faster rate than normal cells. Glutaminase—the enzyme that breaks down glutamine—has increased activity in cancerous cells, and there is evidence that glutaminase activity correlates with the proliferation of malignant cells.

Immunological effects

Glutamine and arginine may be referred to as immunonutrients because of their important roles in the functioning of the immune system that protects the body from foreign entities, including cancer cells. Glutamine helps to regulate the immune system and is a major fuel for lymphocytes (a type of white blood cell) and other immune system cells. In cancer patients undergoing chemotherapy and total body irradiation, glutamine has been shown to boost the immune system by increasing the levels of circulating lymphocytes and other cells of the immune system.

In patients undergoing chemotherapy with radioactive drugs for advanced **esophageal cancer**, oral glutamine supplementation helped to protect immune system function by causing lymphocytes to divide and multiply. Glutamine supplementation also reduced the permeability of the gastrointestinal tract in these patients.

Antioxidative effects

Glutamine appears to be the rate-limiting factor for the production of liver and intestinal glutathione (GSH), a chemical that protects cells against the damaging effects of oxidation. As cancer cells deplete the glutamine in normal cells, the levels of GSH drop. It has been suggested that PN without added glutamine may itself decrease GSH levels and increase oxidative damage. By increasing GSH levels, oral glutamine supplementation also may increase the selectivity of anticancer drugs by protecting normal cells from oxidative damage caused by the drugs. Glutamine supplementation also appears to protect normal cells from radiation-induced oxidative damage. Since GSH depletion reduces the activity of natural killer cells (immune system cells that destroy cancer cells) glutamine supplementation may increase GSH levels and restore natural-killer-cell activity. Some evidence suggests that this may diminish tumor growth.

Effectiveness

As of 2005, glutamine supplementation during cancer therapy and bone marrow or stem cell transplantation remains under investigation. Although some studies have demonstrated specific benefits in at least some types of cancer, numerous animal and human studies have shown no clear benefit or any effect on tumor response or on the side effects of chemotherapy. However, one study suggested that glutamine supplementation could increase the likelihood of long-term survival in patients with cancers of the blood.

Other studies have found that glutamine supplementation in cancer patients receiving high-dose chemotherapy and BMT decreases the incidence and/or severity of the following:

- chemotherapy-associated mucositis
- diarrhea associated with **irinotecan**, a drug used to treat colon and rectal cancers
- nervous system damage caused by the anticancer drug paclitaxel
- cardiac toxicity caused by the drug anthracycline

Combination supplements

Cancer-related cachexia (severe malnutrition, weakness, and muscle-wasting) is caused by the increased breakdown of proteins and reduced protein synthesis in patients with advanced cancer. One study demonstrated that supplementation with specific nutrients, including a combination of glutamine, beta-hydroxy-beta-methylbutyrate (HMB), and arginine, could reverse these processes. Patients with stage IV cancer who received this combination gained significant fat-free body mass in four weeks and continuing over a period of 24 weeks, as compared to control patients who lost body mass.

Case studies have reported that the administration of glutamine orally and intravenously, in combination with oral vitamin E, decreases the signs and symptoms of hepatic veno-occlusive disease. This is an often-fatal type of liver failure that occurs in patients treated with high-dose chemotherapy in preparation for BMT.

KEY TERMS

Arginine—An essential amino acid derived from dietary protein; sometimes used in combination with glutamine to boost the immune system.

Beta-hydroxy-beta-methylbutyrate, HMB—A nutritional supplement used to buildup muscles and to treat muscle-wasting caused by disease.

Bone marrow transplant, BMT—The destruction of bone marrow by high-dose chemotherapy or radiation and its replacement with healthy bone marrow taken from the patient prior to chemotherapy or from a donor.

Cachexia—Severe malnutrition, weakness, and muscle-wasting caused by disease.

Gluconeogenesis—The formation of glucose from non-carbohydrates such as protein or fat.

Glutaminase—The enzyme that breaks down glutamine; high glutaminase activity may be correlated with the proliferation of cancer cells.

Glutathione (GSH)—A three-amino-acid tripeptide that reduces harmful oxygen radicals and activates some proteins, including natural killer cells.

Hepatic veno-occlusive disease—Liver failure caused by chemotherapy that may benefit from glutamine supplementation.

Lymphocyte—A white blood cell of the immune system, making up 25–33% of all adult white blood cells.

Mucositis—A common, painful inflammation of the membranes of the mouth caused by chemotherapy.

Natural killer cell—A type of lymphocyte that kills cancer cells and certain microorganisms.

Parenteral nutrition (PN)—Intravenous feeding.

Short bowel syndrome—A condition that occurs after a large segment of the small intestine has been removed; it is treated with glutamine.

Tryptophan—An essential amino acid that is sometimes used in combination with glutamine supplementation.

Recommended dosage

Glutamine supplementation generally is started three to five days before chemotherapy. The glutamine dosage used to treat short bowel syndrome is 5 g, six times per day for up to 16 weeks. It is taken with food, every two to three hours while awake. Nutritional guidelines for cancer patients generally recommend 2–4 g of glutamine per day to protect against radiation-induced **enteritis** (intestinal inflammation).

Dosages used in clinical studies of glutamine supplementation in cancer patients vary:

- 18–30 g per day, orally
- 10 g three times per day, orally
- 0.57 g per kg (2.2 lb.) of body weight per day
- 50 g per day of dipeptide glycyl-glutamine, in-travenously
- 0.4 g per kg (2.2 lb.) of body weight per day of dipeptide glycyl-glutamine, intravenously
- 14 g of glutamine per day in combination with arginine and HMB for up to 24 weeks

Precautions

Glutamine, taken orally or by injection, appears to be safe; however, precautions include the following:

- Excess amino acids may be excreted in the urine without being absorbed by the body.
- Excess amino acids can harm the kidneys.
- Glutamine, like any drug, can potentially cause an allergic reaction.
- It is not known whether glutamine supplementation is safe during pregnancy or while breastfeeding.
- Elderly patients may be more sensitive to glutamine supplementation, requiring lower doses.
- Glutamine can worsen liver disease.

Since glutamine is essential for the growth of both healthy and cancerous cells, it is theoretically possible that glutamine could fuel tumor cells, leading to more rapid growth. However, there is no evidence to suggest this, nor is there evidence that glutamine supplementation adversely affects treatment or clinical outcomes.

Side effects

Glutamine supplementation in cancer patients does not appear to cause side effects or adversely affect quality of life.

Interactions

Glutamine supplementation is not known to negatively interact with other medications.

Goserelin acetate

Definition

Goserelin acetate is a synthetic (man-made) hormone that acts similarly to the naturally occurring gonadotropin-releasing hormone (GnRH). It is available in the United States under the tradename Zoladex.

Purpose

Goserelin acetate is used primarily to counter the symptoms of late-stage **prostate cancer** in men or is offered as an alternative to treat prostate cancer when surgery to remove the testes or estrogen therapy is not an option or is unacceptable for the patient. Goserelin is also given as combination therapy with the drug flutamide to manage prostate cancer that is locally confined and not widespread. It is often used to ease the pain and discomfort of women suffering from endometrosis and to relieve symptoms in women with advanced **breast cancer**.

Description

Goserelin acetate is a man-made protein that mimics many of the actions of gonadotropin-releasing hormone (GnRH). In men, this results in decreased blood levels of the male hormone **testosterone**. In women, it decreases blood levels of the female hormone estrogen.

Recommended dosage

Goserelin acetate is given in the form of an implant containing 3.6 mg of the medication. This implant is placed just under the skin of the upper abdominal wall. The drug lasts for 28 days, after which a new implant has to be placed. Goserelin is also available in a dose of 10.8 mg, in which case the drugs lasts for three months.

Precautions

If a woman becomes pregnant while taking this drug, goserelin acetate may cause birth defects or the loss of the pregnancy. It is not known if goserelin is passed into breast milk; therefore, it is not recommended to breast feed while on this drug.

Goserelin acetate will also interfere with the chemical actions of birth control pills. For this reason, sexually active women who do not wish to become pregnant should use some form of birth control other than birth control pills during treatment with goserelin acetate and for at least 12 weeks after the completion of treatment.

Goserelin acetate will cause sterility in men, at least for the duration of the treatment.

Side effects

In patients of both sexes, common side effects of goserelin acetate include:

- sweating accompanied by feelings of warmth (hot flashes)
- a decrease in sex drive
- depression or other mood changes
- headache
- tumor flare, which is exhibited as **bone pain** (this is due to a temporary initial increase in testosterone/estrogen before its production is finally decreased)

Other common side effects in men include:

- impotence (erectile dysfunction)
- sterility
- breast enlargement

Other common side effects in women include:

- light, irregular, vaginal bleeding
- no menstrual period
- vaginal dryness and/or itching
- emotional instability
- depression
- change in breast size
- an increase in facial or body hair
- deepening of the voice

Less common side effects, in patients of either sex, include:

- nausea and vomiting
- insomnia
- weight gain
- swollen feet or lower legs
- acne or other skin rashes
- abdominal pain
- increased appetite

A doctor should be consulted immediately if the patient experiences any of the above symptoms.

Interactions

There are no known interactions of goserelin acetate with any food or beverage.

Patients taking goserelin acetate should consult their physician before taking any other prescription, over-the-counter, or herbal medication. Patients taking any other

KEY TERMS

Endometrial tissue—The tissue lining the uterus that is sloughed off during a woman's menstrual period.

Gonadotropin releasing hormone (GnRH)—A hormone produced in the brain that controls the release of other hormones that are responsible for reproductive function.

Prostate gland—A small gland in the male genitals that contributes to the production of seminal fluid.

hormone or steroid-based medications should not take goserelin acetate without first consulting their physician.

Graft-vs.-host disease

Description

Graft-vs.-host disease is a response by the immune system that occurs when cells from a blood or bone marrow donor attack those of the recipient. The only transplanted tissues that contain enough immune cells to cause graft-vs.-host disease are the blood and the bone marrow. Blood transfusions are used every day in hospitals for many reasons. Bone marrow transplants are used to replace blood-forming cells and immune cells in cancer patients whose own bone marrow has been destroyed by **radiation therapy** or **chemotherapy**.

Blood transfusion graft-vs.-host disease affects mostly the blood. Blood cells perform three functions: carrying oxygen, fighting infections, and clotting. All of these functions are decreased in a transfusion graft-vs.-host reaction, leading to **anemia** (lack of red blood cells in the blood), reduced resistance to infections, and increased bleeding. The reaction occurs 4–30 days after the transfusion.

The tissues most affected by bone marrow graft-vs.-host disease are the skin, the liver, and the intestines. One of these forms of tissue is affected in nearly half of the patients who receive bone marrow transplants.

Bone marrow graft-vs.-host disease comes in both an acute and a chronic form. The acute form appears within two months of the transplant, while the chronic form usually appears within three months. The acute disease produces a skin rash, liver abnormalities, and **diarrhea** that can be bloody. The skin rash is primarily a patchy thickening of the skin. Chronic disease can produce a similar skin rash, a tightening or an inflammation of the skin, lesions in the mouth, drying of the eyes and mouth, hair loss (alopecia), liver damage, lung damage, and indigestion. The symptoms are similar to an autoimmune disease called scleroderma.

Both forms of graft-vs.-host disease bring with them an increased risk of infections, either because of the process itself or its treatment with cortisone-like drugs and immunosuppressives that inhibit the **immune response**. Patients can die of liver failure, infection, or other severe disturbances of their system.

Causes

Cells from the donor who has an active immune system may be transplanted along with the organ or tissue into the host who has a suppressed immune system. These transplanted cells attack the host's body, causing graft-vs.-host disease. Substances made in the body called cytokines are thought to play a role in the development of this reaction. Cytokines are protein substances made by cells that affect other cells.

Even if the donor and recipient are well matched, graft-vs.-host disease can still occur. There are many different components involved in generating immune reactions, and all people (except identical twins) are different. Testing can often find donors who match all the major components, but there are many minor ones that will always be different. Making a match between a donor and recipient depends upon the urgency of the need for a transplant and the chance that a suitable donor will be found.

Treatments

Both the acute and the chronic diseases are treated with cortisone-like drugs, immunosuppressive agents, or with **antibiotics** and immune chemicals from donated blood (gamma globulin). **Cyclosporine** and prednisone are two immunosuppressive drugs that are often used, and **methotrexate** may enhance efficacy. Another way to prevent graft-vs.-host disease is, before transplantation, rid donor bone marrow of the immune cells (T cells) that would attack the recipient's body. Another possibility to avoid complications in **bone marrow transplantation** is to cleanse the bone marrow of cancer cells and use the patient's own cells to grow more bone marrow. Cancer cells that reside in the bone marrow may be removed, leaving behind only those cells that are needed to grow new blood cells (stem cells). These stem cells from the patient can be grown and returned back to the patient.

For recipients of blood transfusions who are especially likely to have graft-vs.-host reactions, the red blood cells can safely be irradiated (using x rays) to kill all the immune cells. The red blood cells are less sensitive to radiation and are not harmed by this treatment.

New directions in research may help to solve the problem of graft-vs.-host disease. A potential source for new stem cells is the umbilical cord. Cells from this area do not give such strong immune reactions and may be useful for re-establishing cell populations. Another potential is to use genetically engineered cells to correct genetic defects in stem cells within the marrow.

Alternative and complementary therapies

Alternative and complementary therapies range from herbal remedies, vitamin supplements, and special diets to spiritual practices, acupuncture, massage, and similar treatments. When these therapies are used in addition to conventional medicine, they are called complementary therapies. When they are used instead of conventional medicine, they are called alternative therapies.

Complementary or alternative therapies are widely used by people suffering with illness. Good nutrition and activities, such as yoga, meditation, and massage, that reduce stress and promote a positive view of life have no unwanted side effects and appear to be beneficial. Alternative and experimental treatments are normally not covered by insurance.

Special concerns

If graft-vs.-host disease is suspected as a complication to a cancer treatment, a skin punch **biopsy** may be performed to confirm this diagnosis. This is a relatively minor procedure in which the skin is anesthetized in a local area and a small piece is removed for testing in the laboratory.

Infection with one particular virus, called cytomegalovirus (CMV), is so likely a complication of graft-vs.-host disease that some experts recommend treating it in advance, using ganciclovir or valacyclovir.

It is an interesting observation that patients with leukemia who develop graft-vs.-host disease are less likely to have a recurrence of the leukemia that was being treated. This phenomenon is called graft-vs.-leukemia.

Bone marrow transplant patients who do not have a graft-vs.-host reaction gradually return to normal immune function in a year. A graft-vs.-host reaction may prolong the diminished immune capacity indefinitely, requiring supplemental treatment with immunoglobulins (gamma globulin). The grafted cells develop a tolerance to the recipient's body after 6–12 months, and the medications can be gradually withdrawn.

KEY TERMS

Anemia—Too few red blood cells, or too little hemoglobin in them.

Immunoglobulin—Chemicals in the blood that defend against infections.

Immunosuppressive—A chemical that suppresses an immune response.

Lesion—Localized disease or damage.

Scleroderma—Progressive disease of the connective tissue of the skin and internal organs.

Graft-vs.-host disease is not the only complication of blood transfusion or bone marrow transplantation. Host-vs.-graft disease, or rejection, occurs when the recipient's immune system is strong enough to attack the transplant. This is also a common occurrence and may require a repeat transplant with another donor organ. Infections are a constant threat in bone marrow transplant because of the disease being treated, the prior radiation or chemotherapy and the medications used to treat the transplant.

Gynecologic cancers

Definition

Gynecologic cancers are malignant tumors within the female reproductive organs.

Description

Gynecologic cancers account for approximately 13% of all cancers that affect women. They are responsible for 10% of the cancer deaths among women. Eaxh year, more than 80,000 woman are diagnosed with a gynecologic cancer and 26,0000 women die from these diseases.

The female reproductive tract is comprised of the ovaries, fallopian tubes, uterus, cervix, vagina, and vulva. Together, these organs allow a woman to become pregnant, protect and nourish an unborn baby, and give birth. An understanding of each organ and its role in reproduction may help the patient to understand her particular gynecologic cancer. There are two ovaries, which are the internal organs dedicated to producing eggs. Released eggs are captured by the fallopian tubes, through which the egg (or fertilized egg) travels to the womb (uterus). The lining of the uterus (endometrium) responds to female hormones, such as estrogen, and becomes thickened to allow for implantation of a fertilized egg. The cervix is the opening of the uterus which opens (dilates) during labor to allow for passage of the baby. The vagina is a short tube that extends from the outer female genitalia (vulva) to the cervix.

Gynecologic cancers are defined not solely by the organ affected but also by the type of cancerous cells in the tumor. The type of cancer depends on the cell types that make up an organ. Adenocarcinomas are cancers that contain primarily cells originating from glands or ducts. Squamous cell carcinomas are tumors that arose from squamous cells, the main cell type found in skin. Sarcomas are cancers that originated from cells of basic connective tissue (mesenchymal cells). Sarcomas are comprised of cells that have become specialized (differentiated) and are named according to the predominant cell type. Endometiroid tumors are those that originated from the endometrium. Clear-cell **carcinoma** is a rare gynecologic tumor that contains cells from the mullerian duct, which gives rise to the uterus, vagina, and fallopian tubes during development.

Because the reproductive organs are interconnected, spread of cancer from one organ to another (direct extension) is not uncommon. Gynecologic cancer carries the name of the organ where the cancer originated (primary cancer site). For example, a tumor restricted to the vagina would be "primary vaginal cancer," whereas one that has extended from the cervix to the vagina would be "primary cervical cancer."

Gynecologic cancers

Cancer type	Occurs in	Tumor types
Endometrial cancer	Uterus	Endometrioid tumors Clear-cell carcinomas Papillary serous Sarcomas Mixed tumors
Fallopian tube cancer	Fallopian tubes, but frequently spreads	Serous carcinomas Mucinous tumors Endometrioid tumors
Cervical cancer	Cervix	Squamous cell carcinomas Adenocarcinomas Clear-cell carcinoma Serous carcinoma Glassy-cell carcinoma
Ovarian cancer	Ovaries	Serous carcinomas Mucinous tumors Endometrioid tumors
Vaginal cancer	Vagina	Squamous cell carcinoma Adenocarcinoma Melanoma Sarcoma
Vulvar cancer	Vulva	Squamous cell carcinomas Melanoma Basal cell carcinoma Paget's disease Adenocarcinomas

Although many causes exist for the different gynecologic cancers, new research in 2003 as part of the Women's Health Initiative, a major study, found that estrogen-progestin therapy (hormone replacement therapy) for postmenopausal women may have increased risk for some gynecologic cancers, though data was still being studied in late 2003. New legislation also was introduced in that year to improve early detection of gynecologic cancers.

Types of cancers

Ovarian cancer is the second most common cancer of the female reproductive organs. It accounts for 30% of all gynecologic cancers and 53% of the deaths in this group. The high death rate associated with ovarian cancer is due to the fact that most women are not diagnosed until the cancer has progressed to an advanced stage. The average age at diagnosis is 63 years. Serous carcinomas are the most common type of ovarian cancer. Other common types of ovarian cancer include mucinous tumors and endometrioid tumors.

Fallopian tube cancers, as primary cancers, are very rare. They frequently spread widely within the abdominal cavity. Although often diagnosed earlier than ovarian cancer, fallopian tube cancer produces similar symptoms and originates from similar cell types as ovarian cancer.

KEY TERMS

Differentiated—A term describing cells that have matured normally and have become specialized, such as muscle cells.

Direct extension—The spread of cancer directly from one organ to a neighboring organ, such as from the cervix to the vagina.

Glassy cell carcinoma—Tumorous cells that have a glass-like appearance

Human papilloma virus (HPV)—A sexually transmitted virus that causes genital warts. It is associated with certain gynecologic cancers.

Mucinous tumors—Adenocarcinomas that produce significant amounts of the complex sugar molecule known as mucin.

Papillary serous carcinoma—A serous carcinoma with papillary (nipple-like) outgrowths.

Primary cancer (or tumor)—The organ in which a cancerous tumor originated.

Serous carcinoma—A carcinoma that produces or contains serum, the liquid portion of blood.

Uterine cancer, also called **endometrial cancer**, is the most common gynecologic cancer and accounts for 46% of the cases. Endometrial cancer primarily affects postmenopausal women, however, 25% of cases are in premenopausal women. There are two types of endometrial cancer: estrogen-dependent and non-estrogen-dependent. Estrogen-dependent cancers are usually comprised of well-differentiated cells and are associated with a good outcome and a long survival time. Non-estrogen-dependent cancers are usually made up of poorly differentiated cells and are invasive and associated with a poor prognosis. Uterine tumors are most frequently endometrioid tumors, usually adenocarcinomas. Clear-cell carcinomas, papillary serous, sarcomas, and mixed tumors also occur.

Cervical cancer is the third most common cancer of the female reproductive tract. It accounts for 17% of the gynecologic cancers. Although cervical cancer can affect any adult woman, there are peaks of occurrence around the ages of 37 years and 62 years. Between 60% and 80% of the cases of cervical cancer are squamous cell carcinomas with the remainder being adenocarcinomas. Clear-cell carcinoma, serous carcinoma, and glassy-cell carcinoma are less frequent cervical cancers. Cervical cancer is very strongly associated with **human papilloma virus**.

Vaginal cancer is rare and accounts for just 3% of the gynecologic cancers. It most often strikes women in their sixties. Greater than 90% of the vaginal cancers are squamous cell carcinomas. Adenocarcinoma, **melanoma**, and sarcoma account for the remaining cases. There is an association between vaginal cancer and human papilloma virus.

Vulvar cancer is rare and accounts for 4% of the gynecologic cancers. It most often strikes women in their sixties. Squamous cell carcinoma is the most common type and melanoma is the second most common type of vulvar cancer. Other types of vulvar cancer include **basal cell carcinoma**, Paget's disease, and adenocarcinomas (arising from the Bartholin's, Skene's, or sweat glands). There is an association between vulvar cancer and human papilloma virus.

Hair loss *see* **Alopecia**

Hairy cell leukemia

Definition

Hairy cell leukemia is a disease in which a type of white blood cell called the lymphocyte, present in the blood and bone marrow, becomes malignant and proliferates. It is called hairy cell leukemia because the cells have tiny hair-like projections when viewed under the microscope.

Description

Hairy cell leukemia (HCL) is a rare cancer. It was first described in 1958 as *leukemic reticuloendotheliosis*, erroneously referring to a red blood cell because researchers were unsure of the cell of origin. It became more easily identifiable in the 1970s. There are approximately 600 new cases diagnosed every year in the United States, making up about 2% of the adult cases of leukemia each year.

HCL is found in cells located in the blood. There are three types of cells found in the blood: the red blood cells that carry oxygen to all the parts of the body; the white blood cells that are responsible for fighting infection and protecting the body from diseases; and the platelets that help in the clotting of blood. Hairy cell leukemia affects a type of white blood cell called the lymphocyte. Lymphocytes are made in the bone marrow, spleen, lymph nodes, and other organs. It specifically affects B-lymphocytes, which mature in the bone marrow. However, extremely rare variants of HCL have been discovered developing from T-lymphocytes, which mature in the thymus.

When hairy cell leukemia develops, the white blood cells become abnormal both in the way they appear (by acquiring hairy projections) and in the way they act (by proliferating without the normal control mechanisms). Further, the cells tend to accumulate in the spleen, causing it to become enlarged. The cells may also collect in the bone marrow and prevent it from producing normal blood cells. As a result, there may not be enough normal white blood cells in the blood to fight infection.

Demographics

The median age at which people develop HCL is 52 years. Though it occurs in all ages, HCL more commonly develops in the older population. Men are four times more likely to develop HCL than women. There have been reports of familial aggregation of disease, with higher occurrences in Ashkenazi Jewish men. A potential genetic link is undergoing further investigation.

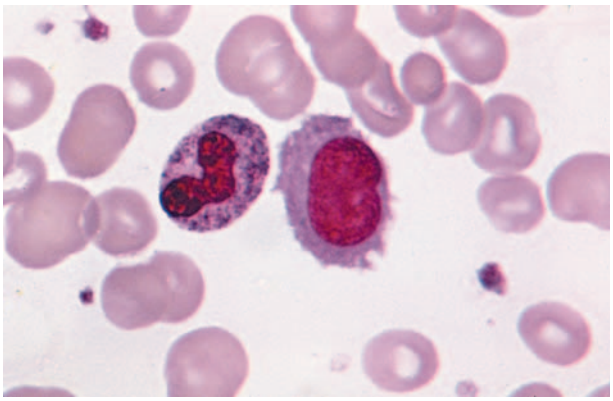
Causes and symptoms

The cause of hairy cell leukemia is not specifically known. However, exposure to radiation is a known cause of leukemia in general. Familial involvement is another theory, suggesting that there is a genetic component associated with this disease.

HCL is a chronic (slowly progressing) disease, and the patients may not show any symptoms for many years. As the disease advances, the patients may suffer from one or more of the following symptoms:

- weakness
- **fatigue**
- recurrent infections
- **fever**
- **anemia**
- bruising
- pain or discomfort in the abdominal area
- weight loss (uncommon)
- night sweats (uncommon)

Pain and discomfort are caused by an enlarged spleen, which results from the accumulation of the



A magnified image of white blood cells with "hairy" projections. *(Photograph by M. Abbey, Photo Researchers, Inc. Reproduced by permission.)*

abnormal hairy cells in the spleen. Blood tests may show abnormal counts of all the different types of cells. This happens because the cancerous cells invade the bone marrow as well and prevent it from producing normal blood cells. Because of the low white cell count in the blood, the patient may have frequent infections. Fever often accompanies the infections. The patient is most susceptible to bacterial infections, but infections of any kind are the major cause of death. The low red cell count may cause anemia, fatigue, and weakness, and the low platelet count may cause the person to bruise and bleed easily.

Diagnosis

When a patient suffers from the above symptoms, the doctor will palpate (examine with fingers) the abdomen and may order scans to see if the spleen is enlarged (splenomegaly). An enlarged spleen is present in 80% of patients. An enlarged liver is less common, but can occur.

If the spleen is enlarged, the doctor may order several blood tests. In these tests, the total numbers of each of the different types of blood cells (CBC) are reported. Sixty to eighty percent of patients suffer from pancytopenia, which is a dramatic reduction in the number of red blood cells, white blood cells, and platelets circulating in the blood.

If the blood tests are abnormal, the doctor may order a **bone marrow aspiration and biopsy**. In order to establish a diagnosis, hairy cells must be present in the bone marrow.

Treatment team

If the patient is seeing a primary care provider, the provider may perform the initial diagnostic tests. However, in order to diagnose and treat HCL comprehensively, the primary care provider will refer the patient to an oncologist (cancer specialist). Radiologists and pathologists will also be involved to read scans and examine tissue samples. Other specialists involved with the treatment of hairy cell leukemia will be nurses and dieticians who are available to explain side effects of treatment and offer suggestions on eating healthy meals that may help fight the side effects.

Clinical staging, treatments, and prognosis

When physicians perform blood tests, they will determine the level of hemoglobin (the oxygen-transporting molecule of red blood cells). Serum hemoglobin levels and the size of the spleen, which can be measured on exam and by using an **x ray**, are proposed criteria for determining the stage of HCL. The following are the three proposed stages and their criteria:

- Stage I: Hemoglobin greater than 12 g/dL (1 g = approximately 0.02 pint and 1 dL = approximately 0.33 ounce) and spleen less than or equal to 10 cm (3.9 inches).
- Stage II: Hemoglobin between 8.5 and 12 g/dL and spleen greater than 10 cm (3.9 inches).
- Stage III: Hemoglobin less than 8.5 g/dL and spleen greater than 10 cm (3.9 inches).

Since there is generally no accepted staging system, another method for evaluating the progression of HCL is to group patients into two categories: untreated HCL and progressive HCL, in which hairy cells are present after therapy has been administered.

Some people with hairy cell leukemia have very few or no symptoms at all, and it is reasonable to expect that 10% of patients may not need any treatment. However, if the patient is symptomatic and needs intervention, HCL is especially responsive to treatment.

There are three main courses of treatment: **chemotherapy**, **splenectomy** (surgical removal of the spleen), and immunotherapy. Once a patient meets treatment criteria, purine analogues, particularly the drugs, **pentostatin** and **cladribine**, are the first-line therapy. Pentostatin is administered at 5mg/m^2 for two days every other week until total remission is achieved. Patients may experience side effects such as fever, nausea and vomiting, photosensitivity, and keratoconjuctivitis. However, follow-up studies estimate a relapse-free survival rate at 76%. Cladribine (2-CdA) taken at 0.1mg/kg/day for seven days also has an impressive response. Eighty-six percent of patients experience complete remission after treatment, while 16% experience partial remission. Fever is the principal side effect of 2-CdA.

Biological therapy (also called immunologic therapy or immunotherapy), where the body's own immune

cells are used to fight cancer, is also being investigated in **clinical trials** for hairy cell leukemia. A substance called interferon that is produced by the white blood cells of the body was the first systemic treatment that showed consistent results in fighting HCL. The FDA approved interferon-alpha (INF-alpha) to fight HCL. The mechanism by which INF-alpha works is not clearly understood. However, it is known that interferon stimulates the body's natural killer cells that are suppressed during HCL. The standard dosage is 2 MU/m^2 three times a week for 12 months. Side effects include fever, myalgia, malaise, rashes, and gastrointestinal complaints.

If the spleen is enlarged, it may be removed in a surgical procedure known as splenectomy. This usually causes a remission of the disease. However, 50% of patients who undergo splenectomy require some type of systemic treatment such as chemotherapy or immunotherapy. Splenectomy is not the most widely used course of treatment as it was many years ago. Although the spleen is not an indispensable organ, it is responsible for helping the body fight infection. Therefore, other therapies are preferred in order to salvage the spleen and its functions.

Most patients have excellent prognosis and can expect to live 10 years or longer. The disease may remain silent for years with treatment. Continual follow-up is necessary to monitor the patient for relapse and determine true cure rates.

Alternative and complementary therapies

Many individuals choose to supplement traditional therapy with complementary methods. Often, these methods improve the tolerance of side effects and symptoms as well as enrich the quality of life. The American Cancer Society recommends that patients talk to their doctors to ensure that the methods they are using are safely supplementing traditional therapy. Some complementary treatments include the following:

- yoga
- meditation
- religious practices and prayer
- music therapy
- art therapy
- massage therapy
- aromatherapy

Coping with cancer treatment

The treatment and the disease interfere with the patient's ability to produce red blood cells, white blood cells, and platelets, causing the patient to be vulnerable to anemia and life-threatening infection and bleeding. Transfusions can be given to patients in order to increase the number of red blood cells and platelets in the blood. In addition, colony-stimulating factors are being studied. These increase the number of the patient's own white blood cells.

Nausea and vomiting can result from chemotherapy and are often controlled by prescription drugs called **antiemetics**. Patients can also curb nausea and vomiting by eating slowly and avoiding large meals. Drinking water an hour before meals and staying away from foods that are sweet or fried is also helpful. Many times, chemotherapy is handled better if the patient is eating well.

KEY TERMS

Anemia—A condition in which there is low iron in the blood due to a deficiency of red blood cells.

Bone marrow—The spongy tissue inside the large bones in the body that is responsible for making the red blood cells, white blood cells, and platelets.

Bone marrow aspiration and biopsy—A procedure in which a needle is inserted into the large bones of the hip or spine and a small piece of marrow is removed for microscopic examination.

Immunotherapy—A mode of cancer treatment in which the immune system is stimulated to fight the cancer.

Keratoconjunctivitis—Inflammation of the conjunctiva and cornea of the eye.

Leukemia—A disease in which the cells that constitute the blood become cancerous or abnormal.

Lymph nodes—Oval-shaped organs that are the size of peas, located throughout the body, and contain clusters of cells called lymphocytes. They filter out and destroy bacteria, foreign particles, and cancerous cells from the blood.

Malignant—Cells that have the ability to invade locally, cause destruction of surrounding tissue, and travel to other sites in the body.

Spleen—An organ that lies next to the stomach. Its function is to remove the worn-out blood cells and foreign materials from the blood stream.

Splenectomy—A surgical procedure that involves the surgical removal of the spleen.

QUESTIONS TO ASK THE DOCTOR

- How long will this course of treatment take?
- How long will the side effects last after treatment ends?
- What kinds of side effects will this course of treatment cause?
- Are there support services available?
- What treatments are currently in clinical trials?
- What treatments will my health care insurance cover?
- What alternative or complementary treatments are safe and effective?
- Why is this type of treatment being used?

Nurses and dieticians can aid patients in choosing healthful foods to incorporate into their diet.

Patients can fight anemia and fatigue by getting plenty of rest and minimizing strenuous activities. A well-balanced diet can also counter anemia and fatigue.

Although physicians will do everything possible to keep a patient's blood count high, there are precautions that can be taken by patients in order to reduce their risk of infection. Patients should regularly wash their hands, especially before and after eating meals and after using the restroom. Patients should avoid individuals who are contagious with colds, the flu, or the chicken pox. It is also helpful if patients do not cut themselves or do anything to expose deeper layers of the skin where bacteria can contaminate and cause infection. Finally, patients should avoid large crowds.

Clinical trials

Clinical trials are being performed to improve the effectiveness of treatment and to minimize the side effects. Patients may choose to volunteer for a clinical trial if they do not respond to standard therapy or if they want to reduce side effects. Clinical trials for the treatment of HCL involving purine analogues were being researched in 2005. Clinical trials are being performed all over the United States, and patients should discuss options with their doctors or contact the Cancer Information Service at (800) 4-CANCER (800-422-6237).

In many cases, insurance companies will not cover procedures that are part of clinical trials. Patients should talk with their doctor and insurance company to determine which procedures are covered.

Prevention

Since the cause for the disease is unknown and there are no specific risk factors, there is no known prevention.

Special concerns

Cancer treatments and their side effects can take a physical and psychological toll on cancer patients and their families. To deal with the psychological impact, there are many different support groups and psychotherapists that can help. Psychiatrists can prescribe medication to help with **depression**. Support groups can encourage and strengthen the psyche by relating to one another through shared experiences and success stories. Relying on faith practices is also beneficial for cancer patients to deal with their condition. Patients should discuss all options with their physician to determine what is available to them.

KEY TERMS

Dose-limited drug—A drug for which the proper dosage is determined by the reaction of each individual patient to the drug.

Hand-foot syndrome

Description

Hand-foot syndrome (HFS), also called palmar-plantar erythrodysesthesia syndrome (PPES), is a relatively common side effect associated with high dosage **chemotherapy** treatments involving fluorouracil (5-FU) and drugs belonging to the chemical class called anthracyclines.

Anthracyclines have been widely used since the 1960s as dose-limited chemotherapy drugs for a variety of cancers, particularly leukemia, metastatic **breast cancer**, **ovarian cancer**, and colorectal cancer. The most familiar anthracyclines are **capecitabine** (Xeloda), **daunorubicin** (Cerubidine), **doxorubicin** (Adriamycin), **idarubicin** (Idamycin), and **vinorelbine** (Navelbine). Each of these drugs is broken down into 5-FU by chemicals inside the cancer cells.

A dose-limited drug is a drug for which the maximum dose is determined by the reactions of an individual patient. Symptoms of HFS usually indicate that a patient is receiving too much 5-FU or a particular anthracycline. In such a case, the dosage of the drug that is causing HFS is usually decreased until these symptoms either disappear completely or become tolerable to the patient.

The primary symptom of HFS is a tingling sensation and/or numbness of the skin, particularly on the palms of the hands or the soles of the feet. Swelling and redness (erythema) often accompany this symptom. In severe cases, the skin may peel, develop ulcerations or blisters, and cause severe pain. In the most extreme cases, symptoms of HFS may make it difficult, or impossible, for the patient to grasp small objects, walk, or conduct other normal daily activities.

Causes

The symptoms of HFS are believed to be caused by some of the chemicals that 5-FU is broken down into by the natural biochemical processes of the body. Since all anthracycline drugs chemically breakdown into 5-FU, these drugs will all eventually be broken down into the chemicals that can cause the symptoms of HFS. For reasons that are not clear, some patients seem more prone to developing symptoms of HFS than other patients.

Treatments

The symptoms of HFS are usually alleviated by lowering the dosage of the drug that the patient is receiving. In severe cases of HFS, it may be necessary to discontinue the use of the drug that is causing these symptoms. In some, but not all, patients the symptoms of HFS are reduced by treatment with steroid-containing skin creams, such as hydrocortisone.

Alternative and complementary therapies

Treatment of the hands and feet with an aloe vera-containing skin cream may help to alleviate some of the symptoms of HFS. Topical treatment of the skin with dimethyl sulfoxide (DMSO) has also been suggested as an alternative treatment.

Head and neck cancers

Definition

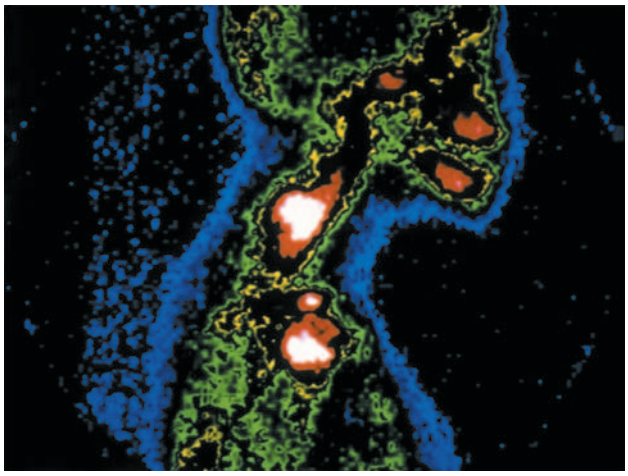
The group of cancers found in the head and neck region, excluding tumors of the eyes and brain.

Description

The tumors associated with head and neck cancers are found in several regions, including the lips, tongue, mouth, nasal passages, pharynx, larynx (voice box), salivary glands, thyroid gland, and parathyroid glands. Many head and neck cancers interfere with the functions of eating and breathing. **Laryngeal cancer** affects speech. Loss of any of these functions is significant. Therefore, early detection and appropriate treatment is of utmost importance.

Roughly 5% of all cancers occur in the head and the neck. The American Cancer Society (ACS) estimates that 56,500 Americans will develop cancer of the head and neck in 2004, and 14,500 will die from the disease.

The most common cancers of the head and neck area are **oral cancers**, **thyroid cancer**, and laryngeal cancer. Half of all head and neck cancers occur in the oral cavity and pharynx, a third are thyroid cancer, and almost 20% are found in the larynx. The American Cancer Society estimates that in 2004 approximately 10,270 new cases of laryngeal cancer will be diagnosed and 3,830 people will die of this disease. New cases of thyroid cancer in 2004 will likely reach over 23,600 and result in 1,460 deaths. Oral cancer is the tenth most common cancer in the United States, reaching nearly 29,000 new cases each year and causing at least 7,300 deaths.



False color scintigram (gamma camera scan) showing metastatic (secondary) cancer affecting the cervical (neck) vertebrae (white area). *(Copyright CNRI, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

The survival rates for head and neck cancers vary from good to poor, depending on the specific cancer. About 54% of the patients diagnosed with oral cancer will survive five years or more after the initial diagnosis. Laryngeal cancer has a five-year survival rate of nearly 65%. Among the different cancers, thyroid cancer has one of the better five-year survival rates, approaching 95%. The poorer survival rates for some head and neck cancers result because the early signs of these cancers are frequently ignored. Hence, when first diagnosed, they are often in an advanced stage and not very amenable to treatment.

Tobacco is regarded as the single greatest risk factor contributing to the occurrence of oral and laryngeal cancer: 75% to 80% of these patients are smokers. Heavy alcohol use has also been included as a risk factor. A combination of tobacco and alcohol use increases the risk for oral cancer by 6 to 15 times more than for users of either substance alone. Exposure to asbestos appears to increase the risk of developing laryngeal cancer. The chance for developing certain types of thyroid cancer is linked to an exposure to radiation. Infection with the Epstein-Barr virus (EBV) is a risk factor for nasopharyngeal cancer.

The risk for both oral cancer and laryngeal cancer seems to increase with age. Most of the cases occur in individuals over 40 years of age, and the average age at diagnosis is 60. While oral cancer strikes men twice as often as it does women, laryngeal cancer is four times more common in men than in women. Both diseases are more common in African Americans than among whites. Thyroid cancer is three times more common in women than in men and is usually diagnosed between the ages of 30 and 50.

Cancers of the head and neck

Cancer types	Cancer occurs in
Hypopharyngeal cancer	Lowest section of the pharynx (region behind mouth)
Laryngeal cancer	Larynx (front of neck, near Adam's apple)
Nasopharyngeal cancer	Behind nose Pharynx
Oral cancer	Lips Lining of lips and cheeks Front two-thirds of tongue Teeth Gums Under tongue
Oropharyngeal cancer	Back one-third of tongue Upper section of pharynx Area around tonsils
Parathyroid cancer	Parathyroid glands (found behind the thyroid gland)
Thyroid cancer	Thyroid gland (found at front of neck, below the Adam's apple)

Types of cancers

There are many types of head and neck cancers. These are classified by where the cancer is found:

- Oral cancers occur in the mouth, or oral cavity, which includes the lips, the lining inside the lips and cheeks, the front two-thirds of the tongue, the teeth, the gums, the floor of the mouth (under the tongue), the roof of the mouth, and the small area behind the wisdom teeth. Symptoms and signs include a mouth sore that does not heal within two weeks, unusual bleeding from the teeth or gums, or a lump in the gums, mouth, or tongue.
- Lip cancers occur on the inside or outside surface of the lips. Signs of this cancer include a lump on the inside of the lip or a sore on the outside, which is usually a form of skin cancer.
- Oropharyngeal cancer is found on the back one-third of the tongue, the upper section of the pharynx, and the area around the tonsils. Symptoms include a lump in the back of the mouth or throat, ear pain, or difficulty swallowing.
- Nasopharyngeal cancer is found in the area behind the nose and the upper section of the pharynx, the area just behind the mouth. Symptoms include difficulty breathing or speaking, pain or ringing in ears, frequent headaches, or trouble hearing.
- Hypopharyngeal cancer is found only in the bottom section of the pharynx. Symptoms include a sore throat that does not subside, difficulty swallowing, a lump in the neck, or ear pain.
- Laryngeal cancer starts in the larynx, which is located in front of the neck, in the region of the Adam's apple. Symptoms include pain when swallowing, a sore throat that does not subside, a change in voice, or ear pain.
- Paranasal sinus cancer and **nasal cancer** develop in the small, hollow spaces in the nose called the sinuses and in the nasal cavity, which is the passageway for air moving to the throat during breathing. Symptoms include frequent sinus infections, nosebleeds, a sore inside the nose that does not heal, or pain in the sinus area.
- Salivary gland tumors form in the salivary glands, which produce saliva to help prevent the mouth from drying out and aids with digestion. They are located under the jaw, in front of the ears, underneath the tongue, and in other regions of the digestive tract. Symptoms include swelling under the chin or around the jawbone, facial numbness, muscles in the face that will not move, or persistent pain in the face, chin, or neck.
- Thyroid cancer is found on the thyroid gland, which is located in the front of neck and secretes hormones that help regulate body temperature and metabolism. Symptoms include a lump on the neck, pain in the neck region, a cough with bleeding, or difficulty swallowing or breathing.
- Parathyroid cancer is found on one or on all four of the small parathyroid glands, which secrete a hormone that controls the level of calcium in the blood. They are located in neck area, with a pair on either side of the thyroid gland. Symptoms include **bone pain**, a lump in the neck, weak muscles, or nausea.

Treatment

Most head and neck cancers are treated initially with surgery and/or radiation therapy; chemotherapy may also be used to shrink tumors, but is more commonly given as palliative treatment to patients whose cancers have not responded to surgical removal or radiotherapy. The most common drugs used in treating head and neck cancers are cisplatin, fluorouracil, bleomycin, and methetrexate.

A newer form of radiotherapy that has proved beneficial to patients with head and neck cancer is intensity-modulated radiation therapy, or IMRT. IMRT allows the radiologist to deliver controlled doses of radiation to cancerous tissues while leaving nearby normal tissues and organs unaffected.

KEY TERMS

Larynx—The voice box or sound-producing organ in the body, located in the upper section of the trachea (windpipe). The movement of the muscles of this organ alters the sounds emitted by the vocal cords.

Palliative care—Care that is given to relieve the symptoms of a disease without curing it.

Pharynx—The space behind the mouth that connects to the trachea and the esophagus (swallowing tube). It serves as a passageway for food and air.

Risk factor—Anything that increases a person's chance of developing a disease.

One of the most difficult aspects of treating head and neck cancer for many years has been the necessity of reconstructive surgery and rehabilitation therapy following removal of the patient's lips, tongue, voice box, or other structures. Recent advances in reconstructive surgery, however, have provided patients with better functioning as well as appearance, thus improving their quality of life as well as length of survival.

Health insurance

Definition

Health insurance is insurance that pays for all or part of a person's health care bills. The types of health insurance are group health plans, individual plans, workers' compensation, and government health plans such as Medicare and Medicaid.

Health insurance can be further classified into fee-for-service (traditional insurance) and managed care. Both group and individual insurance plans can be either fee-for-service or managed care plans.

The following are types of managed care plans:

- Health Maintenance Organization (HMO)
- Preferred Provider Organization (PPO)

Purpose

The purpose of health insurance is to help people cover their health care costs. Health care costs include doctor visits, hospital stays, surgery, procedures, tests, home care, and other treatments and services.

Description

Health insurance is available to groups as well as individuals. Government plans, such as Medicare, are offered to people who meet certain criteria.

Group and individual plans can be further classified as either fee-for-service or managed care. Cancer patients may have specific concerns, such as the freedom to select specialists, that play a factor in choosing a health care plan. Fee-for-service plans traditionally offer greater freedom when choosing a health care professional. Managed care often limits a patient to health care professionals listed by the managed care insurance company.

Group health plans

A group health plan offers health care coverage for employers, student organizations, professional associations, religious organizations, and other groups. Many employers offer group health plans to employees and their dependents as a benefit of working with that particular employer (medical benefits). The employer may pay for part or all of the insurance cost (premium).

When an employee leaves a job he or she may be eligible for continued health insurance as a result of the Consolidated Omnibus Budget Reconciliation Act of 1986 (COBRA). This federal law protects employees and their families in certain situations by allowing them to keep his or her health insurance for a specified amount of time. The individual must, however, pay a premium to keep their insurance plan in effect It is important to note that COBRA only applies under certain conditions, such as job loss, death, divorce, or other life events. The COBRA law usually applies to group health plans offered by companies with more than 20 employees. Some states have laws that require employers to offer continued health care coverage for people who do not qualify for COBRA. Each state's insurance board can provide additional information.

Individual plans

These type of health care plans are sold directly to individuals.

Fee-for-service

Fee-for-service is traditional health insurance in which the insurance company reimburses the doctor, hospital, or other health care provider for all or part of the fees charged. Fee-for-service plans may be offered to groups or individuals. This type of plan gives people the highest level of freedom to choose a doctor, hospital, or other health care provider. A person may be able to receive medical care anywhere in the United States and, often, in the world.

Under this type of insurance a premium is paid and there is usually a yearly deductible, which means benefits do not begin until this deductible is met. After the person has paid the deductible (an amount specified by the terms of the insurance policy) the insurance company pays a portion of covered medical services. For example, the deductible may be $250 so the patient pays the first $250 of yearly covered medical expenses. After that he or she may pay 20% of covered services while the insurance company pays 80%. The exact percentages and deductibles will vary with each policy. The person may have to fill out forms (claims) and send them to the insurance company to have their claims paid.

People who have cancer may be attracted to the freedom of choice that traditional fee-for-service plans offer. However, they will most likely have higher out-of-pocket costs than they would in a managed care plan.

Managed care

Managed care plans are also sold to both groups and individuals. In these plans a person's health care is managed by the insurance company. Approvals are needed for some services, including visits to specialist doctors, medical tests, or surgical procedures. In order for people to receive the highest level of coverage they must obtain services from the doctors, hospitals, labs, imaging centers, and other providers affiliated with their managed care plan.

People with cancer who are considering a managed care plan should check with the plan regarding coverage for services outside of the plan's list of participating providers. For example, if a person wants to travel to a cancer center for treatment, he or she should find out what coverage will be available. In these plans coverage is usually much less if a person receives treatment from doctors and hospitals not affiliated with the plan.

HEALTH MAINTENANCE ORGANIZATION (HMO) An HMO is a type of managed care called a prepaid plan. This type of coverage was designed initially to help keep people healthy by covering the cost of preventive care, such as medical checkups. The patient selects a primary care doctor, such as a family physician, from an HMO list. This doctor coordinates the patient's care and determines if referrals to specialist doctors are needed. People pay a premium, usually every month, and receive their health care services (doctor visits, hospital care, lab work, emergency services, etc.) when they pay a small fee called a copayment. The HMO has arrangements with caregivers and hospitals and the copayment only applies to those caregivers and facilities affiliated with the HMO. This type of coverage offers less freedom than fee-for-service, but out-of-pocket health care costs are generally lower and more predictable. A person's out-of-pocket costs will be much higher if he or she receives care outside of the HMO unless prior approval from the HMO is received.

PREFERRED PROVIDER ORGANIZATION (PPO) A PPO combines the benefits of fee-for-service with the features of an HMO. If patients use health care providers (doctors, hospitals, etc.) who are part of the PPO network, they will receive coverage for most of their bills after a deductible and, perhaps a copayment, is met. Some PPOs require people to choose a primary care physician who will coordinate care and arrange referrals to specialists when needed. Other PPOs allow patients to choose specialists on their own. A PPO may offer lower levels of coverage for care given by doctors and other professionals not affiliated with the PPO. In these cases the patient may have to fill out claim forms to receive coverage.

Government health plans

Medicare and Medicaid are two health plans offered by the U.S. government. They are available to individuals who meet certain age, income, or disability criteria. TRICARE Standard, formerly called CHAMPUS, is the health plan for U.S. military personnel.

MEDICARE Medicare, created in 1965 under Title 18 of the Social Security Act, is available to people who meet certain age and disability criteria. Eligible people include:

- those who are age 65 years and older
- some younger individuals who have disabilities
- those who have end-stage renal disease (permanent kidney failure)

Medicare has two parts: Part A and Part B. Part A is hospital insurance and helps cover the costs of inpatient hospital stays, skilled nursing centers, **home health services**, and **hospice care**. Part B helps cover medical services such as doctors' bills, ambulances, outpatient therapy, and a host of other services, supplies, and equipment that Part A does not cover.

MEDICAID Medicaid, created in 1965 under Title 19 of the Social Security Act, is designed for people receiving federal government aid such as Aid to Families with Dependent Children. This program covers hospitalization, doctors' visits, lab tests, and x rays. Some other services may be partially covered.

TRICARE Eligible military families may enroll in TRICARE Prime, which is an HMO; TRICARE Extra, which offers an expanded choice of providers; or TRICARE Standard, which is the new name for CHAMPUS.

Supplemental insurance

Supplemental insurance covers expenses that are not paid for by a person's health insurance. Cancer insurance is a specific form of supplemental insurance that covers expenses that are not normally covered by health insurance but are specifically related to cancer treatments.

Workers' compensation

Workers' compensation covers health care costs for an injury or illness related to a person's job. Medical conditions that are unrelated to work are not covered under this plan. In some cases an evaluation is done to determine whether or not the medical condition is truly related to a person's employment.

KEY TERMS

Clinical trial—A study to determine the efficacy and safety of a drug or medical procedure. This type of study is often called an experimental or investigational procedure.

Health care provider—A doctor, hospital, lab, or other professional person or facility offering health care services.

Health insurance claim—A bill for health care services that is turned in to the health insurance company for payment.

Special concerns

There are a variety of special concerns that people with cancer have regarding health insurance.

Waiting period

Insurance may not take effect immediately upon signing up for a policy. Sometimes a waiting period exists, during which time premiums are not paid and benefits are not available. Health care services received during this period are not covered.

Preexisting condition

A preexisting condition, such as cancer, is a concern when choosing insurance. If a person received medical advice or treatment for a medical problem within six months of enrolling in new insurance, this condition is called preexisting, and it can be excluded from the new coverage. The six-month time lapse before a person enrolls in a new health insurance policy is called the look-back period. If a person received medical advice, recommendations, prescription drugs, diagnosis, or treatment for a health problem during the look-back period, he or she is considered to have a preexisting condition.

People should check with their state insurance boards to determine preexisting condition rules.

Coverage renewal

Some people with diseases such as cancer worry about group health plans renewing their coverage. As long as the person meets the plan's eligibility requirements and the plan covers similar cases, the coverage must be offered. Coverage cannot be cancelled for health reasons.

Experimental/investigational treatments

Experimental/investigational treatments are often a concern for people with cancer. These treatments may or may not be covered by a person's health insurance. Some states mandate coverage for investigational treatments. People should check with their insurance plans and state insurance boards to determine if coverage is available.

A clinical trial is a type of investigational treatment. Costs involved include patient care costs and research costs. Usual patient care costs that may be covered by insurance are visits to the doctor, stays in the hospital, tests, and other procedures that occur whether a person is part of an experiment or is receiving traditional care. Extra patient care costs that may or may not be covered by insurance are the special tests required as part of the research study.

Health insurance plans have policies regarding coverage for **clinical trials**. People should determine their level of health insurance coverage for clinical trials, and they should learn about the costs associated with a particular study.

In 2000, Medicare began covering certain clinical trials. The trials must meet specific criteria in order to be covered. In eligible trials treatments and services such as tests, procedures, and doctor visits that are normally covered by Medicare are covered. Some items may not be covered including investigational items like the experimental drug itself or items that are used only for data collection in the clinical trial. Patients should check to see if the clinical trial sponsor is providing the **investigational drug** at no charge.

Complementary therapies

Complementary cancer therapies are another coverage consideration. A cancer patient undergoing this type of therapy should check with his or her insurance policy regarding coverage.

Cancer screening coverage

Cancer screening coverage is an important consideration. Forty-four states mandate insurance coverage of screenings for at least one of these cancers: breast, cervical, prostate, and colorectal. **Breast cancer** screening coverage is most commonly mandated. Most mandates refer to screenings that follow the American Cancer Society guidelines. A Women's Health Initiative Observational Study investigated the use of cancer screenings by more than 55,000 women between September 1994 and February 1997. The study found that the type of insurance a woman had was linked with the number of cancer screenings she reported. Women age 65 years and older who had Medicare plus prepaid insurance were more likely to report that they had screenings than those who had Medicare alone.

QUESTIONS TO ASK THE DOCTOR

- What types of insurance do you accept?
- Does your office file claims for patients?
- Will your office get pre-authorization for procedures where it is required?
- Do you have a list of providers for my type of insurance in case a referral is necessary?
- If an experimental procedure is recommended, what costs will be involved?

Health care regulations

The Health Insurance Portability and Accountability Act (HIPAA), passed by the U.S. Congress in 1996, offers people rights and protections regarding their health care plans. Because of HIPAA, there are limits on preexisting condition exclusions, people cannot be discriminated because of health factors, there are special enrollment requirements for people who lose other group plans or have new dependents, small employers are guaranteed group health plan availability, and all group plans have guaranteed renewal if the employer wishes to renew. In summary these rights and protections include:

- Portability. This is the ability for a person to get new health insurance if a change is desired or needed.
- Availability. This refers to whether or not health insurance must be offered to a person and his or her dependents.
- Renewability. This refers to whether or not a person is able to renew his or her health plan.

The Women's Health and Cancer Rights Act of 1998 requires health insurance plans to cover breast reconstruction related to a **mastectomy** if the patient

chooses to have reconstruction and if the health plan covered the mastectomy. The law became effective for different health plans on different dates, with the earliest date of effect being October 21, 1998.

Hemolytic anemia

Description

Red blood cells (erythrocytes) transport oxygen and carbon dioxide in the bloodstream, maintain a normal acid-base balance, and determine how thick or thin the blood is. Hemolytic anemia refers to the premature, increased destruction of erythrocytes. Hemolysis is the rupture of these erythrocytes with the release of hemoglobin into the plasma, and anemia is a reduced delivery of oxygen to the tissues. Some of the symptoms of hemolytic anemia include nosebleeds, bleeding gums, shortness of breath, **fatigue**, rapid heartbeat, pale skin color or yellow skin color (jaundice), chills, and dark-colored urine.

Causes

Erythrocyte (red blood cell) formation takes place in the red bone marrow in an adult and in the liver, spleen, and bone marrow of the fetus. Their formation requires an adequate supply of iron, cobalt, copper, amino acids, and certain **vitamins**. When the bone marrow loses its ability to compensate for the destruction of the erythrocytes by increasing their production, hemolytic anemia occurs. There are many types of hemolytic anemia, which are classified according to the location of this inability to produce red blood cells. If the problem lies within the red blood cell itself, it is referred to as an intrinsic factor, and if the problem is outside the red blood cell, it is referred to as an extrinsic factor. The overall incidence of hemolytic anemia is approximately 4 per 100,000 people.

Rh factor incompatibility refers to genetically determined substances capable of producing an **immune response** (antigens). This can cause hemolytic anemia not only during pregnancy when the mother is Rh negative and the fetus is Rh positive, but in mismatched blood transfusions as well. There are a number of industrial poisons that produce hemolytic anemia. These include:

- antimalarial agents
- organic solvents (benzene)
- certain chemotherapies
- hypersensitivity to certain antibiotics
- metals (chromium, platinum salts, nickel, lead, copper)
- Pyridium
- arsenic
- intravenous (IV) water (an IV that is not normal or half-normal saline)
- snake bites (if the venom contains hemolytic toxins) These are all factors external to the red blood cell and thus are extrinsic in nature.

One important extrinsic factor in the cause of hemolytic anemia is in the course of widespread cancer, leukemia, **Hodgkin's disease**, acute alcoholism and liver disease. Many of the **chemotherapy** agents (**cisplatin**, **carboplatin** and nonplatinum drugs) utilized in treating various cancers have side effects that cause a suppression of bone marrow activity, which results in severe hemolytic anemia. In essence, an individual is not only anemic as a result of cancer, but this anemia is worsened by the treatment. Since nausea, vomiting, and lack of appetite

KEY TERMS

Erythrocytes—Red blood cells.

Erythropoietin—A glyco-protein hormone secreted by the kidney in the adult and by the liver in the fetus, which acts on stem cells of the bone marrow to stimulate red blood cell production (erythropoiesis).

Hemolysis—The rupture of red blood cells with the release of hemoglobin into the plasma.

Spherocytosis—The presence of small, round erythrocytes that have a smaller surface area than normal and carry less oxygen as a result.

Stem cells—Any precursor cell having the ability to both replicate and differentiate and give rise to other precursors of different blood cell lines.

Thalassemia—A hereditary hemolytic anemia marked by a decreased rate of synthesis of hemoglobin chains.

are also side effects of chemotherapy, it is extremely difficult for the patient to overcome this anemia with diet and supplements. Eventually, severe hemolytic anemia is the end result.

Intrinsic factors would include disorders in the immune response and genetically inherited disorders such as glucose-6-phosphate dehydrogenase deficiency, an essential enzyme. People with this disorder do not display any symptoms until exposed to certain medications or stress. Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) can precipitate this reaction. This disorder is more common among African-American males, with approximately 10% to 14% of the population being affected. Other genetic disorders include sickle cell anemia, thalassemia, and spherocytosis. All of these produce structurally abnormal red blood cells to varying degrees.

Treatments

The treatment depends upon the cause and severity of the anemia. Medicines like **folic acid** and **corticosteroids** may be used to treat the anemia if it is not severe. Severe hemolytic anemia may be very quickly fatal and immediate hospitalization is required for transfusion of washed and packed red blood cells. Severe anemias can aggravate pre-existing heart disease, lung disease and cerebrovascular disease.

Frequently with cancer treatments, a patient may undergo numerous blood transfusions to accomodate for the severe anemia suffered as a result of chemotherapy. Researchers, investigating ways to enhance the quality of life for chemotherapy patients, have primarily looked at controlling pain and loss of appetite (**anorexia**). Recent studies, however, have examined the use of **erythropoietin** (a protein hormone that stimulates red blood cell production) in improving fatigue symptoms and enhancing overall quality of life. Once-weekly therapy with erythropoietin was found to increase hemoglobin levels, decrease transfusion requirements, and improve quality of life in patients with cancer and anemia undergoing chemotherapy.

Alternative and complementary therapies

Since there is no known prevention for hemolytic anemia, there is relatively little that can be done except to be aware of the risk factors and know the potential for genetic disorders within the family. Avoiding exposure to chemicals that precipitate the reaction, eating natural, whole grain foods, avoiding stress, and taking vitamin supplements can be helpful. With cancer patients, yoga and meditation provide a means of enhancing relaxation, reducing stress, and incorporating visualization for healing. Those patients who attend and participate in support groups have an increased quality of life with better outcomes from treatments.

Hemoptysis

Description

Hemoptysis is the coughing up of blood or bloody sputum from the respiratory tract. The blood can come

from the nose, mouth, throat, airway passages leading from the lungs, or the lungs.

Hemoptysis can range from small quantities of blood-stained sputum to life-threatening amounts of blood. Massive hemoptysis is defined as the spitting up of so much blood that it interferes with the patient's breathing. Generally, this is 200 to 600 or more milliliters of blood coughed up within a 24 hour period. Massive hemoptysis is considered a medical emergency. Up to 75 percent of patients with massive hemoptysis die from asphyxiation (lack of oxygen) caused by too much blood in the airways.

Hemoptysis refers specifically to the spitting up of blood that comes from the respiratory tract. Often when persons spit up blood, they are not spitting up blood from the respiratory tract, but from somewhere else. When the blood comes from somewhere other than the respiratory tract, such as from a bloody nose or from the gastrointestinal tract, this is called pseudohemoptysis. Vomiting up blood from the gastrointestinal tract, called hematemesis, is one type of pseudohemoptysis. It is important to distinguish between true hemoptysis and pseudohemoptysis because they often involve very different parts of the body and the treatments are radically different.

Causes

Hemoptysis is caused by a variety of medical conditions including tuberculosis, bronchitis, bronchiectasis, **pneumonia**, and respiratory tract trauma. It is also caused by many forms of lung and respiratory tract cancers, such as: bronchial **carcinoma**, bronchial **adenoma**, respiratory tract hemangioma, and occasionally by metastatic cancer to the lungs.

Treatments

The goal of treatment for patients with hemoptysis is to stop the bleeding as soon as possible while also treating the cancer or other underlying disorder that is causing the hemoptysis.

Hemoptysis generally will stop spontaneously and no treatment is necessary, apart from reassurance of the patient that this condition will resolve on its own. Therefore, the general treatment for hemoptysis is to keep the patient calm and to ensure complete bed rest.

If the coughing that accompanies the hemoptysis is troublesome or aggravating the condition, cough suppressants may be recommended.

In cases of massive hemoptysis, the placement of a tube in the respiratory tract (intubation) may be necessary to allow for adequate airflow into and out of the respiratory tract. A **bronchoscopy** may be performed, not only to clear the airway of blood, but also to assist in diagnosing the endobronchial cause of the hemoptysis. When large amounts of blood have been lost, the patient may also require intravenous (IV) fluids and/or a blood transfusion.

In the most severe cases of hemoptysis, surgery to remove the cancer that is causing the spitting up of blood may be necessary to relieve the symptoms of hemoptysis. Other treatment modalities include PDT (photodynamic therapy).

KEY TERMS

Bronchial adenoma—A tumor arising in the linings of the bronchi.

Bronchial carcinoma—Cancer arising from the bronchi, the major vessels that convey air to and from the lungs to the mouth and nose.

Hemangioma—A tumor of the blood vessels that is usually present at birth. When these occur on a visible portion of the skin, they are called "birthmarks." When they occur within the respiratory tract, they may lead to hemoptysis.

Sputum—Material ejected from the lungs, bronchi, or trachea, through the mouth.

Alternative and complementary therapies

Inhalation of the fumes of a tea made from the bark of the wild cherry (*Prunus virginiana*) tree has been an herbal remedy for many respiratory tract ailments, including tuberculosis and hemoptysis among the Native Americans for centuries.

Hydrazine sulfate, a naturally occurring monoamine oxidase inhibitor (MAOI), has also been suggested as a treatment for hemoptysis.

Heparin

Definition

Heparin is a drug that helps prevent blood clots from forming and belongs to the family of drugs called anticoagulants (blood thinners), although it does not actually thin the blood. It is sold in the United States under the brand names of Calciparine, Liquaemin, Calciparine, Hepalean, and Heparin Leo, and Calcilean in Canada.

Purpose

Heparin is used to decrease the clotting ability of the blood and to help prevent harmful clots from forming in the blood vessels. Heparin will not dissolve blood clots that have already formed, but it may prevent the clots from becoming larger and causing more serious problems. Heparin possesses several antithrombotic mechanisms. It is often used as a treatment for certain blood vessel, heart, and lung conditions and is also used to prevent blood clotting during open-heart surgery, bypass surgery, and dialysis. Heparin is used in low doses to prevent the formation of blood clots in certain patients, especially those who must have certain types of surgery or who must remain in bed for a long time. It is also used for the long-term treatment of thromboembolic disease, a common side effect of cancer.

One of the most common hematological complications is disordered coagulation. Approximately 15% of all cancer patients are affected by thromboembolic disease, which is the second leading cause of death for cancer patients. However, thromboembolic disease may represent only one of many complications in end-stage patients. Thromboembolic disease includes superficial and deep venous thrombosis, pulmonary emboli, thrombosis of venous access devices, arterial thrombosis, and embolism. The cancer itself or cancer treatments may induce coagulation. For example, **chemotherapy** can increase the risk of thromboembolic disease. An increased risk for arterial thrombosis has been observed with chemotherapy treatment.

Cancer and its treatment can affect all three causes of thromboembolic disease, including the alteration of blood flow, damage to endothelial cells (the cells in blood vessels), and enhancing procoagulants (causing the blood to clot). Cancer can affect blood flow by mechanically affecting blood vessels close to a tumor. In addition, tumors cause angiogenesis, which may create complexes of blood vessels that have a disordered appearance and flow (varying in magnitude and direction). Chemotherapy or tumors may directly damage endothelial cells. Procoagulants may be secreted into the blood stream by cancer cells or can be increased on the surface of cancer cells.

Antithrombotic treatment, in the form of the low-molecular-weight heparin reviparin, has been shown for the first time to safely improve the outcomes of patients with an acute myocardial infarction. The new findings show that reviparin "clearly improves the outcomes of patients who undergo thrombolysis with streptokinase or urokinase, and it also appears to be a useful adjunct for patients treated with primary percutaneous coronary intervention [PCI]," said Dr. Anderson, associate chief of the division of cardiology at LDS Hospital in Salt Lake City. The study has some limitations.

Description

Heparin is the most common anticoagulant used and the generic name product may be available in the U.S. and Canada.

Mechanisms of action:

Heparin increases the release of specific proteins, like tissue plasminogen activator and tissue factor pathway inhibitor (TFPI), into the blood in order to inhibit blood coagulation. It can also increase the activity of these proteins. Heparin augments the activity of antithrombin III, a natural compound that inhibits activated clotting factors from contributing to more coagulation. Furthermore, heparin has been found to inhibit substances that may contribute to angiogenesis, including vascular endothelial growth factor, tissue factor, and platelet-activating factor.

Whether anticoagulants like heparin may also improve cancer survival rates independent of their effect on thromboembolism has been investigated. In fact, experimental and clinical data have demonstrated that heparin is an effective compound in preventing metastases. Many investigators have shown that heparin inhibits tumor **metastasis** in experimental animals; a few **clinical trials** also suggest a positive effect in humans with cancer.

Recommended dosage

Heparin is available only with a doctor's prescription, in parenteral and injection (United States and Canada) dosage forms. A doctor will need to prescribe a specific dose for an individual's based on the type of heparin, as well as the patient's medical condition and body weight.

Dosing schedule

Heparin should be taken under the doctor's direction and at the same time every day. If a dose is missed, take

it as soon as possible. However, if a dose is missed until the following day, patients should not double-dose, but just take the usual daily dose. Double-dosing may cause bleeding.

Precautions

Some medications should not be combined. Over-the-counter medicines, **vitamins**, and herbal products may cause interactions when combined with heparin, so the patient should check with the doctor monitoring the heparin medication before taking any new medication, even when prescribed by another doctor.

Patients who are pregnant, breastfeeding, have given birth recently, or using an IUD for birth control should consult their doctors. The doctor should also be notified if radiation treatments, surgery, or a fall or other injury has recently occurred.

The presence of other medical problems may affect the use of heparin. Patients should be sure to tell their doctors about any other medical problems, in particular:

- allergies or asthma (or history of)
- blood disease or bleeding problems
- colitis or stomach ulcer (or history of)
- diabetes mellitus
- high blood pressure (hypertension)
- kidney disease
- liver disease
- tuberculosis (active)

Side effects

The doctor should be contacted immediately if any of these side effects are present:

- wheezing or trouble breathing
- skin rash, **itching**, or hives
- red or "coffee ground" vomit
- unexplained nosebleeds
- swelling in the face, lips, or tongue
- blood in urine or stools
- black tarry stools

Interactions

Using any of the following medicines together with heparin may increase the risk of bleeding. Again, candidates for heparin should alert their physicians if they are taking any of these medications:

- aspirin
- persantine
- carbenicillin by injection (Geopen)
- cefamandole (Mandol)
- cefoperazone (Cefobid)
- cefotetan (Cefotan)
- dipyridamole (Persantine)
- divalproex (Depakote)
- medicine for inflammation or pain (Motrin, Aleve), except narcotics
- medicine for overactive thyroid
- pentoxifylline (Trental)

KEY TERMS

Angiogenesis—The formation of new blood vessels that occurs naturally under certain circumstances, for example, in the healing of a cut.

Anticoagulant—Anticoagulants are nonhabit-forming medications that prevent the formation of new blood clots and keep existing blood clots from growing larger.

Blood clot—A clump of blood that forms in or around a vessel as a result of coagulation. The formation of blood clots when the body has been cut is essential because without blood clots to cease the bleeding, a person would bleed to death from a relatively small wound.

Coagulation—The blood's natural tendency to clump and stick.

Embolism—An embolism occurs when a clump of material such as a broken-off piece of plaque, a blood clot, or air travels through the bloodstream and becomes lodged in a blood vessel.

Endothelial cells—The cells lining the inside of blood vessels.

Parenteral—Medications administered through intravenous, subcutaneous, or intramuscular injection.

Procoagulants —Inducing the blood to clot.

Thromboembolism—Another word for embolism (see embolism).

Thrombosis—The formation of a blood clot in an artery or vein that may be accompanied by inflammation. If untreated in arteries, thrombosis can lead to death of the nearby tissue.

- plicamycin (Mithracin)
- probenecid (Benemid)
- sulfinpyrazone (Anturane)
- ticarcillin (Ticar)
- valproic acid (Depakene)
- medicines via intramuscular injection

See also Low molecular weight heparin; Warfarin.

Crystal Heather Kaczkowski, MSc.

Hepatic arterial infusion

Definition

Hepatic arterial infusion (HAI) therapy, delivers chemotherapeutic agents directly to the liver through a catheter placed in the hepatic artery. The hepatic artery is the main route of blood supply to liver tumors. HAI is also known as regional **chemotherapy**.

Purpose

Approximately 160,000 patients are diagnosed with **colon cancer** in the U.S. each year. The cancer spreads to the liver in about 70 percent of those patients. For patients with colorectal liver metastases, tumor progression within the liver is typically the primary cause of death.

Systemic chemotherapy using various agents has some efficacy, but the side effects can have a profound negative impact on the patient's quality of life during treatment. HAI therapy may be an effective option because it delivers chemotherapy medication directly to the site of the tumor, making it appropriate as an alternative or adjuvant treatment to systemic chemotherapy. When metastases is limited to the liver, HAI with **floxuridine** (FUDR) or radioactive microspheres through an implantable pump under the skin or an external pump worn on the belt may be a better option than systemic chemotherapy.

HAI may extend life expectancy and reduce the chance that more liver tumors will develop.

Precautions

- Strict aseptic techniques should be used to prevent infection during all procedures.
- Pump flow rate will vary depending on factors such as body temperature, altitude, arterial pressure at the catheter tip, and solution viscosity.
- Patients should not attempt to resterilize the pump.
- The manufacturer's instructions should be followed regarding drug preparation, dosage, and administration.
- FUDR should be used with added caution in patients with impaired liver or kidney function.

Systemic therapy should be considered for patients with disease known to extend beyond the area capable of being infused.

Description

HAI enhances cancer therapy by increasing drug delivery directly to the site of the tumor (the liver) while minimizing systemic drug exposure and side effects. Development of fully implanted infusion systems have allowed for long-term delivery of hepatic regional chemotherapy.

Benefits of HAI therapy:

- yields higher tumor response rates and delays cancer progression
- trend toward increased survival rates
- enhances quality of life
- reduced systemic side effects

Preparation

Patient selection criteria

Successful results depend on careful patient selection. Candidates for HAI therapy should:

- have primary liver cancer or liver metastases from primary colorectal cancer
- show an absence of tumors outside the liver
- have demonstrated portal vein patency
- be a suitable surgical candidate
- show no evidence of infection
- be willing to participate in frequent pump refill appointments

Studies have demonstrated that patients with metastatic colorectal cancer who had liver disease only, had less than 70% of their liver involved with metastases, and had a good performance status responded best to HAI. When metastases are also located outside of the liver, HAI does not offer an advantage over systemic chemotherapy.

KEY TERMS

Adjuvant treatment—A treatment that is added to increase effectiveness of the first treatment.

Cancer—A term for diseases in which abnormal cells divide without control. Cancer cells can invade nearby tissues and can spread through the bloodstream and lymphatic system to other parts of the body.

Catheter—A flexible tube used to administer or withdraw fluids. During a course of chemotherapy, an indwelling catheter can be placed in a vein to administer intravenous fluids and chemotherapy. Catheters can stay in place for several weeks or months with proper care.

Chemotherapy—A cancer treatment using medicines.

Hepatic—Refers to the liver.

Implant—A device inserted into the body to either treat cancer or to replace or substitute for a lost part or ability.

Metastases—The spread of cancer to other body parts.

Tumor—An abnormal mass of tissue that serves no purpose. Tumors may be either benign (non-cancerous) or malignant (cancerous).

Aftercare

During the course of treatment, pump pocket infections occur rarely. At the first sign of infection at the pump pocket, systemic **antibiotics** need to be started. The pump needs to be moved to a new location in a newly created pocket if the infection does not resolve itself. The old pocket should be opened and drained.

Risks

The major problems with HAI are not surgical. They include gastritis, duodenitis, and biliary sclerosis.

Drug toxicity and medication side effects may occur. The most commonly reported side effects for FUDR are nausea and vomiting, **diarrhea**, and intestinal inflammation.

Other possible complications include:

- Arterial thromboses.
- Catheter dislodgement.
- The catheter may erode through the wall of the duodenum when the pump has been in place for more than a year.
- Overdose or underdose of medication if certain conditions affect the rate at which the pump delivers medication, i.e. pump damage due to strenuous activity, high heat, or a change in air pressure.
- Disruption in therapy if the pump is damaged by improper handling or filling.

Normal results

Morbidity or mortality occurring as a result of this procedure should be close to zero. Appropriate selection of patients and new combinations of chemotherapy should provide at least a 70% response rate from HAI for the treatment of hepatic metastases from colorectal primary tumors. This response rate is at least twice that of current systemic chemotherapies.

When used in conjunction with traditional chemotherapy, HAI therapy has been shown to extend life expectancy and reduce recurrence of liver tumors after two years for certain patients.

Abnormal results

Complications that can occur with surgery:

- infection
- fluid build up around the implant site
- skin erosion over the site of the implant
- incision breakdown
- drugs may be delivered to organs other than the liver

Herceptin

Definition

Herceptin is a medicine that is used to slow or stop the growth of a cancerous tumor.

Purpose

Herceptin is used to treat **breast cancer** that has spread to other parts of the body in women whose tumor cells produce an overabundance of a protein known as the human epidermal growth factor receptor 2 (HER2).

Description

Also known by its generic name, **trastuzumab**, Herceptin is an antineoplastic drug manufactured by Genentech, Inc. A monoclonal antibody, Herceptin works differently than **chemotherapy** or hormonal anticancer drugs. It targets cancer cells that make too much of the HER2 protein, which is found on the surface of the cancer cells and thought to fuel cancer growth. Used only to treat cancers that make an overabundance of HER2 protein, Heceptin works by binding to the protein's particles and blocking its effect, thereby slowing down or stopping the cancer cell growth. The HER2 proteins with Herception are removed from the surface the cell. When this happens, they cannot tell the cell to grow and divide.

In addition, Genentech, Inc. explains that there may be two other factors that account for Herceptin's effectiveness; Herceptin signals the immune system and works with chemotherapy. After Herceptin binds to the HER2 protein, the natural killer cells of the immune system are attracted to Herceptin. Herceptin, in turn, binds to the natural killer cells and determines which cells are abnormal and helps to kill them. When this occurs, chemotherapy may be ehanced. Although Herceptin and chemotherapy work differently, Genentech points out that when used together, "the two drugs can be synergistic. Treatment with Herceptin prevents DNA repair following the impact of DNA-damaging chemotherapy that stops the tumor cells from growing."

According to the National Cancer Institute, approximately 25–30% of breast cancers make too much HER2 protein. These kinds of tumors tend to grow faster and are more likely to recur. The amount of HER2 that is present in a tumor is determined by a lab test and a score from 0, which is a negative score, to 3+, which is a highly positive score, is assigned. Only patients with high scores are expected to benefit from Herceptin treatment.

Clinical Trial Results and FDA Approval

Two groundbreaking **clinical trials** were conducted to test the safety and efficacy of Herceptin. One of them, conducted by Slamon and colleagues, produced data that led to Herceptin's approval by the U.S. Food and Drug Administration (FDA) in 1998. In 2001, The *New England Journal of Medicine* published the study results by Slamon and colleagues, which involved 234 randomly assigned patients who received chemotherapy alone and 235 patients who received chemotherapy plus Herceptin. All the patients in the study were diagnosed with metastasic breast cancer that overproduced HER2. Ultimately, Slamon and colleagues concluded that the addition of Herceptin to chemotherapy was associated with "a longer time to disease progression, a higher rate of response [to the treatment], longer survival, and a 20% reduction in the risk of death," as compared to treatment with chemotherapy alone. Specifically, for example, Herceptin combined with **paclitaxel** proved to be especially valuable; the overall response rate rose from 15% in women treated with paclitaxel to 38% in women treated with Herceptin and paclitaxel. All factors considered Herceptin seems to increase the clinical benefits of first-line chemotherapy.

In another clinical trial, as explained by the National Cancer Institute, "Women were given only Herception. In 14% of these women, the tumor got smaller or disappeared." Therefore, in September 1998, the FDA announced its approval of Herceptin for the treatment of metastatic breast cancer. Herceptin was specifically approved in combination with paclitaxel as therapy for HER2 breast cancer. It is also used alone as a therapy after other therapies have failed." Used by itself or with chemotherapy, Herceptin is the first FDA-approved therapy that targets a particular genetic defect known to play a role in cancer development.

Other Possible Uses for Herceptin

Herceptin is also being studied as an adjuvant therapy for the treatment of nonmetastatic breast cancer that has spread to the lymph nodes, but not anywhere else.

Herceptin may also be useful in fighting cancers of the lung, colon, prostate, and bladder in patients whose tumors have an overabundance of HER2. Several studies are underway to test the effectiveness of Herceptin with and without other anticancer drugs.

Recommended dosage

Herceptin is administered intravenously on a weekly basis in a hospital or clinic setting. Based on the patient's

body weight, the typical dosage is 0.9 to 3.6 mg per pound.

Precautions

It is important to have periodic blood tests while taking Heceptin, because it can cause **anemia** and a low white blood cell count in many patients. Guarding the cardiac health of patients taking Herceptin is imperative, because using it can lead to congestive heart failure. Therefore, some patients may not be able to take Herceptin.

It isn't known whether Herceptin is safe to take while a patient is pregnant. Nonetheless, patients should avoid becoming pregnant while they are taking Herceptin. Pregnant patients should talk with their physicians regarding any possible risks to the fetus. Mothers should not breastfeed their babies while they are being treated with Herceptin, because it does pass to the breast milk. In fact, mothers should not breastfeed for at least 6 months after being treated with Herceptin.

Side effects

The two most serious side effects associated with the use of Herceptin are cardiac amd lung related. Damage to the heart muscle, which can cause heart failure, and lung complications, which can cause serious breathing problems can occur. In both cases, immediate medical attention is required. Whether during or after treatment, patients experiencing difficulty breathing or any of the signs associated with heart failure, such as shortness of breath, a fast heartbeat, or swelling in the feet or legs, should contact their physicians without delay. Cardiac side effects are more frequently experienced by elderly patients. Also, in clinical trials, it was found that patients receiving Herceptin with anthracycline chemotherapy were more likely to experience cardiac dysfunction than those who did not receive anthracyclines. Patients treated with Herceptin must be monitored carefully and screened prior to their treatment for any lung or heart problems. It is sometimes necessary to discontinue treatment with Herceptin.

The National Cancer Institute cautions patients that Herceptin can cause severe allergic reactions, such as low blood pressure, shortness of breath, rashes, and wheezing. These reactions are usually more common in patients who already suffer from lung disease.

Fever and chills are common during the first infusion and occur less frequently thereafter. Throughout Herceptin treatment it is not uncommon for patients to experience nausea, vomiting, **diarrhea**, dizziness, sleeplessness, appetite loss, cough, abdominal and back pain, headache, and sore throat. **Depression**, tingling in the hands or feet, fluid retention, sinus irritation, and flu-like symptoms are less commonly reported. Uncommon side effects are acne, cold sores, and urinary infection, as well as pain in the joints, bones, or nerves. As reminded by the National Cancer Institute, it is important to note that patients being treated with Herceptin alone in comparison to patients being treated with Herceptin and chemotherapy may have different side effects. For example, when Herceptin is used in combination with chemotherapy, patients are more likely to experience anemia leukopenia, diarrhea, and infection. Therefore, blood tests may be required more frequently for patients being treated with both Herceptin and chemotherapy. Rare side effects can develop in any part of the body, however, regardless of whether a patient is being treated with Herceptin only or in combination with chemotherapy. Patients should inform their physicians when they experience any side effects, regardless of whether the side effects are mild or severe. Some side effects, such as pain, can be managed medically.

Whether in the early or advanced stages, cancer itself can cause pain. In fact, numerous studies, such as the one by Reuben and colleagues published in 1998 in the Archives of Internal Medicine, have validated that patients with advanced cancer are likely to have a number of symptoms in addition to pain, such as insomnia, depression, and **fatigue**. Therefore, it is valuable, if possible, to determine the source of the pain whether it is the drug therapy or the cancer itself causing the pain. Once the source of the pain is determined, it is easier to decide what the next course of action should be. Patients should be their own health care advocates and work as closely as possible with their physicians regarding treatment strategies for adverse side effects and cancer-related pain. Patients should talk with their physicians about a variety of treatment modalities that range from conventional options to alternative therapies, such as acupuncture, for example.

Pain intensity should also be considered when developing a treatment plan to cope with unpleasant side effects. Certain pain measurement tools, such as the Visual Analogue Pain Scale (VAPS) and the McGill Pain Questionnaire, are commonly used by physicians to assess pain intensity. Patients having difficulty coping with the pain associated with cancer and cancer drugs might find it helpful to be referred to a physician who specializes in **pain management** or a painclinic. Physicians specializing in the treatment of pain come from a variety of medical backgrounds, such as anesthesiology, obstetrics and gynecology, neurology, and surgery.

KEY TERMS

Adjuvant therapy—Adjuvant therapy is treatment given in addition to the primary therapy.

Metastatic cancer—Cancer that has spread from the place in which it started to other parts of the body.

Because of the complicated nature of cancer and cancer-related pain, ideally a pain management team should be formed that works with the patient's primary care physician, oncologist, and radiologist to provide comprehensive care to the patient.

Advances in cancer treatment lengthen survival among cancer patients. It is important for cancer patients to understand that they are not alone. Support groups exist to help patients cope not only with the physical aspects of having cancer, but with the psychological ones as well. In addition, the positive support (both emotional and otherwise) provided by caregivers can help to improve a patient's quality of life.

Interactions

There are no known food interactions. However, as mentioned earlier, cardiac dysfunction was especially high in patients who received Herceptin in combination with anthracycline chemotherapy. Patients should discuss any medications (over-the counter, herbal, and prescription) that they are taking with their physician so that an assessment can be made regarding the risk of interactions.

There are, in fact, a multitude of precautions and interactions related to chemotherapy treatment. The best thing for patients to do that are undergoing chemotherapy is to discuss all the precautions and interactions with their physicians. Usually a patient's doctor will provide patient education pamphlets regarding chemotherapy treatment. Pamphlets are also available from local cancer centers and the American Cancer Society.

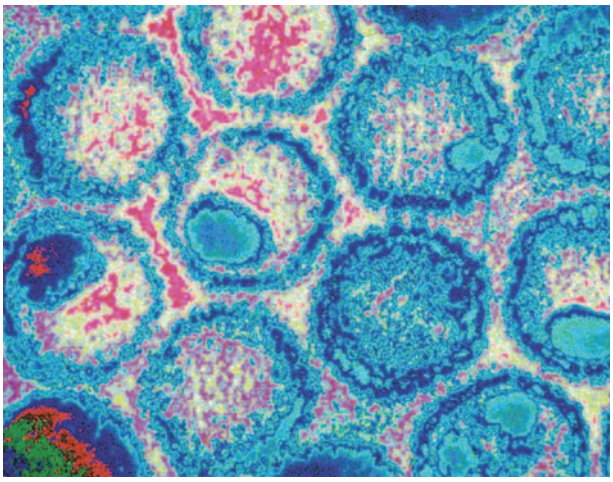
Herpes simplex

Description

Herpes simples virus (HSV, or herpesvirus) is a virus that causes infection of skin and mucous membrane and rarely infects other parts of the body. However, in the immunosuppressed patient, HSV may cause **pneumonia** and other more severe infections. When the infection occurs in the mouth it is commonly referred to as cold sores. An outbreak of HSV infection can be very painful. There are two distinct types of HSV: type 1 and type 2. It was believed that HSV-1 mostly caused oral herpes (herpes labialis), while HSV-2 generally caused genital herpes that typically affects the penis, vulva, and rectum. This is not completely true. Both type 1 and type 2 can cause herpes lesions on the lips or genitals. The first symptoms occur within 2-20 days after contact with an infected person.

Symptoms of the primary infection are usually more severe than those of recurrent infections. The primary infection can cause symptoms like those experienced in other viral infections, including lack of energy, headache, **fever**, and swollen lymph nodes in the neck. The first sign of infection is formation of fluid-filled blisters that may last up to two weeks. However, the pain in the area may last much longer. Once HSV enters the body it spreads to nearby mucosal areas through nerve cells. Once it infects the body the virus remains latent for the life of that individual. During the period of latency there are no symptoms. At times the infected person may shed



Color digitized electron micrograph image of herpes simplex virus. Cancer patients, especially those who are undergoing chemotherapy or radiation treatments, are at greater risk of herpes infections. *(Custom Medical Stock Photo. Reproduced by permission.)*

the virus, even in the absence of visible symptoms, and infect others. Individuals infected with the virus can have recurrent infections; however, normally, recurrent infections are milder and shorter. However, cancer patients can have severe recurrences.

Typically, 50–80% of persons with oral herpes experience a prodrome (symptoms of oncoming disease) of pain, burning, **itching**, or tingling at the site where blisters will form. This prodrome stage may last anywhere from a few hours to one to two days. The herpes infection prodrome occurs in both the primary infection and recurrent infections.

Causes

Everyone with cancer has a higher risk of catching viral infections of any type. This is because the cancer itself, and the methods used to treat it, affect the immune defense mechanisms that fight infection. Normally the mucous membrane is one of the first lines of defense against infectious organisms. However, **chemotherapy** and radiation can damage this very important barrier. The barrier that skin provides is also compromised because of needles used for drawing blood or injecting drugs. Radiation and chemotherapy also suppress the immune system. Certain cancers like Hodgkin's disease, lymphoma, and T-cell leukemia cause defects in cellular immunity, which is a primary defense mechanism against viral infections. Thus cancer patients, especially those who are undergoing chemotherapy or radiation treatments, are at greater risk of primary and secondary herpes infections.

Oral herpes simplex infections are more common in children than adults following chemotherapy. Patients who have the virus latent in the system have a higher chance of recurrent infection. Primary infection generally causes gingivitis (inflammation of the gums, vesicles on the mucosa (blisters on the lining of the mouth), and a coated tongue (white covering on tongue). Women with genital herpes can have severe recurrence following chemotherapy because of immunosuppression.

Treatment

There is no cure for HSV infection although there are antiviral drugs available that have some effect in lessening the symptoms and decreasing the length of herpes outbreaks. There is evidence that some of these drugs may also prevent future outbreaks. For the best results drug treatment should begin during the prodrome stage before blisters are visible. Depending upon the length of the outbreak, drug treatment could continue up to 10 days.

Acyclovir (Zovirax) is the drug of choice for herpes infection and can be given intravenously or taken by mouth. It can be applied directly to sores as an ointment but is not very useful in this form. A liquid form for children is also available. Acyclovir is effective in treating both the primary infection and recurrent outbreaks. When taken by mouth to prevent an outbreak, acyclovir reduces the frequency of herpes outbreaks.

Alternative and complementary therapies

A number of steps can relieve the symptoms of herpes infections. It is important to keep the blisters or sores clean and dry with an agent like cornstarch. One should avoid touching the sores, and wash hands frequently. Local application of ice may relieve the pain. Over-the-counter medication for fever, pain, and inflammation—such as aspirin, acetaminophen, or ibuprofen—may help. Children should never be given aspirin. Sexual intercourse should be avoided during both the active stage and the prodrome stages. During an outbreak of cold sores salty foods, citrus foods (oranges etc.), and other foods that irritate the sores should be avoided. Over-the-counter lip products that contain the chemical "phenol" (such as Blistex Medicated Lip Ointment) and numbing ointments (such as Anbesol) help to relieve the pain of cold sores. A bandage may be placed over the sores to protect them and prevent spreading the virus to other sites on the lips or face.

A diet rich in the amino acid lysine may help prevent recurrences of cold sores. Foods that contain high levels of lysine include most vegetables, legumes, fish, turkey,

and chicken. Oral lysine supplements in the amount of 1000 mg per day may help sores heal faster. There is a belief that foods with high lysine-to-arginine ratio will help prevent outbreaks of herpes simplex. That has not been proven, and it is important to include foods that have a low lysine-to-arginine ratio also, such as nuts, onion, garlic, and green vegetables. It is also suggested that the amount of arginine in the diet be limited as there is a belief that arginine is needed for herpesvirus growth. This amino acid is found in peanuts, beer, chocolate, gelatin, and raisins.

Herpes zoster

Description

Herpes zoster, also called shingles, and referred to as "zosteer", gets its name from both the Latin and French words for belt or girdle and refers to belt-like skin eruptions that may occur on the trunk of the body. The virus that causes chickenpox, the varicella zoster virus (VSV), can become dormant in nerve cells after an episode of chickenpox and later re-emerge as shingles. Any individual who has had chickenpox can develop shingles. People of all ages, even children, can be affected, but the incidence increases with age. There are many other conditions which can predispose people to developing shingles, including newborn infants, bone marrow and other transplant recipients, and individuals with immune systems weakened by diseases like HIV or cancer, or drugs, such as those used in **chemotherapy**.

Shingles erupts along the course of the affected nerve, producing lesions anywhere on the body and may cause severe nerve pain. The most common areas to be affected are the face and trunk, which correspond to the areas where the chickenpox rash is most concentrated. The disease is caused by a reactivation of the chickenpox virus that has been dormant in certain nerves following an episode of chickenpox. Exactly how or why this reactivation occurs is not clear; however, it is believed that the reactivation is triggered when the immune system becomes weakened as in the examples described above. Early signs of shingles are often vague and can easily be mistaken for other illnesses. The condition may begin with **fever** and malaise (a vague feeling of weakness or discomfort). Within two to four days, severe pain, **itching**, and numbness/tingling (paresthesia) or extreme sensitivity to touch (hyperesthesia) can develop, usually on the trunk and occasionally on the arms and legs. Pain may be continuous or intermittent, usually lasting from one to four weeks. It may occur at the time of the eruption, but can precede the eruption by days, occasionally making the diagnosis difficult. Signs and symptoms may include the following:

- itching, tingling, or severe burning pain
- red patches that develop into blisters
- grouped, dense, deep, small blisters that ooze and crust
- swollen lymph nodes

Immunocompromised patients usually have a more severe course that is frequently prolonged for weeks to months. They develop shingles frequently and the infection can spread to the skin, lungs, liver, gastrointestinal tract, brain, or other vital organs.

Potentially serious complications can result from herpes zoster. Many individuals continue to experience persistent pain long after the blisters heal. This pain, called post-herpatic neuralgia, can be severe and debilitating. Post-herpetic neuralgia can persist for months or years after the lesions have disappeared.

Other complications include a secondary bacterial infection, and rarely, potentially fatal inflammation of the brain (encephalitis) and the spread of an infection throughout the body. These rare, but extremely serious, complications are more likely to occur in those individuals who have weakened immune systems (immunocompromised).

Causes

Herpes zoster has been reported in patients with many different types of cancer. However, the cancers that affect an individual's immune system, such as leukemia or **lymphoma**, are the types that place people at particular risk. Herpes zoster is also a particular problem after the various forms of cancer therapy. A study performed in 1998 looked at 766 episodes of herpes zoster infection at a large cancer center from 1972 to 1980. The highest risk of infection was present among patients with lymphoma and leukemia. In those who received radiation treatment and then developed herpes zoster, half of them developed this within seven months. They

Shingles, or herpes zoster, on patient's buttocks and thigh. *(Custom Medical Stock Photo. Reproduced by permission.)*

developed zoster on the area of their body where the radiation was given. This study showed that a period of months can pass before developing zoster as a consequence of radiation. In those who developed zoster after being treated with chemotherapy, half of them developed zoster within a month.

A study in 1999 looked at 215 consecutive patients who had received high-dose chemotherapy and autologous stem cell rescue to help determine what the incidence and severity of herpes zoster infection was. Herpes zoster was developed in 40 people. Over 80% of these infections occurred within six months of receiving the autologous stem cell rescue. Similar rates of herpes zoster have been seen in patients who received bone marrow transplants. A 1996 study looked at 107 children who had received bone marrow transplants for various malignancies. Thirty-three percent of these children developed herpes zoster. Approximately 90% of the cases developed within one year from the time of bone marrow transplant.

Treatments

Shingles almost always resolves spontaneously and may not require any treatment except for the relief of symptoms. In most people, the condition clears on its own in one or two weeks and seldom recurs. The antiviral drugs acyclovir, valacyclovir, and famciclovir can be used to treat shingles. These drugs may shorten the course of the illness. Their use results in more rapid healing of the blisters when drug therapy is started within 72 hours of the onset of the rash. In fact, the earlier the drugs are administered, the better, because early cases can sometimes be stopped. If taken later, these drugs are less effective but may still lessen the pain. Antiviral drug treatment does not seem to reduce the incidence of post-herpetic neuralgia, but recent studies suggest famciclovir may cut the duration of post-herpetic neuralgia in half. Side effects of typical oral doses of these antiviral drugs are minor with headache and nausea reported by 8-20% of patients. Severely immunocompromised individuals, such as those with cancer, may require intravenous administration of antiviral drugs. Preventive administration of acyclovir to seropositive patients (people who have evidence in their blood of past infection with varicella) who undergo leukemia induction or bone marrow transplant not only effectively prevents herpes zoster recurrence but also reduces the severity of chemotherapy-induced **mucositis**. Therefore, acyclovir prophylaxis should be considered in seropositive patients, especially if they have had a recurrence during previous chemotherapy cycles.

Alternative and complementary therapies

Cool, wet compresses may help reduce pain. If there are blisters or crusting, applying compresses made with diluted vinegar will make the patient more comfortable. The patient can mix one-quarter cup of white vinegar in two quarts of lukewarm water, and use the compress twice each day for 10 minutes. The patient should stop using the compresses when the blisters have dried up.

Soothing baths and lotions such as colloidal oatmeal baths, starch baths or lotions, and calamine lotion may help to relieve itching and discomfort. The skin should be kept clean, contaminated items should not be re-used. While the lesions continue to ooze, the person should be isolated to prevent infecting other susceptible individuals.

Later, when the crusts and scabs are separating, the skin may become dry, tight, and cracked. If that happens, the patient can rub on a small amount of plain petroleum jelly three or four times a day.

There are non-medical methods of prevention and treatment that may speed recovery. For example, getting lots of rest, eating a healthy diet, exercising regularly, and minimizing stress are always helpful in preventing disease. Supplementation with vitamin B_{12} during the first one to two days and continued supplementation with vitamin B complex, high levels of vitamin C with bioflavonoids, and calcium, are recommended to boost the immune system. Herbal antivirals such as echinacea can be effective in fighting infection and boosting the immune system. Patients should consult physician before taking supplements.

KEY TERMS

Acyclovir—An antiviral drug that is available under the trade name Zovirax, in oral, intravenous, and topical forms. The drug blocks the replication of the varicella zoster virus.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Famciclovir—An oral antiviral drug that is available under the trade name Famvir. The drug blocks the replication of the varicella zoster virus.

Immunocompromised—A state in which the immune system is suppressed or not functioning properly.

Post-herpetic neuralgia—The term used to describe the pain after the rash associated with herpes zoster is gone.

Valacyclovir—An oral antiviral drug that is available under the trade name Valtrex. The drug blocks the replication of the varicella zoster virus.

Although no single alternative approach, technique, or remedy has yet been proven to reduce the pain, there are a few options which may be helpful. For example, topical applications of lemon balm (*Melissa officinalis*) or licorice (*Glycyrrhiza glabra*) and peppermint (*Mentha piperita*) may reduce pain and blistering. Homeopathic remedies include *Rhus toxicodendron* for blisters, *Mezereum* and *Arsenicum album* for pain, and *Ranunculus* for itching. Practitioners of Eastern medicine recommend self-hypnosis, acupressure, and acupuncture to alleviate pain. All of these or similar alternative therapies should be discussed with the treating physician before using.

See also Antiviral therapy.

Histamine 2 antagonists

Definition

Histamine 2 antagonists are drugs that block the production of acid in the stomach.

Purpose

Histamine 2 antagonists are used to treat the precancerous condition of **Barrett's esophagus**. They are also used to treat **Zollinger-Ellison syndrome** and multiple endocrine neoplasia, rare cancerous conditions in which the stomach makes too much acid and to prevent the development of gastric (stomach) and duodenal (upper part of the small intestine) ulcers.

Description

Histamine 2 blockers are familiar to most people as the over-the counter heartburn medications Tagamet (cimetidine), Pepcid, (famotidine), and Zantac (ranitidine). Axid (nizatidine) is less well known. These drugs also come in prescription strengths. Histamine 2 blockers work by reducing the amount of acid the stomach produces.

The esophagus is a tube 10–13 inches long and about 1 inch wide that carries food from the mouth to the stomach. Normally, the esophagus is lined with cells that are similar to skin cells and look smooth and pinkish-white.

The stomach makes acid to help digest food. A different type of cell that is resistant to acid lines the stomach. These cells look red and velvety. At the place where the esophagus meets the stomach, there is a ring of muscle called a sphincter that normally keeps acid stomach juices from backflowing into the esophagus. When this sphincter is not working correctly, stomach acid enters the bottom portion of the esophagus. This backflow is called reflux or heartburn. When reflux occurs frequently over an extended period of time, it is called gastroesophageal reflux disease (GERD).

Barrett's esophagus is a pre-cancerous condition in which normal cells lining the esophagus are repeatedly exposed to stomach acid and are replaced with abnormal cells that, in some people, develop into a type of cancer of the esophagus called adenocarcinoma. Histamine 2 blockers are given to reduce acid in the stomach and eliminate exposure of the esophageal cells to acid.

Histamine 2 blockers are also used to treat two rare cancerous conditions: multiple endocrine neoplasia (MEN) and Zollinger-Ellison syndrome, both of which

can cause the stomach to produce too much acid. In MEN, an inherited form of cancer, tumors form in more than one gland. Depending on which glands are affected, the stomach may be stimulated to produce excess acid. In Zollinger-Ellison syndrome, a tumor in the digestive tract secretes a hormone called gastrin that stimulates the production of stomach acid. These tumors are malignant (cancerous) in 50% to 65% of people with Zollinger-Ellison syndrome.

Histamine 2 blockers are sometimes given in advance of **chemotherapy** to help reduce the gastrointestinal side effects of chemotherapy drugs. Cimetidine was the first histamine 2 blocker approved by the United States Food and Drug Administration (FDA) in 1976.

Recommended dosage

Recommended dose varies depending on how much stomach acid is produced. Histamine 2 blockers are available in low doses without a prescription and in higher doses with a prescription. They are available in tablet, chewable tablet, liquid, and injectable liquid form. In 2004, the FDA also approved a 25 mg effervescent tablet form of ranitidine (Zantac 25 Efferdose). If histamine 2 inhibitors are unsuccessful in controlling acid reflux, proton pump inhibitors (Prevacid, Prilosec) are usually given as an alternative.

Precautions

People who have trouble with heartburn should stay away from acidic foods such as orange, grapefruit, and tomato juice, coffee, and carbonated drinks (sodas) because these all increase stomach acid. Waiting at least two hours after eating before lying down, avoiding smoking, limiting drinking of alcohol, losing excess weight, and avoiding wearing tight-fitting clothes are other ways to prevent heartburn. Although animal studies show that histamine 2 blockers appear to be safe during pregnancy, these drugs pass into breast milk and should not be taken by nursing mothers.

Side effects

Histamine 2 blockers have few side effects. These drugs are excreted by the kidney, and may slow the excretion of other drugs excreted by the kidney. People with reduced kidney function may need a reduced dose of histamine 2 blockers.

Rare cases of irregular heart rhythms and high blood pressure have been reported when histamine 2 blockers are given intravenously (IV, injected directly into a vein). Mild **diarrhea** has been reported by some people taking these drugs.

KEY TERMS

Esophagus—The canal between the pharynx and stomach that allows passage of food and liquids.

Gastrointestinal—Pertaining to the stomach and intestine.

Interactions

Histamine 2 blockers are reported to have few interactions with other drugs. However, because they reduce the level of acid in the stomach, they may inhibit the uptake of drugs such as ketoconazole that depend on an acid environment in the stomach to work. These drugs should be administered at least two hours before histamine 2 blockers are taken. Prior to starting any over-the-counter medications, herbal medications, or new medications, patients should notify their physician and check with their pharmacists for any potential drug interactions.

Histiocytosis X

Definition

Histiocytosis X is a generic term that refers to an increase in the number of histiocytes, a type of white blood cell, that act as scavengers to remove foreign material from the blood and tissues. Since recent research demonstrated Langerhans cell involvement as well as histiocytes, this led to a proposal that the term Langerhans Cell Histiocytosis (LCH) be used in place of histiocytosis X. Either term refers to three separate illnesses (listed in order of increasing severity): eosinophilic granuloma; Hand-Schuller-Christian disease; and Letterer-Siwe disease.

Description

Epidermal (skin) Langerhans cells (a form of dendritic cell) accumulate with other immune cells in various parts of the body and cause damage by the release of chemicals. Normally, Langerhans cells recognize foreign material, including bacteria, and stimulate the immune system to react to them. Langerhans cells are usually found in skin, lymph nodes, lungs, and the gastrointestinal tract. Under abnormal conditions these cells affect skin, bone, and the pituitary gland as well as the lungs, intestines, liver, spleen, bone marrow, and brain. Therefore, the disease is not confined to areas where Langerhans cells are normally found. The disease is more common in children than adults and tends to be most severe in very young children.

Histiocytosis X or LCH is a family of related conditions characterized by a distinct inflammatory and proliferative process but differs from each other in which parts of the body are involved. The least severe of the histiocytosis X/LCH family is eosinophilic granuloma. Approximately 60–80% of all diagnosed cases are in this classification, which usually occurs in children aged 5–10 years. The bones are involved 50–75% of the time, which includes the skull or mandible, and the long bones. If the bone marrow is involved, **anemia** can result. With skull involvement, growths can occur behind the eyes, bulging them forward. One recent case study involved swelling of the eyes caused by histiocytosis in a three-year-old girl. The lungs are involved less than 10% of the time, and this involvement signals the worst prognosis.

Next in severity is Hand-Schuller-Christian disease, a chronic, scattered form of histiocytosis. It occurs most commonly from the age of one to three years and is a slowly progressive disease that affects the softened areas of the skull, other flat bones, the eyes, and skin. Letterer-Siwe disease is the acute form of this series of diseases. It is generally found from the time of birth to one year of age. It causes an enlarged liver, bruising and skin lesions, anemia, enlarged lymph glands, other organ involvement, and extensive skull lesions.

Causes and symptoms

This is a rare disorder affecting approximately 1 in 200,000 children or adults each year. The International Histiocyte Society formed a registry in 2000 that has registered a total of 274 adults from 13 countries as of 2003. Because histiocytic disorders are so rare, little research has been done to determine their cause. Over time, histiocytosis may lessen in its assault on the body but there are still problems from damage to the tissues. There are no apparent inheritance patterns in these diseases with the exception of a form involving the lymphatic system; of the 274 adults in the international registry, only one came from a family with a history of the disease.

The symptoms of histiocytosis are caused by substances called cytokines and prostaglandins, which are normally produced by histiocytes and act as messengers between cells. When these chemicals are produced in excess amounts and in the wrong places, they cause tissue swelling and abnormal growth. Thus, symptoms may include painful lumps in the skull and limbs as well as rashes on the skin. General symptoms may include: poor appetite, failure to gain weight, recurrent **fever**, and irritability. Symptoms from other possible sites of involvement include:

- Gums: swelling, usually without significant discomfort.
- Ear: chronic discharge.
- Liver or spleen: abdominal discomfort or swelling.
- Pituitary: This gland at the base of the brain is affected at some stage in approximately 20%–30% of children causing a disturbance in water balance to produce thirst and frequent urination.
- Eyes: Due to the bony disease, behind-the-eye bulging may occur (exophthalmos).
- Lungs: Breathing problems.

Diagnosis

The diagnosis can be made only by performing a **biopsy**, that is, taking a tissue sample under anesthesia from a site in the patient thought to be involved. Blood and urine tests, chest and other x rays, **magnetic resonance imaging** (MRI) and **computed tomography** scans (CAT scans) (to check the extent of involvement), and possibly bone marrow or breathing tests may be required to confirm the diagnosis.

Treatments and prognosis

Although this disease is not cancer, most patients diagnosed with it are treated in cancer clinics. There are two reasons for this:

- Historically, cancer specialists treated it before the cause was known.
- The treatment requires the use of drugs typically required to treat cancer.

Any cancer drugs utilized are usually given in smaller doses, which diminishes the severity of their side effects. **Radiation therapy** is rarely used, and special drugs may be prescribed for skin symptoms. If there is

KEY TERMS

Anemia—Abnormally low level of red blood cells in the blood.

Biopsy—Surgical removal of tissue for examination.

CT or CAT—Computed tomography, a radiologic imaging that uses computer processing to generate an image of tissue density in slices through the patient's body.

Cytokines—The term used to include all protein messengers that regulate immune responses.

Dendritic—Branched like a tree.

Eosinophils—A leukocyte with coarse, round granules present.

Epidermal—The outermost layer of the skin.

Inflammatory—A localized protective response of the body caused by injury or destruction of tissues.

MRI—Magnetic resonance imaging, a noninvasive nuclear procedure for imaging tissues of high fat and water content that cannot be seen with other radiologic techniques.

Pituitary gland—The master gland located in the middle of the head that controls the endocrine glands and affects most bodily functions.

Prostaglandins—A group of nine naturally occurring chemicals in the body that affect smooth muscles.

Serous—Thin and watery, like serum.

only one organ affected, steroids may be injected locally, or a drug called indomethacin may be used. Indomethacin is an anti-inflammatory medication that may achieve a similar response with less severe side effects.

The disease fluctuates markedly. If only one system is involved, the disease often resolves by itself. Multisystem disease usually needs treatment although it may disappear spontaneously. The disease is not normally fatal unless organs vital to life are damaged. In general, the younger the child at diagnosis and the more organs involved, the poorer the outlook. If the condition resolves, there could still be long-term complications because of the damage done while the disease was active.

Hodgkin's disease

Definition

Hodgkin's disease is a rare **lymphoma**, a cancer of the lymphatic system.

Description

Hodgkin's disease, or Hodgkin's lymphoma, was first described in 1832 by Thomas Hodgkin, a British physician. Hodgkin clearly differentiated between this disease and the much more common **non-Hodgkin's lymphomas**. Prior to 1970, few individuals survived Hodgkin's disease. Now, however, the majority of individuals with this cancer can be cured.

The lymphatic system

The lymphatic system is part of the body's immune system, for fighting disease, and a part of the blood-producing system. It includes the lymph vessels and nodes, and the spleen, bone marrow, and thymus. The narrow lymphatic vessels carry lymphatic fluid from throughout the body. The lymph nodes are small organs that filter the lymphatic fluid and trap foreign substances, including viruses, bacteria, and cancer cells. The spleen, in the upper left abdomen, removes old cells and debris from the blood. The bone marrow, the tissue inside the bones, produces new red and white blood cells.

Lymphocytes are white blood cells that recognize and destroy disease-causing organisms. Lymphocytes are produced in the lymph nodes, spleen, and bone marrow. They circulate throughout the body in the blood and lymphatic fluid. Clusters of immune cells also exist in major organs.

Hodgkin's lymphoma

Hodgkin's disease is a type of lymphoma in which antibody-producing cells of the lymphatic system begin to grow abnormally. It usually begins in a lymph node and progresses slowly, in a fairly predictable way, spreading via the lymphatic vessels from one group of lymph nodes to the next. Sometimes it invades organs that are adjacent to the lymph nodes. If the cancer cells spread to the blood, the disease can reach almost any site in the body. Advanced cases of Hodgkin's disease may involve the spleen, liver, bone marrow, and lungs.

There are different subtypes of Hodgkin's disease:

- nodular sclerosis (30–60% of cases)
- mixed cellularity (20–40% of cases)
- lymphocyte predominant (5–10% of cases)
- lymphocyte depleted (less than 5% of cases)
- unclassified

Demographics

The American Cancer Society estimates that there will be 7,400 new cases of Hodgkin's disease in the United States in 2001—3,500 in females and 3,900 in males. It is estimated that 700 men and 600 women in the United States will die of the disease in 2001.

Hodgkin's disease can occur at any age. However, the majority of cases develop in early adulthood (ages 15–40) and late adulthood (after age 55). Approximately 10–15% of cases are in children under age 17. It is more common in boys than in girls under the age of 10. The disease is very rare in children under five.

Causes and symptoms

The cause of Hodgkin's disease is not known. It is suspected that some interaction between an individual's genetic makeup, environmental exposures, and infectious agents may be responsible. Immune system deficiencies also may be involved.

Early symptoms of Hodgkin's disease may be similar to those of the flu:

- fevers, **night sweats**, chills
- **fatigue**
- loss of appetite (anorexia)
- weight loss
- itching
- pain after drinking alcoholic beverages
- swelling of one or more lymph nodes

Sudden or emergency symptoms of Hodgkin's disease include:

- sudden high fever
- loss of bladder and/or bowel control
- numbness in the arms and legs and a loss of strength

As lymph nodes swell, they may push on other structures, causing a variety of symptoms:

- pain due to pressure on nerve roots
- loss of function in muscle groups served by compressed nerves
- coughing or shortness of breath due to compression of the windpipe and/or airways, by swollen lymph nodes in the chest
- kidney failure from compression of the ureters, the tubes that carry urine from the kidneys to the bladder
- swelling in the face, neck, or legs, due to pressure on veins
- paralysis in the legs due to pressure on the spinal cord

As Hodgkin's disease progresses, the immune system becomes less effective at fighting infection. Thus, patients with Hodgkin's lymphoma become more susceptible to both common infections caused by bacteria and unusual (opportunistic) infections. Later symptoms of Hodgkin's disease include the formation of tumors.

Significantly, as many as 75% of individuals with Hodgkin's disease do not have any typical symptoms.

Diagnosis

As with many forms of cancer, diagnosis of Hodgkin's disease has two major components.

- identification of Hodgkin's lymphoma as the cause of the patient's disease
- staging of the disease to determine how far the cancer has spread

The initial diagnosis of Hodgkin's disease often results from abnormalities in a chest **x ray** that was performed because of nonspecific symptoms. The physician then takes a medical history to check for the presence of symptoms and conducts a complete physical examination.

Lymph node biopsy

The size, tenderness, firmness, and location of swollen lymph nodes are determined and correlated with any signs of infection. In particular, lymph nodes that do not shrink after treatment with **antibiotics** may be a cause for concern. The lymph nodes that are most often affected by Hodgkin's disease include those of the neck, above the collarbone, under the arms, and in the chest above the diaphragm.

Diagnosis of Hodgkin's disease requires either the removal of an entire enlarged lymph node (an excisional **biopsy**) or an incisional biopsy, in which only a small part of a large tumor is removed. If the node is near the skin, the biopsy is performed with a local anesthetic. However, if it is inside the chest or abdomen, general anesthesia is required.

The sample of biopsied tissue is examined under a microscope. Giant cells called Reed-Sternberg cells must be present to confirm a diagnosis of Hodgkin's disease. These cells, which usually contain two or more nuclei, are named for the two pathologists who discovered them. Normal cells have only one nucleus (the organelle within the cell that contains the genetic material). Affected lymph nodes may contain only a few Reed-Sternberg cells and they may be difficult to recognize. Characteristics of other types of cells in the biopsied tissue help to diagnose the subtype of Hodgkin's disease.

A fine needle aspiration (FNA) biopsy, in which a thin needle and syringe are used to remove a small amount of fluid and bits of tissue from a tumor, has the advantage of not requiring surgery. An FNA may be performed prior to an excisional or incisional biopsy, to check for infection or for the spread of cancer from another organ. However an FNA biopsy does not provide enough tissue to diagnose Hodgkin's disease.

Occasionally, additional biopsies are required to diagnose Hodgkin's disease. In rare instances, other tests, that detect certain substances on the surfaces of cancer cells or changes in the DNA of cells, are used to distinguish Hodgkin's disease from non-Hodgkin's lymphoma.

Clinical staging

Staging is very important in Hodgkin's disease. This is because the cancer usually spreads in a predictable pattern, without skipping sets of lymph nodes until late in the progression of the disease.

IMAGING Imaging of the abdomen, chest, and pelvis is used to identify areas of enlarged lymph nodes and abnormalities in the spleen or other organs. Computed tomography (CT or CAT) scans use a rotating x-ray beam to obtain pictures. **Magnetic resonance imaging** (MRI) uses magnetic fields and radio waves to produce images of the body. Chest x rays also may be taken. These images will reveal rounded lumps called nodules in the affected lymph nodes and other organs.

Another imaging technique for Hodgkin's disease is a **gallium scan**, in which the radioactive element gallium is injected into a vein. The cancer cells take up the gallium and a special camera that detects the gallium is used to determine the location and size of tumors. Gallium scans are used when Hodgkin's disease is in the chest and may be hard to detect by other methods. Gallium scans also are used to monitor progress during treatment.

A lymphangiogram, a radiograph of the lymphatic vessels, involves injecting a dye into a lymphatic vessel in the foot. Tracking of the dye locates the disease in the abdomen and pelvis. This method is used less frequently and is usually not used with children.

Positron emission tomography (PET) scans are an extremely accurate method for staging Hodgkin's disease. A very low dose of radioactive glucose, a sugar, is injected into the body. The glucose travels to metabolically active sites, including cancerous regions that require large amounts of glucose. The PET scan detects the radioactivity and produces images of the entire body that distinguish between cancerous and non-cancerous tissues.

BONE MARROW **Anemia** (a low red-blood-cell count), fevers, or night sweats are indications that Hodgkin's disease may be in the bone marrow. In these cases, a bone marrow aspiration and biopsy may be ordered. In biopsy, a large needle is used to remove a narrow, cylindrical piece of bone. Alternatively, an aspiration, in which a needle is used to remove small bits of bone marrow, may be used. The marrow usually is removed from the back of the hip or other large bone. This procedure may help to determine cancer spread.

Pathological staging

Sometimes further staging, called pathological staging or a staging laparotomy, is used for Hodgkin's disease. In this operation, a surgeon checks the abdominal

lymph nodes and other organs for cancer and removes small pieces of tissue. A pathologist examines the tissue samples for Hodgkin's disease cells. Usually the spleen is removed (a **splenectomy**) during the laparotomy. The splenectomy helps with staging Hodgkin's disease, as well as removing a disease site.

Treatment team

The cancer care team for Hodgkin's disease includes a medical oncologist (a physician specializing in cancer), oncology nurses, technicians, and social workers. A surgeon performs the biopsies, as well as the laparotomy and splenectomy if required. Pathologists examine the biopsy specimens for the presence of Reed-Sternberg and other abnormal cells.

In the United States, most children with Hodgkin's disease are treated at children's cancer centers. Here, the treatment team includes psychologists, child life specialists, nutritionists, and educators, as well as a pediatric oncologist.

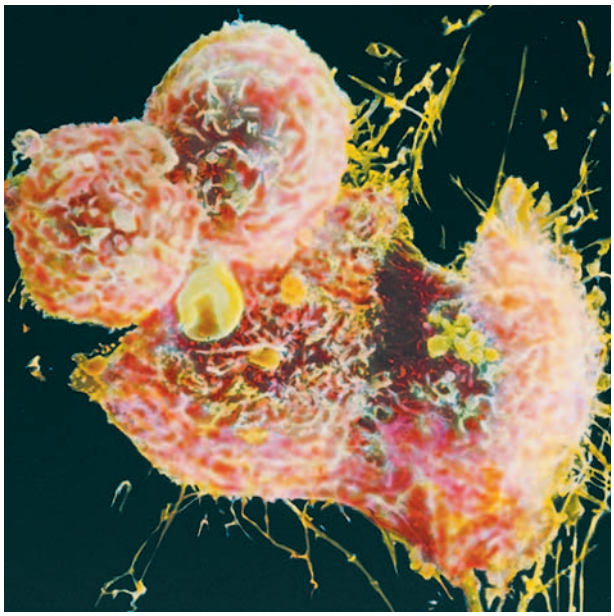
Clinical staging, treatments, and prognosis

The stages

All of the available treatments for Hodgkin's disease have serious side effects, both short and long-term. However, with accurate staging, physicians and patients often can choose the minimum treatment that will cure the disease. The staging system for Hodgkin's disease is the Ann Arbor Staging Classification, also called the Cotswold System or the Revised Ann Arbor System.

Hodgkin's disease is divided into four stages, with additional substages:

- Stage I: The disease is confined to one lymph node area
- Stage IE: The disease extends from the one lymph node area to adjacent regions
- Stage II: The disease is in two or more lymph node areas on one side of the diaphragm (the muscle below the lungs)
- Stage IIE: The disease extends to adjacent regions of at least one of these nodes
- Stage III: The disease is in lymph node areas on both sides of the diaphragm
- Stage IIIE/IIISE: The disease extends into adjacent areas or organs (IIIE) and/or the spleen (IIISE)
- Stage IV: The disease has spread from the lymphatic system to one or more other organs, such as the bone marrow or liver



A scanning electron micrograph (SEM) image of dividing Hodgkin's cells from the pleural effusions (abnormal accumulations of fluid in the lungs) of a 55-year-old male patient. *(Photograph by Dr. Andrejs Liepins, National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)*

Treatment for Hodgkin's disease depends both on the stage of the disease and whether or not symptoms are present. Stages are labeled with an A if no symptoms are present. If symptoms are present, the stage is labeled with a B. These symptoms include:

- loss of more than 10% of body weight over the previous six months
- fevers above 100 degrees F
- drenching night sweats

Treatments

RADIATION THERAPY **Radiation therapy** and/or **chemotherapy** (drug therapy) are the standard treatments for Hodgkin's disease. If the disease is confined to one area of the body, radiotherapy is usually used. This treatment, with x rays or other high-energy rays, also is used when the disease is in bulky areas such as the chest, where chemotherapeutic drugs cannot reach all of the cancer. External-beam radiation, a focused beam from an external machine, is used to irradiate only the affected lymph nodes. This procedure is called involved field radiation.

More advanced stages of Hodgkin's disease may be treated with mantle field radiation, in which the lymph nodes of the neck, chest, and underarms are irradiated. Inverted Y field radiation is used to irradiate the spleen

Swollen lymph nodes of a Hodgkin's disease patient. *(Custom Medical Stock Photo. Reproduced by permission.)*

and the lymph nodes in the upper abdomen and pelvis. Total nodal irradiation includes both mantle field and inverted Y field radiation.

Since external-beam radiation damages healthy tissue near the cancer cells, the temporary side effects of radiotherapy can include sunburn-like skin damage, fatigue, nausea, and **diarrhea**. Other temporary side effects may include a sore throat and difficulty swallowing. Long-term side effects depend on the dose and the location of the radiation and the age of the patient. Since radiation of the ovaries causes permanent sterility (the inability to have offspring), the ovaries of girls and young women are protected during radiotherapy. Sometimes the ovaries are surgically moved from the region to be irradiated.

CHEMOTHERAPY If the Hodgkin's disease has progressed to additional lymph nodes or other organs, or if there is a recurrence of the disease within two years of radiation treatment, chemotherapy is used.

Chemotherapy utilizes a combination of drugs, each of which kills cancer cells in a different way. The most common chemotherapy regimens for Hodgkin's disease are MOPP (either **mechlorethamine** or **methotrexate** with Oncovin, **procarbazine**, prednisone) and ABVD (Adriamycin or **doxorubicin**, **bleomycin**, **vincristine**, **dacarbazine**). Each of these consists of four different drugs. ABVD is used more frequently than MOPP because it has fewer severe side effects. However MOPP is used for individuals who are at risk for heart failure. The chemotherapeutic drugs may be injected into a vein or muscle, or taken orally, as a pill or liquid.

Children who are sexually mature when they develop Hodgkin's disease, and whose muscle and bone mass are almost completely developed, usually receive the same treatment as adults. Younger children usually are treated with chemotherapy, since radiation will adversely affect bone and muscle growth. However, radiation may be used in low dosages, in combination with chemotherapy. The chemotherapy for children with Hodgkin's disease usually includes more drugs than ABVD and MOPP.

The side effects of chemotherapy for Hodgkin's disease depend on the dose of drugs and the length of time they are taken. Since these drugs target rapidly dividing cancer cells, they also affect normal cells that grow rapidly. These include the cells of the bone marrow, the linings of the mouth and intestines, and hair follicles. Damage to bone marrow leads to lower white blood cell counts and lower resistance to infection. It also leads to lower red blood cell counts that can result in fatigue and easy bleeding and bruising. Damage to intestinal cells leads to a loss of appetite (anorexia), and nausea and vomiting. Mouth sores and hair loss (alopecia) also are common side effects of chemotherapy. These side effects disappear when the chemotherapy is discontinued. Some drugs can reduce or prevent the **nausea and vomiting**.

Chemotherapy for Hodgkin's disease may lead to long-term complications. The drugs may damage the heart, lungs, kidneys, and liver. In children, growth may be impeded. Some chemotherapy can cause sterility, so men may choose to have their sperm frozen prior to treatment. Women may stop ovulating and menstruating during chemotherapy. This may or may not be permanent.

Treatment for higher-stage Hodgkin's disease often involves a combination of radiotherapy and chemotherapy. Following three or four chemotherapy regimens, involved field radiation may be directed at the most affected areas of the body. The long-term side effects often are more severe when radiation and chemotherapy are used in combination.

The development of a second type of cancer is the most serious risk from radiation and chemotherapy treatment for Hodgkin's disease. In particular, there is a risk of developing leukemia, **breast cancer**, bone cancer, or **thyroid cancer**. Chemotherapy, particularly MOPP, or chemotherapy in conjunction with radiotherapy, significantly increases the risk for leukemia.

RESISTANT, PROGRESSIVE, AND RECURRENT HODGKIN'S DISEASE Following treatment, the original diagnostic tests for Hodgkin's disease are repeated, to determine whether all traces of the cancer have been eliminated and to check for long-term side effects of treatment. In resistant Hodgkin's disease, some cancer cells remain following treatment. If the cancer continues to spread during treatment, it is called progressive Hodgkin's disease. If the disease returns after treatment, it is known as recurrent Hodgkin's disease. It may recur in the area where it first started or elsewhere in the body. It may recur immediately after treatment or many years later.

KEY TERMS

Antibody—An immune system protein that recognizes a specific foreign molecule.

Biopsy—The removal of a small sample of tissue for examination under a microscope; used for the diagnosis of cancer and to check for infection.

Bone marrow—Tissue inside the bones that produce red and white blood cells.

Chemotherapy—Treatment with various combinations of chemicals or drugs, particularly for the treatment of cancer.

Epstein-Barr virus (EBV)—Very common virus that infects immune cells and can cause mononucleosis.

Interferon—A potent immune-defense protein produced by viral-infected cells; used as an anti-cancer and anti-viral drug.

Interleukins—A family of potent immune-defense molecules; used in various medical therapies.

Laparotomy—A surgical incision of the abdomen.

Leukapheresis—A technique that uses a machine to remove stem cells from the blood; the cells are frozen and then returned to the patient following treatment that has destroyed the bone marrow.

Lymph nodes—Small round glands, located throughout the body and containing lymphocytes that remove foreign organisms and debris from the lymphatic fluid.

Lymphatic system—The vessels, lymph nodes, and organs, including the bone marrow, spleen, and thymus, that produce and carry white blood cells to fight disease.

Lymphocyte—White blood cells that produce antibodies and other agents for fighting disease.

PBSCT—Peripheral blood stem cell transplant; a method for replacing blood-forming cells that are destroyed by cancer treatment.

Radiotherapy—Disease treatment involving exposure to x rays or other types of radiation.

Reed-Sternberg cells—An abnormal lymphocyte that is characteristic of Hodgkin's disease.

Spleen—An organ of the lymphatic system, on the left side of the abdomen near the stomach; it produces and stores lymphocytes, filters the blood, and destroys old blood cells.

Splenectomy—Surgical removal of the spleen.

Staging—The use of various diagnostic methods to accurately determine the extent of disease; used to select the appropriate type and amount of treatment and to predict the outcome of treatment.

Stem cells—The cells from which all blood cells are derived.

Thymus—An organ of the lymphatic system, located behind the breast bone, that produces the T lymphocytes of the immune system.

Thyroid—A gland in the throat that produces hormones that regulate growth and metabolism.

Additional treatment is necessary with these types of Hodgkin's disease. If the initial treatment was radiation therapy alone, chemotherapy may be used, or vice versa. Chemotherapy with different drugs, or higher doses, may be used to treat recurrent Hodgkin's. However, radiation to the same area is never repeated.

BONE MARROW AND PERIPHERAL BLOOD STEM CELL TRANSPLANTATIONS An autologous bone marrow and/or a peripheral blood stem cell transplantation (PBSCT) often is recommended for treating resistant or recurrent Hodgkin's disease, particularly if the disease recurs within a few months of a chemotherapy-induced remission. These transplants are autologous because they utilize the individual's own cells. The patient's bone marrow cells or peripheral blood stem cells (immature bone marrow cells found in the blood) are collected and frozen prior to high-dosage chemotherapy, which destroys bone marrow cells. A procedure called leukapheresis is used to collect the stem cells. Following the high-dosage chemotherapy, and possibly radiation, the bone marrow cells or stem cells are reinjected into the individual.

Alternative and complementary therapies

Most complementary therapies for Hodgkin's disease are designed to stimulate the immune system to destroy cancer cells and repair normal cells that have been damaged by treatment. These therapies are used in conjunction with standard treatment.

Immunologic therapies, also known as immunotherapies, biological therapies, or biological response modifier therapies, utilize substances that are produced by the immune system. These include interferon (an immune system protein), **monoclonal antibodies**

(specially engineered antibodies), colony-stimulating (growth) factors (such as **filgrastim**), and **vaccines**. Many immunotherapies for Hodgkin's disease are experimental and available only through **clinical trials**. These biological agents may have side effects.

Coenzyme Q10 (CoQ10) and polysaccharide K (PSK) are being evaluated for their ability to stimulate the immune system and protect healthy tissue, as well as possible anti-cancer activities. Camphor, also known as 714-X, green tea, and hoxsey (which is a mixture of a number of substances), have been promoted as immune system enhancers. However there is no evidence that they are effective against Hodgkin's disease. Hoxsey, in particular, can produce serious side effects.

Prognosis

Hodgkin's disease, particularly in children, is one of the most curable forms of cancer. Approximately 90% of individuals are cured of the disease with chemotherapy and/or radiation.

The one-year relative survival rate following treatment for Hodgkin's disease is 93%. Relative survival rates do not include individuals who die of causes other than Hodgkin's disease. The percentage of individuals who have not died of Hodgkin's disease within five years of diagnosis is 90–95% for those with stage I or stage II disease. The figure is 85–90% for those diagnosed with stage III Hodgkin's and approximately 80% for those diagnosed with stage IV disease. The 15-year relative survival rate is 63%. Approximately 75% of children are alive and cancer free 20 years after the original diagnosis of Hodgkin's.

Acute myelocytic leukemia, a very serious cancer, may develop in as many as 2–6% of individuals receiving certain types of treatment for Hodgkin's disease. Women under the age of 30 who are treated with radiation to the chest have a much higher risk for developing breast cancer. Both men and women are at higher risk for developing lung or thyroid cancers as a result of chest irradiation.

Individuals with the type of Hodgkin's disease known as nodular lymphocytic predominance have a 2% chance of developing non-Hodgkin's lymphoma. Apparently, this is a result of the Hodgkin's disease itself and not the treatment.

Coping with cancer treatment

Sufficient rest and good nutrition are important for relieving the side effects of treatment for Hodgkin's disease. As strength returns, a weekly exercise routine should be initiated. Support groups can be beneficial for helping with emotional problems that may arise during treatment.

QUESTIONS TO ASK THE DOCTOR

- What type of Hodgkin's disease do I have?
- What is the stage of my disease?
- What are the choices for treatment and what do you recommend?
- Should I obtain a second opinion?
- What are the short-term side effects of the treatment and what can be done about them?
- What are the possible long-term side effects of the treatment?
- Are there other risks from the treatment?
- How should I prepare for the treatment?
- How long will the treatment continue?
- What is the recovery time following the treatment?
- What are the chances of success?
- Are there clinical trials which may be appropriate for me?
- Are there complementary or alternative therapies that may be helpful?
- What is the likelihood that the cancer will return? How will a recurrence be diagnosed?
- Is a recurrence more likely with one treatment than with another?

Clinical trials

At least 115 clinical trials for the treatment of Hodgkin's disease were recruiting or planning to recruit participants. A number of these studies are directed at treating resistant (refractory) or recurrent (relapsed) Hodgkin's disease in both children and adults. Some are aimed at specific stages or subtypes of Hodgkin's disease. Some trials are for previously treated individuals and others are for those who have not yet received treatment.

Clinical trials of new treatments for Hodgkin's disease include:

- new drugs
- new chemotherapies
- monoclonal antibody therapy
- interferon, interleukin-2, and interleukin-12
- a vaccine made from cancer cells that contain the **Epstein-Barr virus**

- bone marrow and umbilical cord blood transplantations
- PBSCT
- various combinations of treatments

There also are ongoing genetic studies of children and adults with Hodgkin's disease and quality-of-life studies of children who are undergoing treatment.

Prevention

There are very few known risk factors for Hodgkin's disease. A family history of the disease and the presence of the Epstein-Barr virus are associated with an increased risk. Individuals with acquired immunodeficiency syndrome (AIDS) are particularly susceptible to Hodgkin's disease.

Special concerns

Follow-up examinations continue for many years following treatment for Hodgkin's disease. Women who have had chest irradiation must have frequent mammograms and clinical and breast self examinations for early detection of breast cancer. Frequent physical exams and chest x rays may help to detect lung or thyroid cancer. Treatment with mantle field radiation causes hyperthyroidism, which requires thyroid medication and annual thyroid function tests.

Individuals with Hodgkin's disease do not have normal immune system function, a problem that can be intensified by chemotherapy, radiation, and removal of the spleen. Therefore, vaccinations and prompt treatment of infections are very important.

Home health services

Definition

Home health services refers to those health care services provided to the patient in his or her own home.

Description

Home health services can vary depending on the insurance coverage, but usually include nursing, physical therapy, occupational therapy, speech therapy, home health aides, social work, nutritional education, infusion therapy, blood drawing, and other laboratory services. Such services may also include bringing medical equipment into the home for patient use. Home health services do not provide around-the-clock care, but rely on the patient having other caregivers, such as family members, friends, or other community resources.

Home care services can be provided by many different organizations, such as the Visiting Nurses Association (VNA), home health agencies (which vary in the range of services provided), hospice organizations, providers of home medical equipment, and pharmacies with delivery services. Patients requiring a range of specialized services may find more continuity of care if one agency is able to provide all, or almost all, of the services they need. **Hospice care** is care provided to patients who are terminally ill. Most hospices care for their clients within the home. The goal of hospice is to help the client and their family deal with the physical, emotional, and spiritual issues associated with dying. Excellent pain management is a priority.

Nursing care

Skilled nursing care provides the backbone for home care. Visits may include wound and ostomy care; infusion therapy such as home **chemotherapy**, **antibiotics**, or home parenteral nutrition (HPN); patient and caregiver teaching; ongoing assessment of the client's physical and emotional condition and progress; pain control; psychological support; and supervision of home health aides. The nurse may function as a case manager and coordinate the various other services the client is receiving. The nurse assesses the home environment for safety and for appropriateness of continued home care.

Physical therapy

Physical therapists develop a plan for the client to restore (as much as possible) the physical condition lost following surgery or as a result of a decline due to the disease process. They also teach patients how to prevent further injury or deterioration and how to maintain gains made.

A home healthcare nurses tends to a patient. *(Reproduced by permission.)*

Occupational therapy

Occupational therapists assist patients in restoring or enhancing their ability to perform their tasks of daily living. Patients may need to learn how to use adaptive equipment such as a prosthesis. The goal is to achieve the highest level of functioning possible.

Speech therapy

Speech therapists work with clients who have difficulty swallowing or clearly communicating.

Home health aides

Home health aides function under the supervision of a registered nurse. They provide care with personal hygiene, such as bathing and dressing, feeding, and ambulating. They may assist a nurse in providing patient care. They may provide homemaking services and companionship, or those tasks may be covered by a homemaker or attendant.

Social work

Social workers may assist clients in accessing the services that are available to them based on their insurance, and in learning what community resources exist. They may also facilitate the referral process, and provide counseling and patient advocacy.

Nutritional education

Nutritionists and registered dieticians may educate clients on their nutritional needs, and on how to go about attaining them. They may also be involved if HPN is required.

Infusion therapy

Some patients may receive their chemotherapy or antibiotics at home, or may require infusion of liquid

nutrition (HPN). While these services may be provided by a nurse, a separate agency or company may provide the equipment and products.

Laboratory work

Blood drawing and other laboratory services may be provided by a nurse, a phlebotomist, or a laboratory technician.

Home medical equipment

Following surgery or treatment in a hospital, patients may need the delivery and servicing of items such as special beds, wheelchairs, walkers, catheters, and wound care and ostomy supplies.

Volunteers

Volunteers may provide a range of assistance such as respite care for the primary caregiver(s), caring for the home, cooking, cleaning, emotional support, companionship, running errands, making telephone calls, child care, elder care, and providing transportation. They may come from the patient's circle of friends or religious organization, or from such agencies as Meals on Wheels.

Causes

Many individuals with conditions that do not necessitate care in a hospital setting often require short-term or long-term home care. They may need care to assist them in regaining their health similar to that prior to their illness, or may need ongoing care as their condition deteriorates due to metastatic disease. One trend that is gathering speed in the early 2000s is an increase in home health care services as opposed to nursing home care.

Special concerns

Insurance coverage plays a major role in funding home health care. In organizing home care the patient must fully understand which services will be fully covered, covered but with a co-payment, or not covered at all. Insurance coverage may vary depending on whether the service provider is within a specified approved network. It must also be clear how often and for how long the services will be needed, and whether the insurance benefits cover the entire time period of anticipated care. The patient's safety must always remain a priority. The patient and the caregiver(s) may suffer from isolation and **depression**. Primary caregivers may become overwhelmed with caring for the patient, and there may come a point at which the level of care needed may no longer be able to be provided in the home setting. The health of the primary caregiver must periodically be assessed.

KEY TERMS

Home parenteral nutrition (HPN)—HPN provides liquid nutrition via infusion for patients who are malnourished, or who have had surgery altering the usual process of chewing, swallowing, or digesting food.

Meditation—Meditation is a technique in which the individual focuses on a word or phrase to the exclusion of other thoughts. It has been shown to lower blood pressure and reduce stress.

Respite care—A form of temporary home health care that allows family members some time away from patient care. Respite care is usually short-term, ranging from a few hours to a weekend.

T'ai chi—An Asian practice of breathing and slow physical movements that develops strength and reduces stress.

Telehealth—The use of the telephone, Internet, and other forms of telecommunication to support long-distance health care, education of health care professionals, and public health concerns.

Treatments

Treatments provided in the home include wound and ostomy care, intravenous (IV) chemotherapy or antibiotics, HPN, and physical, occupational, and speech therapy.

Newer trends and future concerns

One trend in home health care is greater use of the telephone and Internet for contact between home health care workers and medical professionals, and for information gathering. The U. S. Department of Health and Human Services has sponsored a new web site intended to help consumers as well as professionals make informed choices about home health care agencies. In addition, the growth of so-called telehealth systems has already had an impact on nursing education and practice in the home health care field. The field of telehealth is expected to expand dramatically in the early 2000s, as experts estimate that home health care is 10–15 years behind other fields in its use of computers.

Another trend is the growing emphasis on culturally sensitive home health care. In many cases, patients from minority ethnic groups and cultures are more comfortable being cared for in their homes by caregivers who share their background or have been trained to

QUESTIONS TO ASK THE DOCTOR

- What kind of home care will I need?
- For how long will I need the different services?
- What happens if my condition worsens?
- Will my insurance cover the services you are prescribing?
- What kind of care is available to help my family care for me?
- Are there alternative therapies that would help my condition?
- Are any of these therapies covered by my insurance?
- Are there any side effects to these therapies?
- Who is in charge of making sure my pain is well controlled?

understand it than to be sent to large urban nursing homes where they are isolated from familiar customs and language. Studies of the feasibility of home health care for Native Americans in remote locations are presently being conducted in Canada.

One worrisome concern for the future is the increasing difficulty of recruiting and retaining high-quality home health care workers in the United States and Canada. The aging of the general North American population coupled with the high turnover in the field of home health care poses a serious problem for policy makers.

Alternative and complementary therapies

Clients may contract to have home acupuncture or massage therapy. On their own they may engage in yoga, t'ai chi, meditation, guided imagery, visualization, or other stress-reducing techniques that help them better cope with their situation. They may also choose to investigate herbal supplements and medications; all supplemental medications should be approved by a physician before use.

Horner's syndrome

Description

William Edmonds Horner (1793–1853) first described a small muscle at the angle of the eyelid (tensor tarsi) as well as a description of an ingenious

operation to correct problems with the lower lid in 1824 in the American Journal of the Medical Sciences. Since that time, his name has been associated with the syndrome of a small, regular pupil, drooping of the eyelid on the same side and occasional loss of sweat formation on the forehead of the affected eye. In appearance, it occurs on one side of the face with a sinking in of the eyeball (enophthalmos), drooping upper eyelid (ptosis), slight elevation of the lower lid, excessive contraction of the pupil of the eye (miosis), narrowing of the eyelid, and an absence of facial sweat on the affected side (anhidrosis). Other symptoms may include a variation in eye color of the iris and changes in the consistency of tears.

Causes

Horner's syndrome is caused by damage or interruption of the sympathetic nerve to the eye. There are two major divisions of the nervous system: the voluntary (conscious control) and involuntary (without conscious control). The involuntary (autonomic nervous system) has two divisions: sympathetic and parasympathetic nervous systems. Under normal conditions, there is a fine balance between sympathetic and parasympathetic stimulation. If an individual is threatened by a situation, the pupils dilate, blood is shifted to the muscles and the heart beats faster as the person prepares to fight or flee. This is sympathetic stimulation. The eye has both sympathetic (responds to challenges) and parasympathetic (slows the body down) innervation. The nerve that carries the sympathetic innervation travels down the spinal cord from the brain (hypothalamus), emerges in the chest cavity, and then finds it way up the neck along with the carotid artery and jugular vein through the middle ear and into the eye. If these sympathetic impulses were blocked, the eye would have an overbalance of parasympathetic supply, which would result in a constriction of the pupil, relaxation of all the muscles around the eye and a sinking of the eye into the orbit—Horner's syndrome. Thus, damage that occurs anywhere along the course of this nerve's route from the brain to the eye can evoke this syndrome.

If the syndrome exists from birth (congenital), it is typically noted around the age of two years with the presence of a variation in the color of the iris and the lack of a crease in the drooping eye. Since eye color is completed by the age of two, a variation in color is an uncommon finding in Horner's syndrome acquired later in life.

The common causes of acquired Horner's syndrome include aortic dissection (a tear in the wall of the aorta to create a false channel where blood becomes trapped), carotid dissection, tuberculosis, Pancoast tumor (a tumor in the upper end of the lung), brain tumors, spinal cord injury in the neck, trauma to the cervical or thoracic portions of the spinal cord, cluster migraine headache, vertebrae destruction or collapse, compression of the spinal cord by enlarged lymph nodes, and neck or thyroid surgery.

The diagnosis and localization of this disorder is made with the use of pharmacological testing by an ophthalmologist. The physician places drops of a 10% liquid cocaine into the eyes, blocking the parasympathetic nerves so the sympathetic nervous system can be evaluated. After thirty minutes, the dilation of the pupils is noted and a Horner's pupil dilates poorly. A positive cocaine test does not, however, localize the area of the damage. After waiting for 48 hours, other medications are used to determine where the nerve interruption occurs. This solution routinely has been hydroxyamphetamine bromide. However, it has not been routinely available and in 2004, a study reported that a phenylephrine solution works as well. An individual's urine can test positive for cocaine up to two days following the initial test.

Treatments

Treatment for congenital cases

Children who are diagnosed with Horner's syndrome of a congenital origin may undergo surgical correction to strengthen the muscle of the eyelid and give it an appearance similar to the unaffected eye. The surgery improves the appearance of the child but does not alleviate the syndrome. For these cases a plastic surgeon may be preferred. Occasionally Horner's syndrome may be seen in a newborn with a **neuroblastoma** (tumor originating from nerve cells). This is almost always a sign of a localized tumor and is associated with a relatively good prognosis. In these cases, a neurologist may be consulted for treatment since their specialty is the nervous system.

Treatment for acquired cases

The treatment for acquired Horner's syndrome depends upon the cause and is focused toward eliminating the disease that produces the syndrome. Frequently, there is no treatment that improves or reverses the condition, but recognition of the signs and symptoms is extremely important for early diagnosis and treatment. Early detection of the syndrome may facilitate treatment related to those caused by tumors as they can be removed before extensive damage is done. Causes related to an interruption in nerve transmission once the nerve leaves the spinal cord are usually related to blood circulation and are easier to treat. Any numbness or paralysis on one side of the body means the problem is within the spinal cord or brain and is more difficult to treat. Some acquired Horner's may be corrected slightly by plastic surgery for appearance changes.

KEY TERMS

Congenital—Present at and existing from the time of birth.

Hypothalamus—That part of the third ventricle in the brain which anatomically contains the optic nerves.

Neuroblastoma—A tumor of nervous system origin composed chiefly of neruoblasts (embryonic nerve cells), affecting mostly infants and children up to 10 years of age, usually arising in the autonomic nervous system.

Pancoast tumor—A tumor or growth in the pointed end of the lung.

Alternative and complementary therapies

Acupuncture may be utilized to enhance disruptions in nerve transmissions and herbs or supplements that improve circulation may benefit some cases of acquired syndrome. These herbs and supplements would include Gingko biloba and vitamin E. As with any complementary treatment, patients should notify their physician of any herbal or over-the-counter medications they are taking.

Hospice care

Definition

Hospice care is palliative care given to individuals who are terminally ill with an expected survival of six months or less. The focus of hospice care is on meeting the physical, emotional, and spiritual needs of the dying individual, while fostering the highest quality of life possible.

Description

Hospice services provide palliative care to individuals with a life expectancy of six months or less. Most hospice care is provided in the home, but may take place in a hospice home or a hospice/palliative care area within a medical facility. Requesting hospice care may be the first time that individuals, or their families, acknowledge that their condition is not treatable. It may be the first time that they have to deal with their death as a reality taking place within a few months. The emotional journey to be able to deal with these issues may take a while, and therefore may delay the time when the person begins to receive hospice care.

The focus of hospice is not on treatment, but on pain and symptom management, comfort measures, acknowledging that the individual will die, supporting the family, and trying to provide the best quality of life for the time remaining. Hospice functions under the philosophy that although some terminally ill patients may no longer receive treatment, they still require and deserve care.

Hospice care is interdisciplinary in nature, providing the services of physicians, nurses, social workers, physical, speech, or occupational therapists, clergy or other spiritual guides, health care aides, and volunteers. Home hospice care relies on the family and friends of the patient to provide most of the daily care. Nursing and other services are provided daily or weekly, but with 24 hours, 7 days a week on-call access. Addressing the spiritual needs of the hospice client is a fundamental aspect of hospice care.

Some studies about hospice care have gleaned the following:

- When asked their preference, about two-thirds of cancer patients said they preferred to die in their own home.
- The majority of patients still die in the hospital.
- When surveyed, about 95% of families who received hospice care said that it had been helpful.
- Although satisfied with hospice care, caregivers report the job of caregiving as having a negative impact on their own quality of life, and felt the job was burdensome.
- When compared to a control group of noncaregivers, caregivers had higher levels of **depression**, anxiety, anger, and health problems. Caregivers had a higher

rate of deteriorating health, social, and occupational functioning.

- Quality of life was influenced by the individual's spiritual well-being.
- Hospice patients expressed feelings of conflict between a hope for living, and "living in hope," being able to reconcile with others and coming to terms with death.
- Although hospice is focused on helping people in the last six months of their life, most hospice patients only receive about one month of hospice care prior to their death.
- Only 20% of physicians' prognoses about a patient's survival was accurate. Sixty-three percent were overly optimistic, and 17% were overly pessimistic. The more experience the physicians had, the better their accuracy of prognosis.

Causes

Hospice care was first established in the United States in 1974 in Branford, Connecticut. The Branford hospice was patterned on St. Christopher's Hospice in London, which was established by Dame Cicely Saunders in 1967. In 1969, the book *On Death and Dying*, by Dr. Elizabeth Kugler-Ross identified five stages that a terminally ill person goes through. In the book, Dr. Kubler-Ross addressed the importance of patients having a role in the decisions affecting the quality of their life and death. In 1972 she testified at the first U.S. Senate national hearing on dying with dignity.

Deciding on hospice care is a choice made by the terminally ill individual. To be eligible, one's physician needs to document that the individual's survival is expected to be six months or less. Should the patient recover, and the prognosis change, the relationship with hospice is terminated, but can be reestablished when needed at a later date. Not all patients will choose hospice. If only home hospice care is available, individuals who would be eligible may decide that hospice is not a good choice for them. Reasons for not choosing home hospice include:

- The patient lives alone, with little or no family support available.
- The patient has a need for 24-hour nursing care.
- The patient has family, but they are unable to provide the supportive care required.
- The patient is concerned about being a burden to the caregiver.
- The patient feels more secure in a hospital environment.

KEY TERMS

Meditation—Meditation is a technique in which the individual focuses on a word or phrase to the exclusion of other thoughts. It has been shown to reduce stress and anxiety.

Palliative care—Care focused on providing comfort, not cure.

Respite care—A form of temporary home health care that allows family members some time away from patient care. Respite care is usually short-term, ranging from a few hours to a weekend.

T'ai chi—An Asian practice of breathing and slow physical movements that develops strength and reduces stress.

Telehealth—The use of the telephone, Internet, and other forms of telecommunication to support long-distance health care, education of health care professionals, and public health concerns.

Special concerns

A study looking at the communication between physicians and their dying patients found these issues to be very important:

- Being honest and straightforward with patients.
- A willingness to talk about dying.
- Being sensitive when conveying bad news.
- Listening to patients.
- Encouraging patients to ask questions.
- Finding a balance between being honest without discouraging hope.

A *Journal of the American Medical Association* article found that patients at the end of their life expressed these issues as important:

- being mentally aware
- not being a burden
- having their funeral arrangements planned
- helping others
- coming to peace with God
- freedom from pain
- talking about the meaning of death
- Among nine issues, dying at home was rated the least important.

QUESTIONS TO ASK THE DOCTOR

- What do you think is my prognosis?
- What choices are there to manage my pain and other symptoms?
- What level of symptom management can I expect to receive?
- What types of care, conventional or alternative, would improve the quality of the time I have left?
- Will my insurance cover the care you suggest?
- If I choose hospice care, how will that affect my relationship with my doctors and treatment team?
- What kind of support is there for my family, both until I die and afterwards?

Because time is limited for patients in hospice, patients and their caregivers need to act swiftly on areas of dissatisfaction, such as quality of care being provided or insufficient symptom management.

Treatments

Curative treatments are not a part of hospice care. However, hospice places great importance on minimizing or alleviating pain and symptoms such as appetite loss (anorexia), **fatigue**, weakness, constipation, difficulty breathing, confusion, nausea, vomiting, cough, and dry or sore mouth. For many with advanced cancer, fatigue may be their worst symptom. Research has shown that a tailored exercise program can increase activity tolerance without increasing fatigue. In addition, patients reported an increase in quality of life and decreased anxiety. Patients who expressed the most fatigue showed the most decrease in fatigue with the exercise program. Many hospice patients have breakthrough pain in addition to their chronic pain. Research using an indwelling subcutaneous needle for pain control showed 88% pain control with this method when pain was not well controlled with oral medications. Chronic pain requires ongoing pain relief, such as might be handled with a pump or patch. Good pain control may mean waking the patient up at night for oral medication to prevent the pain from mounting during sleep.

Alternative and complementary therapies

Dealing with the issues of death may be addressed through talking with others, writing in a journal, creative expression such as painting, writing a poem, or composing music. Meditation may be beneficial to some patients. Gentle body movements such as with t'ai chi or yoga may be helpful, depending on the patient's activity tolerance.

Recent trends

A recent development in facilitating hospice care in the patient's home is night respite service. In general, respite care refers to home health care offered by volunteers or home health caregivers that allows the patient's family a few hours or a weekend away from direct patient care. Night respite care in a hospice setting involves trained aides who care for the patient in his or her home overnight, thus allowing other family members to catch up on necessary sleep. Studies indicate that many patients as well as family members feel that night respite care is a good option that allows patients to remain at home rather than being transferred to an inpatient hospice.

One trend in hospice care that has attracted considerable interest in the early 2000s is ethnically and culturally sensitive hospice care. As of 2004, hospice services in the United States and Canada are utilized disproportionately by Caucasians. One innovative Native American hospice program that is working well is a palliative care program at the Pueblo of Zuni in New Mexico. The Zuni program combines tribal-based home health care with inpatient care at an Indian Health Service (IHS) hospital.

Another significant trend in hospice care is the greater use of webcams, video phones, and other devices that have been introduced along with the computerization of hospital and hospice facilities. The rapid growth of "telehealth" since the mid-1990s indicates that technological innovations in telecommunications will affect hospice care as they have home health care and other outpatient settings.

Human growth factors

Definition

Human growth factors are compounds made by the body that function to regulate cell division and cell survival. Some growth factors are also produced in the laboratory by genetic engineering and are used in biological therapy.

Description

Human tumors express large amounts of growth factors and their receptors. A tumor will not grow beyond the size of a pinhead without new blood vessels to supply oxygen and nutrients. Growth factors are significant because they can induce angiogenesis, the formation of blood vessels around a tumor. These growth factors also encourage cell proliferation, differentiation, and migration on the surfaces of the endothelial cells—cells found inside the lining of blood vessels. Of the approximately 20 proteins that activate endothelial cell growth, two growth factors in particular, vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), are expressed by many tumors and appear important in contributing to tumor growth and promoting tumor spread throughout the body. Several compounds that block VEGF or its receptor are now in **clinical trials**.

See also Angiogenesis inhibitors.

Crystal Heather Kaczkowski, MSc.

Human papilloma virus

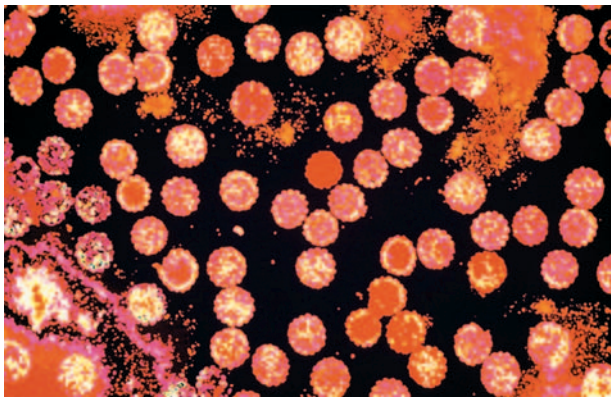
Definition

Human papilloma viruses (HPV) are a large group of related viruses, some of which play a part in the development of cervical epithelial cancers. HPV is also associated with skin cancer, cancers of the mouth, and anal cancers.

More recently, it has been suggested that HPV may be associated with an increased risk of lung cancer. In addition, a group of researchers at a cancer research center in Seattle reported in 2004 that smoking appears to increase the risk of anal cancer in women as well as men infected with HPV who practice anal sex.

Description

The family of human papilloma viruses includes a large number of genetically related viruses. Many of these cause warts, including the warts commonly found on the skin. Another group of HPV preferentially infect the mucosal surfaces of the genitals, including the penis, vagina, vulva, and cervix. These are spread among adults by sexual contact. One group of HPV that infect the genitals causes soft warts, often designated condylomata acuminata. These genital warts are quite common



Transmission electron micrograph of human papilloma virus, magnified 40,000 times. HPV is the cause of warts, including genital warts, and has been implicated in cervical cancer. *(Custom Medical Stock Photo. Reproduced by permission.)*

KEY TERMS

Ablative—Also known as "ablation" and referring to the surgical removal of lesions associated with HPV.

Biopsy—The removal of a small bit of tissue for diagnostic examination

Cervical intra-epithelial neoplasia (CIN)—A precancerous condition in which a group of cells grow abnormally on the cervix but do not extend into the deeper layers of this tissue.

Colposcopy—Procedure in which the cervix is examined using a special microscope.

Condylomata acuminata (singular, condyloma acuminatum)—The medical term for infectious warts on the genitals caused by HPV.

Cryotherapy—The use of extreme cold to destroy tissue.

Epithelial—Referring to the epithelium, the layer of cells forming the epidermis of the skin and the surface layer of mucous membranes.

High-risk HPV type—A member of the HPV family of viruses that is associated with the development of cervical cancer and precancerous growths.

Pap smear—A test that checks for abnormal cells that can lead to cervical cancer.

and rarely if ever become cancerous. The most common of these low-risk HPV types are designated HPV 6 and 11. The second group of viruses, termed high-risk HPV types, is associated with the development of **cervical cancer**. Individuals infected with these viruses are at higher risk for the development of precancerous lesions. Typically, infection with these viruses is common in adolescents and women in their twenties, and usually do not result in cancerous growth. The most common high-risk HPV is type 16. The appearance of abnormal cells containing high-risk HPV types is seen most frequently in women over the age of 30 who have abnormal Pap smears.

It is possible that other viruses work together with human papilloma viruses to produce precancerous changes in tissue. Cases of tongue cancer have been reported in which HPV was found together with Epstein-Barr virus, or EBV.

HPV infections are very common. At some point in their lives, greater than 75% of people are infected with HPV, making HPV the most common sexually transmitted disease. According to the Centers for Disease Control and Prevention (CDC), 20 million Americans are infected with HPV as of 2004, with 6.2 million new cases occurring each year.

In general, HPV infections do not cause any obvious symptoms, which increases the likelihood of sexual transmission. Genital warts will occur in 1 or 2 of every 100 people. Abnormal Pap smears with atypical cells due to HPV can occur in 2–5% of women. If untreated, these women are at increased risk to develop cervical cancer. Virtually all cases of cervical cancer involve high-risk HPV types. It is believed that most cervical cancers take about five years to progress from early cellular changes to an invasive, life-threatening cervical cancer. It is not fully understood why most infections with high-risk HPV are of short duration, while a small percentage persist and eventually transform cervical cells to a state of cancerous growth.

In addition to producing precancerous lesions in some patients, HPV infections in women are a health concern because they can be transmitted to the respiratory tract of a baby during childbirth. This type of HPV infection may lead to juvenile-onset recurrent respiratory papillomatosis (JO-RRP), in which papillomas or warts form in the child's airway, producing hoarseness or partial blockage of the windpipe. As of 2004, surgery is the usual treatment for JO-RRP, but the warts often recur and require additional surgery to remove them. Cidofovir and interferon are often given as adjuvant treatments for this disease as of the early 2000s. JO-RRP is a serious illness, leading to death in a significant number of affected children.

The relationship among HPV, precancerous cellular changes, and cervical cancer have led to the suggestion that testing for the presence of HPV can be a useful

QUESTIONS TO ASK THE DOCTOR

- If my Pap smear is abnormal, do you think I should have an HPV test?
- Based upon my Pap smear result and HPV testing, when should I have my next Pap smear?
- What can I do to decrease my risk of becoming (re)infected with HPV?

Large brown genital wart of a female. *(Custom Medical Stock Photo. Reproduced by permission.)*

addition to Pap smears. Pap smears involve microscopic analysis of cells removed from the cervix. The results of these tests are generally reported as normal, or consistent with the presence of cancer or a precancerous condition. Patients receiving the latter diagnosis usually are treated, either by excisional or ablative therapy surgery or some other means, in order to remove the tumor or precancerous lesion. In some cases the cytologist or pathologist examining a Pap smear reports a "borderline" result when abnormal cells are observed, but it is not possible to distinguish whether the changes seen are due to early precancerous changes, or inflammation caused by some infectious agent or irritant. In these cases, some physicians and scientists believe that testing for the presence of HPV can help to identify those women who should be closely followed for the development of early cancerous lesions, or who should undergo colposcopy, a procedure to examine the cervix for precancerous lesions. These cancer precursors, termed cervical intraepithelial neoplasia (CIN) when identified early, before they have become invasive, can almost always be completely removed by minor surgery, essentially curing the patient before the cancer has had a chance to develop. The cervical tissue removed, which includes the precancerous tissue, is examined as part of a **biopsy** to confirm the diagnosis, and if requested by a doctor, can be tested for the presence of high-risk HPV types. This does not occur often.

Treatments

The only accepted treatment for HPV-related lesions is removal or eradication by surgery, lasers, cryotherapy, or electrocauterization. Since the incidence of latent and recurrent infections is high, the eradication of HPV is not always 100% effective. It is essential to be aware that HPV is a sexually transmitted disease and women must engage in safe sex practices to decrease the risk of spreading the virus or becoming re-infected. The development of an HPV vaccine that would render individuals resistant to infection by at least some of the high-risk HPV types is a matter of considerable interest. It is possible that such a vaccine will be available by 2010. As of 2004, a phase I study of a vaccine for HPV type 18, which causes 70% of cervical cancers, is under way at the University of Iowa.

Hydroxyurea

Definition

Hydroxyurea, also known by its trade name Hydrea, is an antineoplastic agent, meaning it is used to treat cancer. It is taken orally.

Purpose

Hydroxyurea is used to treat the following conditions:

- Melanoma
- **Chronic myelocytic leukemia** that is resistant to other therapies
- Ovarian cancer that is recurrent, metastatic or inoperable.
- Squamous cell carcinoma of the head and neck, excluding the lip. (In this case, hydroxyurea is given with radiation therapy.)
- Sickle cell anemia
- Other: Hydroxyurea has shown promise in the management of thrombocytosis, a condition in which platelet levels are abnormally high

Description

Hydroxyurea belongs to antimetabolites, a group of compounds that interfere with the production of nucleic acids. Hydroxyurea exerts its anticancer activity by inhibiting ribonucleotide reductase, an enzyme required for DNA synthesis. When used in conjunction with **radiation therapy**, the effectiveness of hydroxyurea increases because it also inhibits the ability of cells damaged by radiation to repair themselves.

Recommended dosage

Hydroxyurea dosages are calculated based on a person's weight as milligrams per kilogram (mg/kg). Doctors will usually use whichever value is lowest—the patient's actual weight or the patient's ideal weight—to calculate dosages. The drug is not given if white blood cell levels drop below 2500 mm^3, or if red blood cell levels drop below 100,000 mm^3. Usually, bone marrow recovery is rapid, and few doses are missed. Hydroxyurea is usually given for six weeks before its effectiveness can be adequately evaluated.

Hydroxyurea is administered in a capsule form, each containing 500 mg of the drug. If a patient is unable to swallow the capsule, its contents can be dissolved in a glass of water and swallowed immediately. The drug will not completely dissolve in water. Dosages have not been established for children in part because the cancers for which hydroxyurea is useful do not normally occur in that age group.

In the treatment of solid tumors, such as ovarian cancers, patients are usually given 80 mg/kg once every three days. Alternatively, a dose of 20–30 mg/kg may be given every day.

In **head and neck cancers** also treated with radiation, 80 mg/kg of hydroxyurea is given once every three days. The drug should be started a week before radiation therapy begins, and should continue for some time after radiation therapy.

When it is used to treat resistant chronic myelocytic leukemia, hydroxyurea is given in the dosage of 20–30 mg/kg once a day.

In thrombocytosis, doses of 15–30 mg/kg taken once a day are usually effective. Platelet levels return to a normal level within two to six weeks of therapy. In more severe cases, doses of 1.5–3.0 grams per day have been given with plateletpheresis, a procedure that removes platelets from the blood.

KEY TERMS

Mucositis—A painful inflammation of the mucous membranes.

Mutagen—An agent capable of causing DNA changes.

Myelosuppression—Diminished bone marrow activity resulting in decreased red blood cells, white blood cells, and platelets.

Plateletpheresis—A procedure in which platelets are removed from whole blood.

Precautions

This drug should not be administered to a person who has had a previous allergic reaction to it. Liver and kidney function should be evaluated prior to, and during, treatment. The drug may interfere with certain lab tests. For example, creatinine levels may be elevated. Patients taking hydroxyurea should stay well-hydrated, drinking up to 12 glasses per day of water or other fluids.

Hydroxyurea is potentially mutagenic, meaning that it causes mutations in DNA. Patients taking the drug should discuss the potential effects on their future conception plans. Hydroxyurea should not be administered to pregnant women, and women taking the drug should use birth control methods to prevent pregnancy. Hydroxyurea is excreted in breast milk; therefore, women taking the drug should not breast-feed.

Side effects

Hydroxyurea and radiation therapy each cause adverse side effects. When they are used together, the incidence and severity of side effects may increase.

Bone marrow suppression is the major side effect of hyroxyurea therapy, and may develop within two days of the first dose. Blood tests are performed routinely to monitor for changes. Usually, leukopenia (decreased white blood cells) develops first. Reduced red blood cells and platelets can also occur, but generally not as frequently. If anemia develops, it should be corrected with whole blood transfusions. Hydroxyurea causes red blood cell abnormalities that are not severe and that do not reduce the red blood cell survival time.

Gastrointestinal symptoms are not as common as **myelosuppression** and are usually mild. These symptoms may include nausea, vomiting, **diarrhea**, and constipation. Usually, medications can control **nausea and vomiting**. **Mucositis**, a painful swelling of the mucous membranes, may also develop, especially if the patient is undergoing radiation treatment to the head and neck. Mucositis can be managed with medicated mouthwashes, good oral hygiene, and hydration to keep the mouth moist.

Headache and dizziness may occur. With long-term use, skin changes, such as hyperpigmentation of the skin and nails, have also been reported.

Hydroxyurea has also been linked to leg ulcers. Studies suggest that leg ulcers have been reported mainly in older patients who might be at an increased risk. There have also been reports of hydroxyurea causing leg ulceration when it is used in psoriasis for a prolonged period.

Interactions

Patients at risk for bone marrow suppression should inform their doctor about all medications they are taking, both prescription and non-prescription. Many over-the-counter medications contain aspirin, which acts as a blood-thinner, increasing the potential for bleeding. Patients with reduced platelets should not take aspirin.

Tamara Brown, R.N.

Hypercalcemia

Description

Hypercalcemia is an abnormally high level of calcium in the blood, usually more than 10.5 milligrams per deciliter of blood. It is the most common life-threatening metabolic disorder associated with cancer.

Calcium plays an important role in the development and maintenance of bones in the body. It is also needed in tooth formation and is important in other body functions. As much as 99% of the body's calcium is stored in bone tissue. A healthy person experiences a constant turnover of calcium as bone tissue is built and reshaped. The remaining 1% of the body's calcium circulates in the blood and other body fluids. Calcium in the blood plays an important role in the control of many body functions, including blood clotting, transmission of nerve impulses, muscle contraction, and other metabolic activities.

Cancer-caused hypercalcemia produces a disruption in the body's ability to maintain a normal level of calcium. This abnormally high level of calcium in the blood

develops because of increased bone breakdown and release of calcium from the bone. The disorder occurs in approximately 10-20% of all cancer cases. The most common cancers associated with hypercalcemia are breast, prostate, and lung cancer, as well as **multiple myeloma** or other tumors with extensive **metastasis** to the bone. It may also occur in patients with head and neck cancer, cancer of unknown primary, **lymphoma**, leukemia, kidney cancer, and gastrointestinal cancer. Hypercalcemia most commonly develops as a late complication of cancer, and its appearance constitutes an emergency.

Several clinical symptoms are associated with cancer-related hypercalcemia. Symptoms may appear gradually and often look like signs of other cancers and diseases. The symptoms of hypercalcemia are not only related to the elevated level of calcium in the blood, but—more importantly—to how rapidly the hypercalcemia develops. The severity of the symptoms is often dependent upon factors such as previous cancer treatment, reactions to medications, or other illnesses a patient may have. Most patients do not experience all of the symptoms of hypercalcemia, and some may not have any signs at all. Rapid diagnosis of hypercalcemia may be complicated because the symptoms are often nonspecific and are easily ascribed to other factors. These symptoms include:

- decreased muscle tone and muscle weakness
- delirium, disorientation, incoherent speech, and psychotic symptoms such as hallucinations and delusion
- constipation
- **fatigue**
- poor appetite, nausea and/or vomiting
- frequency of urination and increased thirst
- pain

Causes

The fundamental cause of cancer-related hypercalcemia is increased movement of calcium out of the bones and into the bloodstream, and secondarily, an inadequate ability of the kidneys to get rid of higher calcium levels. Normally, healthy kidneys are able to filter out large amounts of calcium from the blood, getting rid of the excess that is unneeded by the body and keeping the amount of the calcium the body does need. However, the high levels of calcium in the body caused by cancer-related hypercalcemia may cause the kidneys to become overworked, thus making them unable to excrete the excess. Another problem is that some tumors produce a substance that may cause the kidneys to get rid of too little calcium.

Two types of cancer-caused hypercalcemia have been identified: osteolytic and humoral. Osteolytic occurs because of direct bone destruction by a primary or metastatic tumor. Humoral is caused by certain factors secreted by malignant cells, which ultimately cause calcium loss from the bones. Certain types of hormonal therapy may precipitate hypercalcemia and the use of some diuretics may contribute to the disorder.

Because immobility causes an increase in the loss of calcium from bone, cancer patients who are weak and spend most of their time in bed are more prone to hypercalcemia. Cancer patients are often dehydrated because they take in inadequate amounts of food and fluids and often suffer from **nausea and vomiting**. Dehydration reduces the ability of the kidneys to remove excess calcium from the body, and therefore is another contributing factor in the development of hypercalcemia in cancer patients.

Treatments

Individuals at risk for developing hypercalcemia may be the first to recognize symptoms, such as fatigue. The patient and family should be aware of the signs and symptoms so that a health care professional can be notified as early as possible should they occur. Patients can take several preventative measures like ensuring adequate fluid intake, controlling nausea and vomiting, maintaining the highest possible mobility, and avoiding drugs that affect the functioning of the kidneys. This includes avoiding those medications containing calcium, vitamin D, or vitamin A. Since absorption of calcium is usually decreased in individuals with hypercalcemia, dietary calcium restriction is unnecessary.

The mortality rate for untreated hypercalcemia is quite high. Early diagnosis and prompt treatment are essential. The magnitude of hypercalcemia and the severity of symptoms is usually the basis for determining what type of treatment is indicated.

For those patients who have mild hypercalcemia, are experiencing no symptoms, and have cancer that is responsive to treatment, giving intravenous fluids and observing the patient may be all that is necessary to treat the condition. If the patient is experiencing symptoms or has a cancer that is expected to respond poorly to treatment, then medication to treat the hypercalcemia should be initiated. Additional treatment focuses on controlling nausea and vomiting, encouraging activity, and avoiding any medication that causes drowsiness.

In treating moderate or severe hypercalcemia, replacing fluids is the first treatment intervention. Though providing fluid replacement will not restore normal calcium levels in all patients, it is still the most important initial step. Improvement in mental status and nausea and

KEY TERMS

Calcium—A silvery-yellow metal that is the most abundant mineral in the human body. Calcium and phosphorous combine as calcium phosphate, the hard material of bones and teeth.

Humoral hypercalcemia—An abnormally elevated blood calcium level caused by factors released from cancer cells, ultimately causing the loss of calcium from bone.

Osteolytic hypercalcemia—An abnormally elevated blood calcium level caused by destruction of bone by a primary or metastatic tumor.

vomiting is usually apparent within 24 hours for most patients. However, rehydration is only a temporary measure. If the cancer is not treated, then drugs that will help to control the hypercalcemia are necessary. Many drugs are used to treat hypercalcemia, including **calcitonin**, **plicamycin** (formerly mithramycin), **gallium nitrate**, and **bisphosphonates**. Bisphosphonates are some of the most effective drugs for controlling hypercalcemia. Loop diuretics like furosemide are often given because they help to increase the excretion of excess serum calcium. For severe hypercalcemia that is complicated by kidney failure, dialysis is an option. Because of the large amounts of intravenous fluids given to treat hypercalcemia, the health care team will carefully observe for any signs of overhydration or other electrolyte imbalances.

The severity of hypercalcemia determines the amount of treatment necessary. Severe hypercalcemia should be treated immediately and aggressively. Less severe hypercalcemia should be treated according to the symptoms. A positive response to the treatment is exhibited by the disappearance of the symptoms and a decreased level of calcium in the blood. Mild hypercalcemia does not usually need to be treated aggressively. After calcium levels return to normal, urine and blood should continue to be checked often to make certain the treatment is still working.

Alternative and complementary therapies

There are no known proven alternative treatments for cancer-related hypercalcemia. Some of the medications used are more effective than others, and the patient and family should discuss which ones are the most appropriate for the patient's needs.

Hypercalcemia usually develops as a late complication of cancer, and its appearance is very serious. The outlook is often quite grim. However, it is not clear if death occurs because of the hypercalcemia crisis or because of the advanced cancer. Because hypercalcemia is often a complication that occurs in the final stages of cancer, the decision to treat it depends upon the overall goals of treatment determined by the patient, family, and physician. The natural course of untreated hypercalcemia will progress to loss of consciousness and coma. Some patients may prefer this at the end of life rather than have unrelieved suffering and/or untreatable symptoms. It is therefore important for the patient and caregivers to discuss what supportive care measures are wanted.

Hypercoagulable states, Trousseau's syndrome, Blood clots *see* **Hypercoagulation disorders**

Hypercoagulation disorders

Description

Hypercoagulation disorders (or hypercoagulable states or disorders) cause an increased tendency for clotting of the blood. In normal hemostasis (the stoppage of bleeding) clots form at the site of the blood vessel's injury. However, in hypercoagulation disorders the clots can develop in circulating blood. This may put a patient at risk for obstruction of veins and arteries (phlebitis, thrombosis, or thrombophlebitis). The hypercoagulable state and thrombophlebitis is common cases of cancer involving solid tumors such as pancreatic, breast, ovarian, and **prostate cancer**.

Hypercoagulation disorders can cause clots throughout the body's blood vessels, a condition known as thromboembolic disease. Thromboembolic disease can lead to infarction (death of tissue as a result of blocked blood supply to the tissue). Other serious results of hypercoagulation make this a dangerous condition. Clotting (thrombosis) in the veins and arteries leading to the lungs can prevent blood flow, causing sudden and severe

loss of breath and chest pain. These clots, called pulmonary embolisms, are potentially fatal. Clots in the blood vessels of the brain can result in a stroke, and clots in the heart's blood vessels can result in a heart attack.

Symptoms of hypercoagulation disorders include swelling or discoloration of the limbs, pain or tenderness of the skin, visible obstructions in the surface veins, and ulcers of the lower parts of the legs.

The diagnosis of hypercoagulation disorders is completed with a combination of physical examination, **imaging studies**, and blood tests. The presence of deep clots can be determined using Doppler ultrasound examination—special x-ray techniques called venography or arteriography (in which a solution is injected into the blood vessel to aid in imaging), or a specific type of blood pressure test called plethysmography. There are a number of blood tests that can determine the presence or absence of proteins, clotting factors, and platelet counts in the blood. Among the tests used to detect hypercoagulation is the Antithrombin III assay. Protein C and Protein S concentrations can be diagnosed with immunoassay or plasma antigen level tests.

KEY TERMS

Antithrombin—Any substance that counters the effect of thrombin. Thrombin is an enzyme that converts fibrinogen into fibrin, leading to blood coagulation.

Congenital—A condition or disorder present at birth.

Hemostasis— The arrest of bleeding.

Heparin—An anticoagulant, or blood clot dissolver.

Phlebitis—Inflammation of a vein.

Polycythemia—A condition characterized by an overabundance of red blood cells.

Thrombophlebitis—Inflammation of the vein with the formation of a thrombosis (blood clot).

Thrombosis—Formation of a clot in the blood that either blocks, or partially blocks, a blood vessel. The thrombus may lead to infarction (death of tissue due to a blocked blood supply).

Causes

Hypercoagulation disorders are associated with cancer of the pancreas. About half of patients with pancreatic cancer experience incidence of thrombosis. Approximately 10% of patients with pancreatic cancer develop a specific type of hypercoagulation disorder known as migratory thrombophlebitis, or Trousseau's syndrome. In Trousseau's syndrome the blood vessels become inflamed and clots in the blood vessels spontaneously appear and disappear. Other types of cancer may also result in hypercoagulation disorders.

In order for blood coagulation to occur, platelets (small, round fragments in the blood) help contract blood vessels to lessen blood loss and also to help plug damaged blood vessels. The conversion of platelets into actual clots is a complicated process involving proteins that are identified clotting factors. The factors are carried in the plasma, or liquid portion, of the blood. Proteins C and S are two of the clotting factors that are present in the plasma to help regulate or activate parts of the clotting process. It is believed that pancreatic tumors produce chemicals that promote clotting, or coagulation, of the blood (procoagulants), or that they activate platelet function. It is also possible that tumors interfere with the functions of proteins C and S.

Treatments

The treatment for patients with hypercoagulation disorders varies depending upon the severity of the clotting and the other conditions it may have caused. Medications may include blood thinners (anticoagulants) such as **heparin** and **warfarin**, which prevent the formation of new blood clots; antiplatelet drugs such as aspirin; or thrombolytic drugs to dissolve existing clots. Pain medications and nonsteroidal anti-inflammatory medications may be given to reduce pain and swelling. **Antibiotics** will be prescribed if infection has occurred.

Hyperthermia

Definition

Hyperthermia is the use of therapeutic heat to treat various cancers on and inside the body.

Purpose

The purpose of hyperthermia is to shrink and hopefully destroy cancer without harming noncancerous cells. It can be used to treat cancer in many areas of the body, including the brain, thyroid, lung, breast, and prostate. It is thought that high temperatures, up to 106 degrees Fahrenheit, can help shrink cancerous tumors. Hyperthermia is starting to be more widely used because it does not have side effects like other forms of cancer treatment such as radiation or **chemotherapy**. In some instances, hyperthermia is used at the same time with other forms of cancer therapy.

Through years of research, it has been found that the effectiveness of some forms of **radiation therapy** and chemotherapy are enhanced when combined with hyperthermia.

Although the treatment was considered experimental 15–20 years ago, its proponents believe that the treatment has been accepted by many physicians, and that use of hyperthermia will increase as more cancer centers install the high-tech equipment necessary for regional and whole body hyperthermia. (Currently, cancer care centers offering this treatment are limited.) The American Cancer Society acknowledged that hyperthermia can make the cancer cells of some cancers more responsive to treatment, but still considers the treatment experimental, especially in whole-body form. The National Institutes of Health are sponsoring ongoing **clinical trials** studying hyperthermia.

Precautions

Patients who have extensive **metastasis** (spreading of the cancer throughout their body) may not be good candidates for hyperthermia. Patients need to be free of major infections and able to tolerate the high temperatures of the treatment. Caution must be used when areas of the body are heated with external heat sources such as heating pads to avoid potentially dangerous burns.

Description

Hyperthermia can be used on the body from very small areas of the body to the entire body itself. Local hyperthermia refers to heating just one area of body, usually where the tumor is located. Heat can be applied from outside the body using microwaves or high-frequency radio waves. Heat can be applied from inside the body or even inside the tumor itself by the use of thin, heated wires, small tubes filled with hot water, or implanted microwave antennae.

If heat is used to treat an entire organ or limb, it is referred to as regional hyperthermia. High-energy magnets or other devices that produce high energy, and thus heat, are placed over the larger areas to be heated. Another method of regional hyperthermia is the use of perfusion. Hyperthermia perfusion uses the patient's own blood; the blood is removed, heated outside the body, then pumped back into the area that contains the cancer.

For treatment of cancers that have spread throughout the body, whole-body hyperthermia can be considered. Various methods are used to heat up a patient's entire body, including warm-water or electric blankets, hot wax, or thermal chambers which are very much like incubators used to warm newborn babies, except much larger.

Preparation

There are generally no advance preparations needed for a patient considering the use of hyperthermia.

Risks

The major risks of hyperthermia use are pain and external burns. Heat applied directly to the skin can cause minor discomfort to significant pain, especially when high temperatures are used. Blistering and actual burning of the skin can also occur at higher temperatures, although with careful application of the hyperthermia, these side effects are very rare.

Normal results

The goal of hyperthermia is to control the growth and shrink hyperthermia-sensitive tumors. As stated earlier, hyperthermia can also be used to help sensitize tumors to other cancer treatment modalities such as radiation and chemotherapy.

Abnormal results

There are generally no abnormal results seen with the use of hyperthermia. Side effects, such as pain and burning from external heat sources, can be minimized with careful application of the heat.

Ibritumomab

Definition

Ibritumomab is a radioimmunotherapy used to treat **non-Hodgkin's lymphoma** (NHL).

Purpose

Ibritumomab is used to treat individuals with low grade follicular NHL that has failed to respond or that has stopped responding to the drug **rituximab** (Rituxan).

NHL is a cancer that arises in the organs of the lymph system. It is the most common type of **lymphoma** in the United States. The lymph system is important in creating and transporting blood cells called lymphocytes that fight infection throughout the body. The major organs of the lymph system are the spleen, thymus, tonsils, and bone marrow. These organs produce several different kinds of cells that fight infection. The major ones are called T-cells and B-cells. Ibritumomab specifically targets both mature and immature B-cells.

In NHL, abnormal (cancerous) lymphocytes grow out of control. So many of these abnormal lymphocytes develop that they prevent other immune system cells and blood vessel from forming. There are several types of NHL. One form is called follicular lymphoma. In this form, the cancerous cells clump together. They may grow quickly, in which case the disease is called a high-grade lymphoma, or they may grow slowly, in which case the cancer is called low-grade lymphoma.

Standard treatments for NHL include **chemotherapy**, **radiation therapy**, stem cell therapy, and a newer form of therapy called biologic therapy. Biologic therapy uses the biopharmaceutical rituximab. Ibritumomab is used in patients with low-grade B-cell NHL who have failed to respond or who have relapsed after standard treatment.

Description

Ibritumomab, which is also called ibritumomab tiuxetan, is manufactured in the United States and sold under the brand name Zevalin by IDEC Pharmaceuticals. It was approved for use in February 2002 and was the first radioimmunotherapy approved by the United States Food and Drug Administration (FDA). Generic substitutes are not available, and currently there is only one American manufacturer.

Radioimmunotherapy is a form of biologic therapy that combines a protein that attaches to the target cell with a small dose of radioactive material that disrupts and kills the cell. Unique proteins called antigens exist on the surface of every cell. The body monitors these proteins, and when it recognizes a cell as foreign or defective, it creates other antigen-specific proteins called antibodies to attach to the unwanted cells and disable them. With NHL, this system of protection fails and defective cancerous cells are allowed to continue growing.

Ibritumomab is an antibody made of mouse (murine) protein that comes from Chinese hamster ovary cells. It binds with the a protein called CD20 that is found on the surface of both normal and malignant B-cells. Ibritumomab alone does not kill B-cells, so it is bound to a radioactive material, either Indium-111 (In-111) or Yttrium-90 (Y-90). The role of ibritumomab is to deliver the radioactive material to specific target cells and bind it there. The radioactive rays given off by IN-111 or Y-90 disrupt the cell's functions, resulting in cell death. This therapy kills both healthy and cancerous B-cells.

Recommended dosage

Ibritumomab is given only in a two-step cycle in conjunction with another non-radioactive antibody called rituximab. Rituximab attacks the same B-cells as ibritumomab but does not deliver a dose of radioactive material to the cell. The two-step cycle of administration of ibritumomab is intended to occur only once.

The material needed for the therapeutic administration of ibritumomab is sold under the name Zevalin. The ibritumomab carrier antibody is mixed with the radioactive material by the physician shortly before use.

Step 1 includes a single dose of rituximab. The dose is determined by the patient's body size. Rituximab is infused slowly into a vein while the physician watches for hypersensitivity reactions. Within four hours following administration of rituximab, a single dose of 5.0 milliCuries (mCi) ibritumomab tiuxetan that contains the radioactive material In-111 is injected intravenously (IV) over a period of 10 minutes.

Step 2 follows seven to nine days after Step 1. The patient is given another IV dose of rituximab, again based on body size. Within four hours following the rituximab, the patient is injected with a dose of radioactive ibritumomab Y-90. This dose is also based on body size up to a total maximum allowable dose of 32.0 mCi. This completes the active part of the therapy, but patients must continue to have their blood count monitored for several months, as the therapy continues to kills cells for weeks.

Precautions

People who are allergic to any type of mouse (murine) protein, rituximab, yttrium chloride or indium chloride should not use this therapy. Ibritumomab can cause harm to the developing fetus and should not be used by pregnant women. Women should use birth control for 12 months after receiving this therapy. It has not been established whether this therapy is safe to use in breastfeeding women. A pediatric dose has not been established.

Zevalin is radioactive when it is being administered, and care should be taken to minimize exposure of patients and health care providers.

Side effects

Side effects are many and varied. Serious but rare side effects include:

- potentially fatal infusion hypersensitivity reactions, usually to the first dose of rituximab, that can cause low blood pressure, difficulty breathing, heart attack, and anaphylactic shock
- severe drop in platelet count (**thrombocytopenia**) or neutrophil count (**neutropenia**); uncontrolled bleeding
- development of secondary malignancies that arise from the therapy

More common but less serious side effects include:

- susceptibility to infections; **fever** or chills
- nausea, vomiting, **diarrhea**, black, tarry stools
- loss of appetite
- anemia
- joint pain
- dizziness
- increased cough or hoarseness
- rash, swelling, or puffiness around the face and neck

KEY TERMS

Anaphylactic shock—A whole body allergic reaction that is often fatal.

Malignant—Cancerous.

Neutrophil—A type of blood cell important to fighting infection.

Non-Hodgkin's lymphoma—A cancer of the lymph system that causes the accumulation of large numbers of defective (cancerous) immune system cells.

Platelet—A white blood cell that produces proteins that help blood clot.

Radioimmunotherapy—A treatment in which a radioactive material is delivered to specific cells by using a protein that binds to the surface of the target cells.

Interactions

It is important to tell the physician about all prescription medications, over-the counter medications, and herbal or alternative remedies that are being taken before treatment with Zevalin is begun. No formal drug interaction studies have been completed, however, Zevalin therapy does interfere with blood clotting and should not be used while individuals are taking blood thinners such as **warfarin** (Coumadin) or clopidogrel bisulfate (Plavix). Individuals who have a very low platelet count may not be able to use this therapy.

Individuals should not be vaccinated with a live virus vaccine prior to or soon after receiving this therapy. The interaction of live virus **vaccines** and this therapy has not been investigated, but it is recommended that individuals receiving ibritumomab avoid people who have recently been vaccinated with live virus oral polio vaccine.

Tish Davidson, A. M.

Idarubicin

Definition

Idarubicin is a medication that kills cancer cells.

Purpose

Idarubicin is approved to treat only one single cancer, acute myelocytic leukemia (AML) in adults. Recent research suggests that using idarubicin rather than the more traditional **daunorubicin** in treating AML results in higher rates of complete remission (CR) and longer survival for patients. CR is the total elimination of all diseased cells detectable following therapy. The Food and Drug Administration (FDA) has not approved idarubicin as treatment for **acute lymphocytic leukemia** (ALL).

Much research involving idarubicin is now being conducted. Some of this has involved acute lymphocytic leukemia (ALL) as well as AML. For example, a recent study was conducted in patients with either AML or ALL who had received **bone marrow transplantation** and then relapsed. Patients received a combination of **cytarabine**, idarubicin, and **etoposide**, as well as a medicine called G-CSF (filgrastim). This treatment achieved a high CR rate in these patients.

Another recent study looked at the use of idarubicin in children with AML. All of the children received cytarabine and etoposide. In addition, some of the children received idarubicin, while some received daunorubicin. Overall, patients in both groups fared equally well in terms of survival length. However, patients who had larger numbers of cells known as blasts (immature cells) tended to do better if they received idarubicin rather than daunorubicin. In addition, high-risk patients tended to do better with idarubicin than with daunorubicin. No subgroup of patients achieved better outcomes with daunorubicin than with idarubicin.

For older patients with acute nonlymphocytic leukemia, treatment with Idarubicin is effective and has acceptable side effects. According to recent research from Italy, "There is growing interest in autologous stem cell transplantation (ASCT) for elderly patients with acute myeloid leukemia (AML). While mortality and toxicity from ASCT have been reduced, relapse rate is still high.

Description

Idarubicin is an antibiotic, although doctors do not use this drug to attack infections. Its only use is to kill cancer cells. It does so by affecting how the DNA of cancer cells work.

KEY TERMS

Bilirubin—A pigment produced when the liver processes waste products. A high bilirubin level causes yellowing of the skin.

Blasts—Immature cells

Complete remission (CR)—Complete remission is the total elimination of all diseased cells detectable following therapy.

Necrosis—The sum of the morphological changes indicative of cell death. It may affect groups of cells or part of a structure or an organ.

Recommended dosage

In the treatment of AML, 12 mg of idarubicin per square meter may be given over a period of two to three days every three weeks in combination with other medications. Patients with liver problems may be given lower doses than other patients receive. Idarubicin is not typically given by mouth, as an insufficient amount of the medication would be transported through the stomach wall if this were done. Rather, this medication is usually administered through an intravenous (IV) procedure. During this time, it circulates widely throughout the body.

A new formulation of idarubicin has been developed. This permits idarubicin to be taken orally. However, this formulation is currently available only in France and only for older patients who are not good candidates for intensive intravenous treatment. There is little information currently available on the effectiveness of this oral formulation. The studies that have been performed suggest that it is less effective than other formulations of idarubicin.

Precautions

Idarubicin may be associated with excessive toxicity in patients with congestive heart failure, liver function characterized by a high bilirubin level, or prior chest radiation to the heart.

Side effects

Like daunorubicin and **doxorubicin**, idarubicin may adversely affect the patient's heart. However, doctors are not certain how much of the drug it takes to cause such harm and, therefore, how to limit dosage so that such harm is not caused. However, idarubicin appears to be less likely to cause heart damage than similar drugs such as daunorubicin and doxorubicin. Another

serious side effect that limits how much of the drug is given to patients is its potential adverse effect upon the bone marrow, where blood cells are produced.

Idarubicin may cause nausea and vomiting, baldness (alopecia), and stomach problems. In addition, idarubicin may cause blistering if extravasation occurs. Extravasation is when **chemotherapy** gets outside of the vein during infusion. If this occurs, the drug may cause severe local pain, swelling, or tissue necrosis that may require plastic surgery.

Patients receiving idarubicin in conjunction with certain other anticancer drugs may develop a type of leukemia. However, this is extremely rare.

In the few studies that have been conducted on the oral formulation of idarubicin, the most prominent side effects seen are low blood cell counts, nausea, vomiting, **diarrhea**, and **alopecia**.

Bob Kirsch

Ifosfamide

Definition

Ifosfamide is an anticancer (antineoplastic) agent. It also acts as a suppressor of the immune system. It is available under the brand name IFEX.

Purpose

Ifosfamide is approved by the Food and Drug Administration (FDA) to treat germ cell **testicular cancer**. It is generally prescribed in combination with another medicine (**mesna**), which is used to prevent the bladder problems that may be caused by ifosfamide alone.

Ifosfamide also has activity against other cancers and is prescribed in practice for these cancer types:

- pancreatic cancer
- stomach cancer
- soft-tissue sarcoma
- Ewing's sarcoma
- acute and chronic lymphocytic leukemia
- bladder cancer
- bone cancer
- breast cancer
- cervical cancer
- head and neck cancers
- lung cancer
- lymphomas
- neuroblastomas
- ovarian cancer
- **Wilms' tumor**

Description

Ifosfamide chemically interferes with the synthesis of the genetic material (DNA and RNA) of cancer cells by cross-linking of DNA strands, which prevents these cells from being able to reproduce and continue the growth of the cancer.

Recommended dosage

Ifosfamide may only be taken as an injection into the vein. The dosage prescribed varies widely depending on the patient, the cancer being treated, and whether or not other medications are also being taken. Examples of common doses for adults are: 50 mg per kg per day, or 700 to 2000 mg per square meter of body surface area for five days every three to four weeks. Another alternative regimen is 2400 mg per square meter of body surface area for three days or 5000 mg per square meter of body surface area as a single dose every three to four weeks. Examples of common dosing regimens for children are: 1200 to 1800 mg per square meter of body surface area per day for three to five days every 21 to 28 days; 5000 mg per square meter of body surface area once every 21 to 28 days; or 3000 mg per square meter of body surface area for two days every 21 to 28 days.

Precautions

Ifosfamide can cause an allergic reaction in some people. Patients with a prior allergic reaction to ifosfamide should not take this drug.

Ifosfamide should always be taken with plenty of fluids.

Ifosfamide can cause serious birth defects if either the man or the woman is taking this drug at the time of conception or if the woman is taking this drug during pregnancy. Contraceptive measures should be taken by both men and women while on this drug. Because ifosfamide is easily passed from mother to child through breast milk, breast feeding is not recommended during treatment.

Ifosfamide suppresses the immune system, and its excretion from the body is dependent on a normal

functioning kidney and liver. For these reasons, it is important that the prescribing physician is aware of any of the following pre-existing medical conditions:

- a current case of, or recent exposure to, chicken pox
- herpes zoster (shingles)
- all current infections
- kidney disease
- liver disease

Also, because ifosfamide is such a potent immunosuppressant, patients taking this drug must exercise extreme caution to avoid contracting any new infections.

Side effects

Inflammation and irritation of the bladder, causing blood in the urine, is the most common and severe side effect of ifosfamide. However, this side effect can be prevented and controlled with the administration of the bladder protectant drug mesna and vigorous hydration with intravenous fluids before, during, and after **chemotherapy**. Patients should also urinate frequently (at least every 2 hours) to enhance removal of the drug from the body, and drink 2 to 3 liters of fluids a day for 2 to 3 days after discontinuation of the chemotherapy.

Other common side effects of ifosfamide are:

- confusion
- hallucinations
- drowsiness
- dizziness
- temporary hair loss (alopecia)
- increased susceptibility to infection
- increased risk of bleeding (due to a decrease of the platelets involved in the clotting process)
- nausea and vomiting (can be prevented with prescribed antiemetics)

Less common side effects include:

- increased coloration (pigmentation) of the skin and fingernails
- loss of appetite (anorexia)
- diarrhea
- nasal stuffiness
- skin rash, **itching**, or hives

A doctor should be consulted immediately if the patient experiences any of these side effects:

- painful or difficult urination

KEY TERMS

Antineoplastic—A drug that prevents the growth of a neoplasm by interfering with the maturation or proliferation of the cells of the neoplasm.

Neoplasm—New abnormal growth of tissue.

- increase in frequency or feeling of urgency to urinate
- blood in the urine
- blood in the stool
- severe diarrhea
- mental status changes such as confusion, drowsiness, or hallucinations
- signs of infection such as cough, sore throat, **fever** and chills
- shortness of breath
- chest or abdominal pain
- pain in the lower back or sides
- unusual bleeding or bruising
- tiny red dots on the skin

Interactions

Ifosfamide should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician.

Paul A. Johnson, Ed.M.

Imaging studies

Definition

Imaging studies are tests performed with a variety of techniques that produce pictures of the inside of a patient's body. They have become indispensable tools in cancer screening and detection.

Description

Imaging tests are performed using sound waves, radioactive particles, magnetic fields, or x rays that are detected and converted into images after passing through body tissues. Dyes are sometimes used as contrasting agents with x-ray tests so that organs or tissues not seen with conventional x rays can be enhanced. The operating

principle of the various techniques is based on the fact that rays and particles interact differently with various types of tissues, especially when cancerous growths are present. In this way, the interior of the body can be visualized and pictures are provided of normal structure and function as well as of abnormalities.

Imaging tests differ from endoscopic tests, which are carried out with a flexible, lighted piece of tubing connected to a viewing lens or camera.

Imaging studies are used to detect cancer in its early stages in a procedure called screening. Screening is performed in patients who have no obvious cancer symptoms. Imaging studies are also used to locate tumors in patients who have symptoms which the physician may wish to investigate further so as to distinguish between benign growths or cancerous tumors. They are also used to determine the extent of a cancer and indicate how a given treatment is unfolding. As such, they represent crucial tools for cancer diagnosis and management.

Major imaging techniques

Computed tomography scan (CT scan)

Computed tomography scans show a cross-section of a part of the body. In this technique, a thin beam is used to produce a series of exposures detected at different angles. The exposures are fed into a computer which overlaps them so as to yield a single image analogous to a slice of the organ or body part being scanned. A dye is often injected into the patient so as to improve contrast and obtain images that are clearer than images obtained with x rays.

Magnetic resonance imaging (MRI)

Magnetic resonance imaging also produces cross-sectional images of the body using powerful magnetic fields instead of radiation. MRI is especially useful to detect and locate cancers of the liver and the central nervous system, which occur in the brain or the spinal cord. It uses a cylinder housing a magnet which will induce the required magnetic field. The patient lies on a platform inside the scanner. The magnetic field aligns the hydrogen atoms present in the tissue being scanned in a given direction. Following a burst of radio-frequency radiation, the atoms flip back to their original orientation while emitting signals which a fed into a computer for conversion into a two- or three-dimensional image. Dyes can also be injected into patients to produce clearer images.

Mammography

Mammography is an x-ray examination of the breast. It is often used as a screening tool to detect breast abnormalities and cancers before they can be felt. Mammograms (the image produced) are acquired using an x-ray machine working at lower radiation levels than conventional **x ray**. The breast is compressed between two plates so as to allow the low-level x-ray radiation to produce a film.

Nuclear scan

Nuclear scans, also called radionuclide imaging or scintigraphy, use substances called tracers or radionuclides that release low levels of radioactivity. The test is based on the principle that the tracers will be absorbed to a different degree by different tissues, thus allowing to distinguish between normal and cancerous tissues. Common **nuclear medicine scans** for cancer patients to receive are bone scans; liver, spleen, and thyroid scans are also frequently performed.

Position emission tomography (PET)

Positron emission tomography uses a form of sugar that contains a radioactive atom which emits particles called positrons. The positrons are absorbed to a different extent by cells varying in their metabolic rate. PET scans are especially useful for brain imaging studies and are widely applied to the assessment of the spread of cancers in the lungs. PET scans are also being used experimentally in the assessment of breast, colon, rectum, and ovarian cancers.

X rays

X rays produce shallow images of certain specific organs or tissues. X rays are a form of high-energy radiation and tissues of the body can absorb it to varying degrees. For example, bones absorb less x rays than soft tissue. After passing through the body, the x rays are directed on a film, where the dense tissue appears as a white shadow, thus providing contrast with the soft tissue, which produces a darker impression on the film. X rays produce a single image.

Chest x rays are used to detect lung and bronchial cancers, and also to evaluate a patient's symptoms, such as shortness of breath. Other types of x rays, such as abdominal x rays, may also be ordered to assess a patient's symptoms, but are not used as cancer screening tools as chest x rays may be used.

X rays with dye studies

Dye studies are usually performed by injecting the contrasting agent in the patient's circulatory system or in the target organ. These studies are used to produce angiograms, cystograms, myelograms, lymphangiograms and fistulograms.

ANGIOGRAM An angiogram is an examination of the blood vessels using x rays. It is usually performed with intravenous injection of fluorescein dye followed by multiframe photography. The doctor inserts a small tube (catheter) into the blood vessel and then injects the dye that makes the vessels visible when the x-ray pictures are acquired.

CYSTOGRAM A cystogram is a scan of the bladder and ureters. The ureters are passages that lead from the kidneys to the bladder. A catheter is inserted into the bladder or a radioactive material, called a radioisotope, is introduced into the bladder. An oral cholecystogram (OCG) is an x-ray examination of the gallbladder, the organ that helps release bile into the small intestine for the digestion of fats. The gallbladder is not seen well on conventional x-ray pictures and special tablets are ingested by mouth to enhance contrast.

MYELOGRAM A myelogram is an x ray of the spine and spinal cord. The spinal cord is the nerve tissue enclosed in the vertebral column that goes from the bottom of the brain to halfway down the back. During a myelogram, x-ray dye is injected into the spinal fluid and mixes with it, flowing around the spinal cord which can then be seen and recorded on x-ray film.

LYMPHANGIOGRAM A lymphangiogram is an x ray of the lymphatic system, also carried out with dye injection for contrasting purposes. It is used to screen for lymph node involvement in cancer.

FISTULOGRAM A fistula is an abnormal passage within body tissue. For example, a fistula may connect two organs inside the body that are not normally connected. A fistula may also lead from an internal organ inside the body to the surface outside. Examples are: between the skin and the bowel (enterocutaneous fistula), between the stomach and the colon (gastrocolic fistula). A fistulogram is an x-ray examination of this abnormal passage. The contrasting agent is injected directly into the fistula so that it will show up on x-ray pictures.

Fluoroscopy

Fluoroscopy is one of the oldest areas of diagnostic radiology. It is similar to x ray in that a small dose of x rays is directed through a body part but the image obtained is displayed on a monitor rather than on the conventional x-ray film. The fluoroscope provides images of internal body parts as they move, similar to a movie. A continuous x-ray beam is passed through the body part being examined, and is transmitted to an image-intensifying tube, which is a TV-like monitor so that the body part and its motion can be seen in detail.

KEY TERMS

Cancer screening—A procedure designed to detect cancer even though a person has no symptoms, usually performed using an imaging technique.

CT scan—An imaging technique that uses a computer to combine multiple x-ray images into a two-dimensional cross-sectional image

Mammography—An imaging technique producing x-ray pictures of the breast called mammograms.

MRI—A special imaging technique used to image internal parts of the body, especially soft tissues.

PET—A highly specialized imaging technique using radioactive substances to identify active tumors.

Radionuclide imaging—An imaging technique in which a radionuclide is injected through tissue and a display is obtained from a scanner device.

During fluoroscopy, the patient is placed between the x-ray source and the monitor. The live images generated by the x-ray source strike the image-intensifying tube and allow doctors to see the size, shape, and structure of a patient's internal structures. Because the radiation is blocked more effectively by dense tissue, such as that of a tumor, the result is a dark shadow of the tumor on the screen, against a light background. Most fluoroscopy devices include television or video cameras attached to the image-intensifier tube. The camera output can be digitized and sent through a computer for image enhancement.

In fluoroscopic studies, the radiologist can either insert an intravenous (IV) catheter (hollow tube inserted into blood vessels or into an organ) to **biopsy** a tumor or he can use a contrast agent to visualize the organ or area of interest. The contrast agent allows the image to be viewed more clearly. Contrast agents may be introduced into the patient's body by injection, swallowing, or an enema. Fluoroscopic exams include the following types of tests: barium swallow, **barium enema**, and intravenous pyelography (also called intravenous urography).

BARIUM SWALLOW Used for GI series. The patient drinks a chalky, milkshake-like concoction containing barium, which coats the esophagus and stomach. The barium absorbs the x rays so that the lining of the upper digestive tract can be clearly seen. In barium x rays, fluoroscopy allows the physician to see the movement of the intestines as the barium moves through them.

BARIUM ENEMA In a lower GI series, the patient receives a barium enema, which coats the intestines and rectum. A gap in the image in the stomach or small intestine could indicate an ulcer and bubbles in the normally smooth large intestinal lining may be abnormal growths.

INTRAVENOUS PYELOGRAPHY (IVP) Pyelography, also called urography, consists of several x rays of all the urinary system, meaning kidneys, ureter, bladder and urethra. A contrast agent is injected through a vein, to make the organs visible for the x rays.

Imatinib mesylate

Definition

Imatinib mesylate is an enzyme inhibitor used for cancer therapy. Imatinib mesylate is also known as STI571 and is sold under the brand name, Gleevec. It was given the name STI571 during early development. STI stands for signal transduction inhibitor.

Purpose

Imatinib mesylate is approved by the U. S. Food and Drug Administration to treat a rare cancer called chronic myeloid leukemia (CML). (CML is also called chronic myelogenous leukemia or **chronic myelocytic leukemia**, as well.)

Description

Imatinib mesylate is the first drug of its kind developed. It fights cancer by turning off an enzyme called tyrosine kinase that causes CML cells to lose their ability to die so they can multiply at an abnormal rate. Its function is different from other cancer drugs because it specifically targets an enzyme that allows the growth of CML cells. This drug has been shown to significantly reduce the number of cancer cells in the blood and bone marrow of treated patients.

Patients who are diagnosed with CML in the three phases of disease can be treated with imatinib mesylate. Chronic myeloid leukemia appears to respond within one to three months following administration of this drug.

Recommended dosage

A doctor experienced in the treatment of patients with CML should initiate therapy.

To minimize the risk of gastrointestinal irritation, imatinib mesylate should be taken with food and a large glass of water. The recommended dosage varies according to clinical circumstances and phase of disease, but generally ranges between 300 and 600 mg per day. As long as the patient continues to benefit, treatment should be continued.

Precautions

Studies have not been performed with imatinib mesylate to determine if it is a carcinogen (cancer causing); therefore it is not known whether this drug may cause mutations or may have cancer-causing effects. In

addition, imatinib mesylate's safety and effectiveness has not been established in pediatric patients.

- Fluid retention and edema. If patients experience swelling or weight gain from water retention, they should inform their doctor and should be closely monitored. Signs and symptoms of fluid retention should be closely monitored and patients should be weighed regularly. Appropriate treatment must be provided if an unexpected rapid weight gain occurs. The likelihood of edema is increased with higher doses and in those over age 65 years.
- gastrointestinal irritation
- hematologic toxicity (toxicity of the blood)
- hepatotoxicity (toxicity of the liver)
- toxicities from long-term use

Side effects

Commonly reported side effects include **nausea and vomiting**, muscle cramps, edema (water retention), skin rash, **diarrhea**, heartburn, and headache. Serious side effects occur less frequently, but if they occur may include severe edema liver toxicity, and the potential for bleeding especially in the elderly.

Interactions

Imatinib mesylate interacts with many other drugs. In some cases, side effects may be increased because imatinib mesylate might increase blood levels of certain drugs. Alternatively, imatinib mesylate may decrease blood levels of the drugs, thus reducing their effectiveness. In addition, the blood levels of imatinib mesylate may rise or fall because of other drugs. Therefore, side effects of imatinib mesylate may be increased or effectiveness may be reduced. The patient must discuss all of their medications with their doctor due to many potential drug-drug interactions.

CYP3A4 is an enzyme that is predominately responsible for the metabolism of imatinib mesylate. The following drugs or families of drugs may interact with imatinib mesylate:

- Inhibitors of the CYP3A4 family, such as ketoconazole, itraconazole, erythromycin.
- Co-medications that induce CYP3A4, such as **dexamethasone**, **phenytoin**, **carbamazepine**, rifampicin, phenobarbital or St. John's Wort). No formal studies have been conducted on these medications and imatinib mesylate together.
- CYP3A4 substrates, such as **cyclosporine** or pimozide.
- CYP3A4 metabolized drugs, such as certain HMG-CoA reductase inhibitors, triazolo-benzodiazepines, and dihydropyridine calcium channel blockers.
- Warfarin. Patients needing anticoagulant therapy while taking imatinib mesylate should be prescribed low-molecular weight or standard heparin. This list is not all-inclusive of all possible interactions. Patients must inform their doctors of any drugs they are taking in order to avoid drug interactions.

Investigators also evaluated the effect of St. John's wort, an herb used to treat mild to moderate depression, on the pharmacokinetics of imatinib. Studies showed that the administration of St. John's wort along with imatinib mesylate reduced absorption and increased elimination of imatinib, reducing drug exposure by as much as 42%. Since clinical efficacy of imatinib is dependent on drug dose and concentration, the interaction with St. John's wort could result in a loss of therapeutic effect. Therefore, the concurrent use of St. John's wort and imatinib should be avoided.

Crystal Heather Kaczkowski, MSc.

KEY TERMS

CYP3A4—An enzyme that is predominately responsible for the metabolism of imatinib mesylate.

Enzyme—Any protein that acts as a catalyst, increasing the rate of a chemical reaction.

Kinase—An enzyme.

Leukemia—A type of cancer in which the bone marrow produces an excessive number of abnormal (leukemic) white blood cells. White blood cells protect the body against infection but the abnormal cells suppress the production of normal white blood cells.

Tumor—An abnormal mass of tissue that serves no purpose. Tumors may be either benign (non-cancerous) or malignant (cancerous).

Tyrosine—A non-essential amino acid. Amino acids are the building blocks of protein. They are the raw materials used by the body to make protein. Tyrosine is labeled "nonessential" because, when the amino acids are lacking in the diet, they can be manufactured in the body.

Immune globulin

Definition

Immune globulin is a concentrated solution of antibodies, pooled from donated blood, which is sometimes given to cancer patients whose own immune systems are either not working or are suppressed as a side effect of treatment. Immune globulin can also be called gamma globulin; in the United States some of the brand names are Gamimune, Gammagard, Gammar-P, Iveegam, Polygam, Sandoglobulin, and Venoglobulin.

Purpose

A healthy human body produces proteins called antibodies that act to destroy microorganisms (bacteria and viruses) that invade the body. Some cancer patients, due to the illness itself or side effects of treatment, become depleted of these proteins and therefore susceptible to serious infections. Immune globulin is given to these patients to restore their body's immunity. The use of immune globulin in this way is also called passive immunization. For example, immune globulin is given to bone marrow transplant recipients to prevent the development of severe bacterial infections while their own immune systems are not functioning, and **chronic lymphocytic leukemia** patients (of the type whose antibody-producing cells are the malignant cells) are given immune globulin to prevent the recurrent infections these patients sometimes suffer. Use in this disorder also allows the use of aggressive **chemotherapy** that will destroy the patient's own cancerous antibody-producing cells.

Immune globulin is also used to treat other diseases such as **Eaton-Lambert Syndrome**, a rare neurological disorder that sometimes occurs in association with small cell lung cancer called Eaton-Lambert syndrome, an autoimmune disease in which a patient's own antibodies attack nerve cells. The use of immune globulin appears to cause the body to reduce its own production of antibody, thereby improving the neurological disorder.

Description

Immune globulin primarily consists of antibody proteins of the type called IgG or gamma, although the solution may contain small amounts of other antibody types as well as sugars, proteins, and salt.

It is produced by pooling donated blood from at least 1000 people who have been tested to be free of blood-borne diseases like HIV or hepatitis. The antibody proteins are then separated out of the whole blood, and the pH of the immune globulin solution is adjusted to match the normal pH of blood. The preparation is also treated to remove any contaminants, including infectious bacteria or viruses.

Recommended dosage

The dose of immune globulin used varies with the specific problem that it is being used for. When immune gobulin is used in patients with Eaton-Lambert Syndrome, the effective dose is usually about 1 g/kg of body weight/day. (One gram equals 0.035274 ounce; one kilogram equals 2.2046 pounds.) When used to counteract immunodeficiency, the dose is designed to produce an antibody level that stays at an effective threshold over a period of time.

When immune globulin is given to bone marrow transplant recipients, it is usually begun at the time of the transplant and continued for 100 days thereafter, with the objective of maintaining the level of IgG in the patient's blood above 400 mg per deciliter. (A deciliter equals 3.38 fluid ounces.) In patients with chronic lymphocytic leukemia (B-cell type) the target threshold for antibodies in the patient's blood is usually about 600 mg/dL. Although the amount required to maintain these levels varies from patient to patient (because different patients metabolize the drug at different rates) a dose between 10 and 200 mg/kg of body weight, given every 3-4 weeks, is usually sufficient.

Immune globulin is usually given intravenously, although intramuscular shots are available.

Precautions

Some people may have experienced severe reactions, including allergy-type reactions, to other antibody preparations. Generally, these people should not be given intravenous immune globulin. Patients with deficiency of antibody IgA, specifically, should also avoid the use of immune globulin. People with a tendency to form blood clots, or those with kidney problems should also avoid the use of this product, especially if elderly. While many pregnant women have been treated with immune globulin for different problems that have occurred during their pregnancy, since the method of action and specific effects on the fetus are not completely understood, pregnant women should avoid the use of immune globlulin unless it is clearly necessary. Any patient who is given immune globulin should be watched carefully, and epinephrine should be kept available in case a severe allergic reaction is experienced. Immune globulin which was made to be given through intramuscular injection should never be administered intravenously.

KEY TERMS

Autoimmune disease—A disease in which the body produces an immunologic reaction against itself.

Epinephrine—A medication used to treat heart failure and severe allergic reactions.

Immunoglobulins—An antibody of a specific type. Five main types are produced, known as IgA, IgD, IgE, Ig G, and IgM. Most antibody in the blood is IgG.

Intramuscular administration—A shot usually in the hip or arm, in which medication is delivered into a muscle.

Intravenous administration—Introduction of medication straight into a vein (commonly called IV).

Neurologic—Involving the nervous system.

Side effects

Administration of intramuscular immune globulin may result in tenderness, swelling, and possibly hives at the site of the injection.

Intravenous immune globulin may cause more severe reactions related to rapid introduction into the blood system. Possible side effects include headache, backache, aching muscles, **fever**, low blood pressure, and chest pain. More commonly, fever accompanied by chills or **nausea and vomiting** may be experienced. If these side effects occur, they are usually related to the immune globulin being administered too rapidly. If the rate of infusion is reduced, or if the infusion is stopped temporarily, negative effects will generally disappear. Rare, but potentially serious, side effects observed have been kidney failure and aseptic meningitis.

Interactions

Use of immune globulin may reduce the effectiveness of vaccinations (for example, measles, mumps, and rubella) for a few months following the use of the immune globulin preparation. Patients who have been given immune globulin should notify their doctors before any vaccinations are given. In addition, in some situations patients may need to have antibody levels measured to determine whether or not they have had previous infection with a specific microorganism. Use of immune globulin can create the false impression of prior exposure to the organism due to the donated antibodies in their blood.

Immune response

Definition

The ability of any given cell in the body to distinguish self from nonself is called the immune response.

All cells in the body are recognized as self. Any microorganism (for example, a foreign body or tumor) that invades or attacks the cells is recognized as nonself—or foreign—requiring the immune system to mount a combat against the nonself.

Immune system

The immune system is comprised of a network of immune cells that are generated in the bone marrow stem cell (a cell whose daughter cells may develop into other types of cells). From stem cells different types of immune cells originate that can handle specific immune functions. Phagocytes (cell eaters), serve as the first line of defense, engulfing dead cells, debris, virus, and bacteria. Macrophages are an important type of phagocyte, often presenting the antigen—which is usually a foreign protein—to other immune cells and thus are also called "antigen-presenting cells" (APC). T and B lymphocytes, important immune-system cells, are also capable of recognizing the antigen and become activated. T lymphocytes are classified into two subtypes: killer T cells (also called cytotoxic T cells) and helper T cells. Killer T cells recognize and kill the infected or cancer cells that contain the antigen or the foreign protein. Helper T cells release cytokines (chemical messengers) upon activation that either directly destroy the tumor or stimulate other cells to kill the target (tumor). B lymphocytes produce antibodies after recognizing the antigens. The antibodies, which help protect the body from the antigen, are normally specific to that particular antigen. In cases of tumor the specific antibodies attach to tumor cells and, through various mechanisms, impair the functions of the tumor, ultimately leading to the death of the cancer cell.

In addition to these lymphocytes are natural killer (NK) cells that particularly perform the task of eliminating foreign cells. Natural killer cells differ from

killer T cells in that they target tumor cells and do not have to recognize an antigen before activation. These cells have been shown to be of potential use in treating cancer.

Immune system and cancer

The immune system serves as one of the primary defenses against cancer. When normal tissue becomes a tumor or cancerous tissue, new antigens develop on their surface. These antigens send a signal to immune cells such as the cytotoxic T lymphocytes, NK cells, and macrophages, which in turn directly kill the tumor cells or release substances like cytokines that may bring about tumor cell death. Thus, under normal circumstances, the immune system provides continued surveillance and eliminates cells that become cancers. However, tumors may survive by hiding or disguising their tumor antigens, or by producing substances that allow suppressor T cells (cells that block cytotoxic, or killer T cells that would normally attack the tumor) to proliferate (multiply).

Biological response modifiers in cancer therapy

Researchers have been working on stimulating the immune cells during cancer with substances broadly classified as biological response modifiers. Cytokines are one such substance. These are proteins that are predominantly released by immune cells upon activation or stimulation. During the 1990s the number of cytokines identified increased enormously and the functions associated with them are of immense potential in diagnostics and immune therapy. Some of the key cytokines that have proven therapeutic value in cancer are interleukin-2 (IL-2), Interferon gamma, and interleukin-12 (IL-12). Cytokines are normally injected directly to cancer patients; however, there are other cases where a cancer patient's own lymphocytes are modified under laboratory conditions and injected back into the patient. Examples of these are lymphokine-activated killer (LAK) cells and tumor-infiltrating lymphocytes (TILs). These modified cells are capable of devouring cancer cells.

Immunoprevention of cancer

Immunotherapy is emerging as one of the management strategies for cancer. However, established tumors or large masses of tumor do not respond well to immunotherapy. There is clinical evidence, however, that suggests that patients with minimal residual cancer cells (a few cells left after other forms of cancer treatment) are potential candidates for effective immunotherapy. In these cases immunotherapy often results in a prolonged tumor-free survival. Thus, immune responses can be manipulated to prevent recurrence, even though it does not destroy large tumors. Based on results of immunotherapy trials, most immune therapies are geared towards designing immunoprotective strategies such as cancer **vaccines**.

KEY TERMS

Antigen—Molecules or fragments of molecules that belong to a foreign invader that can elicit an immune response. These may include germs, toxins, and tissues from another person used in organ transplantation.

Cytokines—Proteins (chemical messengers) that are predominantly released by immune cells upon activation or stimulation that help bring about tumor cell death.

Stem cell—A cell whose daughter cells may differentiate (develop into other cell types).

Cancer vaccines

Cancer vaccines can be made either with whole, inactivated tumor cells, or with fragments or cell surface substances (called cell-surface antigens) present in the tumors. In addition to the whole cell or antigen vaccines, biological modifiers, like cytokines, serve as substances that boost immune response in cancer patients.

Since cancer vaccines are still under clinical evaluation, caution should be exercised while choosing them as the mode of therapy. The cancer care team will provide further insight on whether or not cancer vaccine or cytokine therapy will be beneficial after they assess the patient's stage and the various modes of treatments available.

Immunoelectrophoresis

Definition

Immunoelectrophoresis, also called gamma globulin electrophoresis, or immunoglobulin electrophoresis, is a method of determining the blood levels of three major immunoglobulins: immunoglobulin M (IgM), immunoglobulin G (IgG), and immunoglobulin A (IgA).

Purpose

Immunoelectrophoresis is a powerful analytical technique with high resolving power as it combines separation of antigens by electrophoresis with immunodiffusion against an antiserum. The increased resolution is of benefit in the immunological examination of serum proteins. Immunoelectrophoresis aids in the diagnosis and evaluation of the therapeutic response in many disease states affecting the immune system. It is usually requested when a different type of electrophoresis, called a serum **protein electrophoresis**, has indicated a rise at the immunoglobulin level. Immunoelectrophoresis is also used frequently to diagnose **multiple myeloma**, a disease affecting the bone marrow.

Precautions

Drugs that may cause increased immunoglobulin levels include therapeutic gamma globulin, hydralazine, isoniazid, **phenytoin** (Dilantin), procainamide, oral contraceptives, methadone, steroids, and tetanus toxoid and antitoxin. The laboratory should be notified if the patient has received any vaccinations or immunizations in the six months before the test. This is mainly because prior immunizations lead to the increased immunoglobulin levels resulting in false positive results.

It should be noted that, because immunoelectrophoresis is not quantitative, it is being replaced by a procedure called immunofixation, which is more sensitive and easier to interpret.

Description

Serum proteins separate in agar gels under the influence of an electric field into albumin, alpha 1, alpha 2, and beta and gamma globulins. Immunoelectrophoresis is performed by placing serum on a slide containing a gel designed specifically for the test. An electric current is then passed through the gel, and immunoglobulins, which contain an electric charge, migrate through the gel according to the difference in their individual electric charges. Antiserum is placed alongside the slide to identify the specific type of immunoglobulin present. The results are used to identify different disease entities, and to aid in monitoring the course of the disease and the therapeutic response of the patient with such conditions as immune deficiencies, autoimmune disease, chronic infections, chronic viral infections, intrauterine fetal infections, multiple myeloma, and monoclonal gammopathy of undetermined significance.

There are five classes of antibodies: IgM, IgG, IgA, IgE, and IgD.

IgM is produced upon initial exposure to an antigen. For example, when a person receives the first tetanus vaccination, antitetanus antibodies of the IgM class are produced 10 to 14 days later. IgM is abundant in the blood but is not normally present in organs or tissues. IgM is primarily responsible for ABO blood grouping and rheumatoid factor, yet is involved in the immunologic reaction to other infections, such as hepatitis. Since IgM does not cross the placenta, an elevation of this immunoglobulin in the newborn indicates intrauterine infection such as rubella, cytomegalovirus (CMV) or a sexually transmitted disease (STD).

IgG is the most prevalent type of antibody, comprising approximately 75% of the serum immunoglobulins. IgG is produced upon subsequent exposure to an antigen. As an example, after receiving a second tetanus shot, or booster, a person produces IgG antibodies in five to seven days. IgG is present in both the blood and tissues, and is the only antibody to cross the placenta from the mother to the fetus. Maternal IgG protects the newborn for the first months of life, until the infant's immune system produces its own antibodies.

IgA constitutes approximately 15% of the immunoglobulins within the body. Although it is found to some degree in the blood, it is present primarily in the secretions of the respiratory and gastrointestinal tract, in saliva, colostrum (the yellowish fluid produced by the breasts during late pregnancy and the first few days after childbirth), and in tears. IgA plays an important role in defending the body against invasion of germs through the mucous membrane-lined organs.

IgE is the antibody that causes acute allergic reactions; it is measured to detect allergic conditions. IgD, which constitutes the smallest portion of the immunoglobulins, is rarely evaluated or detected, and its function is not well understood.

Preparation

This test requires a blood sample.

Aftercare

Because this test is ordered when either very low or very high levels of immunoglobulins are suspected, the

patient should be alert for any signs of infection after the test, including **fever**, chills, rash, or skin ulcers. Any **bone pain** or tenderness should also be immediately reported to the physician.

Risks

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, fainting or feeling lightheaded after venipuncture, or bruising.

Normal results

Reference ranges vary from laboratory to laboratory and depend upon the method used. For adults, normal values are usually found within the following ranges (1 mg = approximately .000035 oz. and 1 dL = approximately 0.33 fluid oz.):

- IgM: 60–290 mg/dL
- IgG: 700–1,800 mg/dL
- IgA: 70–440 mg/dL

Abnormal results

Increased IgM levels can indicate **Waldenström's macroglobulinemia**, a malignancy caused by secretion of IgM at high levels by malignant lymphoplasma cells. Increased IgM levels can also indicate chronic infections, such as hepatitis or mononucleosis and autoimmune diseases, like rheumatoid arthritis.

Decreased IgM levels can be indicative of AIDS, immunosuppression caused by certain drugs like steroids or dextran, or leukemia.

Increased levels of IgG can indicate chronic liver disease, autoimmune diseases, hyperimmunization reactions, or certain chronic infections, such as tuberculosis or sarcoidosis.

Decreased levels of IgG can indicate Wiskott-Aldrich syndrome, a genetic deficiency caused by inadequate synthesis of IgG and other immunoglobulins. Decreased IgG can also be seen with AIDS and leukemia.

Increased levels of IgA can indicate chronic liver disease, chronic infections, or inflammatory bowel disease.

Decreased levels of IgA can be found in ataxia, a condition affecting balance and gait, limb or eye movements, speech, and telangiectasia, an increase in the size and number of the small blood vessels in an area of skin, causing redness. Decreased IgA levels are also seen in conditions of low blood protein (hypoproteinemia), and drug immunosuppression.

KEY TERMS

Antibody—A protein manufactured by the white blood cells to neutralize an antigen in the body. In some cases, excessive formation of antibodies leads to illness, allergy, or autoimmune disorders.

Antigen—A substance that can cause an immune response, resulting in production of an antibody, as part of the body's defense against infection and disease. Many antigens are foreign proteins not found naturally in the body, and include germs, toxins, and tissues from another person used in organ transplantation.

Autoimmune disorder—A condition in which antibodies are formed against the body's own tissues, for example, in some forms of arthritis.

Immunohistochemistry

Definition

Immunohistochemistry is a method of analyzing and identifying cell types based on the binding of antibodies to specific components of the cell. It is sometimes referred to as immunocytochemistry.

Purpose

Immunohistochemistry (IHC) is used to diagnose the type of cancer and to help determine the patient's prognosis. In cases such as metastases or **carcinoma of unknown primary** origin, where it may be difficult to determine the type of cell from which the tumor originated, immunohistochemistry can identify cells by the characteristic markers on the cell surface. IHC can also help distinguish between benign and malignant tumors.

KEY TERMS

Antibody—A protein formed by the immune system to react with a specific antigen.

Antigen—Any protein that elicits a unique immune response.

Biopsy—A sample of tissue taken from a tumor to compare with other normal tissue.

Histology—The study of tissues.

QUESTIONS TO ASK THE DOCTOR

- What do you expect to learn from this test?
- What are the alternatives to this test?
- Are there any risks or complications?
- Are any special preparations required?
- Is hospitalization required?
- Is it possible that the test may give a false positive, a false negative, or unclear results?

Description

Immunohistochemistry requires a sample of tissue from a **biopsy**; usually the tissue sample is examined fresh, but frozen or chemically preserved material can be used. A blood sample or bone marrow may also be examined. The tissue sample is sliced extremely thinly, so that it is approximately one cell thick, then the sample is fixed onto a glass slide. The tumor cells in the sample have characteristic markers, or antigens, on their cell surfaces which can be used to help identify the specific type of tumor cell. Antibodies against these characteristic antigens are added to the sample on the slide, and the antibodies bind wherever the antigens are present. Excess antibody is then washed away. The antibodies that remain bound to the cell have labels on them that either fluoresce (glow) or undergo a chemical reaction that makes them visible by microscope. The pathologist is able to see the specially labeled tumor antigens as they appear in the patient's tissue.

The pathologist will try to assess the level of maturity of the tumor cells, which will help him to determine their origin. He will be checking for cell types that are found in an inappropriate part of the body, for example prostate cells in a lymph node. He will also look for cell characteristics that will indicate if the tumor is benign or malignant. Proteins involved in the replication of genetic material and cell growth may be present in greater amounts; for example, antibodies against the antigen Ki-67 are used to evaluate malignant melanomas, breast carcinomas, and **non-Hodgkin's lymphomas**. Hormone receptors may also be examined. The presence of receptors to estrogen and progesterone indicate a good prognosis for **breast cancer** patients. Pathologists may also look for an increase in tumor suppressor proteins. A wide variety of antibodies are available to help determine the origin of the tumor, whether it is growing rapidly, and whether it is a type of tumor that responds well to particular treatments.

Preparation

The physician will choose the type of sample to be taken based on the type of tumor. If the patient has a solid tumor, a tissue sample may be biopsied; if the entire tumor is being removed a biopsy may be taken during surgery. In this case the patient should prepare for the surgery or the biopsy as the physician suggests. A routine blood sample may also be required; in most cases, no additional preparation is required.

Aftercare

The only aftercare that might be required is from the sample collection process.

Risks

The risks associated with IHC are the risks associated with the sample collection, either the biopsy of the tumor or the drawing of blood. The only other concern is the possibility that the test could yield unclear results.

Normal results

Normal results will simply look like normal cells. The cells will have a high level of maturity and be located only in sites appropriate to their cell type. For example, analysis of lymph nodes will show only the cells that belong there, not cells that would normally be present in the breast. No specific tumor antigens will be present in increased numbers.

Abnormal results

An abnormal result would consist of cells which appear immature or poorly differentiated, or that are found in an inappropriate tissue for their cell type. The pathologist may test for the presence of a particular antigen, such as Ki-67, carcinoembryonic antigen (CEA), or prostate specific antigen (PSA). In this case, there may be a numerical standard value to compare normal to abnormal results and help the physician in determining prognosis.

Immunologic therapies

Definition

Immunologic therapy is the treatment of disease using medicines that boost the body's natural **immune response**. Some forms of immunologic therapy are intended to bypass the body's weakened immune system while others are intended to repair or direct it.

Purpose

Immunologic therapy is used to improve the immune system's natural ability to fight diseases such as cancer, hepatitis and AIDS. These drugs may also be used to help the body recover from immunosuppression resulting from treatments such as **chemotherapy** or **radiation therapy**.

Description

Most drugs in this category are synthetic versions of substances produced naturally in the body. In their natural forms, these substances help defend the body against disease. For example, **aldesleukin** (Proleukin) is an artificially made form of interleukin-2, which helps white blood cells work. Aldesleukin is administered to patients with kidney cancers and skin cancers that have spread to other parts of the body. **Filgrastim** (Neupogen) and **sargramostim** (Leukine) are versions of natural substances called colony stimulating factors, which drive the bone marrow to make new white blood cells. Another type of drug, epoetin (Epogen, Procrit), is a synthetic version of human **erythropoietin** that stimulates the bone marrow to make new red blood cells. **Thrombopoietin** stimulates the production of platelets, disk-shaped bodies in the blood that are important in clotting. **Interferons** are substances the body produces naturally using immune cells to fight infections and tumors. The synthetic interferons carry brand names such as Alferon, Roferon, or Intron A. Some of the interferons that are currently in use as drugs are Recombinant Interferon Alfa-2a, Recombinant Interferon Alfa-2b, Interferon Alfa-n1, and Interferon Alfa-n3. Alfa interferons are used to treat **hairy cell leukemia**, malignant **melanoma**, and AIDs-related **Kaposi's sarcoma**. In addition, interferons are also used for other conditions such as laryngeal papillomatosis, genital warts, and certain types of hepatitis.

Recommended dosage

The recommended dosage depends on the type of immunologic therapy. For some medicines, the physician will decide the dosage for each patient, taking into account a patient's weight and whether he/she is taking other medicines. Some drugs used in immunologic therapy are given only in a hospital, under a physician's supervision. For those that patients may give themselves, check with the physician who prescribed the medicine or the pharmacist who filled the prescription for the correct dosage.

Most of these drugs come in injectable form. These drugs are generally administered by the cancer care provider.

Precautions

Aldesleukin

This medicine may temporarily increase the chance of getting infections. It may also lower the number of platelets in the blood, and thus possibly interfering with the blood's ability to clot. Taking these precautions may reduce the chance of such problems:

- Avoid people with infections, if possible.
- Be alert to signs of infection, such as **fever**, chills, sore throat, pain in the lower back or side, cough, hoarseness, or painful or difficulty with urination. If any of these symptoms occur, get in touch with a physician immediately.
- Be alert to signs of bleeding problems, such as black, tarry stools, inky red spots on the skin, blood in the urine or stools, or any other unusual bleeding or bruising.
- Take care to avoid cuts or other injuries. Be especially careful when using knives, razors, nail clippers, and

other sharp objects. Check with a dentist for the best ways to clean the teeth and mouth without injuring the gums. Do not have dental work done without checking with a physician.

- Wash hands frequently, and avoid touching the eyes or inside of the nose unless the hands have just been washed.

Aldesleukin may make some medical conditions worse, such as chickenpox, shingles (**herpes zoster**), liver disease, lung disease, heart disease, underactive thyroid, psoriasis, immune system problems, and mental problems. The medicine may increase the chance of seizures (convulsions) in people who are prone to having them. Also, the drug's effects may be greater in people with kidney disease, because their kidneys are slow to clear the medicine from their bodies.

Colony stimulating factors

Certain drugs used in treating cancer reduce the body's ability to fight infections. Although colony stimulating factors help restore the body's natural defenses, the process takes time. Getting prompt treatment for infections is important, even while taking this medicine. Call the physician at the first sign of illness or infection, such as a sore throat, fever, or chills.

People with certain medical conditions could have problems if they take colony stimulating factors. People who have kidney disease, liver disease, or conditions caused by inflammation or immune system problems can worsen these problems with colony stimulating factors. Those who have heart disease may be more likely to experience side effects such as water retention and heart rhythm problems while taking these drugs. Finally, patients who have lung disease might increase their chances of suffering from shortness of breath. Those who have any of these medical conditions should check with their personal physicians before using colony stimulating factors.

Epoetin

Epoetin is a medicine that may cause seizures (convulsions), especially in people who are prone to having them. No one who takes these drugs should drive, use machines, or do anything considered dangerous in case of a seizure.

Epoetin helps the body make new red blood cells, but it is not effective unless there is adequate iron in the body. The physician may recommend taking iron supplements or certain **vitamins** that help supply the body with iron. It is necessary to follow the physician's advice in this instance—recommendations for iron in this case, as with any supplements should only come from a physician.

In studies of laboratory animals, epoetin taken during pregnancy caused birth defects, including damage to the bones and spine. However, the drug has not been reported to cause problems in human babies whose mothers take it. Women who are pregnant or who may become pregnant should check with their physicians for the most up-to-date information on the safety of taking this medicine during pregnancy.

People with certain medical conditions may have problems if they take this medicine. For example, the chance of side effects may be greater in people with high blood pressure, heart or blood vessel disease, or a history of blood clots. Epoetin may not work properly in people who have bone problems or sickle cell anemia.

Interferons

Interferons can add to the effects of alcohol and other drugs that slow down the central nervous system, such as antihistamines, cold medicine, allergy medicine, sleep aids, medicine for seizures, tranquilizers, some pain relievers, and muscle relaxants. They may also add to the effects of anesthetics, including those used for dental procedures. Those taking interferons should check with their physicians before taking any of the above.

Some people experience dizziness, unusual fatigue, or become less alert than usual while being treated with these drugs. Because of these possible problems, anyone who takes these drugs should not drive, use machines, or do anything else considered dangerous until they have determined how the drugs affect them.

Interferons often cause flu-like symptoms, including fever and chills. The physician who prescribes this medicine may recommend taking acetaminophen (Tylenol) before—and sometimes after—each dose to keep the fever from getting too high. If the physician recommends this, follow instructions carefully.

Like aldesleukin, interferons may temporarily increase the chance of getting infections and lower the number of platelets in the blood, leading to clotting problems. To help prevent these problems, follow the precautions for reducing the risk of infection and bleeding listed for aldesleukin.

People who have certain medical conditions may have problems if they take interferons. For example, the drugs may worsen some medical conditions, including heart disease, kidney disease, liver disease, lung disease, diabetes, bleeding problems, and mental problems. In people who have overactive immune systems, these drugs can even increase the activity of the immune

system. People who have shingles or chickenpox, or who have recently been exposed to chickenpox may increase their risk of developing severe problems in other parts of the body if they take interferons. People with a history of seizures or mental problems could at risk if taking interferon.

In teenage women, interferons may cause changes in the menstrual cycle. Young women should discuss this possibility with their physicians. Older people may be more sensitive to the effects of interferons. This may increase the chance of side effects.

These drugs are not known to cause fetal death, birth defects, or other problems in humans when taken during pregnancy. Women who are pregnant or who may become pregnant should ask their physicians for the latest information on the safety of taking these drugs during pregnancy.

Women who are breastfeeding their babies may need to stop while taking this medicine. Whether interferons pass into breast milk is not known. Because of the chance of serious side effects to the baby, breast-feeding while taking interferon is discouraged. Check with a physician for advice.

General precautions for all types of immunologic therapy

Regular physician visits are necessary during immunologic therapy treatment. This gives the physician a chance to make sure the medicine is working and to check for unwanted side effects.

Anyone who has had unusual reactions to drugs used in immunologic therapy should let the physician know before resuming the drugs. Any allergies to foods, dyes, preservatives, or other substances should also be reported.

Side effects

Aldesleukin

In addition to its helpful effects, this medicine may cause serious side effects. Generally, it is given only in a hospital, where medical professionals can watch for early signs of problems. Medical tests might be performed to check for unwanted effects.

Anyone who has breathing problems, fever, or chills while being given aldesleukin should check with a physician immediately.

Other side effects should be brought to a physician's attention as soon as possible:

- dizziness
- drowsiness
- confusion
- agitation
- depression
- **nausea and vomiting**
- **diarrhea**
- sores in the mouth and on the lips
- tingling of hands or feet
- decrease in urination
- unexplained weight gain of five or more pounds

Some side effects are usually temporary and do not need medical attention unless they are bothersome. These include dry skin; itchy or burning skin rash or redness followed by peeling; loss of appetite; and a general feeling of illness or discomfort.

Colony stimulating factors

As this medicine starts to work, the patient might experience mild pain in the lower back or hips. This is nothing to cause undue concern, and will usually go away within a few days. If the pain is intense or causes discomfort, the physician may prescribe a painkiller.

Other possible side effects include headache, joint or muscle pain and skin rash or **itching**. These side effects tend to disappear as the body adjusts to the medicine, and do not need medical treatment. If they continue, or they interfere with normal activities, check with a physician.

Epoetin

This medicine may cause flu-like symptoms, such as muscle aches, **bone pain**, fever, chills, shivering, and sweating, within a few hours after it is taken. These symptoms usually go away within 12 hours. If they do not, or if they are troubling, check with a physician. Other possible side effects that do not need medical attention are diarrhea, nausea or vomiting and fatigue or weakness.

Certain side effects should be brought to a physician's attention as soon as possible. These include headache, vision problems, increased blood pressure, fast heartbeat, weight gain and swelling of the face, fingers, lower legs, ankles or feet.

Anyone who has chest pain or seizures after taking epoetin should seek professional emergency medical attention immediately.

Interferons

This medicine may cause temporary hair loss (alopecia). While upsetting, it is not a sign that something is

seriously wrong. The hair should grow back normally after treatment ends.

As the body adjusts to the medicine many other side effects usually go away during treatment. These include flu-like symptoms, taste alteration, loss of appetite (anorexia), nausea and vomiting, skin rash, and unusual fatigue. If these problems persist, or if they interfere with normal life, check with a physician.

A few more serious side effects should be brought to a physician's attention as soon as possible:

- confusion
- difficulty thinking or concentrating
- nervousness
- depression
- sleep problems
- numbness or tingling in the fingers, toes and face

General caution regarding side effects for all types of immunologic therapy

Other side effects are possible with any type of immunologic therapy. Anyone who has unusual symptoms during or after treatment with these drugs should should contact the physician immediately.

Interactions

Anyone who has immunologic therapy should let the physician know all other medicines being taken. Some combinations of drugs may interact, that can increase or decrease the effects of one or both drugs or can increase the likelihood of side effects. Consultation with a physician is highly recommended to get the insight on whether the possible interactions can interfere with drug therapy or cause harmful effects.

Immunoprevention

Considering that most of the biological modifiers such as cytokines elicit immune response that inhibit incipient tumors before they are clinically evident, immunoprevention has been proposed as a recent strategy for combating cancer. Treatment involving immune molecules (such as cytokines) prepared synthetically or that are not produced by the patients themselves is called as passive immunotherapy. Conversely, a vaccine is a form of active immune therapy because it elicits an immune response in patients. A cancer vaccine may be made of whole tumor cell or of substances or fragments contained in the tumor called antigens.

Newer types of immunologic therapy that are still considered investigational as of 2003 include cell-based

KEY TERMS

AIDS—Acquired immunodeficiency syndrome. A disease caused by infection with the human immunodeficiency virus (HIV). In people with this disease, the immune system breaks down, increasing vulnerability to other infections and some types of cancer.

Bone marrow—Soft tissue that fills the hollow centers of bones. Blood cells and platelets (disk-shaped bodies in the blood that are important in clotting) are produced in the bone marrow.

Chemotherapy—Treatment of an illness with chemical agents. The term is usually used to describe the treatment of cancer with drugs.

Clot—A hard mass that forms when blood gels.

Dendritic cells—Immune system cells derived from a type of white blood cell called monocytes. Dendritic cells help to activate the B cells, helper T cells, and killer T cells in the immune system.

Hepatitis—Inflammation of the liver caused by a virus, chemical, or drug.

Immune response—The body's natural, protective reaction to disease and infection.

Immune system—The system that protects the body against disease and infection through immune responses.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Psoriasis—A skin disease that manifests itself with itchy, scaly, red patches on the skin.

Seizure—A sudden attack, spasm, or convulsion.

Shingles—A disease caused by an infection with the Herpes zoster virus—the same virus that causes chickenpox. Symptoms of shingles include pain and blisters along one nerve, usually on the face, chest, stomach, or back.

Sickle cell anemia—An inherited disorder in which red blood cells contain an abnormal form of hemoglobin, a protein that carries oxygen. The abnormal form of hemoglobin causes the red cells to become sickle-shaped. The misshapen cells may clog blood vessels, preventing oxygen from reaching tissues and leading to pain, blood clots and other problems. Sickle cell anemia is most common in people of African descent and in people from Italy, Greece, India, and the Middle East.

therapies. Instead of using synthetic chemicals that resemble substances produced by the body, cell-based therapies use modified stem cells or dendritic cells as vaccines against cancer. Stem cells are undifferentiated cells whose daughter cells can develop into various types of specialized cells, while dendritic cells are cells that are able to initiate and modify the immune system's responses to cancer by activating B cells and T cells. Dendritic cells appear to offer a promising new form of immunotherapy for cancer.

Another investigational form of treatment is the development of cell-free tumor-specific peptide vaccines. Peptides are subunits of protein molecules that contain two or more amino acids. Peptide vaccines are intended to induce responses in the patient's T cells that inhibit tumor growth. As of late 2003, however, peptide-based tumor vaccines have been shown to shrink cancerous tumors only in patients with limited disease.

Adoptive immunotherapy

Adoptive immunotherapy involves stimulating T lymphocytes by exposing them to tumor antigens. These modified cells are grown in the laboratory and then injected into patients. Since the cells taken from a different individual for this purpose often results in rejection, patients serve both as donor and recipient of their own T cells. Adoptive immunotherapy is particularly effective in patients who have received massive doses of radiation and chemotherapy. In such patients, therapy results in immunosuppression (weakened immune systems), making them vulnerable to viral infections. For example, CMV-specific T cells can reduce the risk of cytomegalovirus (CMV) infection in transplant patients.

Incontinence

Description

Incontinence is the loss of normal control of the bowel or bladder. Incontinence can involve the involuntary voiding of urine (urinary incontinence) or of stool and gas (fecal or bowel incontinence). There are several types of urinary incontinence. Those most frequently seen as side effects of cancer include overflow incontinence, urge incontinence, and stress incontinence. In rare cases incontinence occurs as the result of cancer, but more commonly it is a side effect of treatment. Because the subjects of bowel and bladder control are perceived as socially unacceptable, those affected with incontinence often feel ashamed or embarrassed by the problem. Instead of seeking medical attention, these individuals try to hide the problem or manage it themselves. For this reason, incontinence is sometimes referred to as "the silent affliction." Impacts of incontinence include low self-esteem, social withdrawal and isolation, and **depression**. In most cases incontinence can be successfully treated, so affected individuals should discuss the problem with a doctor.

Causes

Incontinence can result from damage to the muscle, nerves, or the structure of the body parts involved in the

control of voiding. Complex systems of hollow organs (such as the bladder) and tube-shaped structures (such as the rectum and urethra) work together to store and release waste. Special muscles, including sphincters, are especially important in maintaining the tight seals that hold in waste. When physical damage to muscle or organ structure occurs, the system can no longer maintain these tight seals, and waste can leak out.

Nerves carry messages between the brain and the bowel and bladder systems. Injury to these nerves, or the related part of the brain, interferes with the delivery of these messages, which can prevent the body from recognizing the signals telling it when to void. Without these signals and messages, an individual cannot coordinate the brain with the bowel and bladder systems, and incontinence results.

Several types of cancer and its treatments are associated with incontinence. Usually, it is the treatment of cancer that causes incontinence, rather than the cancer itself.

Prostate cancer

The treatment of **prostate cancer** is one of the most common causes of cancer-related urinary incontinence, largely because the prostate is located so closely to the nerves, muscles, and structures involved in urine control. Surgical removal of the prostate, or **prostatectomy**, carries the highest risk of urinary incontinence as a side effect; the risk from **radiation therapy** is somewhat lower. The incontinence (typically stress or urge incontinence) is often temporary, but in a small percentage of men it may be long lasting.

Prostate cancer itself seldom causes incontinence. However, this depends on the location and size of the cancer; a large cancerous prostate can interfere with the flow of urine and result in overflow incontinence.

Bladder cancer

Incontinence is only occasionally the direct result of **bladder cancer**, but it is a common side effect of some treatments. For early-stage cancer where treatment does not require the bladder to be removed, incontinence almost never occurs. But removal of the bladder and surrounding structures is often necessary to treat more advanced cancer. This requires creation of an artificial system for storing and releasing urine and carries a risk of long-term incontinence.

Colon cancer and rectal cancer

Muscles in the anal and rectal region largely control bowel evacuation, with the colon storing stool and gas.

KEY TERMS

Evacuation—Release of stool or gas from the bowel system.

Overflow incontinence—Slow leaking or dripping of urine from an overfilled bladder that may be unable to empty completely.

Sphincter—A circular muscle that relaxes and tightens to control the storage and release of bodily waste.

Stress incontinence—Involuntary loss of waste resulting from sudden pressure or force, such as by coughing, sneezing, laughing, or lifting an object.

Urethra—A tube-like structure allowing the passage of urine between the bladder and the outside of the body.

Urge incontinence—Involuntary loss of waste after feeling a strong, sudden need to void, without enough time to get to a toilet.

Voiding—Release of urine from the bladder system.

When these regions are removed or damaged during cancer treatment, or if injury to the related nerves occurs, fecal incontinence can result. Fecal incontinence is most commonly a side effect of surgery. Weakening of bowel muscles or damaging of nerves by radiation therapy can also cause incontinence, but this type is more likely to be mild and temporary, and will often improve as these areas heal. However, in some patients, radiation causes permanent and severe fecal incontinence.

Other causes

Loss of voluntary bowel and bladder control is less commonly associated with other cancers of the genital and urinary systems, mainly as a side effect of treatment. Incontinence can also result from cancer or treatment damage in the brain and spinal cord. Other cancers indirectly cause incontinence; for example, constant coughing from lung cancer can lead to stress incontinence. Very rarely, incontinence can be a side effect of certain medications.

Treatments and complementary therapies

The method of treatment depends on the cause and type of incontinence. Surgical treatment is usually reserved for severe or long-lasting incontinence. An artificial pouch for storing urine or stool can be placed inside the body as a substitute for a removed bladder, colon, or rectum. Placement of an artificial sphincter

successfully treats other cases. For mild or temporary incontinence, treatment may include medications, dietary changes, muscle-strengthening exercises, or behavioral training, such as establishing a time pattern for voiding. A small group of patients, however, requires a permanent colostomy or **urostomy**.

Electrical stimulation therapy, which targets involved muscles with low-current electricity, can be used to treat either urinary or fecal incontinence. Biofeedback uses electronic or mechanical devices to improve bladder or bowel control by teaching an individual how to recognize and respond to certain body signals.

Embarrassment may lead some people to manage the symptoms of incontinence themselves by wearing absorbent pads to prevent the soiling of their clothes. However, many treatments exist to successfully restore or improve control of bowel and bladder function, so individuals experiencing incontinence should speak to a doctor or nurse.

Infection and sepsis

Description

Infection is characterized by an inflammatory response to the presence of microorganisms in the body. This response may include **fever**, chills, redness, swelling, pus formation, and other responses. The most common cause of illness and death in patients with cancer is infection. Patients with cancer who are treated with **chemotherapy**, **radiation therapy**, and/or surgery are at increased risk of developing an infection. Mortality, or death, from infection in cancer patients decreased during the late 1900s due to the development of new types of **antibiotics**, the use of hematopoietic growth factors (HGFs) which activate proliferation (multiplication) and maturation of blood cell lines, and due to the prophylactic (preventive) use of antifungal and antiviral agents. Blood cell lines, markedly decreased due to chemotherapy, are required to fight infections. Most infections in cancer patients are due to bacteria; however, fungal infections are usually the cause of fatal infections.

If left untreated, or if inadequately treated, infection can progress to sepsis. Sepsis is defined as a systemic (total body) inflammatory response to the presence of microorganisms in the body. Several conditions indicate sepsis, including a temperature of greater than 38 degrees Centigrade (100.4 Fahrenheit) or less than 36 degrees Centigrade (96.8 Fahrenheit), heart rate greater than 90 beats per minutes, and respiratory rate greater than 20 breaths per minute. The incidence rate of sepsis in cancer patients is estimated at 45%. Mortality rates from sepsis in cancer patients exceed 30%.

Causes

There are many possible causes of infection in the patient with cancer. For example, certain cancers interfere with the body's immune system response, which results in increased risk of infection to the patient. These cancer types include **acute leukemia**, **chronic lymphocytic leukemia**, **multiple myeloma**, **Hodgkin's disease**, and non-Hodgkin's lymphoma. Certain therapies used to treat cancer, such as chemotherapy (which interrupts bone marrow production of white blood cells, red blood cells, and platelets), radiation therapy, **bone marrow transplantation**, and treatments using **corticosteroids**, can lead to infection in the patient with cancer. The protein-calorie malnutrition that some cancer patients experience can result in suppression of the immune system, which results in increased risk for infection. Many cancer patients develop infections from procedures which break the integrity of the skin, which then leads to the introduction of microorganisms into the body. These procedures include common interventions in the care of cancer patients such as venipunctures, biopsies, insertion of urinary catheters, and use of long-term central venous catheters. Infection rates associated with long-term central venous catheter use in cancer patients is estimated to be as high as 60%. If the cancer patient's immune system is severely compromised, infection can occur from food sources, plants, and/or air the patient comes in contact with.

Myelosuppression is the term used to describe the decrease in numbers of circulating white blood cells (WBC), red blood cells (RBC), and platelets. Myelosuppression is often a side effect of treatment with chemotherapy and/or radiation therapy. Blood counts usually begin to fall one to three weeks after treatment with chemotherapy, depending upon the type of chemotherapy and the lifespan of the blood cell. The counts generally begin to recover to normal levels within two to three weeks. The neutrophil, which is a component of the white blood cells, is the body's first line of defense against infection caused by bacteria. When neutrophils are decreased a state of **neutropenia** exits. Neutropenia is the single greatest predictor of infection in patients with cancer. Three key factors are important in predicting the potential of a patient to experience an infectious episode when myelosuppressed. These factors include: 1) the degree of neutropenia, i.e., the lower the neutrophil count the more likely the patient will become infected, 2) the duration of the neutropenia, i.e., the longer a patient is neutropenic, the greater the likelihood of infection, and 3) the rate at which neutropenia develops the greater the risk of infection.

Bacterial infections in cancer patients develop quickly, especially in the neutropenic patient, and account for 85–90% of the microorganisms associated with neutropenia accompanied by fever. The most serious episodes occur from infections attributed to such gram-negative organisms as *Enterobacteriaceae* or *Pseudomonas aeruginosa*. However, infections from such gram-positive organisms as *Staphylococcus, Streptococcus, Corynebacteria*, and *Clostridia* have increased in the 1990s, probably due to the increased use of implanted central venous catheters and prophylactic antibiotics (to which these organisms develop an immunity). Listeriosis, a severe bacterial infection caused by *Listeria monocytogenes*, is another infection on the increase in cancer patients. Listeriosis has become a common complication of bone marrow transplantation in the early 2000s as well as a frequent cause of patient death.

Other organisms that cause infections in the immunocompromised cancer patient include such herpesviruses as **herpes simplex** virus 1 and 2 (HSV-1, HSV-2), varicella zoster virus (VZV), cytomegalovirus (CMV), and **Epstein-Barr virus** (EBV). Sources of secondary infections include the fungus *Candida albicans*. Common causes of secondary infection in severely immunosuppressed patients include CMV and the filamentous fungus *Aspergillus*. Aspergillosis is an increasingly common and often fatal infection in patients with hematologic cancers.

The incidence of sepsis and septic shock increases when the patient remains neutropenic for longer than seven days. Other factors that put the cancer patient at high risk for the development of sepsis include infection with a gram-negative organism, presence of a central venous catheter, history of prior infection, malnutrition, history of frequent hospitalization, increased age of patient, and concurrent (at the same time) presence of such other diseases as diabetes, cardiovascular, gastrointestinal, hepatic, pulmonary, and/or renal disease. Sites of infection that most often lead to sepsis include infection of the lungs, invasive lines, and urinary tract.

Sepsis manifests (develops) with both local and systemic symptoms that involve the neurologic, endocrine, immunologic, and cardiovascular systems. Signs of sepsis and septic shock include changes in blood pressure, heart rate and respiratory rate, among others. If left untreated, the patient can progress to septic shock which may result in death even if the shock episode is treated. Factors that appear to increase the patient's chances of survival include rapid admission to an intensive care unit and aggressive treatment with antibiotics.

Prevention

Strategies that can be used to prevent or minimize infection in the neutropenic patient include:

- Identification of patients at highest risk for infection.
- Avoiding practices by health care team members that increase colonization of microorganisms.
- Implementation of fewer invasive procedures when possible.

Cancer patients at risk for neutropenia may also benefit from treatment with two new hematopoietic growth factors, pegfilgrastim (Neulasta) and darbepoietin alfa (Aranesp). These drugs appear to be effective in reducing the risk of opportunistic infections in cancer patients as well as improving their overall quality of life.

Specific interventions in the hospital setting that can be used to prevent or minimize infection include:

- scrupulous handwashing by patient, staff, and visitors.
- good personal hygiene, including an oral care protocol by the patient.
- ambulation (movement).
- aggressive efforts to promote lung expansion.
- elimination of uncooked fruits and vegetables from the diet.
- removal of plants and other sources of stagnant water from the patient's room.
- screening and minimizing outside visitors to avoid those with infection

In addition, the hospitalized patient is assessed by the staff at least every four hours and laboratory results

are collected and analyzed to determine risk for and presence of neutropenia.

A newer method to prevent infection in the cancer patient works by decreasing the duration of neutropenia. This method decreases the period of maximum risk for infection by using hematopoietic growth factors (HGFs). These growth factors are administered daily beginning 24 hours after chemotherapy, and shorten the duration and severity of neutropenia. Therefore, the period of risk for infection is shortened. HGFs work by activating the production and maturation of RBCs, WBCs, and platelet cell lines. Specific HGFs stimulate the production and maturation of aggressive neutrophils and macrophages, which are effective in destroying pathogens (bacteria or viruses that cause infection or disease).

Sepsis can be avoided by preventing infection in immunocompromised patients and by recognizing risk factors and altering those factors whenever possible.

Treatment

Empiric antibiotic therapy is the mainstay of treatment for infection in the cancer patient. Empiric therapy refers to initiation of antibiotic therapy prior to the identification of the infecting organism. Broad-spectrum antibiotics, antibiotics effective against both gram-negative and gram-positive organisms, are administered. Commonly used agents include aminoglycosides, fluoroquinolones, glycopeptides, and beta-lactams such as penicillins, cephalosporins, carbapenems, and monobactams. Empiric **antifungal therapy** is initiated five to seven days after empiric antibiotic therapy has been started if the patient remains febrile (with a fever). Antiviral agents may be administered if there is evidence of a viral infection. The Infectious Diseases Society of America recommends a minimum of five to seven days further treatment with parenteral (introduced in other ways than intestinal absorption) antibiotic therapy after the fever resolves (returns to normal). Continued monitoring of bacterial and fungal culture results is essential. This allows the use of more tailored antibiotics for the specific infectious agents.

The neutropenic patient with fever can progress quickly to sepsis and septic shock if left untreated. The patient may also progress to septic shock if empiric antibiotic coverage is inadequate. The most common cause of septic shock in cancer patients is infection with gram-negative bacteria. The management of sepsis and septic shock is considered an emergency situation and includes treatment with broad-spectrum antibacterial coverage and maintenance of ventilation, oxygenation, fluid volume, and cardiac output.

See also Vascular access.

KEY TERMS

Corticosteroids—Adrenal cortex steroids.

Central venous catheters—Devices used for access to the blood stream. The distal tip of the catheter after insertion is located in the superior vena cava, or above the junction of the right atrium. May be used for blood sampling and for the infusion of any type of fluids, medications, nutritional supplements, and blood components.

Gram-negative—Types of bacteria that do not retain Gram stain.

Gram-positive—Types of bacteria that retain Gram stain.

Neutropenia—A decrease in the number of neutrophils (a type of white blood cell) in the blood.

Opportunistic infections—Infections caused by organisms that do not ordinarily produce disease in persons with normally functioning immune systems. Cancer patients are often susceptible to opportunistic infections.

Intensity modulated radiation therapy

Definition

Intensity modulated **radiation therapy** uses a computer to deliver precise, three-dimensional doses of **x rays** to a tumor to treat cancer.

Purpose

As a new and special form of radiation therapy, intensity modulated radiation therapy (IMRT) offers special treatment options for cancer patients. When a patient has cancer, he or she may have radiation therapy to destroy the tumor or cancerous cells. The radiation therapy may be the only treatment given or a treatment prescribed along with surgery and/or **chemotherapy**.

The radiation aimed at the cancerous cells also can destroy nearby healthy cells. IMRT is an advanced treatment method that allows physicians to target the cancer so effectively that healthy tissue receives little to no radiation, even when the tumor is wrapped around a vital organ. This makes IMRT a good choice for many cancer patients, particularly those with small tumors, brain and spinal cord tumors, **prostate cancer**, cancer of the head and neck, many children, infants with certain muscle tumors, and some patients who have previously received radiation treatments. Research continues on expanding use of IMRT for a number of cancers; **clinical trials** are underway around the world.

Precautions

Any time a patient is considered for radiation therapy, physicians weigh the risks and benefits of the procedure. IMRT, like any external radiation therapy procedure, introduces x rays (ionizing radiation) to the patient's skin, tissues, and organs near the treatment area. Some patients will not be candidates for treatment. IMRT will require frequent trips to the radiation oncology facility for the prescribed treatment plan and careful following of instructions to deal with radiation side effects. On the positive side, the accuracy of IMRT means some patients who may not have been candidates for radiation therapy under older, less precise methods now can have radiation treatment. IMRT can deliver radiation to the intended target more precisely and do a better job of sparing surrounding organs and tissues. The oncology treatment team should discuss all risks and benefits of IMRT with the patient.

Description

Physicians have used radiation to treat cancer for more than 100 years. The damaging effects of x rays can destroy cancerous cells in the body and help rid the patient of the pain or related spread and complications of some cancers. For some patients, radiation therapy is the first treatment physicians choose; for others the treatment is used after surgery or chemotherapy or at the same time as chemotherapy. Radiation therapy also sometimes is called "radiotherapy."

The goal of radiation therapy is to destroy as many cancer cells as possible, while limiting damage to nearby healthy tissue. To accomplish this, complicated dose measurements are made based on information gathered by studying the tumor before radiation treatment begins. Today, physicians can use procedures such as **computed tomography** (CT) to produce three-dimensional models that can better pinpoint the tumor. Planning radiation treatments in three dimensions allows physicians to target the radiation beams at the tumor's height, width, and depth. This newer technique is called "3-D conformal radiation therapy."

IMRT is a new type of 3-D conformal radiation therapy that uses beams of varying intensities. By doing so, the beams, which can strike the tumor from three dimensions, also can deliver different doses to small areas of tissue at once. This offers more individualized targeting

of the tumor than in the past, so that the radiation oncologist (a physician who specializes in using radiation to treat cancer) can plan higher doses to the tumor and lower doses to the nearby tissue. Insurance companies have found IMRT a valuable treatment for many cancers in recent years because of its effectiveness.

Tomotherapy is a form of IMRT that delivers the radiation dose by rotating the beams over a small slice of tissue.

Most IMRT procedures are performed at a cancer center, radiation oncology physician office or outpatient facility, or in a hospital. The radiation oncologist oversees the patient's plan, working closely with a team of professionals. A medical physicist has special training in radiation physics and the operation and repair of radiology and radiation therapy equipment. The physicist also may help develop the patient's treatment plan. A medical dosimetrist works under the direction of the radiation oncologist and medical physicist to calculate radiation dose. IMRT treatments normally are performed by a radiation therapist, a specially trained technologist who positions the patient and runs the equipment. A radiation oncology nurse also may help with managing care, side effects, and explaining the treatments.

As the treatment begins, the patient is positioned on a treatment table in a precise location that has been set in treatment planning or simulation sessions. A special molding or other device may be applied to help keep the patient from moving during the procedure. The radiation therapist can observe the patient throughout the entire procedure through a window or closed circuit television. The therapist may reposition the patient during the procedure. A treatment session usually lasts about 15 to 30 minutes. The procedure should be painless, but if the patient is uncomfortable, the therapist can stop the machine. The number of treatments a patient must return for will depend on the type and stage of cancer. Some patients may receive treatments every day for a period of a several weeks.

Preparation

Before beginning IMRT treatment, the radiation oncologist and treatment team will need to know the precise location of the tumor in the body (anatomical position). This means the patient may have to go for several **imaging studies** in addition to those already completed to diagnose the cancer. Computed tomography (CT), **positron emission tomography** (PET) scans, and **magnetic resonance imaging** (MRI) may be used to provide three-dimensional information for the IMRT system. These imaging visits and the resulting work of the treatment team often are called treatment simulation. The patient also may have to go to the radiation therapy facility prior to treatment for a planning session. At this session, a special device may be molded to help the patient maintain an exact treatment position. The patient also may receive a mark or tattoo with colored ink to help align and target the equipment once treatment begins.

KEY TERMS

Ionizing radiation—Energy that is strong enough to remove an electron from an atom. It is used for diagnostic x rays and for radiation therapy.

Recur, recurrence—This refers to cancer that happens again after time has passed.

Aftercare

The radiation oncologist, radiation therapist, or radiation oncology nurse will provide instructions on IMRT aftercare. Since some effects of radiation therapy do not begin to show up until after several treatments, these instructions may vary throughout the course of treatment. Some side effects of radiation therapy occur soon after treatment begins, but others occur later. The most common side effects of external radiation therapy are **fatigue** and skin changes.

People undergoing radiation therapy who become fatigued may need to reduce their routines somewhat and not try to do too much. It is best to keep in touch with the treatment team for advice on feelings of fatigue and care for its effects. If skin becomes irritated, it also is important to follow the team's instructions concerning washing, sun exposure, and use of skin care products.

Risks

Radiation therapy carries the risk of radiation reaching and damaging normal tissues or organs near the area being targeted. However, IMRT treatment is more precise than other external radiation therapy procedures. There also is a small risk of dose being calculated incorrectly and a patient receiving too much radiation, but equipment should be run by FDA-approved software. Facilities have many quality processes in place to ensure the correct dose is given to the precise location on the correct patient. Radiation therapy also can cause low levels of white blood cells and platelets. White blood cells help fight infection and platelets help blood clot. Radiation therapy causes other side effects and risks, depending on the area being treated, though many only last a short time. For example, radiation treatment to the head

QUESTIONS TO ASK YOUR DOCTOR

- How long will my treatment last: how many times will I have to come in?
- How experienced are you and your staff in providing IMRT?
- What are some of the side effects I can expect from IMRT?
- Are there signs I should watch for following treatment that are abnormal and require a call to you or your nurse?

can cause hair loss (**alopecia**), but the hair eventually will grow back.

Normal results

After completion of IMRT treatments, cancer cells should stop dividing and growing, which should slow tumor growth. Often, cancer cells completely die and a tumor shrinks or disappears. With IMRT, there should be little radiation damage to the normal, healthy tissues around the tumor and fewer resulting side effects.

Abnormal results

The treatment may not always completely eliminate cancer cells. A cancer may still partially remain or recur at a later date. Physicians usually follow up with imaging studies to see how the treatment is progressing and set up a future schedule check for cancer recurrence.

Interferons

Definition

Interferons are small, natural or synthetic protein and glycoprotein cytokines that are produced by leucocytes, T-lymphocytes, and fibroblasts in response to infection and other biological stimuli. In cancer treatment, they are used as immunotherapy against the proliferation of cancer cells.

Purpose

The goal of interferon use is to activate tumor-specific cytotoxic T-lymphocytes. T-lymphocytes are cells of the immune system that destroy foreign cells. Thus, tumor cells would be destroyed based on immunotherapy.

Description

Interferons attach to special receptors on the surface of cell membranes. They have a variety of functions, including enhancing or inhibiting enzymes, decreasing cell proliferation, or enhancing the activity of macrophages and T-lymphocytes. There are several different classes of interferons, including alpha, beta, gamma, tau, and omega. The classes can be further broken into subclasses and classified using Arabic numerals and letters. Cancer therapy research primarily focuses on alpha interferons.

In 1957, researchers discovered that the immune system produced a substance in response to a viral infection that acted as an anti-viral agent. They called that substance "interferon." Since then, recombinant DNA technology has provided a larger supply of interferons and has allowed extensive research regarding interferon's therapeutic properties against cancer.

Alpha interferons are used to treat cancers such as **hairy cell leukemia**, malignant **melanoma**, and Kaposi's sarcoma (an AIDS-related cancer). Off the label,

alpha interferons are used to treat many other cancers including **bladder cancer**, **chronic myelocytic leukemia**, kidney cancer, carcinoid tumors, non-Hodgkin's lymphoma, **ovarian cancer**, and skin cancers. Alpha interferons can be combined with other chemotherapeutic drugs such as **doxorubicin**.

In the United States, alpha interferons are sold under the brand names Roferon-A (Interferon Alfa-2a, recombinant) and Intron A (Interferon Alfa-2b, recombinant). There are no generic forms of these drugs.

Recommended dosage

Alpha interferons are only available by prescription and are given parenterally. A physician will determine dosage based on several factors such as what type of cancer is being treated, the patient's weight, and what other types of medications the patient is taking. Therefore, the dose will vary from patient to patient.

Patients can inject this drug themselves. Their physicians may recommend that they drink extra water to avoid low blood pressure while on this medication. Since this drug can have flu-like side effects, it is recommended that patients inject the drug prior to bedtime so that they are sleeping during the worst part of the side effects.

Precautions

Alpha interferons have not been shown to cause problems in the fetus of pregnant women. Because it is not known whether this drug can cross over into breast milk, it is not recommended for use in women who are breast-feeding. Before this drug is given, patients should notify their doctors if they are allergic to immunoglobulins or egg whites.

There are several medical conditions that should be considered prior to deciding whether to use alpha interferons. There can be an increase in the following disorders: bleeding problems, mental problems, convulsions, diabetes mellitus, heart attack, heart disease, liver disease, kidney disease, and lung disease. People with an overactive immune system could also have this disorder exacerbated when using alpha interferons.

Caution should be taken when using alpha interferons because they can depress the number of white blood cells. This can make patients more susceptible to infection. Therefore, they should avoid contact with others who have infections and should contact their physicians immediately if they think they are developing an infection. Patients should take care not to cut themselves, should not touch their eyes or inside of their noses with unwashed hands, and should take care when brushing their teeth so as not to cause bleeding.

KEY TERMS

Cytokines—Molecules released by cells to regulate the length and intensity of an immune response and to mediate intercellular communication.

Glycoprotein—A protein that has a carbohydrate group attached.

Immunotherapy—Treating cancer using molecules that are intended to stimulate the patient's own immune system to fight the disease.

Macrophages—A type of white blood cell that produces antibodies and molecules for cell-to-cell immune responses.

Parenteral—Medications that are administered by some means other than through the gastrointestinal tract, including through intravenous, subcutaneous, or intramuscular injection.

T-lymphocytes—A part of the immune system that fights foreign cells.

The effects of alcohol can be exaggerated while taking alpha interferons. Alcohol should only be used by permission from a physician.

Side effects

Alpha interferons can have side effects that range from minor and irritating to major and severe, needing immediate attention. Some of the less serious side effects are muscle aches, unusual metallic taste in the mouth, **fever** and chills, and general flu-like symptoms such as headache, loss of appetite (anorexia), **nausea and vomiting**, and fatigue. To reduce the flu-like symptoms physicians may suggest that the patient take acetaminophen (e.g., Tylenol) before each dosage.

Other side effects may need medical attention. Any changes with the central nervous system such as confusion, trouble thinking and focusing, mental **depression**, nervousness, or numbness or tingling of fingers, toes and face require immediate medical attention.

The side effects are dependent on the dose. As a result, the physician may modify the dose if the side effects are severe.

Interactions

Alpha interferons can interact with several different drugs, increasing their effects. Most drugs that interact

with alpha interferons are those used with disorders of the central nervous system. Some of the depressants include antihistamines, sedatives, tranquilizers, sleeping medications, prescription pain medicines, seizure medications, muscle relaxants, narcotics, and barbiturates. Prior to treatment, the doctor should be notified if the patient is taking any of these medications because this could impact the dosage prescribed.

Sally C. McFarlane-Parrott

Interleukin 2

Definition

Interleukin-2 (IL2) is a protein produced naturally in the body in very small amounts. It is produced by a type of white blood cell called a T-lymphocyte and acts as part of the immune system by helping white blood cells work. **Aldesleukin** is a biological response modifier, a synthetic form of interleukin-2.

Purpose

Interleukin-2 (IL-2) is a naturally occurring chemical, called a cytokine, produced by certain cells of the immune system. It is also manufactured and administered as a drug to augment immune responses. While it is approved by the U.S. Food and Drug Administration (FDA) only for the treatment of **kidney cancer**, it is, as of 2005, also used in the treatment of HIV and AIDS. Inhaled interleukin-2 may halt disease progression in patients with kidney cancer that has spread to the lungs. Aldesleukin, a synthetic version of interleukin-2, is used to treat cancer of the kidney and skin cancer that has spread to other parts of the body.

Aldesleukin is approved by the United States Food and Drug Administration (FDA) for treatment of metastatic malignant **melanoma** (skin cancer that has spread to other parts of the body) and metastatic renal cell **carcinoma** (kidney cancer that has spread to other parts of the body). It has also been used in combination with other drugs in treatment of AIDS and **cutaneous t-cell lymphoma**.

Description

The kidneys are a pair of bean-shaped organs, located on the sides of the spine. The kidneys filter the blood and eliminate waste in the urine through a complex system of filtration tubules. All of the blood in the body passes through the kidneys approximately twenty times an hour. Renal cell cancer (RCC) is an uncommon form of cancer that is most often characterized by the presence of cancer cells in the lining of the filtration tubules of the kidney. Advanced (metastatic) RCC refers to cancer that has spread outside the kidneys to other locations in the body. The only agent approved for metastatic RCC is high-dose Proleukin (interleukin-2). One site of cancer spread in metastatic RCC is the lungs, referred to as pulmonary **metastasis**.

Recommended dosage

IL-2 is usually administered by injection into a vein but can also be injected under the skin (subcutaneous injection). It can be given in a hospital or clinic setting by a healthcare professional and is sometimes given at home. The dosage depends on the height and weight of the patient. It is given as an infusion for 15 minutes every eight hours for up to five days followed by nine days without the drug and then another five-day cycle of infusion. Up to four subsequent maintenance cycles of IL-2 can be given with four-week intervals without the drug to patients who have responded favorably to the treatment. About 15% of patients respond to treatment. It is difficult to estimate the cost of IL-2 treatment since the dose and number of treatment cycles given varies according to patients' individual responses; however, the cost is quite high, perhaps as much as $2,000 for one cycle. A six-cycle regimen of IL-2 may cost about $14,100. Because of the high cost and low effectiveness of interleukin-2, it is often not covered by insurance plans, especially HMOs. It is covered by Medicare if given in a hospital.

Precautions

IL-2 is highly toxic and usually makes patients feel generally unwell. Any side effects should be reported to a physician, but the course of medicine should continue even though the patient feels ill, unless the physician or healthcare professional tells the patient to stop. While using aldesleukin, IL-2 patients will be more susceptible to infection. They should avoid people with colds, flu, and bronchitis. They should not have any vaccinations without their IL-2 prescriber's approval, and they should avoid anyone who has recently had an oral polio vaccine. Patients should drink several glasses of water a day to help reduce possible kidney problems.

Aldesleukin should not be used by lactating mothers. It should also be avoided in patients with the following conditions:

- acute s-t elevation myocardial infarction
- angina pectoris

- atrial fibrillation
- bacterial infection
- bradycardia
- capillary leak syndrome
- coma
- epilepsy
- fungal infections
- impaired cognition
- intestinal perforation
- ischemic bowel disease
- neoplasm metastatic to the central nervous system
- organ transplantation
- pericardial tamponade
- protozoal infection
- pulmonary disease
- renal failure
- supraventricular tachycardia
- toxic psychosis
- ventricular tachycardia
- viral infection

According to <medscape.com>, the drug should be avoided or used with extreme care in patients with the following:

- arthritis
- bone marrow depression
- bullous pemphigoid
- cerebral arteritis
- cholecystitis
- Crohn's disease
- diabetes mellitus
- disease of liver
- glomerulonephritis
- myasthenia gravis
- psychotic disorder
- renal disease
- scleroderma thyroiditis
- untreated hypothyroidism

According to <MedlinePlus.com>, the drug should be avoided by people who have the following conditions:

- chicken pox (including recent exposure)
- herpes zoster (shingles)
- heart disease
- immune system problems
- liver disease
- lung disease
- psoriasis
- underactive thyroid
- infection
- kidney disease
- mental problems
- history of seizures

Side effects

When IL-2 is given by intravenous infusion, the most common side effect is called capillary leak syndrome. This condition causes weight gain, swelling, low blood pressure, and other problems. At lower doses, people taking IL-2 get flu-like symptoms, including **fever** and muscle aches. Because IL-2 stimulates the immune system, it can make some immune disorders get worse, including arthritis, psoriasis, and diabetes. It can also reduce the number of neutrophils, a particular type of infection-fighting cell, and can cause low levels of thyroid.

When IL-2 is given by subcutaneous injection, the side effects are usually milder than with intravenous infusions. There is the added side effect of irritation at the site of the injection. Side effects show up from two to six hours after injection of IL-2 and disappear quickly after the end of each cycle. IL-2 can cause mood changes, including irritability, insomnia, confusion, or depression. These can continue for several days after IL-2 is stopped.

Interleukin-2 has a number of other side effects. More common ones are fever or chills, shortness of breath, agitation, confusion, **diarrhea**, dizziness, drowsiness, mental depression, **nausea and vomiting**, sores in the mouth and on the lips, tingling of hands or feet, unusual decrease in urination, unusual tiredness, a weight gain of five to ten pounds or more, **anemia**, heart problems, kidney problems, liver problems, low blood pressure, low platelet counts in blood, low white blood cell counts, other blood problems, under active thyroid, dry skin, loss of appetite, skin rash or redness with burning or **itching** followed by peeling, and an unusual feeling of general discomfort or illness.

Less common problems include black and tarry stools, skin blisters, blood in the urine, bloody vomit, chest pain, cough or hoarseness, lower back or side pain, painful or difficult urination, pinpoint red spots on the

KEY TERMS

Cytokine—A protein secreted by cells of the lymph system that affects the activity of other cells and is important in controlling inflammatory responses. Interleukin-2 is a cytokine.

Metastatic—Spreading from one part of the body to another.

Neutrophil—The most common type of white blood cell in humans, responsible for protecting the body against infection.

Subcutaneous—Under the skin.

T-lymphocyte—A cell in the lymphatic system that contributes to immunity by directly attacking foreign bodies, such as viruses and bacteria.

skin, severe stomach pain, unusual bleeding or bruising, bloating and mild stomach pain, blurred or double vision, faintness, fast or irregular heartbeat, loss of taste, rapid breathing, redness, swelling, and soreness of the tongue, trouble in speaking, yellow eyes and skin, constipation, headache, joint pain, and muscle pain.

Rare problems include changes in menstrual periods, clumsiness, coldness, convulsions, listlessness, muscle aches, pain or redness at site of injection, sudden inability to move, swelling in the front of the neck, swelling of the feet or lower legs, and weakness.

Interactions

Interleukin-2 can adversely interact with the anticancer drug **dacarbazine** and hormones such as prednisone or cortisone.

Intravenous urography

Definition

Intravenous urography is a test that x rays the urinary system using intravenous dye for diagnostic purposes.

The kidneys excrete the dye into the urine. X rays can then create pictures of every structure (kidney, renal pelvis, ureter, bladder, urethra) through which the urine passes.

The procedure has several variations and many names:

- Intravenous pyelography (IVP)
- Urography
- Excretory urography
- Pyelography
- Antegrade pyelography differentiates this procedure from "retrograde pyelography," which injects dye into the lower end of the system, therefore flowing backward or "retrograde." Retrograde pyelography is better able to define problems in the lower parts of the system and is the only way to get x rays if the kidneys are not working well.
- Nephrotomography is somewhat different in that the x rays are taken by a moving **x ray** source onto a film moving in the opposite direction. By accurately coordinating the movement, all but a single plane of tissue is blurred, and that plane is seen without overlying shadows.

Every method available gives good pictures of this system, and the question becomes one of choosing among many excellent alternatives. Each condition has special requirements, while each technique has distinctive benefits and drawbacks.

- Nuclear medicine scans rely on the radiation given off by certain atoms. Chemicals containing such atoms are injected into the bloodstream. They reach the kidneys, where images are constructed by measuring the radiation emitted. The radiation is no more dangerous than standard x rays. The images require considerable training to interpret, but unique information (e.g. blood flow, kidney function, etc.) is often available using this technology. Different chemicals can concentrate the radiation in different types of tissue. This technique may require several days for the chemical to concentrate at its destination. It also requires a special detector to create the image.
- Ultrasound is a quick, safe, simple, and inexpensive way to obtain views of internal organs. Although less detailed than other methods, it may be sufficient, especially to detect obstructions.
- Retrograde pyelography is better able to define problems in the lower parts of the system and is the only way to get x rays if the kidneys are not working well. Dye is usually injected through an instrument (cystoscope) passed into the bladder through the urethra.

Intravenous urography showing contrast in distal ureter. Ureter is the narrow tube shown at the lower right of the image, and the dye has traveled from the kidney (above) and is traveling to the bladder. *(Custom Medical Stock Photo. Reproduced by permission.)*

- A **computed tomography** scan (CT or CAT scanning) uses the same kind of radiation used in x rays, but it collects information by computer in such a way that three dimensional images can be constructed, eliminating interference from nearby structures. CT scanning requires a special apparatus, but often gives better information on masses within the kidney.
- Magnetic resonance imaging (MRI) uses magnetic fields and radio frequency signals, instead of ionizing radiation, to create computerized images. This form of energy is entirely safe as long as the patient does not have any implanted metal such as artificial joints, aneurysm clips, etc. The technique is far more versatile than CT scanning as it can not only demonstrate masses, but also look at the blood vessels. However, MRI requires special apparatus and, because of the powerful magnets needed, even a special, separate building. It is quite expensive and only occasionally is this degree of detail required.

Purpose

IVP will provide information concerning most diseases of the kidneys, ureters, and bladder. The procedure is comprised of two phases. First, it requires a functioning kidney to filter the dye out of the blood into the urine. The time required for the dye to appear on x rays correlates accurately with kidney function. The second phase gives detailed anatomical images of the urinary tract. Within the first few minutes the dye "lights up" the kidneys, a phase called the nephrogram. Subsequent pictures follow the dye down the ureters and into the bladder. A final film taken after urinating reveals how well the bladder empties.

IVPs are most often done to assess structural abnormalities or obstruction to urine flow. If kidney function is at issue, more films are taken sooner to catch the earliest phase of the process.

- Stones, tumors and congenital malformations account for many of the findings.
- Kidney cysts and cancers can be seen.
- Displacement of a kidney or ureter suggests a space-occupying lesion (like a cancer of the colon, rectum, or gynecological organs) pushing it out of the way.
- Bad valves where the ureters enter the bladder will often show up.
- Bladder cancers and other abnormalities are often outlined by the dye in the bladder.
- An enlarged prostate gland will show up as incomplete bladder emptying and a bump at the bottom of the bladder.

Precautions

The only serious complication of an IVP is allergy to the iodine-containing dye that is used. Such an allergy is rare, but it can be dramatic and even lethal. Emergency measures taken immediately are usually effective.

Description

IVPs are usually done in the morning. In the x ray suite, the patient undresses and lies down. There are two methods of injecting the dye. An intravenous line can be established, through which the dye is consistently fed through the body during the procedure. The other method is to give the dye all at once through a needle that is immediately withdrawn. X rays are taken until the dye has reached the bladder, an interval of half an hour or less. The patient is asked to empty the bladder before

KEY TERMS

Contrast agent—Any substance that causes shadows on x rays; also known as contrast dye or medium.

Intravenous—Into a vein.

QUESTIONS TO ASK THE DOCTOR

- What should I feel when I am being imaged?
- Why do you recommend intravenous urography rather than another imaging technique?

one last x ray. A compression device (a wide belt containing 2 balloons that can be inflated) may be used to keep the contrast material in the kidneys. The patient needs to urinate after the compression device is removed. Another picture is taken after the bladder is emptied to see how empty the bladder is.

In the past, of the many ways to obtain images of the urinary system, the intravenous injection of a contrast agent has been considered the best. Recent studies are showing, however, that while intravenous urography is a useful technique, there may be other imaging techniques, such as B mode ultrasound, Doppler ultrasound, renal scintigraphy with angiotensin-converting enzyme inhibitors, intra-venous and intra-arterial catheter **angiography**, computed tomographic angiography, and magnetic resonance angiography, that are better or less costly.

Preparation

Emptying the bowel with **laxatives** or enemas prevents bowel shadows from obscuring the details of the urinary system. An empty stomach prevents the complication of vomiting, a rare effect of the contrast agent. Therefore, the night before the IVP the patient is asked to evacuate the bowels and to drink sparingly.

Preparation for infants and children depends on the age of the infant or child.

Aftercare

Feeling weak, nauseous, and/or lightheaded for a short time after the procedure is a possibility.

Risks

Allergy to the contrast agent is the only risk. Anyone with a possible iodine allergy, a previous reaction to x ray dye, or an allergy to shellfish must be particularly careful to inform the x ray personnel.

Exposure to x ray radiation should be noted. Most experts agree that the risk of exposure to low radiation is low compared to the benefits. Pregnant women and children are more sensitive to the risks of x rays.

Normal results

X-ray images of the kidney and bladder structures appear normal.

Abnormal results

An abnormal intravenous urography result may indicate kidney disease, birth defect, tumor, kidney stone, and/or inflammation caused by infections.

Investigational drugs

Definition

"Investigational drugs" refers to drugs that have received FDA approval for human testing, including those drugs still undergoing **clinical trials**, but are not approved for marketing to the general public.

Description

Investigational drugs represent interesting and novel new agents in the fight against cancer. These agents include **chemotherapy** designed to treat specific cancers, to provide palliative therapy for pain and symptoms, and to reduce invasive cancers in high-risk patients. The challenge faced by private and commercial investigators is to reduce the lag time in bringing an investigational drug to market without compromising drug quality or patient safety. The guidelines that insure the correct procedures are being followed in the process of drug development and approval fall under the direction of the Food and Drug Administration (FDA).

At present, the cycle of investigational drug research and development, to clinical trials, to FDA approval can easily cover a period of 10-12 years. Under exceptional circumstances, provisions can be made for patient use of investigational drugs under the guidance of specially trained and registered oncologists. These specific investigational drugs are classified as "Group C" drugs, and have demonstrated a high level of reproducible activity in pre-clinical testing. There is also the route of "Accelerated FDA Approval" for some investigational drugs. Accelerated approval relies on specific indicators that suggest that a particular investigational drug is likely to have beneficial effects before the benefits have been clinically verified. All investigational drugs that have been granted accelerated approval must undergo follow-up testing in order to receive final FDA approval. Some researchers are presently working on a format to combine traditional clinical testing of investigational drugs with a global database of drug information. This integrated system would give FDA monitoring agencies and healthcare providers access to the most comprehensive source of archived data available on investigational drugs. This combined approach is another attempt to reduce approval time for investigational drugs and make these agents available to the cancer patient for treatment.

Irinotecan

Definition

Irinotecan is a drug used to treat certain types of cancer. Irinotecan, also known as CPT-11, is available under the trade name Camptosar, and may also be referred to as irinotecan hydrochloride or camptothecin-11.

Purpose

Irinotecan is an antineoplastic agent used to treat cancer. A primary use of the drug is treatment of colon or rectal cancers that have recurred or progressed while the patient was on 5-FU (fluorouracil) therapy. Irinotecan also can be given as first line therapy with 5-FU and **leucovorin** for patients with metastatic colon or **rectal cancer**. Other uses for irinotecan include treatment of small cell lung cancer, nonsmall cell lung cancer, **ovarian cancer**, stomach cancer, **breast cancer**, pancreatic cancer, leukemia, **lymphoma**, and **cervical cancer**.

Several 2003 studies showed some potential new uses for irinotecan. One reported that a combination of irinotecan and docetaxel can help patients with esophageal cancer who have been extensively pretreated with cisplatin. Weekly use of irinotecan has shown preliminary results in treating patients with nonsmall cell lung cancer with minimal side effects. Another 2003 study reported that when used in combination with cancer

drugs cisplatin and epirubicin, irinotecan might have promising broad antitumor activity. In the future, irinotecan might be used in combination therapies to treat many types of tumors.

Description

Irinotecan is a synthetic derivative of the naturally occurring compound camptothecin. Camptothecin belongs to a group of chemicals called alkaloids and is extracted from plants such as *camptotheca acuminata*. Captothecin was initially investigated as a chemotherapeutic agent due to its anti-cancer activity in laboratory studies. The chemical structure and biological action of irinotecan is similar to that of camptothecin and **topotecan**.

Irinotecan inhibits the normal functioning of the enzyme topoisomerase I. The normal role of topoisomerase I is to aid in the replication, recombination, and repair of deoxyribonucleic acid (DNA). Higher levels of topoisomerase I have been found in certain cancer tumors compared to healthy tissue. Inhibiting topoisomerase I causes DNA damage. This damage leads to apoptosis, or programmed cell death.

Recommended dosage

Patients should be carefully monitored during irinotecan treatment for toxicity. Irinotecan is given at a dose of 125 mg per square meter of body surface area per week for four weeks, followed by a two week rest period. Other dosing schedules include 100 mg per square meter of body surface area per day for three days every three weeks, or 100-115 mg per square meter of body surface area per week, or 200-350 mg per square meter of body surface area every 3 weeks. The drug is administered through the vein over a 90-minute period. The initial dose of irinotecan may be adjusted downward depending on patient tolerance to the toxic side effects of irinotecan.

Treatment may be continued as long as intolerable side effects do not develop and patients continue to benefit from the treatment.

Precautions

Irinotecan should only be used under the supervision of a physician experienced in the use of cancer chemotherapeutic agents. Special caution, especially in those 65 years and older, should be taken to monitor the toxic effects of irinotecan, particularly **diarrhea**, nausea, and vomiting. Because irinotecan is administered intravenously, the site of infusion should be monitored for signs of inflammation. Should inflammation occur, flushing the site with sterile water and applying ice are recommended. Irinotecan may cause **nausea and vomiting**, and premedication with antiemetic agents is recommended.

Neither the effects of irinotecan in patients with significant liver dysfunction nor the safety of irinotecan in children have been established. Irinotecan should not be administered to pregnant women. Women of child-bearing age are advised not to become pregnant during treatment with this drug.

KEY TERMS

Alkaloid—A nitrogen-containing compound occurring in plants.

Anorexia—Loss of appetite and the inability to eat.

Apoptosis—An active process in which a cell dies due to a chemical signal. Programmed cell death.

Diuretic—An agent that increases the amount of urine the body produces.

Inflammation—A response to injury, irritation, or illness characterized by redness, pain, swelling, and heat.

Metastatic—Spread of a disease from the organ or tissue of origin to other parts of the body.

Side effects

Early- or late-onset diarrhea are common side effects of irinotecan. Late-onset diarrhea, occurring more than 24 hours after irinotecan administration, can be life-threatening and should be treated promptly. Patients should immediately report diarrhea to their physician. Patients can also take the antidiarrheal drug loperamide as prescribed by their physician at the first sign of diarrhea. Suppression of bone marrow function is another serious side effect commonly observed in this treatment. Additional side effects, including nausea, vomiting, **anorexia** (loss of appetite), pain, **fatigue**, and hair loss (alopecia) may occur.

Interactions

Irradiation treatment during the course of irinotecan treatment is not recommended. Patients who have received prior pelvic or abdominal irradiation treatment should notify their physician. Since irinotecan may cause diarrhea, the use of **laxatives** should be avoided. The use of diuretics should be closely monitored. The adverse side effects caused by irinotecan may be increased by

other **antineoplastic agents** having similar adverse effects and should generally be avoided.

Itching

Description

Itching, also called pruritus, is an unpleasant sensation of the skin that causes a person to scratch or rub the area to find relief. Itching can be confined to one spot (localized) or over the whole body (generalized). Severe scratching can injure the skin causing redness, bumps, and scratches. Injured skin is prone to infection.

Itching can profoundly affect quality of life. It can torment the patient and cause discomfort, stress, loss of sleep, concentration difficulty, and constant concern.

Causes

The biology underlying itching is not fully understood. It is believed that itching results from the interactions of several different chemical messengers. Although itching and pain sensations were at one time thought to be sent along the same nerve pathways, researchers reported the discovery in 2003 of itch-specific nerve pathways. Nerve endings that are specifically sensitive to itching have been named pruriceptors.

Research into itching has been helped by the recent invention of a mechanical device called the Matcher, which electrically stimulates the patient's left hand. When the intensity of the stimulation equals the intensity of itching that the patient is experiencing elsewhere in the body, the patient stops the stimulation and the device automatically records the measurement. The Matcher was found to be sensitive to immediate changes in the patient's perception of itching as well as reliable in its measurements.

Itching is associated with a variety of factors including skin diseases, blood diseases, emotions, and drug reactions as well as by cancer and cancer treatments. Itching can be a symptom of cancer including **Hodgkin's disease**, non-Hodgkin's lymphoma, leukemia, **Bowen's disease**, **multiple myeloma**, central nervous system (brain and spinal cord) tumors, **germ cell tumors**, and invasive squamous cell carcinoma. The buildup of toxins in the blood, caused by kidney, gallbladder, and liver disease, can cause itching. Cancer treatments that are associated with itching are: **radiation therapy**, **chemotherapy**, and biological response modifiers (drugs that improve the patient's immune system). Skin reactions are more severe when both chemotherapy and radiation therapy are used. Patients treated with **bone marrow transplantation** may develop itching resulting from **graft-vs.-host disease**. Itching can be caused by infection.

General medications that may be used by cancer patients can cause itching. Itching can be caused by drug reactions from **antibiotics**, **corticosteroids**, hormones, and pain relievers (analgesics).

Itching can be a sign that the patient is very sensitive to a particular chemotherapy drug. Chemotherapy drugs and biological response modifiers that can cause itching include:

- allopurinol
- aminoglutethimide
- bleomycin
- carmustine
- chlorambucil
- cyclophosphamide
- cytarabine
- daunorubicin
- doxorubicin
- hydroxyurea
- idarubicin
- interleukin (aldesleukin)
- mechlorethamine
- megestrol acetate
- mitomycin-C
- tamoxifen

- topiramate

Itching commonly occurs during radiation therapy. Parts of the body that are particularly sensitive to radiation are the underarms, groin, abdomen, breasts, buttocks, and skin around the genitals (perineum) and anus (perianal). Itching is usually caused by skin dryness when the oil (sebaceous) glands are damaged by the radiation. Radiation also causes skin darkening, redness, and skin shedding, which can all cause itching.

Itching caused by cancer usually disappears once the cancer is in remission or cured. Chemotherapy-induced itching usually disappears within 30 to 90 minutes after the drug has been administered. Itching caused by radiation therapy will resolve once the injured skin has healed.

Treatments

There are three aspects in the treatment of itching: managing the underlying cancer, maintaining skin health, and relief of itching.

Patients should avoid the particular things that cause or worsen their itching. Also, patients can take measures to maintain skin health. Suggestions include:

- taking short baths in warm water
- using mild soaps and rinsing well
- applying bath oil or moisturizing cream after bathing
- avoiding use of cosmetics, perfumes, deodorants, and starch-based powders
- avoiding wool and other harsh fabrics
- using mild laundry detergents and rinsing thoroughly
- avoiding use of dryer anti-static sheets
- wearing loose-fitting cotton clothing
- avoiding high-friction garments such as belts, pantyhose, and bras
- maintaining a cool environment with a 30% to 40% humidity level
- using cotton sheets
- avoiding vigorous exercise (if sweating causes itching)
- avoiding skin products that are scented or contain alcohol or menthol

To reduce skin injury caused by scratching the patient should keep fingernails short, wear soft cotton mittens and socks at night, and keep the hands clean. Gently rubbing the skin around the itch or applying pressure or vibration to the itchy spot may reduce itching. Using a soft infant toothbrush to gently stroke the itchy area may relieve itching. Itching may be relieved by applying a cool washcloth or ice to the itchy area.

The most effective way to relieve itching is to treat the underlying disease. Sometimes, itching disappears as soon as a tumor is treated or removed.

Itching may be relieved by applying any of a variety of different products to the skin. The patient may need to try several before the most effective one is found. The patient's physician should be consulted before any anti-itch products are used. Topical treatments include:

- Corticosteroids, such as hydrocortisone, reduce inflammation and itching.
- Calamine lotions can cool and soothe itchy skin. These products can be drying, which may be helpful for weeping or oozing rashes.
- Antihistamine creams stop itching that is associated with the chemical messenger histamine.
- Moisturizers treat dry skin which helps to relieve itching. Moisturizers that are recommended to cancer patients include brand names Alpha Keri, Aquaphor, Eucerin, Lubriderm, Nivea, Prax, and Sarna. Moisturizers should be applied after bathing and at least two or three times daily.
- Gels that contain a numbing agent (e.g. lidocaine) can be used on some parts of the body.

Itching may be treated with whole-body medications. Some of these systemic treatments include:

- antihistamines
- tricyclic antidepressants
- sedatives or tranquilizers
- such selective serotonin reputake inhibitors as paroxetine (Paxil) and sertraline (Zoloft)
- binding agents (such as cholestyramine which relieves itching associated with kidney or liver disease).
- aspirin
- cimetidine

Alternative and complementary therapies

A well-balanced diet that includes carbohydrates, fats, minerals, proteins, **vitamins**, and liquids will help to maintain skin health. Capsules that contain eicosapentaenoic acid, which is obtained from herring, mackerel, or salmon, may help to reduce itching. Vitamin A plays an important role in skin health. Vitamin E (capsules or ointment) may reduce itching. Patients should check with their treating physician before using supplements.

Homeopathy has been reported to be effective in treating systemic itching associated with hemodialysis.

KEY TERMS

Chemical messengers—Chemicals that transmit messages from one place to another.

Generalized itching—Itching that occurs over the whole body.

Histamine—A chemical messenger that can be associated with itching.

Localized itching—Itching that is confined to one spot.

Pruriceptors—Nerve endings specialized to perceive itching sensations.

Pruritus—The medical term for itching.

Baths containing oil with milk or oatmeal are effective at relieving localized itching. Evening primrose oil may soothe itching and may be as effective as corticosteroids. Calendula cream may relieve short-term itching. Other herbal treatments that have been recently reported to relieve itching include sangre de drago, a preparation made with sap from a South American tree; and a mixture of honey, olive oil, and beeswax.

Distraction, music therapy, relaxation techniques, and visualization may be useful in relieving itching. Ultraviolet light therapy may relieve itching associated with conditions of the skin, kidneys, blood, and gallbladder. There are some reports of the use of acupuncture and transcutaneous electrical nerve stimulators (TENS) to relieve itching.

K

Kaposi's sarcoma

Definition

Kaposi's sarcoma (KS) is a cancer of the skin, mucous membranes, and blood vessels; it is the most common form of cancer in AIDS patients. It was named for Dr. Moritz Kaposi (1837-1902), a Hungarian dermatologist who first described it in 1872. As of 2001, researchers disagree as to whether KS is a true cancer or a disorder of the skin that develops as a reaction to infection by a herpes virus.

Description

The formal medical term for Kaposi's sarcoma is multiple idiopathic hemorrhagic sarcoma. This term means that KS develops in many different sites on the patient's skin or internal organs; that its cause is unknown; and that it is characterized by bleeding. The lesions (areas of diseased or damaged skin), which are usually round or elliptical in shape and a quarter of an inch to an inch in size, derive their characteristic purple or brownish color from blood leaking out of capillaries (small blood vessels) in the skin. In KS, the capillaries begin to grow too rapidly and irregularly, which causes them to become leaky and eventually break. The lesions themselves may become enlarged and bleed, or cause the mucous membranes of the patient's internal organs to bleed.

There are three types of KS lesions, defined by their appearance:

- Nodular. These are reddish-purple, but are sometimes surrounded by a border of yellowish or brown pigment. Nodular lesions may appear to be dark brown rather than purple in patients with dark skin.
- Infiltrating. Infiltrating lesions may be large or have a raised surface. They typically grow downward under the skin.
- Lymphatic. These lesions are found in the lymph nodes and may be confused with other causes of swollen lymph nodes.

As of 2005, KS is classified into five types:

- Classic KS. This form of KS is sometimes called indolent KS because it is slow to develop. Classical KS is most commonly found in males between 50 and 70 years of age, of Italian or Eastern European Jewish descent.
- African KS. This form of the disease appears in both an indolent and an aggressive form in native populations in equatorial Africa. It accounts for almost 10% of all cancers in central Africa.
- Immunosuppressive treatment-related KS. The third form of KS occurs in kidney transplant patients who have been given drugs to suppress their immune systems-usually prednisone and **azathioprine**. This form of KS is sometimes called iatrogenic KS, which means that it is caused unintentionally by medical treatment.
- Epidemic KS. Epidemic KS was first reported in 1981 as part of the AIDS epidemic. Most cases of epidemic KS in the United States have been diagnosed in homosexual or bisexual men.
- Non-epidemic gay-related KS. This form of KS occurs in homosexual men who do not develop HIV infection. Non-epidemic gay-related KS is an indolent form of the disease that primarily affects the patient's skin.

Demographics

The demographic distribution of KS varies considerably across its five types:

- Classic KS. Classic KS is considered a rare disease, with a male/female ratio of 10:1 or 15:1. In North America and Europe, most patients are between 50 and 70 years old. Classic KS is more common in men from Mediterranean countries and in Ashkenazic Jews.
- African KS. African KS has the same male/female ratio as classic KS, although most patients with African KS are younger. A form of African KS that attacks the lymphatic system primarily affects children, with a male/female ratio of 3:1.

- Immunosuppresive treatment-related KS. This form of KS occurs mostly in kidney-transplant patients, at a rate of 150 to 200 times as often as in the general population. It represents 3% of all tumors that occur in kidney-transplant patients. The male/female ratio is 2:1.
- Epidemic KS. Epidemic KS is overwhelmingly a disease of adult homosexual or bisexual males. It is 20,000 times more common in people with AIDS than in those without HIV infection. According to the National Institutes of Health (NIH), 95% of all the cases of epidemic KS in the United States have been diagnosed in homosexual or bisexual males. Epidemic KS is far more prevalent among homosexual or bisexual males with AIDS than among hemophiliacs or intravenous drug users with AIDS. Prior to 1995, about 26% of all homosexual males with AIDS had KS as their first symptom or eventually developed KS, as compared with fewer than 3% of heterosexual intravenous drug users with AIDS. This clustering of KS cases among a subpopulation of AIDS patients led to the hypothesis that a blood factor transmitted by sexual contact is a partial cause of KS. The number of new cases of AIDS-related KS has declined in recent years, for reasons that are not yet clear. Some researchers think that the introduction of highly active antiretroviral therapy, or HAART, is related to the decline in the number of cases of epidemic KS. As of 2001, only about 12% of AIDS patients develop KS.
- Non-epidemic gay-related KS. This small group of KS patients is entirely male.

Causes and symptoms

Causes

GENETIC FACTORS The role of genetic factors in KS varies across its five types. Classic KS is the only form associated with specific ethnic groups. In addition, patients with classic KS and immunosuppressive treatment-related KS have a higher incidence of a genetically determined immune factor called HLA-DR.

MALE HORMONES The fact that all forms of KS affect men more often than women may indicate that androgens (male sex hormones) may be a factor in the development of KS.

IMMUNOSUPPRESSION In addition to organ transplant patients receiving immunosuppressive drugs, patients who are taking high-dose **corticosteroids** are also at increased risk of developing KS.

INFECTIOUS AGENTS Some researchers think that cytomegalovirus (CMV) and **human papilloma virus** (HPV) may be involved in the development of KS because fragments of these two types of virus have been found in KS tumor samples. The most likely candidate for an infectious agent, however, is human herpesvirus 8 (HHV-8), which is sometimes called KS-associated herpesvirus (KSHV). Fragments of the HHV-8 genome were first detected in 1994 by using a technique based on polymerase chain reaction (PCR) analysis. HHV-8 belongs to a group of herpesviruses called rhadinoviruses, and is the first herpesvirus of this subtype to be found in humans. HHV-8 is, however, closely related to the human herpesvirus called **Epstein-Barr virus** (EBV). EBV is known to cause infectious mononucleosis as well as tumors of the lymphatic system, and may be involved in other malignancies, including the African form of **Burkitt's lymphoma**, **Hodgkin's disease**, and **nasopharyngeal cancer**. HHV-8 has been found in tissue samples from patients with African KS, classic KS, and immunosuppression treatment-related KS as well as epidemic KS. HHV-8 is also associated with a rare noncancerous disease called Castleman's disease, which affects the lymph nodes. Some KS patients have been found to have KS and Castleman's disease occurring together in the same lymph node.

OTHER CAUSES Some practitioners of alternative medicine regard environmental toxins, psychological distress, and constitutional weaknesses as probable or partial causes of KS. These theories are discussed in more detail under the heading of alternative treatments.

Symptoms

CLASSIC KS The symptoms of classic KS include one or more reddish or purplish patches or nodules on one or both legs, often on the ankles or soles of the feet. The lesions slowly enlarge over a period of 10-15 years, with additional lesions sometimes developing. It is rare for classic KS to involve the patient's internal organs, although bleeding from the digestive tract sometimes occurs. About 34% of patients with classic KS eventually develop non-Hodgkin's lymphoma or another primary cancer.

AFRICAN KS The symptoms of the indolent form of African KS resemble those of classic KS. The aggressive form, however, produces tumors that may penetrate the tissue underneath the patient's skin, and even the underlying bone.

EPIDEMIC KS Epidemic KS has more varied presentations than the four other types of KS. Its onset is usually, though not always, marked by the appearance of widespread lesions at many different points on the patient's skin and in the mouth. Most HIV-infected patients who develop KS skin and mouth lesions feel healthy and have no systemic symptoms. On the other hand, KS may affect the patient's lymph nodes or gastrointestinal tract prior to causing skin lesions.

Patients with epidemic KS almost always develop disseminated (widely spread) disease. The illness progesses from a few localized lesions to lymph node involvement and further spread to other organs. Disseminated KS is defined by the appearance of one or more of the following: a count of 25 or more external lesions; the appearance of 10 or more new lesions per month; and the appearance of visible lesions in the patient's lungs or stomach lining.

In some cases, disseminated KS causes painful swelling (edema) of the patient's feet and lower legs. The lesions may also cause the surrounding skin to ulcerate or develop secondary infections. The spread of KS to the lungs, called pleuropulmonary KS, usually occurs at a late stage of the disease. KS involvement of the lungs causes bleeding, coughing, shortness of breath, and eventual respiratory failure. Most patients who die directly of KS die from its pleuropulmonary form.

Diagnosis

Physical examination and patient history

The diagnosis of any form of KS requires a careful examination of all areas of the patient's skin. Even though the characteristic lesions of classic KS appear most frequently on the legs, all forms of KS can produce lesions on any area of the skin. An experienced doctor, who may be a dermatologist, an internist, or a primary care physician, can make a tentative diagnosis of KS on the basis of the external appearance of the skin lesions (size, shape, color, and location on the face or body), particularly when they are accompanied by evidence of lymph node involvement, internal bleeding, and other symptoms associated with disseminated KS. The doctor may touch or press on the lesions to find out whether they turn pale (blanch); KS plaques and nodules do not blanch under fingertip pressure. In addition, KS lesions are not painful when they first appear.

Other signs of KS may appear on the soft palate or the membrane covering the eye (conjunctiva). In addition, the doctor will press on the patient's abdomen in order to detect any masses in the liver or spleen.

A thorough history is necessary in order to determine whether the patient's ethnic background, lifestyle, or medical history places him or her in a high-risk category for KS.

Biopsy

A definitive diagnosis of KS requires a skin **biopsy** in order to rule out bacillary angiomatosis, a bacterial infection resembling cat-scratch disease. It is caused by a bacillus, *Bartonella henselae*. Collecting a tissue sample for a biopsy is not difficult if the patient has skin lesions, but can be complicated if the nodules are primarily internal. An endoscopy of the upper end of the digestive tract may be performed in order to obtain a tissue sample from an internal KS lesion.

Under the microscope, an AIDS-related KS lesion will show an unusually large number of spindle-shaped cells mixed together with small capillaries. The origin of the spindle-shaped cells is still unknown. The tumor cells in a KS lesion resemble smooth muscle cells or fibroblasts, which are cells that help to form the fibers in normal connective tissue.

If the patient's lymph nodes are enlarged, a biopsy may be done in order to rule out other causes of swollen lymph nodes.

Other tests

Other diagnostic tests may be performed if the patient appears to have disseminated KS. These tests include:

- Chest x ray. A radiograph of the patient's lungs will show patchy areas of involved tissue.
- Gallium scan. The results will be negative in KS.
- Bronchoscopy. This procedure allows the doctor to examine the patient's bronchial pathways for visible KS lesions. It is not, however, useful for obtaining tissue samples for biopsy.
- Endoscopy. Examination of the patient's stomach allows the doctor to examine the mucous lining for KS lesions as well as to obtain a tissue sample.

Treatment team

KS patients may receive treatment for skin lesions from a dermatologist or radiologist as well as treatment for lung or lymphatic involvement from internists or primary care practitioners. A surgeon may be called in to remove lesions in the digestive tract if they are bleeding or blocking the passage of food. Children with KS may be treated by pediatricians or by primary care physicians who specialize in treating AIDS patients.

Clinical staging, treatments, and prognosis

Staging

The NIH recommends individualized staging of patients with classic KS, due to the age of most patients, the localized nature of the lesions, the slow progression of the disease, and the low risk of spread to the internal organs.

The criteria for staging epidemic KS have evolved over the past decade in response to changes in the treatment of HIV infection and to the recognition that KS

does not fit well into standard categories of tumor assessment. Several different systems have been used to stage epidemic KS, but none is completely satisfactory.

NYU STAGING SYSTEM One staging system that originated at New York University divides KS patients into four groups according to the following symptom clusters:

- Skin lesions that are indolent (slow-growing) and limited to relatively small areas of the body.
- Skin lesions limited to specific regions of the body but aggressive in growth. There may or may not be involvement of lymph nodes.
- General involvement of the skin and mucous membranes, with or without lymph node involvement.
- Involvement of the internal organs.

AIDS CLINICAL TRIALS GROUP (ACTG) STAGING SYSTEM The ACTG Oncology Committee published a staging system for epidemic KS in 1989. This system was reevaluated in 1995 and is undergoing continued assessment. It is based on three criteria: extent of tumor; condition of the patient's immune system; and presence of systemic illness:

- Tumor (T): Good risk (0) is a tumor limited to the skin and/or lymph nodes and/or minimal oral disease (limited to the palate). Poor risk (1) is any of the following: edema associated with the tumor; widespread KS in the mouth; KS in the digestive tract; KS in other viscera.
- Immune system (I): Good risk (0) is a CD4 cell count greater than 200 per cubic millmeter. Poor risk (1) is a CD4 cell count lower than 200 per cubic millimeter.
- Systemic illness (S): Good risk (0) is no history of opportunistic infections (OI) or **thrush**; no "B" symptoms (unexplained **fever**, **night sweats**, **diarrhea** lasting more than 2 weeks, **weight loss** greater than 10%); performance status above 70 on the Karnofsky scale. Poor risk (1) is any of the following: history of OI or thrush; presence of "B" symptoms; Karnofsky score lower than 70; and other HIV-related illnesses.

Treatment

Treatment of KS depends on the form of the disease.

CLASSIC KS **Radiation therapy** is usually quite effective if the patient has small lesions or lesions limited to a small area of skin. Low-voltage photon radiation or electron beam therapy give good results. Surgical removal of small lesions is sometimes done, but the lesions are likely to recur. The best results are obtained from surgical treatment when many small lesions are removed over a period of years.

For widespread skin disease, radiation treatment with electron beam therapy is recommended. Classic KS has not often been treated with **chemotherapy** in the United States, but some researchers report that treatment with **vinblastine** or **vincristine** has been effective. Disease that has spread to the lymph nodes or digestive tract is treated with a combination of chemotherapy and radiation treatment.

IMMUNOSUPPRESSIVE TREATMENT-RELATED KS The standard pattern of therapy for this form of KS begins with discontinuing the immunosuppressive medications if they are not essential to the patient's care. Treatment of the KS itself may include radiation therapy if the disease is limited to the skin, or single- or multiple-drug chemotherapy.

EPIDEMIC KS As of 2001, there is no cure for epidemic KS. Treatment is aimed at reducing the size of skin lesions and alleviating the discomfort of open ulcers or swollen tissue in the legs. There are no data that indicate that treatment prolongs the survival of patients with epidemic KS. In addition to treatment of the KS itself, these patients also need ongoing retroviral therapy and treatment of any opportunistic infections that may develop. An additional complication in treating epidemic KS is that highly active antiretroviral therapy, or HAART, is not the "magic bullet" that some had hoped when it was introduced in 1998. HAART uses three- or four-drug combinations to treat HIV infection. Problems with HAART include severe psychiatric as well as physical side effects, in addition to the patient's risk of developing a drug-resistant form of HIV if even one dose of medication is missed. The complex dosing schedules as well as the medication side effects make it difficult to assess the effectiveness of treatments aimed at the KS by itself.

Small KS lesions respond very well to radiation treatment. They can also be removed surgically or treated with **cryotherapy**, a technique that uses liquid nitrogen to freeze the lesion. Lesions inside the mouth (on the palate) can be treated with injections of vinblastine. In addition, the patient may be given topical alitretinoin (Panretin gel), which is applied directly to the lesions. Alitretinoin received FDA approval for treating KS in 1999.

Systemic treatments for epidemic KS consist of various combinations of anti-cancer drugs, including vincristine (Oncovin), vinblastine (Velban), **bleomycin** (Blenoxane), **doxorubicin** (Adriamycin), **daunorubicin** (DaunoXome), interferon-alpha (Intron A, Roferon-A), **etoposide** (VePesid), or **paclitaxel** (Taxol). The effectiveness of systemic treatments ranges from 50% for high-dose therapy with interferon-alpha to 80% for

combinations of vincristine, vinblastine, bleomycin, doxorubicin, and etoposide. The drawbacks of systemic treatment include the toxicity of these drugs and their many side effects. Interferon-alpha can be given only to adult patients with relatively intact immune systems and no signs of lymphatic involvement. The side effects of systemic chemotherapy include hair loss (**alopecia**), **nausea and vomiting**, **fatigue**, diarrhea, headaches, loss of appetite (anorexia), allergic reactions, back pain, abdominal pain, and increased sweating.

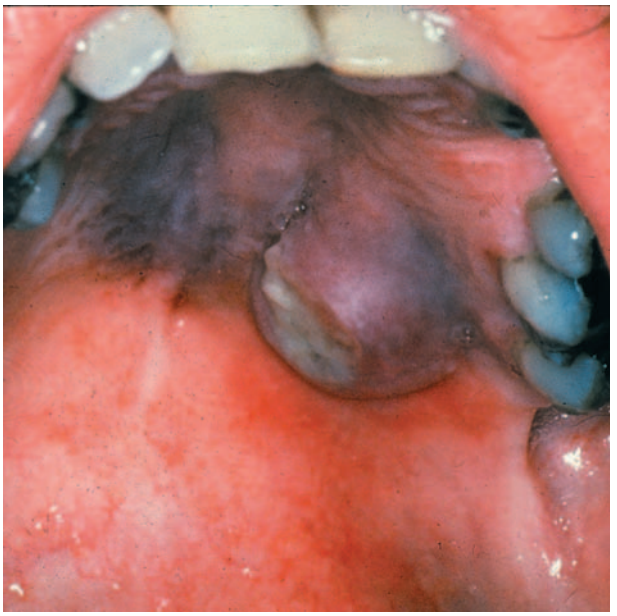
As of 2005, the standard for first-line treatment of epidemic KS is one of the FDA-approved anthracyclines such as liposomal doxorubicin (Doxil) or liposomal daunorubicin (DaunoXome), rather than a combination drug regimen. Liposomes are small sacs consisting of an outer layer of fatty substances used to coat an inner core of another medication. In addition to concentrating the drug's effects on the tumor, liposomes moderate the side effects.

In 1997, the FDA approved paclitaxel (Taxol) for epidemic KS resistant to treatment. Paclitaxel is a drug derived from the bark of the Pacific yew tree that prevents the growth of cancer cells by preventing the breakdown of normal cell structures called microtubules. After paclitaxel treatment, cancer cells become so clogged with microtubules that they cannot grow and divide. The drug has serious side effects, most notably suppression of the patient's bone marrow.

Experimental treatments for AIDS-related KS include retinoic acid, which is derived from vitamin A; and other drugs that inhibit the formation of new blood vessels (angiogenesis) in tumors. The reason for inhibiting angiogenesis is that new blood vessels keep a cancer supplied with oxygen and nutrients, which help the cancer grow and spread to other parts of the body. Antiangiogenic agents that have been proposed for treating KS include Fumagillin, SP-PG, and Platelet 4 factor. As of 2005, the effectiveness of these substances in humans is not yet known. Approval by the Food and Drug Administration will require several years after the test results are known.

Prognosis

The prognosis of KS varies depending on its form. Patients with classic KS often survive for many years after diagnosis; death is often caused by another cancer, such as non-Hodgkin's lymphoma, rather than the KS itself. The aggressive form of African KS has the poorest prognosis, with a fatality rate of 100% within three years of diagnosis. Patients with immunosuppressive treatment-related KS have variable prognoses; in many cases, however, the KS goes into remission once the immune-suppressing drug is discontinued. The prognosis of patients with epidemic KS also varies, depending on the patient's general level of health. As a rule, patients whose KS has spread to the lungs have the poorest prognosis.

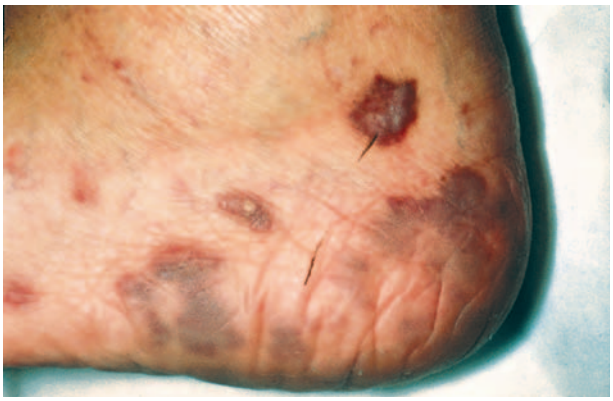


This HIV-positive patient is afflicted with Kaposi's sarcoma inside the mouth. The tumor is toward the back of the mouth, to the right. *(Custom Medical Stock Photo. Reproduced by permission.)*

Alternative and complementary therapies

SHARK CARTILAGE The only alternative treatment for epidemic KS that has been evaluated by the NIH is shark cartilage. Shark cartilage products are widely available in the United States as over-the-counter (OTC) preparations that do not require FDA approval. A 1995 review of alternative therapies found more than 40 brand names of shark cartilage products for sale in the United States to treat arthritis and psoriasis as well as KS. The cartilage can be taken by mouth or by injection.

The use of shark cartilage to treat KS derives from a popular belief that sharks and other cartilaginous fish (skates and rays) do not get cancer. This belief is countered by findings from samples of captured sharks that they do in fact develop various kinds of tumors. There are three explanations of the role of shark cartilage in preventing KS. Some researchers have proposed that it kills cancer cells directly. A second explanation is that cartilage stimulates the human immune system. The third theory, which has more evidence in its favor than the first two, is that the cartilage slows down or prevents angiogenesis. Two complex proteins in shark cartilage,



Purple-colored (violaceous) plaques of Kaposi's sarcoma on the heel and side of foot. *(Centers for Disease Control.)*

identified as U-995 and SCF2, have been shown to inhibit angiogenesis in laboratory studies. As of December 2000, only three studies using human subjects have been published; the results are inconclusive. The complete results of three other studies using shark cartilage in human subjects have not yet been published in complete form. Preliminary reports of NIH-sponsored **clinical trials** are also not yet available; however, all three studies being currently conducted have received the lowest rating (3iii) for the statistical strength of the study's design.

The side effects of treatment with shark cartilage include mild to moderate nausea, vomiting, abdominal cramps, constipation, low blood pressure, abnormally high levels of blood calcium (**hypercalcemia**), and general feelings of weakness.

OTHER ALTERNATIVE THERAPIES Other alternative treatments for KS are aimed almost completely at epidemic KS. Most are based on assumptions that AIDS victims have had their immune systems weakened by such environmental toxins as lead and radioactive materials, or by psychological stress generated by societal disapproval of homosexuality. Naturopaths would add such life-style stresses as the use of tobacco and alcohol, as well as poor sleep patterns and nutritional deficiencies. Homeopaths believe that AIDS is the product of hereditary predispositions to disease called miasms, specifically two miasms related to syphilis and gonorrhea respectively.

Alternative topical treatments for the skin lesions of AIDS-related KS include homeopathic preparations made from periwinkle, mistletoe, or phytolacca (poke root). Other alternative skin preparations include a selenium solution made from aloe gels, selenium, and tincture of silica; a mixture of aloe vera and dried kelp (seaweed); and a mixture of aloe vera, tea tree oil, and tincture of St. John's wort. Alternative treatments for KS lesions on the internal organs include a mixture of warm wine and Yunnan Paiyao powder, a Chinese patent medicine made from ginseng; castor oil packs; or a three-to seven-day grape fast repeated every 120 days.

Alternative systemic treatments for AIDS-related KS include:

- Naturopathic remedies: High doses of vitamin C, zinc, echinacea, or goldenseal to improve immune function; or preparations of astragalis, osha root, or licorice to suppress the HIV virus.
- Homeopathic remedies: These include a homeopathic preparation of **cyclosporine** and another made from a dilution of killed typhoid virus.
- Ozone therapy: There are isolated reports from Europe and the United States of AIDS-related KS going into several months of remission after treatment with ozone given via rectal insufflation.

Alternative treatments aimed at improving the quality of life for KS patients include Reiki, reflexology, meditation, and chromatherapy.

Coping with cancer treatment

Studies of treatment side effects in patients with epidemic KS are complicated by the difficulty of distinguishing between side effects caused by treatment aimed at the HIV retrovirus itself and those caused by treatment for KS. Common problems related to KS treatment include damage to the bone marrow, hair loss, and nerve damage from medications.

Other treatment-related problems include weight loss due to poor appetite, and swelling of body tissues due to fluid retention. Patients may be given nutritional counseling, medications to stimulate the appetite, and radiation treatment or diuretics to reduce the level of fluid in the tissues.

Clinical trials

By 2001, there were thirteen open and active clinical trials being conducted for treatments for KS, twelve for epidemic KS and one for unspecified KS. Some of these are comparing the relative effectiveness of doxorubicin, daunorubicin, and paclitaxel. Others are studies of other agents, including interleukin-11, interleukin-12, cidofovir, and **filgrastim**. One is a study of the effects of HAART on AIDS-related KS. The National Cancer Institute (NCI) reported that clinical trials of **thalidomide** indicated that the drug has some activity against epidemic KS. Updated information about the content of and patient participation in clinical trials can be obtained

KEY TERMS

Angiogenesis—The formation of blood vessels. Some complex proteins found in shark cartilage appear to prevent angiogenesis in tumor cells in laboratory tests.

Cryotherapy—A form of treating KS lesions that involves freezing them with liquid nitrogen.

Disseminated—Widely distributed or spread. Epidemic KS almost always develops into a disseminated form, in which the disease spreads throughout the patient's body.

Highly active antiretroviral therapy (HAART)—A form of drug-combination treatment for HIV infection introduced in 1998. Most HAART regimens are combinations of three or four drugs, usually nucleoside analogs and protease inhibitors.

Iatrogenic—Caused unintentionally by medical treatment. Immunosuppressive treatment-related KS is sometimes called iatrogenic KS.

Immunosuppressive—Any form of treatment that inhibits the body's normal immune response.

Indolent—Relatively inactive or slow-spreading. Classic KS is usually an indolent disease.

Liposomes—Artificial sacs composed of fatty substances that are used to coat or encapsulate an inner core containing another drug. Some drugs used to treat epidemic KS are given in the form of liposomes.

Opportunistic infections (OI)—Diseases caused by organisms that multiply to the point of producing symptoms only when the body's immune system is impaired.

at the web site of the National Cancer Institute: http://cancertrials.nci.nih.gov.

Prevention

The only known preventive strategy for reducing one's risk for epidemic KS is abstinence from intercourse or modification of sexual habits. Homosexual or bisexual males can reduce their risk of developing KS by avoiding passive anal intercourse. Women can reduce their risk by avoiding vaginal or anal intercourse with bisexual males.

Kidney transplant patients who are at increased risk of developing KS as a result of taking prednisone or other immunosuppressive drugs should consult their primary physician about possible changes in dosage.

Special concerns

The two special concerns most likely to arise with epidemic KS are social isolation due to the disfigurement caused by KS lesions on the patient's face, and spiritual or psychological concerns related to the tumor's connection to AIDS and homosexuality. There are many local and regional support groups for cancer patients that can help patients deal with concerns about appearance. With regard to religious/spiritual issues, most major Christian and Jewish bodies in the United States and Canada have task forces or working groups dealing with AIDS-related concerns. The National Catholic AIDS Network (NCAN) maintains an information database and web site (http://www.ncan.org) and accepts call-in referrals at (707) 874-3031.

Ki67

Definition

Ki67 is a molecule that can be easily detected in growing cells in order to gain an understanding of the rate at which the cells within a tumor are growing.

Purpose

Detection of Ki67 is carried out on biopsies, samples of tumor tissue. The goal of this assay is to evaluate an important characteristic of the cells within the tumor, the percentage of tumor cells that are actively dividing and giving rise to more cancer cells. The number obtained through this examination is termed the S-phase, growth, or proliferative fraction. This information can play an important part in deciding the best treatment for a cancer patient.

Precautions

This test is performed on tissue or cells that have been removed during the initial surgery or diagnostic procedure used to determine the precise nature of the cancer. It usually does not require any new surgery or blood draw on the patient and, so, does not entail any additional precautions for the patient.

Description

Cancer is a group of diseases characterized by abnormal, or neoplastic, cellular growth in particular tissues. In many instances this growth is abnormal because cells are growing more rapidly than is normal. This unregulated growth is how a tumor is formed. A tumor is more or less a collection of cells that grow more rapidly than the surrounding normal tissue. Most importantly, this difference in growth rate is central to how many cancer drugs, termed cytotoxic agents, work. The ability of these drugs to eliminate cancer cells depends on their ability to kill cells that are actively proliferating, but do less damage to cells that are not actively dividing. This makes it useful to know how actively the cells in tumor are growing compared to the surrounding tissue. The measurement of Ki67 is one of the most common ways to measure the growth fraction of tumor cells. This molecule can be detected in the nucleus of only actively growing cells.

Analysis of Ki67 in tumors is accomplished by a pathologist who examines a piece of the tumor tissue using special techniques. The technique used is termed immunocytochemistry. This involves the preparation of a histologic section, a very thin piece of tumor tissue placed on a glass microscope slide. These kinds of tissue sections are used in the diagnosis of cancer. In the case of Ki67 assays, the section is incubated with antibodies that can react with the Ki67 molecule, and then treated with special reagents that cause a color to appear where antibody has bound. In this way, when the pathologist looks at the section using a microscope the fraction of growing cells, whose nuclei are stained for Ki67, can be determined for the tumor cells and compared with the normal tissue. In some instances, depending on the particular type of cancer, the pathologist might feel it more appropriate to use a different technique to assess the growth fraction for a specific tumor or leukemia.

KEY TERMS

Immunocytochemistry—Method for staining cells or tissues using antibodies so that the location of a target molecule can be determined

Nucleus—The part of the cell containing chromosomes

S phase—The part of the cell division cycle during which the genetic material, DNA, is duplicated

Preparation, Aftercare, and Risks

Because this test is performed on tissue or cells that had been removed during an initial **biopsy** or other diagnostic procedure, and because no new surgery or sample is required, no additional recommendations regarding preparation, aftercare, or risks are necessary.

Results

The proliferative or growth fraction as determined by Ki67 analysis is interpreted in view of what is normal for the tissue in which the tumor has been found or from which it originated. In the case of certain types of tissue—for example, brain—there is little cellular growth in normal tissue. In other cases, such as breast or the cells that line the colon, cellular growth is a normal part of the function of that tissue. The significance of an increased proliferative fraction is interpreted in light of the experience of the oncologist as well as the knowledge and experience of other clinicians as reported in the medical literature. The Ki67 result, often termed the "Ki67 labeling index," can be used in some cases as a prognostic indicator for some cancers. For example, for brain tumors, such as astrocytomas and glioblastomas, a high Ki67 labeling index is one factor that predicts a poor prognosis. For breast tumors, the clinician will consider the proliferative fraction in conjunction with other factors such as patient age, results of receptor assays, and

QUESTIONS TO ASK THE DOCTOR

- How far from normal is the Ki-67 labeling index of my tumor?
- To what extent is this result influencing the treatment I will receive?
- In your experience, does the proliferative fraction of my tumor predict a good response to chemotherapy?

whether or not there is evidence of spread of the disease to lymph nodes or other sites within the body. The value of Ki67 is not as firmly established for other cancers such as bladder or **pituitary tumors**.

Kidney cancer

Definition

Kidney cancer is a disease in which the cells in certain tissues of the kidney start to grow uncontrollably and form tumors. Renal cell **carcinoma**, sometimes referred to as hypernephroma, occurs in the cells lining the kidneys (epithelial cells). It is the most common type of kidney cancer. Eighty-five percent of all kidney tumors are renal cell carcinomas. **Wilms' tumor** is a rapidly developing cancer of the kidney most often found in children under four years of age.

Description

The kidneys are a pair of organs shaped like kidney beans that lie on either side of the spine just above the waist. Inside each kidney are tiny tubes (tubules) that filter and clean the blood, taking out the waste products and making urine. The urine that is made by the kidney passes through a tube called the ureter into the bladder. Urine is held in the bladder until it is discharged from the body. Renal cell carcinoma (RCC) generally develops in the lining of the tubules that filter and clean the blood. Cancer that develops in the central portion of the kidney (where the urine is collected and drained into the ureters) is known as transitional cell carcinoma of the renal pelvis. Transitional cell cancer is similar to **bladder cancer**. Wilms' tumor is the most common type of childhood kidney cancer and is distinct from kidney cancer in adults.

Demographics

Kidney cancer accounts for approximately 2–3% of all cancers. In the United States, kidney cancer is the tenth most common cancer and the incidence has increased by 43% since 1973; the death rate has increased by 16%. According to the American Cancer Society, 35,710 Americans were diagnosed with kidney cancer in 2004, and 12,480 died from the disease. RCC accounts for 90–95% of malignant neoplasms that originate from the kidney.

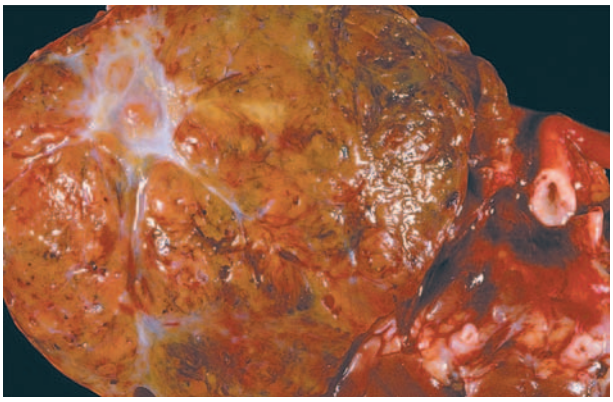
Kidney cancer occurs most often in men over the age of 40. The median age of diagnosis is 65. The male:female ratio is about 3:2.

Causes and symptoms

The causes of kidney cancer are unknown, but there are many risk factors associated with kidney cancer. The risk factors listed from greatest to smallest include:

- von Hippel-Lindau disease (>100)
- Chronic dialysis (32)
- Obesity (3.6)
- Tobacco use (2.3)
- First-degree relative with kidney cancer (1.6)
- Hypertension (1.4)
- Occupational exposure to dry cleaning solvents (1.4)
- Diuretics(non-hypertension use) (1.3)
- Trichloroethylene exposure (1.0)
- Heavy phenacetin use (1.1–6.0)
- Polycystic kidney disease (0.8–2.0)
- Cadmium exposure (1.0–3.9)
- Arsenic exposure (1.6)
- Asbestos (1.1–1.8)

The most common symptom of kidney cancer is blood in the urine (hematuria). Other symptoms include painful urination, pain in the lower back or on the sides, abdominal pain, a lump or hard mass that can be felt in the kidney area, unexplained **weight loss**, **fever**, weakness, **fatigue**, and high blood pressure.



An extracted cancerous kidney. *(Photo by Robert Riedlinger. Custom Medical Stock Photo. Reproduced by permission.)*

Diagnosis

A diagnostic examination for kidney cancer includes taking a thorough medical history and making a complete physical examination in which the doctor will probe (palpate) the abdomen for lumps. Blood tests will be ordered to check for changes in blood chemistry caused by substances released by the tumor. Laboratory tests may show abnormal levels of iron in the blood. Either a low red blood cell count (**anemia**) or a high red blood cell count (erythrocytosis) may accompany kidney cancer. Occasionally, patients will have high calcium levels.

If the doctor suspects kidney cancer, an intravenous pyelogram (also called an IVP or intravenous urography)) may be ordered. An IVP is an x-ray test in which a dye is injected into a vein in the arm. The dye travels through the body, and when it is concentrated in the urine to be discharged, it outlines the kidneys, ureters, and the urinary bladder. On an x-ray image, the dye will reveal any abnormalities of the urinary tract. The IVP may miss small kidney cancers.

Renal ultrasound is a diagnostic test in which sound waves are used to form an image of the kidneys. Ultrasound is a painless and non-invasive procedure that can be used to detect even very small kidney tumors. Imaging tests such as **computed tomography** (CT) scans and **magnetic resonance imaging** (MRI) can be used to evaluate the kidneys and the surrounding organs. These tests are used to check whether the tumor has spread outside the kidney to other organs in the abdomen. If the patient complains of **bone pain**, a special **x ray** called a bone scan may be ordered to rule out spread to the bones. A chest x ray may be taken to rule out spread to the lungs.

A kidney **biopsy** is used to positively confirm the diagnosis of kidney cancer. During this procedure, a small piece of tissue is removed from the tumor and examined under a microscope. The biopsy will give information about the type of tumor, the cells that are involved, and the aggressiveness of the tumor (tumor stage).

Staging, treatment, and prognosis

Staging

Staging guidelines for kidney cancer are as follows (2.5 cm equals approximately 1 in):

- Stage I: Primary tumor is 5 cm or less in greatest dimension and is limited to the kidney, with no lymph node involvement.
- Stage II: Primary tumor is larger than 5 cm in greatest dimension and is limited to the kidney, with no lymph node involvement.
- Stage III: Primary tumor may extend into major veins or invade adrenal glands or perinephric tissues, but not beyond Gerota's fascia. There may be **metastasis** in a single lymph node.
- Stage IV: Primary tumor invades beyond Gerota's fascia. Metastasis in more than one lymph node. Possible metastasis to distant structures in the body.

Treatment

Each person's treatment is different and depends on several factors. The location, size, and extent of the tumor have to be considered in addition to the patient's age, general health, and medical history. In addation, much has changed in the treatment and management of kidney cancer since the 1980s, including new surgical techniques, new anticancer drugs, and the development of effective treatments for advanced disease.

The primary treatment for kidney cancer that has not spread to other parts of the body, which is a Stage I, II, or III tumor, is surgical removal of the diseased kidney (nephrectomy). Because most cancers affect only one kidney, the patient can function well with the remaining one. Two types of surgical procedure are used. Radical nephrectomy removes the entire kidney and the surrounding tissue. Sometimes, the lymph nodes surrounding the kidney are also removed. Partial nephrectomy removes only part of the kidney along with the tumor. This procedure is used either when the tumor is very small or when it is not practical to remove the entire kidney. It is not practical to remove a kidney when the patient has only one kidney or when both kidneys have tumors. There is a small (5%) chance of missing some of the cancer. Nephrectomy can also be useful for Stage IV cancers, but alternative surgical procedures such as transarterial angioinfarction may be used.

The rapid development and widespread use of laparoscopic techniques has made it possible for surgeons to

remove small tumors while sparing the rest of the kidney. Most tumors removed by laparoscopy are 4 cm (1.6 in) in size or smaller. Laparoscopy also allows the surgeon to remove small tumors with cryoablation (destroying the tumor by freezing it) rather than cutting.

Radiation therapy, which consists of exposing the cancer cells to high-energy gamma rays from an external source, generally destroys cancer cells with minimal damage to the normal tissue. Side effects are nausea, fatigue, and stomach upsets. These symptoms disappear when the treatment is over. In kidney cancer, radiation therapy has been shown to alleviate pain and bleeding, especially when the cancer is inoperable. However, it has not proven to be of much use in destroying the kidney cancer cells. Therefore radiation therapy is not used very often as a treatment for cancer or as a routine adjuvant to nephrectomy. Radiotherapy, however, is used to manage metastatic kidney cancer.

Treatment of kidney cancer with anticancer drugs (**chemotherapy**) has not produced good results. However, new drugs and new combinations of drugs continue to be tested in **clinical trials**. One new drug, semaxanib (SU5416), is reported to have good results in treating patients with kidney cancer. As of 2004, however, semaxanib is still undergoing clinical trials in the United States.

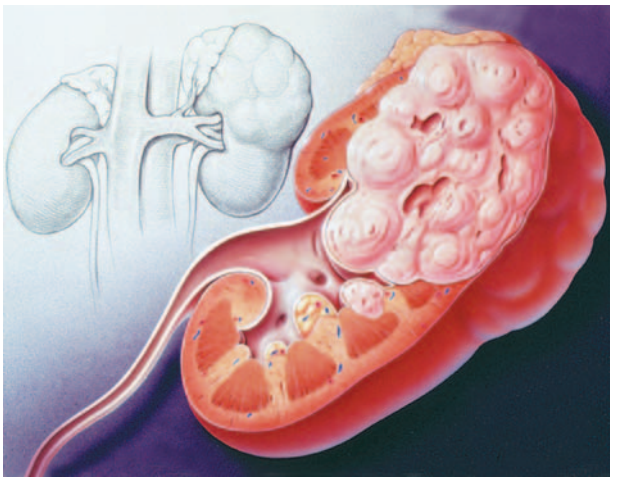
Immunologic therapy (or immunotherapy), a form of treatment in which the body's immune system is harnessed to help fight the cancer, is a new mode of therapy that is being tested for kidney cancer. Clinical trials with substances produced by the immune cells (**aldesleukin** and interferon) have shown some promise in destroying kidney cancer cells. These substances have been approved for use but they can be very toxic and produce severe side effects. The benefits derived from the treatment have to be weighed very carefully against the side effects in each case. Immunotherapy is the most promising systemic therapy for metastatic kidney cancer.

Prognosis

Because kidney cancer is often caught early and sometimes progresses slowly, the chances of a surgical cure are good. It is also one of the few cancers for which there are well-documented cases of spontaneous remission without therapy.

Alternative and complementary therapies

There are several healing philosophies, approaches, and therapies that may be used as supplemental or instead of traditional treatments. All of the items listed



Background of illustration and to left: a pair of kidneys. One kidney is normal, while the other is cancerous. The foreground of the illustration and in color: a cutaway of the cancerous kidney. *(Custom Medical Stock Photo. Reproduced by permission.)*

may have varying effectiveness in boosting the immune system and/or treating a tumor. The efficacy of each treatment also varies from person to person. None of the treatments, however, have demonstrated safety or effectiveness on a consistent basis. Patients should research such treatments for any potential dangers (laetrile, for example, has caused death due to cyanide poisoning) and notify their physician before taking them.

- 714-X
- antineoplastons
- Cancell
- cartilage (bovine and shark)
- Coenzyme Q10
- Gerson Therapy
- Gonzalez Protocol
- Hydrazine sulfate
- immuno-augementative therapy
- Laetrile
- mistletoe

Coping with cancer treatment

Side effects of treatment, as well as nutrition, emotional well-being, and other complications, are all parts of coping with cancer. There are many possible side effects for a cancer treatment that include:

- constipation
- delirium

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Bone scan—An x-ray study in which patients are given an intravenous injection of a small amount of a radioactive material that travels in the blood. When it reaches the bones, it can be detected by x ray to make a picture of their internal structure.

Chemotherapy—Treatment with anticancer drugs.

Computed tomography (CT) scan—A medical procedure in which a series of x-ray images are made and put together by a computer to form detailed pictures of areas inside the body.

Cryoablation—A technique for removing tissue by destroying it with extreme cold.

Hematuria—Blood in the urine.

Immunotherapy—Treatment of cancer by stimulating the body's immune defense system.

Intravenous pyelogram (IVP)—A procedure in which a dye is injected into a vein in the arm. The dye travels through the body and concentrates in the urine to be discharged. It outlines the kidneys, ureters, and the urinary bladder. An x-ray image is then made and any abnormalities of the urinary tract are revealed.

Magnetic resonance imaging (MRI)—A medical procedure used for diagnostic purposes in which pictures of areas inside the body can be created using a magnet linked to a computer.

Nephrectomy—A medical procedure in which the kidney is surgically removed.

Primary tumor—A cancer's origin or initial growth.

Radiation therapy—Treatment with high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Renal ultrasound—A painless and non-invasive procedure in which sound waves are bounced off the kidneys. These sound waves produce a pattern of echoes that are then used by the computer to create pictures of areas inside the kidney (sonograms).

QUESTIONS TO ASK THE DOCTOR

- What should I expect from a biopsy test?
- What type of kidney cancer do I have?
- What is the stage of the disease?
- What are the treatment choices? Which do you recommend? Why?
- What are the risks and possible side effects of each treatment?
- What are the chances that the treatment will be successful?
- What new treatments are being studied in clinical trials?
- How long will treatment last?
- Will I have to stay in the hospital?
- Will treatment affect my normal activities? If so, for how long?
- What is the treatment likely to cost?

- fatigue
- fever, chills, sweats
- nausea and vomiting
- mouth sores, dry mouth, bleeding gums
- pruritus (itching)
- **sexuality**
- sleep disorders

Anxiety, **depression**, loss, post-traumatic stress disorder, sexuality, and substance abuse are all possible emotional side-effects. Nutrition and eating before, during, and after a treatment can also be of concern. Other complications of coping with cancer include fever and pain.

Clinical trials

As of 2005, the National Cancer Institute (NCI) listed 73 clinical trials in place across the United States studying new types of radiation therapy and chemotherapy, new drugs and drug combinations, biological therapies, ways of combining various types of treatment for kidney cancer, side effect reduction, and improving quality of life. Immunostimulatory agents and gene-therapy techniques that modify tumor cells, antiangiogenesis compounds, cyclin-dependent kinase inhibitors, and differentiating agents are all being investigated as possible therapies. The reader may consult <http://ClinicalTrials.gov> and a doctor for a list of kidney cancer clinical trials.

Prevention

The exact cause of kidney cancer is not known, so it is not possible to prevent all cases. However, because a strong association between kidney cancer and tobacco has been shown, avoiding tobacco is the best way to lower one's risk of developing this cancer. Using care when working with cancer-causing agents such as asbestos and cadmium and eating a well-balanced diet may also help prevent kidney cancer.

Laparoscopy

Definition

Laparoscopy is a type of surgical procedure in which a small incision is made, usually in the navel, through which a viewing tube (laparoscope) is inserted. The viewing tube has a small camera on the eyepiece. This allows the doctor to examine the abdominal and pelvic organs on a video monitor connected to the tube. Other small incisions can be made to insert instruments to perform procedures. Laparoscopy can be done to diagnose conditions or to perform certain types of operations. It is less invasive than regular open abdominal surgery (laparotomy).

Purpose

Since the late 1980s, laparoscopy has been a popular diagnostic and treatment tool. The technique dates back to 1901, when it was reportedly first used in a gynecologic procedure performed in Russia. In fact, gynecologists were the first to use laparoscopy to diagnose and treat conditions relating to the female reproductive organs: uterus, fallopian tubes, and ovaries.

Laparoscopy was first used with cancer patients in 1973. In these first cases, the procedure was used to observe and **biopsy** the liver. Laparoscopy plays a role in the diagnosis, staging, and treatment for a variety of cancers.

As of 2001, the use of laparoscopy to completely remove cancerous growths and surrounding tissues (in place of open surgery) is controversial. The procedure is being studied to determine if it is as effective as open surgery in complex operations. Laparoscopy is also being investigated as a screening tool for **ovarian cancer**.

Laparoscopy is widely used in procedures for noncancerous conditions that in the past required open surgery, such as removal of the appendix (appendectomy) and gallbladder removal (cholecystectomy).

Diagnostic procedure

As a diagnostic procedure, laparoscopy is useful in taking biopsies of abdominal or pelvic growths, as well as lymph nodes. It allows the doctor to examine the abdominal area, including the female organs, appendix, gallbladder, stomach, and the liver.

Laparoscopy is used to determine the cause of pelvic pain or gynecological symptoms that cannot be confirmed by a physical exam or ultrasound. For example, ovarian cysts, endometriosis, ectopic pregnancy, or blocked fallopian tubes can be diagnosed using this procedure. It is an important tool when trying to determine the cause of infertility.

Operative procedure

While laparoscopic surgery to completely remove cancerous tumors, surrounding tissues, and lymph nodes is used on a limited basis, this type of operation is widely used in noncancerous conditions that once required open surgery. These conditions include:

- Tubal ligation. In this procedure, the fallopian tubes are sealed or cut to prevent subsequent pregnancies.
- Ectopic pregnancy. If a fertilized egg becomes embedded outside the uterus, usually in the fallopian tube, an operation must be performed to remove the developing embryo. This often can be done with laparoscopy.

This surgeon is performing a laparoscopic procedure on a patient. *(Photo Researchers, Inc. Reproduced by permission.)*

- Endometriosis. This is a condition in which tissue from inside the uterus is found outside the uterus in other parts of (or on organs within) the pelvic cavity. This can cause cysts to form. Endometriosis is diagnosed with laparoscopy, and in some cases the cysts and other tissue can be removed during laparoscopy.
- Hysterectomy. This procedure to remove the uterus can, in some cases, be performed using laparoscopy. The uterus is cut away with the aid of the laparoscopic instruments and then the uterus is removed through the vagina.
- Ovarian masses. Tumors or cysts in the ovaries can be removed using laparoscopy.
- Appendectomy. This surgery to remove an inflamed appendix required open surgery in the past. It is now routinely performed with laparoscopy.
- Cholecystectomy. Like appendectomy, this procedure to remove the gallbladder used to require open surgery. Now it can be performed with laparoscopy, in some cases.

In contrast to open abdominal surgery, laparoscopy usually involves less pain, less risk, less scarring, and faster recovery. Because laparoscopy is so much less invasive than traditional abdominal surgery, patients can leave the hospital sooner.

Cancer staging

Laparoscopy can be used in determining the spread of certain cancers. Sometimes it is combined with ultrasound. Although laparoscopy is a useful staging tool, its use depends on a variety of factors, which are considered for each patient. Types of cancers where laparoscopy may be used to determine the spread of the disease include:

- Liver cancer. Laparoscopy is an important tool for determining if cancer is present in the liver. When a patient has non-liver cancer, the liver is often checked to see if the cancer has spread there. Laparoscopy can identify up to 90% of malignant lesions that have spread to that organ from a cancer located elsewhere in the body. While computed tomography (CT) can find cancerous lesions that are 0.4 in (10 mm) in size, laparoscopy is capable of locating lesions that are as small as 0.04 in (1 millimeter).
- Pancreatic cancer. Laparoscopy has been used to evaluate pancreatic cancer for years. In fact, the first reported use of laparoscopy in the United States was in a case involving pancreatic cancer.
- Esophageal and stomach cancers. Laparoscopy has been found to be more effective than **magnetic resonance imaging** (MRI) or computed tomography (CT) in diagnosing the spread of cancer from these organs.
- **Hodgkin's disease**. Some patients with Hodgkin's disease have surgical procedures to evaluate lymph nodes for cancer. Laparoscopy is sometimes selected over laparotomy for this procedure. In addition, the spleen may be removed in patients with Hodgkin's disease. Laparoscopy is the standard surgical technique for this procedure, which is called a splenectomy.
- **Prostate cancer**. Patients with prostate cancer may have the nearby lymph nodes examined. Laparoscopy is an important tool in this procedure.

Cancer treatment

Laparoscopy is sometimes used as part of a palliative cancer treatment. This type of treatment is not a cure, but can often lessen the symptoms. An example is the feeding tube, which cancer patients may have if they are unable to take in food by mouth. The feeding tube provides nutrition directly into the stomach. Inserting the tube with a laparoscopy saves the patient the ordeal of open surgery.

Precautions

As with any surgery, patients should notify their physicians of any medications they are taking (prescription, over-the-counter, or herbal) and of any allergies. Precautions vary due to the several different purposes

for laparoscopy. Patients should expect to rest for several days after the procedure, and should set up a comfortable environment in their homes (with items such as pain medication, heating pads, feminine products, comfortable clothing, and food readily accessible) prior to surgery.

Description

Laparoscopy is a surgical procedure that is done in the hospital under anesthesia. For diagnosis and biopsy, local anesthesia is sometimes used. In operative procedures, such as abdominal surgery, general anesthesia is required. Before starting the procedure, a catheter is inserted through the urethra to empty the bladder, and the skin of the abdomen is cleaned.

After the patient is anesthetized, a hollow needle is inserted into the abdomen in or near the navel, and carbon dioxide gas is pumped through the needle to expand the abdomen. This allows the surgeon a better view of the internal organs. The laparoscope is then inserted through this incision to look at the internal organs. The image from the camera attached to the end of the laparoscope is seen on a video monitor.

Sometimes, additional small incisions are made to insert other instruments that are used to lift the tubes and ovaries for examination or to perform surgical procedures.

Preparation

Patients should not eat or drink after midnight on the night before the procedure.

Aftercare

After the operation, nurses will check the vital signs of patients who had general anesthesia. If there are no complications, the patient may leave the hospital within four to eight hours. (Traditional abdominal surgery requires a hospital stay of several days).

There may be some slight pain or throbbing at the incision sites in the first day or so after the procedure. The gas that is used to expand the abdomen may cause discomfort under the ribs or in the shoulder for a few days. Depending on the reason for the laparoscopy in gynecological procedures, some women may experience some vaginal bleeding. Many patients can return to work within a week of surgery and most are back to work within two weeks.

Risks

Laparoscopy is a relatively safe procedure, especially if the physician is experienced in the technique. The risk of complication is approximately 1%.

KEY TERMS

Biopsy—Microscopic evaluation of a tissue sample. The tissue is closely examined for the presence of abnormal cells.

Cancer staging—Determining the course and spread of cancer.

Cyst—An abnormal lump or swelling that is filled with fluid or other material.

Palliative treatment—A type of treatment that does not provide a cure, but eases the symptoms.

Tumor—A growth of tissue, benign or malignant, often referred to as a mass.

The procedure carries a slight risk of puncturing a blood vessel or organ, which could cause blood to seep into the abdominal cavity. Puncturing the intestines could allow intestinal contents to seep into the cavity. These are serious complications and major surgery may be required to correct the problem. For operative procedures, there is the possibility that it may become apparent that open surgery is required. Serious complications occur at a rate of only 0.2%.

Rare complications include:

- Hemorrhage
- Inflammation of the abdominal cavity lining
- Abscess
- Problems related to general anesthesia

Laparoscopy is generally not used in patients with certain heart or lung conditions, or in those who have some intestinal disorders, such as bowel obstruction.

Normal results

In diagnostic procedures, normal results would indicate no abnormalities or disease of the organs or lymph nodes that were examined.

Abnormal results

A diagnostic laparoscopy may reveal cancerous or benign masses or lesions. Abnormal findings include tumors or cysts, infections (such as pelvic inflammatory disease), cirrhosis, endometriosis, fibroid tumors, or an accumulation of fluid in the cavity. If a doctor is checking for the spread of cancer, the presence of malignant lesions in areas other than the original site of malignancy is an abnormal finding.

QUESTIONS TO ASK THE DOCTOR

- What is your complication rate?
- What is the purpose of this procedure?
- How often do you do laparoscopies?
- What type of anesthesia will be used?
- Will a biopsy be taken during the laparoscopy if anything abnormal is seen?
- If more surgery is needed, can it be done with a laparoscope?
- What area will be examined with the laparoscope?
- What are the risks?
- How long is the recovery time?

Laryngeal cancer

Definition

Laryngeal cancer is cancer of the larynx or voice box.

Description

The larynx is located where the throat divides into the esophagus and the trachea. The esophagus is the tube that takes food to the stomach. The trachea, or windpipe, takes air to the lungs. The area where the larynx is located is sometimes called the Adam's apple.

The larynx has two main functions. It contains the vocal cords, cartilage, and small muscles that make up the voice box. When a person speaks, small muscles tighten the vocal cords, narrowing the distance between them. As air is exhaled past the tightened vocal cords, it creates sounds that are formed into speech by the mouth, lips, and tongue.

The second function of the larynx is to allow air to enter the trachea and to keep food, saliva, and foreign material from entering the lungs. A flap of tissue called the epiglottis covers the trachea each time a person swallows. This blocks foreign material from entering the lungs. When not swallowing, the epiglottis retracts, and air flows into the trachea. During treatment for cancer of the larynx, both of these functions may be lost.

Cancers of the larynx develop slowly. About 95% of these cancers develop from thin, flat cells similar to skin cells called squamous epithelial cells. These cells line the larynx. Gradually, the squamous epithelial cells begin to change and are replaced with abnormal cells. These abnormal cells are not cancerous but are pre-malignant cells that have the potential to develop into cancer. This condition is called dysplasia. Most people with dysplasia never develop cancer. The condition simply goes away without any treatment, especially if the person with dysplasia stops smoking or drinking alcohol.

The larynx is made up of three parts, the glottis, the supraglottis, and the subglottis. Cancer can start in any of these regions. Treatment and survival rates depend on which parts of the larynx are affected and whether the cancer has spread to neighboring areas of the neck or distant parts of the body.

The glottis is the middle part of the larynx. It contains the vocal cords. Cancers that develop on the vocal cords are often diagnosed very early because even small vocal cord tumors cause hoarseness. In addition, the vocal cords have no connection to the lymphatic system. This means that cancers on the vocal cord do not spread easily. When confined to the vocal cords without any involvement of other parts of the larynx, the cure rate for this cancer is 75% to 95%.

The supraglottis is the area above the vocal cords. It contains the epiglottis, which protects the trachea from foreign materials. Cancers that develop in this

region are usually not found as early as cancers of the glottis because the symptoms are less distinct. The supraglottis region has many connections to the lymphatic system, so cancers in this region tend to spread easily to the lymph nodes and may spread to other parts of the body (lymph nodes are small bean-shaped structures that are found throughout the body; they produce and store infection-fighting cells). In 25% to 50% of people with cancer in the supraglottal region, the cancer has already spread to the lymph nodes by the time they are diagnosed. Because of this, survival rates are lower than for cancers that involve only the glottis.

The subglottis is the region below the vocal cords. Cancer starting in the subglottis region is rare. When it does, it is usually detected only after it has spread to the vocal cords, where it causes obvious symptoms such as hoarseness. Because the cancer has already begun to spread by the time it is detected, survival rates are generally lower than for cancers in other parts of the larynx.

Demographics

About 12,000 new cases of cancer of the larynx develop in the United States each year. Each year, about 3,900 die of the disease. Laryngeal cancer is between four and five times more common in men than in women. Almost all men who develop laryngeal cancer are over age 55. Laryngeal cancer is about 50% more common among African-American men than among other Americans.

It is thought that older men are more likely to develop laryngeal cancer than women because the two main risk factors for acquiring the disease are lifetime habits of smoking and alcohol abuse. More men smoke and drink more than women, and more African-American men are heavy smokers than other men in the United States. However, as smoking becomes more prevalent among women, it seems likely that more cases of laryngeal cancer in females will be seen.

Causes and symptoms

Laryngeal cancer develops when the normal cells lining the larynx are replaced with abnormal cells (dysplasia) that become malignant and reproduce to form tumors. The development of dysplasia is strongly linked to life-long habits of smoking and heavy use of alcohol. The more a person smokes, the greater the risk of developing laryngeal cancer. It is unusual for someone who does not smoke or drink to develop cancer of the larynx. Occasionally, however, people who inhale asbestos particles, wood dust, paint or industrial chemical fumes over a long period of time develop the disease.

The symptoms of laryngeal cancer depend on the location of the tumor. Tumors on the vocal cords are rarely painful, but cause hoarseness. Anyone who is continually hoarse for more than two weeks or who has a cough that does not go away should be checked by a doctor.

Tumors in the supraglottal region above the vocal cords often cause more, but less distinct symptoms. These include:

- persistent sore throat
- pain when swallowing
- difficulty swallowing or frequent choking on food
- bad breath
- lumps in the neck
- persistent ear pain (called referred pain; the source of the pain is not the ear)
- change in voice quality

Tumors that begin below the vocal cords are rare, but may cause noisy or difficult breathing. All the symptoms above can also be caused other cancers as well as by less serious illnesses. However, if these symptoms persist, it is important to see a doctor and find their cause, because the earlier cancer treatment begins, the more successful it is.

Diagnosis

On the first visit to a doctor for symptoms that suggest laryngeal cancer, the doctor first takes a complete medical history, including family history of cancer and lifestyle information about smoking and alcohol use. The doctor also does a physical examination, paying special attention to the neck region for lumps, tenderness, or swelling.

The next step is examination by an otolaryngologist, or ear, nose, and throat (ENT) specialist. This doctor also performs a physical examination, but in addition will also want to look inside the throat at the larynx. Initially, the doctor may spray a local anesthetic on the back of the throat to prevent gagging, then use a long-handled mirror to look at the larynx and vocal cords. This examination is done in the doctor's office. It may cause gagging but is usually painless.

A more extensive examination involves a **laryngoscopy**. In a laryngoscopy, a lighted fiberoptic tube called a laryngoscope that contains a tiny camera is inserted through the patient's nose and mouth and snaked down the throat so that the doctor can see the larynx and surrounding area. This procedure can be done with a sedative and local anesthetic in a doctor's office. More often, the procedure is done in an

outpatient surgery clinic or hospital under general anesthesia. This allows the doctor to use tiny clips on the end of the laryngoscope to take biopsies (tissue samples) of any abnormal-looking areas.

Laryngoscopies are normally painless and take about one hour. Some people find their throat feels scratchy after the procedure. Since laryngoscopies are done under sedation, patients should not drive immediately after the procedure, and should have someone available to take them home. Laryngoscopy is a standard procedure that is covered by insurance.

The locations of the samples taken during the laryngoscopy are recorded, and the samples are then sent to the laboratory where they are examined under the microscope by a pathologist who specializes in diagnosing diseases through cell samples and laboratory tests. It may take several days to get the results. Based on the findings of the pathologist, cancer can be diagnosed and staged.

Once cancer is diagnosed, other tests will probably be done to help determine the exact size and location of the tumors. This information is helpful in determining which treatments are most appropriate. These tests may include:

- Endoscopy. Similar to a laryngoscopy, this test is done when it appears that cancer may have spread to other areas, such as the esophagus or trachea.
- **Computed tomography** (CT or CAT) scan. Using x-ray images taken from several angles and computer modeling, CT scans allow parts of the body to be seen as a cross section. This helps locate and size the tumors, and provides information on whether they can be surgically removed.
- Magnetic resonance imaging (MRI). MRI uses magnets and radio waves to create more detailed cross-sectional scans than computed tomography. This detailed information is needed if surgery on the larynx area is planned.
- Barium swallow. Barium is a substance that, unlike soft tissue, shows up on x rays. Swallowed barium coats the throat and allows x-ray pictures to be made of the tissues lining the throat.
- Chest **x ray**. Done to determine if cancer has spread to the lungs. Since most people with laryngeal cancer are smokers, the risk of also having lung cancer or emphysema is high.
- Fine needle aspiration (FNA) **biopsy**. If any lumps on the neck are found, a thin needle is inserted into the lump, and some cells are removed for analysis by the pathologist.
- Additional blood and urine tests. These tests do not diagnose cancer, but help to determine the patient's general health and provide information to determine which cancer treatments are most appropriate.

Treatment team

An otolaryngologist and an oncologist (cancer specialist) generally lead the treatment team. They are supported by radiologists to interpret CT and MRI scans, a head and neck surgeon, and nurses with special training in assisting cancer patients.

A speech pathologist is often involved in treatment, both before surgery to discuss various options for communication if the larynx is removed, and after surgery to teach alternate forms of voice communication. A social worker, psychologist, or family counselor may help both the patient and the family meet the changes and challenges that living with laryngeal cancer brings.

At any point in the process, the patient may want to get a second opinion from another doctor in the same specialty. This is a common practice and does not indicate a lack of faith in the original doctor, but simply a desire for more information. Some insurance companies require a second opinion before surgery is done.

Clinical staging, treatments, and prognosis

Staging

Once cancer of the larynx is found, more tests will be done to find out if cancer cells have spread to other parts of the body. This is called staging. A doctor needs to know the stage of the disease to plan treatment. In cancer of the larynx, the definitions of the early stages depend on where the cancer started.

STAGE I. The cancer is only in the area where it started and has not spread to lymph nodes in the area or to other parts of the body. The exact definition of stage I depends on where the cancer started, as follows:

- Supraglottis: The cancer is only in one area of the supraglottis and the vocal cords can move normally.
- Glottis: The cancer is only in the vocal cords and the vocal cords can move normally.
- Subglottis: The cancer has not spread outside of the subglottis.

STAGE II. The cancer is only in the larynx and has not spread to lymph nodes in the area or to other parts of the body. The exact definition of stage II depends on where the cancer started, as follows:

- Supraglottis: The cancer is in more than one area of the supraglottis, but the vocal cords can move normally.

- Glottis: The cancer has spread to the supraglottis or the subglottis or both. The vocal cords may or may not be able to move normally.
- Subglottis: The cancer has spread to the vocal cords, which may or may not be able to move normally.

STAGE III. Either of the following may be true:

- The cancer has not spread outside of the larynx, but the vocal cords cannot move normally, or the cancer has spread to tissues next to the larynx.
- The cancer has spread to one lymph node on the same side of the neck as the cancer, and the lymph node measures no more than 3 centimeters (just over 1 inch).

STAGE IV. Any of the following may be true:

- The cancer has spread to tissues around the larynx, such as the pharynx or the tissues in the neck. The lymph nodes in the area may or may not contain cancer.
- The cancer has spread to more than one lymph node on the same side of the neck as the cancer, to lymph nodes on one or both sides of the neck, or to any lymph node that measures more than 6 centimeters (over 2 inches).
- The cancer has spread to other parts of the body.

RECURRENT Recurrent disease means that the cancer has come back (recurred) after it has been treated. It may come back in the larynx or in another part of the body.

Treatment

Treatment is based on the stage of the cancer as well as its location and the health of the individual. Generally, there are three types of treatments for cancer of the larynx. These are surgery, radiation, and **chemotherapy**. They can be used alone or in combination based in the stage of the caner. Getting a second opinion after the cancer has been staged can be very helpful in sorting out treatment options and should always be considered.

SURGERY The goal of surgery is to cut out the tissue that contains malignant cells. There are several common surgeries to treat laryngeal cancer.

Stage III and stage IV cancers are usually treated with total **laryngectomy**. This is an operation to remove the entire larynx. Sometimes other tissues around the larynx are also removed. Total laryngectomy removes the vocal cords. Alternate methods of voice communication must be learned with the help of a speech pathologist.

Smaller tumors are sometimes treated by partial laryngectomy. The goal is to remove the cancer but save as much of the larynx (and corresponding speech capability) as possible. Very small tumors or cancer in situ are sometimes successfully treated with laser excision surgery. In this type of surgery, a narrowly targeted beam of light from a laser is used to remove the cancer.

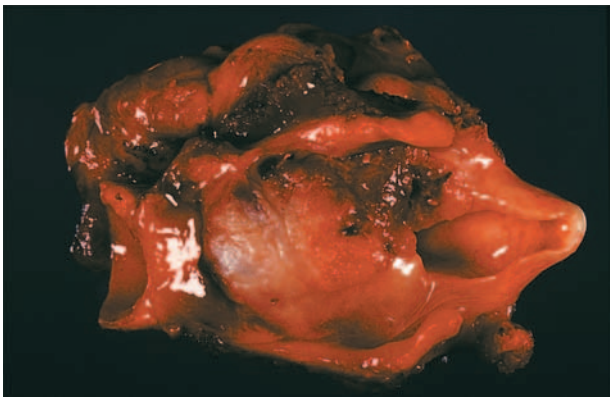
Advanced cancer (Stages III and IV) that has spread to the lymph nodes often requires an operation called a neck dissection. The goal of a neck dissection is to remove the lymph nodes and prevent the cancer from spreading. There are several forms of neck dissection. A **radical neck dissection** is the operation that removes the most tissue.

Several other operations are sometimes performed because of laryngeal cancer. A tracheotomy is a surgical procedure in which an artificial opening is made in the trachea (windpipe) to allow air into the lungs. This operation is necessary if the larynx is totally removed. A gastrectomy tube is a feeding tube placed through skin and directly into the stomach. It is used to give nutrition to people who cannot swallow or whose esophagus is blocked by a tumor. People who have a total laryngectomy usually do not need a gastrectomy tube if their esophagus remains intact.

RADIATION **Radiation therapy** uses high-energy rays, such as x rays or gamma rays, to kill cancer cells. The advantage of radiation therapy is that it preserves the larynx and the ability to speak. The disadvantage is that it may not kill all the cancer cells. Radiation therapy can be used alone in early stage cancers or in combination with surgery. Sometimes it is tried first with the plan that if it fails to cure the cancer, surgery still remains an option. Often, radiation therapy is used after surgery for advanced cancers to kill any cells the surgeon might not have removed.

There are two types of radiation therapy. External beam radiation therapy focuses rays from outside the body on the cancerous tissue. This is the most common type of radiation therapy used to treat laryngeal cancer. With internal radiation therapy, also called brachytherapy, radioactive materials are placed directly on the cancerous tissue. This type of radiation therapy is a much less common treatment for laryngeal cancer.

External radiation therapy is given in doses called fractions. A common treatment involves giving fractions five days a week for seven weeks. **Clinical trials** are underway to determine the benefits of accelerating the delivery of fractions (accelerated fractionation) or dividing fractions into smaller doses given more than once a day (hyperfractionation). Side effects of radiation therapy include dry mouth, sore throat, hoarseness, skin problems, trouble swallowing, and diminished ability to taste.



A pathology photograph of an extracted tumor found on the larynx. *(Photograph by William Gage. Custom Medical Stock Photo. Reproduced by permission.)*

CHEMOTHERAPY Chemotherapy is the use of drugs to kill cancer cells. Unlike radiation therapy, which is targeted to a specific tissue, chemotherapy drugs are either taken by mouth or intravenously (through a vein) and circulate throughout the whole body. They are used mainly to treat advanced laryngeal cancer that is inoperable or that has metastasized to a distant site. Chemotherapy is often used after surgery or in combination with radiation therapy. Clinical trials are underway to determine the best combination of treatments for advanced cancer.

The two most common chemotherapy drugs used to treat laryngeal cancer are **cisplatin** and 5-fluorouracil (5-FU or fluorouracil). There are many side effects associated with chemotherapy drugs, including **nausea and vomiting**, loss of appetite (anorexia), hair loss (alopecia), **diarrhea**, and mouth sores. Chemotherapy can also damage the blood-producing cells of the bone marrow, which can result in low blood cell counts, increased chance of infection, and abnormal bleeding or bruising.

Prognosis

Cure rates and survival rates can predict group outcomes, but can never precisely predict the outcome for a single individual. However, the earlier laryngeal cancer is discovered and treated, the more likely it will be cured.

Cancers found in stage 0 and stage 1 have a 75% to 95% cure rate depending on the site. Late stage cancers that have metastasized have a very poor survival rate, with intermediate stages falling somewhere in between. People who have had laryngeal cancer are at greatest risk for recurrence (having cancer come back), especially in the head and neck, during the first two to three years after treatment. Check-ups during the first year are needed every other month, and four times a year during the second year. It is rare for laryngeal cancer to recur after five years of being cancer-free.

Alternative and complementary therapies

Alternative and complementary therapies range from herbal remedies, vitamin supplements, and special diets to spiritual practices, acupuncture, massage, and similar treatments. When these therapies are used in addition to conventional medicine, they are called complementary therapies. When they are used instead of conventional medicine, they are called alternative therapies.

Complementary or alternative therapies are widely used by people with cancer. One large study published in the *Journal of Clinical Oncology* in July 2000, found that 83% of all cancer patients studied used some form of complementary or alternative medicine as part of their cancer treatment. No specific alternative therapies have been directed toward laryngeal cancer. However, good nutrition and activities that reduce stress and promote a positive view of life have no unwanted side effects and appear to be beneficial in boosting the immune system in fighting cancer.

Unlike traditional pharmaceuticals, complementary and alternative therapies are not evaluated by the United States Food and Drug Administration (FDA) for either safety or effectiveness. These therapies may have interactions with traditional pharmaceuticals. Patients should be wary of "miracle cures" and notify their doctors if they are using herbal remedies, vitamin supplements or other unprescribed treatments. Alternative and experimental treatments normally are not covered by insurance.

Coping with cancer treatment

Cancer treatment, even when successful, has many unwanted side effects. In laryngeal cancer, the biggest side effects are the loss of speech due to total laryngectomy and the need to breathe through a hole in the neck called a stoma. Several alternative methods of sound production, both mechanical and learned, are available, and should be discussed with a speech pathologist. Support groups also exist for people who have had their larynx removed. Coping with speech loss and care of the stoma is discussed more extensively in the laryngectomy entry.

Chemotherapy brings with it a host of unwanted side effects, many of which disappear after the chemotherapy stops. For example, hair will re-grow, and until it does, a wig can be used. Medications are available to

treat nausea and vomiting. Side effects such as dry skin are treated symptomatically.

Clinical trials

Clinical trials are government-regulated studies of new treatments and techniques that may prove beneficial in diagnosing or treating a disease. Participation is always voluntary and at no cost to the participant. Clinical trials are conducted in three phases. Phase 1 tests the safety of the treatment and looks for harmful side effects. Phase 2 tests the effectiveness of the treatment. Phase 3 compares the treatment to other treatments available for the same condition.

The selection of clinical trials underway changes frequently. Clinical trials for laryngeal cancer currently focus treating advanced cancers by combining radiation and surgical therapy, radiation and chemotherapy, and different combinations of chemotherapy drugs. Other studies are examining the most effective timing and duration of radiation therapy.

Current information on what clinical trials are available and where they are being held is available by entering the search term "laryngeal cancer" at the following web sites:

- National Cancer Institute. <http://cancer-trials.nci.nih.gov> or (800) 4-CANCER.
- National Institutes of Health Clinical Trials. <http://clinicaltrials.gov>
- Center Watch: A Clinical Trials Listing. <http://www.centerwatch.com>

Prevention

By far, the most effective way to prevent laryngeal cancer is not to smoke. Smokers who quit smoking also significantly decrease their risk of developing the disease. Other ways to prevent laryngeal cancer include limiting the use of alcohol, eating a well-balanced diet, seeking treatment for prolonged heartburn, and avoiding inhaling asbestos and chemical fumes.

Special concerns

Being diagnosed with cancer is a traumatic event. Not only is one's health affected, one's whole life suddenly revolves around trips to the doctor for cancer treatment and adjusting to the side effects of these treatments. This is stressful for both the cancer patient and his or her family members. It is not unusual for family members to feel resentful of the changes that occur in the family, and then feel guilty about feeling resentful.

KEY TERMS

Dysplasia—The abnormal change in size, shape or organization of adult cells.

Lymph—Clear, slightly yellow fluid carried by a network of thin tubes to every part of the body. Cells that fight infection are carried in the lymph.

Lymphatic system—Primary defense against infection in the body. The lymphatic system consists of tissues, organs, and channels (similar to veins) that produce, store, and transport lymph and white blood cells to fight infection.

Lymph nodes—Small, bean-shaped collections of tissue found in a lymph vessel. They produce cells and proteins that fight infection, and also filter lymph. Nodes are sometimes called lymph glands.

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Metastasize—Spread of cells from the original site of the cancer to other parts of the body where secondary tumors are formed.

The loss of voice because of laryngeal surgery may be the most traumatic effect of laryngeal cancer. Losing the ability to communicate easily with others can be isolating. Support groups and psychological counseling is helpful for both the cancer patient and family members. Many national organizations that support cancer education can provide information on in-person or on-line support and education groups.

QUESTIONS TO ASK THE DOCTOR

- What stage is my cancer, and what exactly does that mean?
- What are possible treatments for my cancer?
- How long will my treatment last?
- What are some of the changes in my activities that will occur because of my treatment?
- What is daily life like after a laryngectomy?
- How will I speak?
- I've heard about clinical trials using radiation and drugs to treat cancer of the larynx. Where can I find out more about these trials?
- What changes in my lifestyle can I make to help improve my chances of beating this cancer?
- How often will I have to have check-ups?
- What is the likelihood that I will survive this cancer?
- Can you suggest any support groups that would be helpful to me or my family?

Laryngeal nerve palsy

Description

Laryngeal nerve palsy is damage to the recurrent laryngeal nerve (or less commonly the vagus nerve) that results in paralysis of the larynx (voice box). Paralysis may be temporary or permanent. Damage to the recurrent laryngeal nerve is most likely to occur during surgery on the thyroid gland to treat cancer of the thyroid. Laryngeal nerve palsy is also called recurrent laryngeal nerve damage.

The vagus nerve is one of 12 cranial nerves that connect the brain to other organs in the body. It runs from the brain to the large intestine. In the neck, the vagus nerve gives off a paired branch nerve called the recurrent laryngeal nerve. The recurrent laryngeal nerves lie in grooves along either side of the trachea (windpipe) between the trachea and the thyroid gland.

The recurrent laryngeal nerve controls movement of the larynx. The larynx is located where the throat divides into the esophagus, a tube that takes food to the stomach, and the trachea (windpipe) that takes air to the lungs. The larynx contains the apparatus for voice production: the vocal cords, and the muscles and ligaments that move the vocal cords. It also controls the flow of air into the lungs. When the recurrent laryngeal nerve is damaged, the movements of the larynx are reduced. This causes voice weakness, hoarseness, or sometimes the complete loss of voice. The changes may be temporary or permanent. In rare life-threatening cases of damage, the larynx is paralyzed to the extent that air cannot enter the lungs.

Causes

Laryngeal nerve palsy is an uncommon side effect of surgery to remove the thyroid gland (thyroidectomy). It occurs in 1% to 2% of operations for total thyroidectomy to treat cancer, and less often when only part of the thyroid is removed. Damage can occur to either one or both branches of the nerve, and it can be temporary or permanent. Most people experience only transient laryngeal nerve palsy and recover their normal voice within a few weeks.

Laryngeal nerve palsy can also occur from causes unrelated to thyroid surgery. These include damage to either the vagus nerve or the laryngeal nerve, due to tumors in the neck and chest or diseases in the chest such as aortic aneurysms. Both tumors and aneurysms press on the nerve, and the pressure causes damage.

Treatments

Once the recurrent laryngeal nerve is damaged, there is no specific treatment to heal it. With time, most cases of recurrent laryngeal palsy improve on their own. In the event of severe damage, the larynx may be so paralyzed that air cannot flow past it into the lungs. When

KEY TERMS

Aortic aneurysm—The ballooning of a weak spot in the aorta (the major heart artery).

Thyroid gland—A gland that produces hormones that regulate the body's metabolism. It is shaped like a flying bat with its wings outstretched and lies over the windpipe in the front of the neck.

this happens, an emergency tracheotomy must be performed to save the patient's life. A tracheotomy is a surgical procedure to make an artificial opening in the trachea (windpipe) to allow air to bypass the larynx and enter the lungs. If paralysis of the larynx is temporary, the tracheotomy hole can be surgically closed when it is no longer needed.

Some normal variation in the location of the recurrent laryngeal nerve occurs among individuals. Occasionally the nerves are not located exactly where the surgeon expects to find them. Choosing a board certified head and neck surgeon who has had a lot of experience with thyroid operations is the best way to prevent laryngeal nerve palsy.

Alternative and complementary therapies

There are no alternative or complementary therapies to heal laryngeal nerve palsy. The passage of time alone restores speech to most people. Some alternatives for artificial speech exist for people whose loss of speech is permanent.

Laryngectomy

Definition

Laryngectomy is the partial or complete surgical removal of the larynx, usually as a treatment for cancer of the larynx.

Purpose

Normally a laryngectomy is performed to remove tumors or cancerous tissue. In rare cases, it may be done when the larynx is badly damaged by gunshot, automobile injuries, or similar violent accidents. Laryngectomies can be total or partial. Total laryngectomies are done when cancer is advanced. The entire larynx is removed. Often if the cancer has spread, other surrounding structures in the neck, such as lymph nodes, are removed at the same time. Partial laryngectomies are done when cancer is limited to one spot. Only the area with the tumor is removed. Laryngectomies may also be performed when other cancer treatment options, such as radiation therapy or **chemotherapy**, fail.

Precautions

Laryngectomy is done only after cancer of the larynx has been diagnosed by a series of tests that allow the otolaryngologist (a specialist often called an ear, nose, and throat doctor) to look into the throat and take tissue samples (biopsies) to confirm and stage the cancer. People need to be in good general health to undergo a laryngectomy, and will have standard pre-operative blood work and tests to make sure they are able to safely withstand the operation.

Description

The larynx is located slightly below the point where the throat divides into the esophagus, which takes food to the stomach, and the trachea (windpipe), which takes air to the lungs. Because of its location, the larynx plays a critical role in normal breathing, swallowing, and speaking. Within the larynx, vocal folds (often called vocal cords) vibrate as air is exhaled past, thus creating speech. The epiglottis protects the trachea, making sure that only air gets into the lungs. When the larynx is removed, these functions are lost.

Once the larynx is removed, air can no longer flow into the lungs. During this operation, the surgeon removes the larynx through an incision in the neck. The surgeon also performs a tracheotomy. He makes an artificial opening called a stoma in the front of the neck. The upper portion of the trachea is brought to the stoma and secured, making a permanent alternate way for air to get

to the lungs. The connection between the throat and the esophagus is not normally affected, so after healing, the person whose larynx has been removed (called a laryngectomee) can eat normally. However, normal speech is no longer possible. Several alternate means of vocal communication can be learned with the help of a speech pathologist.

Preparation

As with any surgical procedure, the patient will be required to sign a consent form after the procedure is thoroughly explained. Many patients prefer a second opinion, and some insurers require it. Blood and urine studies, along with chest **x ray** and EKG may be ordered as the doctor deems necessary. The patient also has a pre-operative meeting with an anesthesiologist. If a complete laryngectomy is planned, it may be helpful to meet with a speech pathologist and/or an established laryngectomee for discussion of post-operative expectations and support.

Aftercare

A person undergoing a laryngectomy spends several days in intensive care (ICU) and receives intravenous (IV) fluids and medication. As with any major surgery, the blood pressure, pulse, and respirations are monitored regularly. The patient is encouraged to turn, cough, and deep breathe to help mobilize secretions in the lungs. One or more drains are usually inserted in the neck to remove any fluids that collect. These drains are removed after several days.

It takes two to three weeks for the tissues of the throat to heal. During this time, the laryngectomee cannot swallow food and must receive nutrition through a tube inserted through the nose and down the throat into the stomach. During this time, even people with partial laryngectomies are unable to speak.

When air is drawn in normally through the nose, it is warmed and moistened before it reaches the lungs. When air is drawn in through the stoma, it does not have the opportunity to be warmed and humidified. In order to keep the stoma from drying out and becoming crusty, laryngectomees are encouraged to breathe artificially humidified air. The stoma is usually covered with a light cloth to keep it clean and to keep unwanted particles from accidentally entering the lungs. Care of the stoma is extremely important, since it is the person's only way to get air to the lungs. After a laryngectomy, a healthcare professional will teach the laryngectomee and his or her caregivers how to care for the stoma.

Immediately after a laryngectomy, an alternate method of communication such as writing notes, gesturing, or pointing must be used. A partial laryngectomy patient will gradually regain some speech several weeks after the operation, but the voice may be hoarse, weak, and strained. A speech pathologist will work with a complete laryngectomee to establish new ways of communicating.

KEY TERMS

Larynx—Also known as the voice box, the larynx is composed of cartilage that contains the apparatus for voice production. This includes the vocal cords and the muscles and ligaments that move the cords.

Lymph nodes—Accumulations of tissue along a lymph channel, which produce cells called lymphocytes that fight infection.

Tracheostomy—A surgical procedure in which an artificial opening is made in the trachea (windpipe) to allow air into the lungs.

There are three main methods of vocalizing after a total laryngectomy. In esophageal speech the laryngectomee learns how to "swallow" air down into the esophagus and creates sounds by releasing the air. This method requires quite a bit of coordination and learning, and produces short bursts (7 or 8 syllables) of low-volume sound.

Tracheoesophageal speech diverts air through a hole in the trachea made by the surgeon. The air then passes through an implanted artificial voice prosthesis (a small tube that makes a sound when air goes through it). Recent advances have been made in implanting voice prostheses that produce good voice quality.

The third method of artificial sound communication involves using a hand-held electronic device that translates vibrations into sounds. There are several different styles of these devices, but all require the use of at least one hand to hold the device to the throat. The choice of which method to use depends on many things including the age and health of the laryngectomee, and whether other parts of the mouth, such as the tongue, have also been removed.

Many patients resume daily activities after surgery. Special precautions must be taken during showering or shaving. Special instruction and equipment is also required for those who wish to swim or water ski, as it is dangerous for water to enter the windpipe and lungs through the stoma.

Regular follow-up visits are important following treatment for cancer of the larynx because there is a higher-than-average risk of developing a new cancer in the mouth, throat, or other regions of the head or neck. Many self-help and support groups are available to help patients meet others who face similar problems.

QUESTIONS TO ASK THE DOCTOR

- Is laryngectomy my only viable treatment option?
- What specific lifestyle changes will I have to make?
- Is there a support group in the area that can assist me post-surgery?
- How long will it be until I can verbally communicate? What are my options?
- How sizable is the risk of recurring cancer?

Risks

Laryngectomy is often successful in curing early stage cancers. However it does cause lifestyle changes. Laryngectomees must learn new ways of speaking. They must be continually concerned about the care of their stoma. Serious infections can occur if water or other foreign material enters the lungs through an unprotected stoma. Also, women who undergo partial laryngectomy or who learn some types of artificial speech will have a deep voice similar to that of a man. For some women this presents psychological challenges.

Normal results

Ideally, removal of the larynx will remove all cancerous material. The person will recover from the operation, make lifestyle adjustments, and return to an active life.

Abnormal results

Sometimes cancer has spread to surrounding tissues and it is necessary to remove lymph nodes, parts of the tongue, or other cancerous tissues. As with any major operation, post-surgical infection is possible. Infection is of particular concern to laryngectomees who have chosen to have a voice prosthesis implanted, and is one of the major reasons for having to remove the device.

Laryngoscopy

Definition

Laryngoscopy refers to a procedure used to view the inside of the larynx (the voice box).

Description

The purpose and advantage of seeing inside the larynx is to detect tumors, foreign bodies, nerve or structural injury, or other abnormalities. Two methods allow the larynx to be seen directly during the examination. In one, a flexible tube with a fiber-optic device is threaded through the nasal passage and down into the throat. The other method uses a rigid viewing tube passed directly from the mouth, through the throat, into the larynx. A light and lens affixed to the endoscope are used in both methods. The endoscopic tube may also be equipped to suction debris or remove material for **biopsy**. **Bronchoscopy** is a similar, but more extensive procedure in which the tube is continued through the larynx, down into the trachea and bronchi.

Preparation

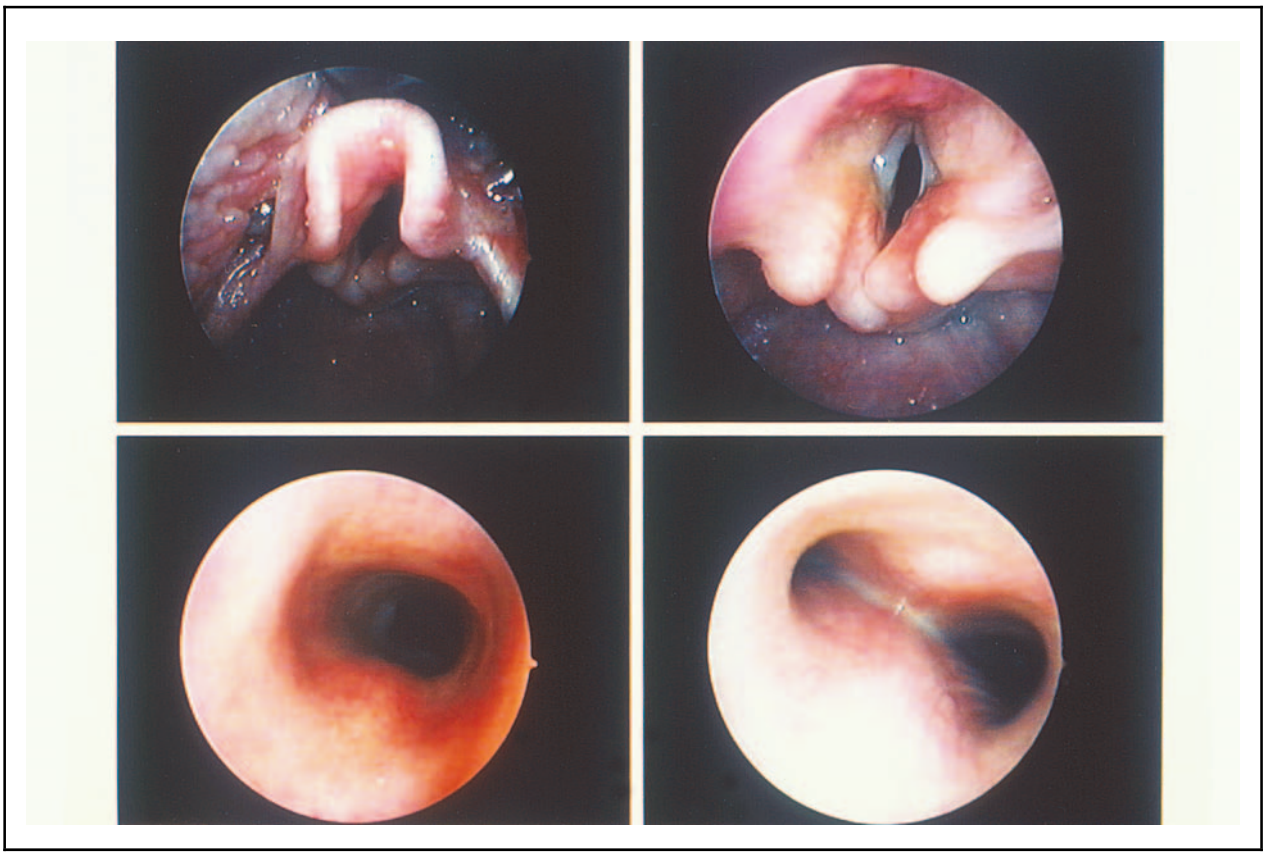
Laryngoscopy is done in the hospital with a local anesthetic spray to minimize discomfort and suppress the gag reflex. Patients are requested not to eat for several hours before the examination.

Aftercare

If the throat is sore, soothing liquids or lozenges will probably relieve any temporary discomfort.

Risks

This procedure carries no serious risks, although the patient may experience soreness of the throat or



Laryngoscopy. Multiple images of epiglottis, vocal cords, and interior of trachea and bronchus. *(Custom Medical Stock Photo. Reproduced by permission.)*

KEY TERMS

Endoscopic tube—A tube that is inserted into a hollow organ permitting a physician to see the inside it.

cough up small amounts of blood until the irritation subsides.

Normal results

A normal result would be the absence of signs of disease or damage.

Abnormal results

An abnormal finding, such as a tumor or an object lodged in the tissue, would either be removed or described for further medical attention.

Jill S. Lasker

Laxatives

Definition

A laxative is a drug that promotes bowel movements.

Purpose

Laxatives are used to prevent or treat constipation. They are also used to prepare the bowel for an examination or surgical procedure.

Description

Laxatives work in different ways, by stimulating colon movement, adding bulk to the contents of the colon, or drawing fluid or fat into the intestine. Some laxatives work by combining these functions. Most primary care physicians recommend that patients try the bulk-producing laxatives first before taking saline or stimulant laxatives.

Bisacodyl

Bisacodyl is a non-prescription stimulant laxative. It reduces short-term constipation and is also used to prepare the colon or rectum for an examination or surgical procedure. The drug works by stimulating colon movement (peristalsis); constipation is usually relieved within 15 minutes to one hour after administration of a suppository form and in 6 to 12 hours after taking the drug orally.

Calcium polycarbophil

Calcium polycarbophil is a non-prescription bulk-forming laxative that is used to reduce both constipation and **diarrhea**. It draws water to the intestine, enlarging the size of the colon and thereby stimulating movement. It reduces diarrhea by taking extra water away from the stool. This drug should relieve constipation in 12 to 24 hours and have maximum effect in three days. Colitis patients should see a reduction in diarrhea within one week.

Docusate calcium/docusate sodium

Docusate, a non-prescription laxative, helps a patient avoid constipation by softening the stool. It works by increasing the penetration of fluids into the stool by emulsifying feces, water and fat. Docusate prevents constipation and softens bowel movements and fecal impactions. This laxative should relieve constipation within one to three days.

Lactulose

Lactulose, a prescription laxative, reduces constipation and lowers blood ammonia levels. It works by drawing fluid into the intestine, raising the amount of water in the stool, and preventing the colon from absorbing ammonia. It is used to help people who suffer from chronic constipation.

Psyllium

Psyllium is a non-prescription bulk-forming laxative that reduces both constipation and diarrhea. It mixes with water to form a gel-like mass that can be easily passed through the colon. Constipation is relieved in 12 to 24 hours and maximum relief is achieved after several days.

Senna/senokot

Senna/senokot is a non-prescription laxative that reduces constipation by promoting colon movement. It is used to treat bouts of constipation and to prepare the colon for an examination or surgical procedure. This laxative reduces constipation in eight to 10 hours.

New and investigational treatments for constipation

Some newer options for the treatment of chronic constipation are being developed by various groups of researchers. These include such alternative therapies as biofeedback; newer drugs like tegaserod (Zelnorm) and prucalopride, which stimulate peristalsis; a nerve growth factor known as neurotrophin-3; and electrical stimulation of the colon.

Recommended dosage

Laxatives may be taken by mouth or rectally (suppository or enema).

Bisacodyl

- Adults or children over 12 years: 5 to 15 mg taken by mouth in morning or afternoon (up to 30 mg for surgical or exam preparation).
- Adult (rectal): 10 mg.
- Children age 2 to 11 years: 10 mg rectally as single dose.
- Children over three years: 5 to 10 mg by mouth as single dose.
- Children under two years: 5 mg rectally as single dose.

Calcium polycarbophil

- Adult: 1 g by mouth every day, up to four times a day as needed (not to exceed 6 g by mouth in a 24-hour time period).
- Children age 6 to 12 years: 500 mg by mouth twice a day as needed (not to exceed 3 g in a 24-hour time period).
- Children age 3 to 6 years: 500 mg twice a day by mouth, as needed (not to exceed 1.5 g in a 24-hour time period).

Docusate

- Adult (docusate sodium): 50 to 300 mg by mouth per day.
- Adult (docusate calcium or docusate potassium): 240 mg by mouth as needed.
- Adult (docusate sodium enema): 5 ml.
- Children over 12 years (docusate sodium enema): 2 ml.
- Children age 6 to 12 years (docusate sodium): 40 to 120 mg by mouth per day.
- Children age 3 to 6 years (docusate sodium): 20 to 60 mg by mouth per day.

- Children under 3 years (docusate sodium): 10 to 40 mg by mouth every day.

Lactulose

FOR CONSTIPATION:

- Adult: 15 to 60 ml by mouth every day.
- Children: 7.5 ml by mouth every day.

FOR ENCEPHALOPATHY:

- Adult: 20 to 30 g three or four times a day until stools become soft. Retention enema: 30 to 45 ml in 100 ml of fluid.
- Infants and children: Parents should follow physician's directions for infants and children with encephalopathy.

Psyllium

- Adult: 1 to 2 teaspoons mixed in 8 ounces of water two or three times a day by mouth, followed by 8 ounces water; or one packet in 8 ounces water two or three times a day, followed by 8 ounces of water.
- Children over 6 years: 1 teaspoon mixed in 4 ounces of water at bedtime.

Senna/senokot

- Adult (Senokot): 1 to 8 tablets taken by mouth per day or 1/2 to 4 teaspoons of granules mixed in water or juice.
- Adult (rectal suppository): 1 to 2 at bedtime.
- Adult (syrup): 1 to 4 teaspoons at bedtime.
- Adult (Black Draught): 3/4 ounce dissolved in 2.5 ounces liquid given between 2 p.m. and 4 p.m. on the day prior to a medical exam or procedure.
- Children: Parents should ask their doctor as dosage is based on weight. Black Draught is not to be used by children.
- Children age 1 month to 1 year (Senokot): 1.25 to 2.5 ml of syrup at bedtime.

Precautions

The doctor should be informed of any prior allergic drug reaction, especially prior reactions to any laxatives. Pregnancy is also a concern. Animal studies have shown laxatives to have adverse effects on pregnancy, but no human studies regarding pregnancy are currently available. These drugs are only given in pregnancy after the risks to the fetus have been taken under consideration. Nursing mothers should use caution and consult their doctors before receiving these drugs.

Bisacodyl should not be administered to patients with rectal fissures, abdominal pain, nausea, vomiting, appendicitis, abdominal surgery, ulcerated hemorrhoids, acute hepatitis, fecal impaction, or blockage in the biliary tract. Calcium polycarbophil should not be given to anyone with a gastrointestinal blockage (obstruction).

Both psyllium and docusate calcium/docusate sodium should be avoided by patients with intestinal blockage, fecal impaction, or **nausea and vomiting**. Lactulose should be avoided by patients who are elderly, have diabetes mellitus, eat a low galactose diet, or whose general health is poor.

Senna/senokot is inadvisable for patients with congestive heart failure, gastrointestinal bleeding, intestinal blockage, abdominal pain, nausea and vomiting, appendicitis, or prior abdominal surgery.

The American College of Toxicology states that cathartics should *not* be used as a means of clearing poisons from the digestive tract of a poisoning victim. Although some physicians have administered these laxatives along with activated charcoal in order to reduce the body's absorption of the poison, this treatment is no longer recommended.

Side effects

Laxatives may have side effects. Some, such as nausea and vomiting, are more common than others. Side effects related to specific laxatives are described in this section. With repeated use, people may become dependent on laxatives. All side effects should be reported to a doctor.

Bisacodyl

Common side effects:

- nausea
- vomiting
- loss of appetite (anorexia)
- cramps

Less common side effects:

- muscle weakness
- diarrhea
- electrolyte changes
- rectal burning (when suppositories are used).

Life-threatening:

- severe muscle spasms (tetany)

Calcium polycarbophil

Side effects may include:

- abdominal bloating (distention)
- gas
- laxative dependency

Life-threatening:

- gastrointestinal obstruction

Docusate calcium/docusate sodium

Side effects include:

- bitter taste in the mouth
- irritated throat
- nausea
- cramps
- diarrhea
- loss of appetite
- rash

Lactulose

Common side effects include:

- nausea
- vomiting
- loss of appetite
- abdominal cramping
- bloating
- belching
- diarrhea

Psyllium

Common side effects include:

- nausea
- vomiting
- loss of appetite
- diarrhea

Less common side effects include:

- abdominal cramping
- blockage of the esophagus or intestine

KEY TERMS

Cathartic—A general term for any agent that causes the bowel to empty. Cathartics are also known as purgatives.

Constipation—Difficult or infrequent bowel movements.

Diarrhea—Frequent, watery stools.

Electrolyte levels—In the bloodstream, electrolyte levels are the amounts of certain acids, bases, and salts. Abnormal levels of certain electrolyes can be life-threatening.

Encephalopathy—a brain disease

Peristalsis—Wave-like movement of the colon to pass feces along.

Tetany—Muscle spasms that can be life-threatening.

Senna/senokot

Common side effects include:

- nausea
- vomiting
- loss of appetite
- abdominal cramping

Less common side effects include:

- diarrhea
- gas
- urine that is pink-red or brown-black in color
- abnormal electrolyte levels

Life-threatening:

- Severe muscle spasms (tetany)

Interactions

Laxatives may interact with other drugs. Sometimes, the laxative can interfere with proper absorption of another drug. A patient must notify their doctor or pharmacist if he or she is already taking any medications so that the proper laxative can be selected or prescribed. Specific drug interactions are:

- Bisacodyl: Antacids, H2-blockers, and some herbal remedies (lily of the valley, pheasant's eye, squill).
- Calcium polycarbophil: (lowers the absorption of) tetracycline.

- Docusate calcium/docusate sodium: Unknown.
- Lactulose: Neomycin and other laxatives.
- Psyllium: Cardiac glycosides, oral anticoagulants, and salicylates.
- Senna/senokot: Disulfiram should never be taken with this drug. Also, senna/senokot lowers the absorption of other drugs taken by mouth.

Leiomyosarcoma

Definition

Leiomyosarcoma is cancer that consists of smooth muscle cells and small cell sarcoma tumor. The cancer begins in smooth muscle cells that grow uncontrollably and form tumors.

Description

Leiomyosarcomas can start in any organ that contains smooth muscle, but can be found in the walls of the stomach, large and small intestines, esophagus, uterus, or deep within the abdomen (retroperitoneal). But for perspective, smooth muscle cancers are quite rare: Less than 1% of all cancers are leiomyosarcomas. Very rarely, leiomyosarcomas begin in blood vessels or in the skin.

Most leiomyosarcomas are in the stomach. The second most common site is the small bowel, followed by the colon, rectum, and esophagus.

Demographics

Leiomyosarcomas do occur in the breast and uterus, but they are very rare. Uterine **sarcomas** comprise less than 1% of gynecological malignancies and 2% to 5% of all uterine malignancies. Of these numbers, leiomyosarcomas are found in only 0.1% of women of childbearing age who have tumors of the uterus. Less than 2% of tumors in women over age 60 who are undergoing hysterectomy are leiomyosarcomas.

Causes and symptoms

The exact causes of leiomyosarcoma are not known, but there are genetic and environmental risk factors associated with it. Certain inherited conditions that run in families may increase the risk of developing leiomyosarcoma. High-dose radiation exposure, such as radiotherapy used to treat other types of cancer, has also been linked to leiomyosarcoma. It is possible that exposure to certain chemical herbicides may increase the risk of developing sarcomas, but this association has not been proven.

Since leiomyosarcoma can occur in any location, the symptoms are different and depend on the site of the tumor. When leiomyosarcoma begins in an organ in the abdomen, such as the stomach or small bowel, the physician may be able to feel a large lump or mass when he examines the abdomen. When leiomyosarcoma affects a blood vessel, it may block the flow of blood to the body part supplied by the artery. Commonly occurring symptoms include:

- painless lump or mass
- painful swelling
- abdominal pain
- **weight loss**
- nausea and vomiting

Diagnosis

Some patients who have leiomyosarcomas may be visiting the doctor because they have discovered a lump or mass or swelling on a body part. Others have symptoms related to the internal organ that is affected by the leiomyosarcoma. For example, a tumor in the stomach may cause nausea, feelings of fullness, internal bleeding, and weight loss. The patient's doctor will take a detailed medical history to find out about the symptoms. The history is followed by a complete physical examination with special attention to the suspicious symptom or body part.

Depending on the location of the tumor, the doctor may order **imaging studies** such as **x ray**, **computed tomography** (CT) scan, and **magnetic resonance imaging** (MRI) to help determine the size, shape, and exact location of the tumor. A **biopsy** of the tumor is necessary to make the definitive diagnosis of leiomyosarcoma. The tissue sample is examined by a pathologist (specialist in the study of diseased tissue).

Types of biopsy

The type of biopsy done depends on the location of the tumor. For some small tumors, the doctor may perform an excisional biopsy, removing the entire tumor and a margin of surrounding normal tissue. Most often, the doctor will perform an incisional biopsy, a procedure that involves cutting out only a piece of the tumor that is used to determine its type and grade.

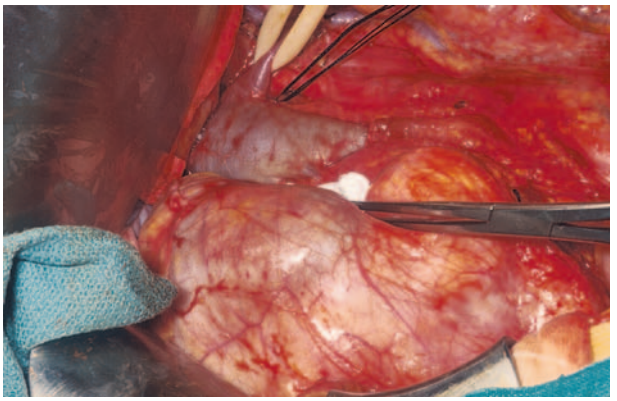
Treatment team

Patients with leiomyosarcoma are usually cared for by a multidisciplinary team of health professionals. The patient's family or primary care doctor may refer the patient to other specialists, such as surgeons and oncologists (specialists in cancer medicine), radiologic technicians, nurses, and laboratory technicians. Depending on the tumor location and treatment plan, patients may benefit from rehabilitation therapy with physical therapists and nutritional counseling from dieticians.

Clinical staging, treatments, and prognosis

Staging

The purpose of staging a tumor is to determine how far it has advanced. This is important because treatment varies depending on the stage. Stage is determined by the size of the tumor, whether the tumor has spread to nearby lymph nodes, whether the tumor has spread elsewhere in the body, and what the cells look like under the microscope.



Surgery to remove a leiomyosarcoma in the tissue near a kidney. *(Custom Medical Stock Photo. Reproduced by permission.)*

Examining the tissue sample under the microscope, using special chemical stains, the pathologist is able to classify tumors as high grade or low grade. High-grade tumors have the more rapidly growing cells and so are considered more serious.

Tumors are staged using numbers I through IV. The higher the number, the more the tumor has advanced. Stage IV leiomyosarcomas have involved either lymph nodes or have spread to distant parts of the body.

Treatment

Treatment for leiomyosarcoma varies depending on the location of the tumor, its size and grade, and the extent of its spread. Treatment planning also takes into account the patient's age, medical history, and general health.

Leiomyosarcomas on the arms and legs may be treated by **amputation** (removal of the affected limb) or by limb-sparing surgery to remove the tumor. These tumors may also be treated with **radiation therapy**, **chemotherapy**, or a combination of both.

Generally, tumors inside the abdomen are surgically removed. The site, size, and extent of the tumor determine the type of surgery performed. Leiomyosarcomas of organs in the abdomen may also be treated with radiation and chemotherapy.

Side effects

The surgical treatment of leiomyosarcoma carries risks related to the surgical site, such as loss of function

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of cancerous cells or by killing them.

Oncologist—A doctor who specializes in cancer medicine.

Pathologist—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

Radiation therapy—Treatment using high energy radiation from x-ray machines, cobalt, radium, or other sources.

Stage—A term used to describe the size and extent of spread of cancer.

resulting from amputation or from nerve and/or muscle loss. There also are risks associated with any surgical procedure, such as reactions to general anesthesia or infection after surgery.

The side effects of radiation therapy depend on the site being radiated. Radiation therapy can produce side effects such as **fatigue**, skin rashes, nausea, and **diarrhea**. Most of the side effects lessen or disappear completely after the radiation therapy has been completed.

The side effects of chemotherapy vary depending on the medication, or combination of anticancer drugs, used. Nausea, vomiting, **anemia**, lower resistance to infection, and hair loss (alopecia) are common side effects. Medication may be given to reduce the unpleasant side effects of chemotherapy.

Alternative and complementary therapies

Many patients explore alternative and complementary therapies to help to reduce the stress associated with illness, improve immune function, and feel better. While there is no evidence that these therapies specifically combat disease, activities such as biofeedback, relaxation, therapeutic touch, massage therapy, and guided imagery have been reported to enhance well-being.

Prognosis

The outlook for patients with leiomyosarcoma varies. It depends on the location and size of the tumor and its type and extent of spread. Some patients, such as those who have had small tumors located in or near the skin surgically removed, have excellent prognoses. Their 5-year survival is greater than 90%. Among patients with leiomyosarcomas in organs in the abdomen, survival is best when the tumor has been completely removed. In general, high-grade tumors that have spread widely throughout the body are not associated with favorable survival rates.

Coping with cancer treatment

Fatigue is one of the most common complaints during cancer treatment and recovery. Many patients benefit from learning energy-conserving approaches to accomplish their daily activities. They should be encouraged to rest when tired and take breaks from strenuous activities. Planning activities around times of day when energy is highest is often helpful. Mild exercise, small, frequent nutritious snacks, and limiting physical and emotional stress also help to combat fatigue.

Depression, emotional distress, and anxiety associated with the disease and its treatment may respond to counseling from a mental health professional. Many cancer patients and their families find participation in mutual aid and group support programs helps to relieve feelings of isolation and loneliness. By sharing problems with others who have lived through similar difficulties, patients and families can exchange ideas and coping strategies.

Clinical trials

Several clinical studies were underway as of 2001. For example, doctors at Memorial Sloan-Kettering Cancer Center were using specific chemotherapeutic drugs to treat patients with leiomyosarcoma that cannot be removed by surgery or has recurred. These drugs, **gemcitabine**, **docetaxel**, and **filgrastim** (G-CSF), work by stopping tumor cells from dividing, so they cannot grow. To learn more about this clinical trial and the availability of others, patients and families may wish to contact Memorial Sloan-Kettering Cancer Center at (212) 639-6555, or visit the National Cancer Institute (NCI) website at <http://cancertrials.nci.nih.gov>.

Prevention

Since the causes of leiomyosarcoma are not known, there are no recommendations about how to prevent its development. It is linked to radiation exposure; however, much of this excess radiation exposure is the result of therapy to treat other forms of cancer. Among families

QUESTIONS TO ASK THE DOCTOR

- What stage is the leiomyosarcoma?
- What are the recommended treatments?
- What are the side effects of the recommended treatment?
- Is treatment expected to cure the disease or only to prolong life?

with an inherited tendency to develop soft tissue sarcomas, careful monitoring may help to ensure early diagnosis and treatment of the disease.

Special concerns

Leiomyosarcoma, like other cancer diagnoses, may produce a range of emotional responses. Education, counseling, and participation in support group programs may help to reduce feelings of fear, anxiety and hopelessness. For many patients suffering from spiritual distress, visits with clergy members and participation in organized prayer may offer comfort.

Leucovorin

Definition

Leucovorin (also known as Wellcovorin and citrovorum factor or folinic acid) is a drug that can be used either to protect healthy cells from **chemotherapy** or to enhance the anti-cancer effect of chemotherapy.

Purpose

Leucovorin is most often used in cancer patients undergoing either **methotrexate** or **fluorouracil** chemotherapy. Methotrexate is used to treat a wide range of cancers including **breast cancer**, **head and neck cancers**, acute leukemias, and **Burkitt's lymphoma**. Fluorouracil is used in combination with leucovorin to treat colorectal cancer. When leucovorin and methotrexate are used together, this therapy often is called leucovorin rescue because leucovorin rescues healthy cells from the toxic effects of methotrexate. In patients with colorectal cancer, however, leucovorin increases the anti-cancer effect of fluorouracil.

Leucovorin also is used to treat megaloblastic anemia, a blood disorder in which red blood cells become larger than normal, and to treat accidental overdoses of drugs such as methotrexate.

Description

Leucovorin is a faster acting and stronger form of **folic acid**, and has been used for several decades. Folic acid also is known as vitamin B9, and is needed for the normal development of red blood cells. In humans, dietary folic acid must be reduced metabolically to tetrahydrofilic acid (THFA) to exert its vital biochemical functions. The coenzyme THFA and its subsequent other cofactors participate in many important reactions including DNA synthesis.

Leucovorin rescue

Some chemotherapy drugs, such as methotrexate (Mexate, Folex), work by preventing cells from using folic acid. Methotrexate therapy causes cancer cells to develop a folic acid deficiency and die. However, normal cells also are affected by folic acid deficiency. As a result, patients treated with drugs such as methotrexate often develop blood disorders and other toxic side effects. When these patients are given leucovorin, it goes into normal cells and rescues them from the toxic effects of the methotrexate. Leucovorin cannot enter cancer cells, however, and they continue to be killed by methotrexate. Leucovorin also works by rescuing healthy cells in patients who take an accidental overdose of drugs similar to methotrexate.

KEY TERMS

Folic acid—Vitamin B9.

Leucovorin rescue—A cancer therapy where the drug leucovorin protects healthy cells from toxic chemotherapy.

Combination therapy

Patients with colorectal cancer frequently are treated with fluorouracil (Adrusil). Fluorouracil, commonly called 5-FU, is effective, but only works for a short time once it is in the body. Leucovorin enhances the effect of fluorouracil by increasing the time that it stays active. As a result, the combination of the two drugs produces a greater anti-cancer effect than fluorouracil alone.

Recommended dosage

Leucovorin can be given as an injection, intravenously, or as oral tablets. For rescue therapy, leucovorin usually is given intravenously or orally within 24 hours of methotrexate treatment. Dosage varies from patient to patient. When used in combination with fluorouracil, leucovorin is given to the patient intravenously first, followed by fluorouracil treatment. To treat unintentional folic acid antagonist overdose, leucovorin is usually given intravenously as soon as possible after the overdose. Patients with megaloblastic anemia receive oral leucovorin.

Precautions

Patients with anemia, or any type of blood disorder, should tell their doctors. Leucovorin can treat only anemia caused by folic acid deficiency. Patients with other types of anemia should not take leucovorin. The effect of leucovorin on the fetus is not known, and it is not known if the drug is found in breast milk. Leucovorin should therefore be used with caution during pregnancy. Elderly patients treated with leucovorin and fluorouracil for advanced colorectal cancer are at greater risk for developing severe side effects.

Side effects

The vast majority of patients do not experience side effects from leucovorin therapy. Side effects are usually caused by the patient's chemotherapy, not by leucovorin. In rare cases, however, some patients can develop allergic reactions to the drug. These include skin rash, hives, and **itching**. In 2004, Swiss researchers found that oral desensitization may work in cases of severe allergic reaction to leucovorin.

Interactions

Although there are no listed drug interactions for leucovorin, patients should tell their doctors about any over the counter or prescription medication they are taking, particularly medication that can cause seizures.

Leukoencephalopathy

Description

Leukoencephalopathy is a disease occurring primarily in the white matter of the brain that involves defects in either the formation or the maintenance of the myelin sheath, a fatty coating that protects nerve cells. Leukoencephalopathy has several different forms and causes.

The symptoms of leukoencephalopathy reflect the mental deterioration that occurs as, at multiple sites within the brain, the myelin cover of nerve cells is eroded, leaving nerve cells exposed and with no protective insulation. Patients may exhibit problems with speech and vision, loss of mental function, uncoordinated movements, and extreme weakness and **fatigue**. Patients may have no desire to eat. The disease is usually progressive; patients continue to lose mental function, may have seizures, and finally lapse into a coma before death. Some patients stabilize, however, although loss of neurologic function is usually irreversible.

Leukoencephalopathy as it relates to cancer patients is primarily associated with **methotrexate chemotherapy**, which is used in treatment of many different types of cancer. Some other medications, including **cytarabine**, **fludarabine**, **carmustine** and **fluorouracil** in conjunction with **levamisole**. The disease may appear years

after the administration of methotrexate. Although rare, the incidence of leukoencephalopathy is increasing, as stronger drugs are developed and increased survival times allow time for the side effects of the treatments to appear.

A devastating type of leukoencephalopathy, called multifocal, or disseminated, necrotizing leukoencephalopathy, has been shown to occur primarily when methotrexate or cytarabine therapy is used in conjunction with a large cumulative dose of whole head irradiation. This disease is characterized by multiple sites of necrosis of the nerve cells in the white matter of the brain, involving both the myelin coating and the nerve cells themselves. Although some patients may stabilize, the course is usually progressive, with patients experiencing relentless mental deterioration and, finally, death.

Although leukoencephalopathy is primarily associated with methotrexate therapy, this disease has also been observed in association with other chemotherapeutic drugs (like intrathecal cytarabine) and occasionally been reported in association with cancers that have not yet been treated.

Another, particularly lethal, type of leukoencephalopathy called progressive multifocal leukoencephalopathy (PML) is an opportunistic infection that occurs in cancer patients who experience long-term immunosuppression as a result of the cancer (as in leukemia or **lymphoma**) or as a result of chemotherapy or immunosuppressive drugs. PML results when, due to chronic immunosuppression, the JC virus, widely found in the kidneys of healthy people, becomes capable of entering the brain. The virus infects the cells that produce myelin and causes multiple sites in the brain of nerve cells without the protective fatting coating. For reasons that are not completely clear, PML has a rapid and devastating clinical course, with death occurring typically less than six months after diagnosis.

Causes

It is only relatively recently that longer survival times for cancer patients have enabled scientists to identify an association of leukoencephalopathy with intensive chemotherapy (particularly methotrexate), especially when combined with large doses of whole head radiation. The causes of the neural degeneration observed are still not completely understood.

Most cases of leukoencephalopathy observed have occurred in patients who received methotrexate (either directly into the brain, through a tube in the skull, or intravenously) or who have received large doses of radiation to the head. Up to 50% of children who have received both treatments have developed necrotizing leukoencephalopathy, which differs from regular leukoencephalopathy in that the multiple sites of demyelinization also involve necrosis (the death of cells due to the degradative action of enzymes). Deterioration of the nerve tissue in necrotizing leukoencephalopathy appears to begin with the nerve and then spread into the myelin coating.

The method of action in PML is also not well understood. Long-term immunosuppression somehow appears to create an environment where the JC virus that inhabits most healthy human kidneys can mutate into a form that gains access to the brain. When in the brain, the virus infects and kills the cells that produce the myelin that forms a protective coating around the nerve.

Treatments

Unfortunately, there is no cure for any form of leukoencephalopathy, and no treatments approved. Although some medications have shown some effect against the deterioration involved in this disease, those identified have been highly toxic themselves, and none so far have been effective enough to justify use. The treatment of people with this disorder, therefore, tends to concentrate on alleviating discomfort.

Since there are no effective treatments, prevention must be emphasized. As the risks of certain treatment choices have become more defined, physicians must pursue careful treatment planning to produce optimal chance of tumor eradication while avoiding increased risk of the onset of a fatal and incurable side effect. This is especially true in children. The cases observed have largely been in children, which implies that the developing brain is at higher risk of developing treatment-associated leukoencephalopathy.

Alternative and complementary therapies

There are no commonly used alternative treatments, although since the disease is incurable, there is little risk involved in trying nontraditional medications. Complementary therapies (yoga, t'ai chi, etc.) that improve patient well being are appropriate if the patient finds them helpful.

Leuprolide acetate

Definition

Leuprolide acetate is a synthetic (man-made) hormone that acts similarly to the naturally occurring gonadotropin releasing hormone (GnRH). It is available under the tradename Lupron.

Purpose

Leuprolide acetate is used primarily to counter the symptoms of advanced **prostate cancer** in men when surgery to remove the testes or estrogen therapy is not an option or is unacceptable to the patient. It is often used to ease the pain and discomfort of women suffering from endometrosis, advanced **breast cancer**, or advanced **ovarian cancer**.

Two less common uses of this drug are the treatment of **anemia** caused by bleeding uterine fibroids, and the treatment of early onset (precocious) puberty.

Description

Leuprolide acetate is a man-made protein that mimics many of the actions of gonadotropin releasing hormone. In men, it decreases blood levels of the male hormone **testosterone**. In women, it decreases blood levels of the female hormone estrogen.

Recommended dosage for prostate cancer

In men, there are three methods of dosing: daily injections, a monthly injection, or an annual implanted capsule. In the case of daily injections, 1 mg of leuprolide acetate is injected under the skin (subcutaneously). In the case of monthly injections, an implanted capsule that contains 7.5 mg of leuprolide acetate is injected into a muscle. In the case of an annual implanted capsule, the capsule contains 72 mg of leuprolide acetate. Both the monthly and the annual capsules are specially designed to slowly release the drug into the patient's bloodstream over the specified time. The monthly capsule dissolves completely over the course of the month. The annual capsule must be removed after 12 months.

In the case of self-administered daily injections, a patient who misses a dose should take that dose as soon as it is noticed. However, if he or she does not remember until the next day, the missed dose should be skipped. Dosages should not be doubled.

Precautions

People taking leuprolide acetate should not drive a car, cook, or engage in any activity that requires alertness until they have been taking the medication long enough to be sure how it affects them.

Leuprolide acetate may cause birth defects if taken during pregnancy, and may be passed to an infant via breast milk. Therefore, women who are pregnant or nursing should not take leuprolide acetate without first consulting their doctors.

Leuprolide acetate will also interfere with the chemical actions of birth control pills. For this reason, sexually active women who do not wish to become pregnant should use some form of birth control other than birth control pills.

Side effects

In patients of both sexes, common side effects of leuprolide acetate include:

- tumor flare, which is exhibited as **bone pain** (due to a temporary initial increase in testosterone/estrogen before its production is finally decreased)
- sweating accompanied by feelings of warmth (hot flashes)
- lack of energy (lethargy)
- depression, or other mood changes
- headache
- enlargement of the breasts
- decreased sex drive

Other common side effects in women include:

- light, irregular vaginal bleeding
- no menstrual period
- pelvic pain
- vaginal dryness and/or **itching**
- emotional instability
- increase in facial or body hair
- deepening of the voice

Less common side effects, in patients of either sex, include:

- burning or itching at the site of the injection
- nausea and vomiting

KEY TERMS

Endometrial tissue—The tissue lining the uterus that is sloughed off during a woman's menstrual period.

Fibroid—A benign smooth muscle tumor of the uterus.

Gonadotropin releasing hormone (GnRH)—A hormone produced in the brain that controls the release of other hormones that are responsible for reproductive function.

Prostate gland—A small gland in the male genitals that contributes to the production of seminal fluid.

- insomnia
- weight gain
- swollen feet or lower legs
- constipation

Other side effects in men can include impotence and decreased testicle size.

A doctor should be consulted immediately if the patient experiences any of the above symptoms.

Interactions

There are no known interactions of leuprolide acetate with any food or beverage. People taking leuprolide acetate should consult their physician before taking any other prescription drug, over-the-counter drug, or herbal remedy. People currently taking any other hormone or steroid-based medications should not take leuprolide acetate without first consulting their physician.

See also Endometrial cancer.

Paul A. Johnson, Ed.M.

Levamisole

Definition

Levamisole is used to treat **colon cancer**, specifically stage III colon cancer. Levamisole takes the full name of levamisole hydrochloride, and it is also known by the brand name Ergamisol.

Purpose

Levamisole is used to treat patients with stage III colon cancer after they have had surgery to remove the tumor, or as much of the tumor as possible. In stage III colon cancer, the cancer has spread to nearby lymph nodes. Levamisole is approved for use with **fluorouracil** (specifically, 5-fluorouracil), a drug that is thought to prevent cells from replicating, or making more of themselves, by interfering with the manufacture of the hereditary material the cells carry. The use of levamisole with fluorouracil makes it an adjuvant therapy, or one that when used in conjunction with another drug seems to increase the defenses of the patient.

Description

Levamisole was first made (by laboratory synthesis) in 1966, and since then it has been used in veterinary medicine to eliminate intestinal, or lower gut, parasites in domestic animals. It was found to be immunostimulant in 1972 and approved for use for colon cancer in 1990.

The drug seems to have a number of benefits for the patient. It increases the response of T cells, or cells belonging to the lymphatic system that can fight cancer cells. It also seems to increase the activity of cells that attack and destroy invading or cancer cells, including both monocytes and macrophages.

Because of the response levamisole brings from T cells, causing them to be more active, it falls into the category of drugs known as biological response modifiers.

Recommended dosage

The drug is given orally in tablet form. Tablets contain 50 milligrams of levamisole hydrochloride, and a standard dose is one tablet every eight hours for three days. Thereafter, the patient takes the same three-day course every two weeks for about a year.

Dosage must be adjusted according to the count of white blood cells and platelets in a patient's blood. In some cases, levamisole can be continued, even when fluorouracil must be stopped.

Precautions

The drug can cause changes in the composition of the blood, which can be fatal. For example, agranulocytosis, also known as **neutropenia**, may develop. The condition refers to a drop in a kind of white blood cells known as neutrophils that are important in the defense against bacteria and fungus. Thus, the patient becomes more likely to get a bacterial or fungal infection.

KEY TERMS

Adjuvant therapy—Addition of a drug to another course of drug therapy to increase or enhance the immune response of a patient.

Macrophage—Large cell-eating cell.

Monocyte—A specialized type of white blood cell that attacks other cells, and acts as a phagocyte.

Neutrophil—A specialized type of white blood cell that attacks other cells, and acts as a phagocyte.

Parasite—An organism that lives by taking its nourishment from another organism.

Phagocyte—Cell-eating cell.

T cell—A cell in the lymphatic system that contributes to immunity by attacking foreign bodies, such as bacteria and viruses, directly.

Side effects

Nausea and vomiting, **diarrhea**, hair loss (**alopecia**), and changes in the composition of the white blood cells, such as neutropenia, are among the most common side effects.

Interactions

Levamisole often interacts with alcohol in the same way that the drug disulfiram, which is used to discourage **alcohol consumption** in alcoholics (alcohol deterrent), does. The reaction is extremely unpleasant, and alcohol use is best avoided when levamisole is being taken.

The drug also interacts with **warfarin**, which is often given to heart patients to reduce the chance of blood clots forming. Levamisole can interfere with the action of warfarin, allowing blood clots to form; therefore, adjustments in the amount of warfarin heart patients take may be necessary if they are also taking levamisole.

Diane M. Calabrese

Li-Fraumeni syndrome

Definition

Li-Fraumeni syndrome (LFS) is a genetic disorder caused by a hereditary mutation in a cancer susceptibility gene. Individuals with LFS have an increased risk for developing certain types of cancer, often at younger ages than is typically observed in the general population.

Description

Li-Fraumeni syndrome (LFS) was first described by Dr. Frederick Li and Dr. Joseph Fraumeni in 1969. It is caused by mutations in the TP53 gene, located on chromosome 17. The types of mutations that cause LFS are known as hereditary mutations, and therefore can be inherited, or passed from a parent to a child.

Cancer risks

The TP53 gene is a tumor suppressor gene. When an individual inherits a mutation in this type of gene from one of his or her parents, there is an increased risk for developing certain kinds of cancer. The most common kinds of cancer associated with LFS are sarcomas, or tumors that arise in connective tissue, like bone or cartilage.

Females with LFS have an increased risk for developing **breast cancer**. Males and females may also be at risk for developing leukemia, **melanoma**, colon, pancreatic, and brain cancer. They may also develop adrenalcorticoid tumors, which develop on the outer surface of the adrenal glands. These cancers often occur at younger ages than are typically observed in the general population, often before age 45.

Some individuals with LFS may develop certain cancers, such as brain tumors, sarcomas, or adrenalcorticoid tumors in childhood. In addition, individuals with a mutation in the TP53 gene have a higher risk for developing multiple primary cancers. For example, a person with LFS who develops a sarcoma at a young age and survives that cancer has an increased risk for developing a second, or possibly even a third different kind of cancer.

Genetic counseling and testing

Genetic testing for mutations in the TP53 gene is usually performed on a blood sample from the relative in the family who has had one of the cancers associated with LFS at a young age. One of the most effective ways to test for mutations in the TP53 gene is by sequencing, a process whereby the chemical components of a patient's DNA is compared to that of DNA that is known to be normal. If the entire DNA code of the TP53 gene is sequenced, it is believed that the majority (98%) of the (mutations) that are responsible for Li-Fraumeni syndrome can be identified. However, as the process of sequencing is a difficult and often time-consuming

Age of onset for cancers associated with Li-Fraumeni syndrome

Age of onset	Type of cancer
Infancy	Development of adrenocortical carcinoma
Under five years of age	Development of soft-tissue sarcomas
Childhood and young adulthood	Acute leukemias and brain tumors
Adolescence	Osteosarcomas
Twenties to thirties	Premenopausal breast cancer is common

process, it is not always performed for every patient. Often, only specific areas of the TP53 gene, where there is most likely to be a mutation associated with LFS, are analyzed. The length of time to receive results depends on the extent of testing that is performed and the laboratory that is used.

Due to the fact that some of the cancers associated with LFS can occur at very young ages, there is a question as to whether genetic testing should be an option for at-risk children. Typically, genetic testing is not offered to anyone under the age of 18. However, because there are some screening options available for children with LFS, it is thought that the option of testing could not be denied if a parent feels that it is important for his or her son or daughter's future health. Groups such as the National Society of Genetic Counselors are beginning to explore the issue of genetic testing in minors (those under age 18) for mutations in cancer susceptibility gene, especially if these minors would be at risk for developing **childhood cancers**.

It is important to understand the various categories of results that are associated with undergoing genetic testing for mutations in the TP53 gene. A positive result indicates the presence of a genetic mutation that is known to be associated with an increased risk for developing the types of cancer associated with LFS. Once this kind of mutation has been found in an individual, it is possible to test this person's relatives, such as the children, for the presence or absence of that particular mutation. Individuals who have a mutation in the TP53 gene have a 50% chance of passing on this mutation to their children.

Even if a patient has a mutation in the TP53 gene, it does not mean that he or she will definitely develop one of the cancers that are associated with Li-Fraumeni. However, the risk for those with the mutation is much higher than for someone in the general population. The likelihood that a person will develop cancer if they have a mutation in a cancer susceptibility gene like TP53 is called penetrance.

If the first person tested within a family is not found to have an alteration in the TP53 gene, his or

KEY TERMS

Adrenalcorticoid tumors—Cancer that arises on the outer surface of the adrenal glands.

Adrenal glands—Structures located on top of the kidneys that secrete hormones.

Cancer—The process by which cells grow out of control and subsequently invade nearby cells and tissue.

Cancer susceptibility gene—The type of genes involved in cancer. If a mutation is identified in this type of gene it does not reveal whether or not a person has cancer, but rather whether an individual has an increased risk (is susceptible) to develop cancer (or develop cancer again) in the future.

Chromosome—Structures found in the center of a human cell on which genes are located.

Gene—Packages of DNA that control the growth, development and normal function of the body.

Genetic counselor—A specially trained health care provider who helps individuals understand if a disease (such as cancer) is running in their family and their risk for inheriting this disease. Genetic counselors also discuss the benefits, risks and limitations of genetic testing with patients.

Leukemia—Cancer that arises in blood cells.

Mammogram—A screening test that uses x rays to look at a woman's breasts for any abnormalities, such as cancer.

Mutation—An alteration in the number or order of the DNA sequence of a gene.

Penetrance—The likelihood that a person will develop a disease (such as cancer), if he or she has a mutation in a gene that increases the risk for developing that disorder.

Sarcoma—Cancer that occurs in connective tissue, such as cartilage or bone.

Sequencing—A method of performing genetic testing where the chemical order of a patient's DNA is compared to that of normal DNA.

Tumor suppressor gene—Genes that typically prevent cells from growing out of control and forming tumors that may be cancerous.

Ultrasound—A test that uses sound waves to examine organs in the body

QUESTIONS TO ASK THE DOCTOR

- What is the likelihood that the cancer in my family is due to a mutation in a cancer susceptibility gene, particularly the TP53 gene?
- If my family is found to have Li-Fraumeni syndrome, what is the chance that I carry a mutation in the TP53 gene?
- What are the benefits, limitations and risks of undergoing genetic testing?
- What is the cost of genetic testing and how long will it take to obtain results?
- If I undergo genetic testing, will my insurance company pay for testing? If so, will I want to share my results with them?
- What does a positive test result mean for me?
- What does a negative test result mean for me?
- If I test positive for a mutation in a cancer susceptibility gene, what are the best options available for screening and prevention? What research studies may I be eligible to participate in?
- What legislation is in effect to protect me against discrimination by my insurer or employer?

her result is negative. Often this result is called indeterminate, because a negative test result cannot completely rule out the possibility of hereditary cancer being present within a family. The interpretation of this type of result can be very complex. For example, a negative result may mean that the method used to detect mutations in the TP53 gene may not be sensitive enough to identify all mutations. Additionally, the mutation might be located in a part of the gene that is difficult to analyze. It may also mean that a person has a mutation in another cancer susceptibility gene that has not yet been discovered or is very rare. Finally, a negative result could mean that the person tested does not have an increased risk for developing cancer because of a mutation in a single cancer susceptibility gene.

Screening and prevention options

With the exception of screening for breast cancer, there are no effective means to screen for and/or prevent the cancers that are associated with Li-Fraumeni syndrome. However, researchers have developed some screening guidelines for those with LFS. For men and women, it is recommended that they undergo a thorough physical exam with their doctor every year. This should include skin and **colon cancer** screening along with a complete exam of the nervous system. Women should also undergo breast cancer screening, which consists of annual mammograms, self-breast exams, and breast exams by a physician or health care provider. Individuals with Li-Fraumeni syndrome may choose to undergo screening more often and at an earlier age then people in the general population.

For children with a TP53 mutation, it is recommended that they also undergo a complete physical exam once a year by their physician. This should include an analysis of their urine and blood and an abdominal ultrasound.

Limb salvage

Definition

Limb salvage is a type of surgery that removes a cancerous tumor or lesion while preserving the nearby muscles, tendons, and blood vessels.

Purpose

Doctors perform limb salvage to remove cancer and avoid **amputation**, while preserving the patient's appear-

ance and the greatest possible degree of function in the affected limb. The procedure is most commonly performed for bone tumors and bone **sarcomas**, but is also commonly performed for soft tissue sarcomas affecting the extremities.

This complex alternative to amputation is used to cure cancers that are slow to spread from the limb where they originate to other parts of the body, or that have not invaded soft tissue.

Precautions

Limb salvage should only be performed by experienced surgeons with specialized expertise. It should also be limited to cases in which the surgery would restore more and longer-lasting function than could be achieved by amputating the affected limb and fitting the patient with an artificial replacement (prosthesis).

If the cancer's location makes it impossible to remove the malignancy without damaging or removing vital organs, essential nerves, key blood vessels, or if it is impossible to reconstruct a limb that will function satisfactorily, salvage surgery may not be an appropriate treatment.

Biopsy is a critical component of limb-salvage surgery. A poorly planned or improperly performed biopsy can limit the patient's surgical options and make amputation unavoidable.

Description

Also called limb-sparing surgery, limb salvage involves removing the cancer and about an inch of healthy tissue surrounding it, and, if bone was removed, replacing the removed bone. The replacement can take the form of synthetic metal rods or plates (prostheses), pieces of bone (grafts) taken from the patient's own body (autologous transplant), or pieces of bone removed from a donor body (cadaver) and frozen until needed for transplant (allograft). In time, transplanted bone grows into the patient's remaining bone. **Chemotherapy**, radiation, or a combination of both treatments may be used to shrink the tumor before surgery is performed.

Stages of surgery

Limb salvage is performed in three parts. Doctors remove the cancer and a margin of healthy tissue, implant a prosthesis or bone graft (when necessary), and close the wound by transferring soft tissue and muscle from other parts of the patient's body to the surgical site. This treatment cures some cancers as successfully as amputation.

Surgical techniques

BONE TUMORS Doctors remove the malignant lesion and a cuff of normal tissue (wide excision) to cure low-grade tumors of bone or its components. To cure high-grade tumors, they also remove muscle, bone, and other tissues affected by the tumor (radical resection).

SOFT TISSUE SARCOMAS Doctors use limb-sparing surgery to treat about 80% of soft tissue sarcomas affecting extremities. The surgery removes the tumor, lymph nodes or tissues to which the cancer has spread, and at least one inch of healthy tissue on all sides of the tumor.

Radiation and/or chemotherapy may be administered before or after the operation. Radiation may also be administered during the operation by placing a special applicator against the surface from which the tumor has just been removed, and inserting tubes containing radioactive pellets at the site of the tumor. These tubes remain in place during the operation and are removed several days later.

To treat a soft tissue sarcoma that has spread to the patient's lung, the doctor may remove the original tumor, administer radiation or chemotherapy treatments to shrink the lung tumor, and surgically remove the lung tumor.

Limb salvage for children

Doctors use expandable prostheses to perform limb-salvage surgery on children who have not stopped growing (skeletal immaturity). These children may need as many as four additional operations, at intervals of six to 12 months, to expand the prostheses as their limbs lengthen.

Because expandable prostheses have been available only since the 1980s, the long-term effects of using them are unknown.

Preparation

Before deciding that limb salvage is appropriate for a particular patient, the doctor considers what type of cancer the patient has, the size and location of the tumor, how the illness has progressed, and the patient's age and general health.

After determining that limb salvage is appropriate for a particular patient, the doctor makes sure that the patient understands what the outcome of surgery is likely to be, that the implant may fail, and that additional surgery—even amputation—may be necessary.

Preoperative rehabilitation

Physical and occupational therapists help prepare the patient for surgery by introducing the muscle-strengthening, ambulation, and range of motion (ROM) exercises the patient will begin performing right after the operation.

Aftercare

During the five to ten days the patient remains in the hospital following surgery, nurses monitor sensation and blood flow in the affected extremity and watch for signs that the patient may be developing **pneumonia**, pulmonary embolism, or deep-vein thrombosis.

The doctor prescribes broad-spectrum **antibiotics** for at least the first 48 hours after the operation and often prescribes medication (prophylactic anticoagulants) and antiembolism stockings to prevent blood clots. A drainage tube placed in the wound for the first 24–48 hours prevents blood (hematoma) and fluid (seroma) from accumulating at the surgical site. As postoperative pain becomes less intense, mild narcotics or anti-inflammatory medications replace the epidural catheter or patient-controlled analgesic pump used to relieve pain immediately after the operation.

Exercise intervention

Limb salvage requires extensive surgical incisions, and patients who have these operations need extensive rehabilitation. The amount of bone removed and the type of reconstruction performed dictate how soon and how much the patient can exercise, but most patients begin muscle-strengthening, continuous passive motion (CPM), and ROM exercises the day after the operation and continue them for the next 12 months.

A patient who has had upper-limb surgery can use the opposite side of the body to perform hand and shoulder exercises. Patients should not do active elbow or shoulder exercises for two to eight weeks after having surgery involving the bone between the shoulder and elbow (humerus). Rehabilitation following lower-extremity limb salvage focuses on strengthening the muscles that straighten the legs (quadriceps), maintaining muscle tone, and gradually increasing weight-bearing so that the patient is able to stand on the affected limb within three months of the operation. A patient who has had lower-extremity surgery may have to learn a new way of walking (gait retraining) or wear a lift in one shoe.

Goals of rehabilitation

Physical and occupational therapy regimens are designed to help the patient move freely, function independently, and accept changes in **body image**. Even patients who look the way they did before surgery are likely to feel that the operation has altered their appearance.

Before a patient goes home from the hospital or rehabilitation center, the doctor decides whether the patient needs a walker, brace, cane, or other device, and should make sure that the patient can climb stairs. Also, the doctor should emphasize the life-long importance of preventing infection and give the patient written instructions about how to prevent infection and what to do if infection does develop.

Risks

The major risks associated with limb salvage include superficial or deep infection at the site of the surgery; loosening, shifting, or breakage of implants; rapid loss of blood flow or sensation in the affected limb; and severe blood loss and **anemia** from the surgery.

Postoperative infection is a serious problem. Chemotherapy or radiation can weaken the immune system, and extensive bone damage can occur before the infection is identified. Tissue may die (necrosis) if the surgeon used a large piece of tissue (flap) to close the wound. This is most likely to occur if the surgical site was treated with radiation before the operation. Treatment for postoperative infection involves removing the graft or implant, inserting drains at the infected site, and giving the patient oral or intravenous antibiotic therapy for as long as 12 months. Doctors may have to amputate the affected limb.

Normal results

A patient who has had limb-sparing surgery will remain disease-free as long as a patient whose affected extremity has been amputated.

Salvaged limbs always function better than artificial ones. However, it takes a year for patients to learn to walk again following lower-extremity limb salvage, and patients who have undergone upper-extremity salvage must master new ways of using the affected arm or hand.

Successful surgery reduces the frequency and severity of patient falls and of the fractures that often result from disease-related changes in bone. Although successful surgery results in limbs that look and function very much like normal, healthy limbs, it is not unusual for patients to feel that their appearance has changed.

Abnormal results

Some patients will need additional surgery within five years of the first operation. Some will eventually require amputation.

Post-operation directives from the patient's physician may include the following items:

- Patients may be told that they should never jog, lift heavy objects, or play racquet sports.

QUESTIONS TO ASK THE DOCTOR

- Why do you think limb salvage will be successful in my case?
- How will I look and feel after the operation?
- Will I be able to enjoy my favorite sports and other activities after the operation?

- Wearing a splint or cast can damage nerves and veins in the affected limb.
- Implants can loosen, shift to a new position, or break.

Lip cancers

Definition

Lip cancer is a malignant tumor, or neoplasm, that originates in the surface layer cells of the epithelial tissue in the upper or lower lip.

Description

The upper and lower lips are the well-defined red (often called vermilion) areas that surround the opening to the mouth. They contain muscles and special cells (receptors) that are sensitive to heat and cold and feeling. Largely taken for granted, the lips are important in identifying types of food to the brain and in getting food into the mouth. Lips also play a crucial role in speech.

A malignant tumor, or neoplasm, that originates in the cells of one of the lips is a cancer of the lip. Lip cancer almost always begins in the flat, or squamous, epithelial cells. Epithelial cells form coverings (tissues) for the surfaces of the body. Skin, for example, has an outer layer of epithelial tissue.

If a part of the lip is affected by cancer and must be removed by surgery, there will be significant changes in eating ability and speech function. The more lip tissue removed, the greater the disturbances to the normal patterns of talking and eating.

Demographics

Nine out of ten cases of lip cancer are diagnosed in people over the age of 45. Age, or the aging process, may contribute to the way the cancer develops. As a line of cells gets older, the genetic material in a cell loses some of its ability to repair itself. When the repair system is operating normally, damage to the genetic material, or DNA, caused by ultraviolet light from the sun is quickly weeded out. When the system fails, changes in the genetic material are kept, and they multiply when a cell divides.

If the genetic material cannot repair itself, damage caused by exposure to environmental factors such as sunlight and chemicals can quickly set in motion the uncontrolled growth of cells.

The effects of factors that are known to cause lip cancer, such as smoking and exposure to sunlight, also add up as a person ages. Thus, the combination of a breakdown in the repair system in the genetic material and the considerable periods of time (decades) over which a person is exposed to cancer agents probably causes lip cancers. However, researchers are still investigating how lip cancers start.

Men are at greater risk for lip cancer than women. Depending on where they live, men are two or three times more likely to be diagnosed than women. Fair-skinned people are more likely to get lip cancer than those with dark skin. For reasons not yet understood, people in Asia have a much lower risk of lip cancer than those living on other continents. In many parts of Asia, lip cancer is extremely rare. In North America, nearly 13

out of 100,000 men will be diagnosed with lip cancer during their lifetime. In Australia, about 13.5 men per 100,000 will be diagnosed.

The frequency of lip cancer is often lumped together with oral cancer, although lip cancer is probably much more like skin cancer in origin. There are about 30,000 new diagnoses of mouth and lip cancer in the United States each year. About 38% percent of all cancers of the mouth begin in the lower lip; on the other hand, cancers of the upper lip are more aggressive than those of the lower lip.

In some places, such as South Australia, women are experiencing a striking increase in lip cancer diagnoses. There are several theories to explain the trend. Among them, perhaps fewer women regularly wear hats, which offer protection from the sun. Women might also be forgoing lipstick, which serves as another barrier to sunlight.

Causes and symptoms

Exposure to sunlight and smoking, particularly pipe smoking, increases the risk of developing lip cancer. However, the way they do so is not understood. Alcohol consumption is tied to **oral cancers** and may contribute to lip cancer as well.

Much of the evidence about the link between time spent in the sun and lip cancer comes from a look at those who are most likely to be diagnosed. Among them are farmers, golfers, and others who spend long periods of time outdoors.

Lip cancer seems to share some properties with skin cancer in the way it originates. Yet several studies suggest that it takes more than exposure to sun to increase the risk of lip cancer. Viral infection is a risk factor, as is reduced immunity, which is a condition that may be caused by viral infection. A team of researchers in the Netherlands recently reported a link between liver transplants and a higher risk of lip and skin cancer following the transplant. The results are not unexpected. In this procedure, drugs are used to suppress, or lower, the activity of a recipient's immune system so that a donor organ will be accepted. Thus, the immunity of the organ recipient is low, and lower immunity is linked to lip cancer.

Individuals with acquired immunodeficiency syndrome (AIDS) are at a greater risk for lip cancer. People infected with **herpes simplex** viruses, papilloma viruses and other viruses may also be at greater risk.

Vitamin deficiency may also be a factor that contributes to lip cancer. The sorts of **vitamins** found in fruits and vegetables, particularly carotene, the substance the body uses to form vitamins A and C, seem to be important in preventing lip cancer.

Particular symptoms of this cancer include white spots, sores, or lumps on the lip. Pain can also be a symptom, particularly pain in a lymph node near the affected part of the lip. This is a troubling symptom, since it indicates that the cancer has metastasized (spread) beyond the lip.

Diagnosis

Dentists frequently identify a suspicious spot, sore, or lump on the lip. A good dental exam includes an examination of the lips and the mouth. **X ray** and **biopsy**, the taking of a tissue sample for analysis, can be used to determine whether or not cancer is present.

Because spots and sores on the lips can be short-lived, people should not be alarmed by every change that appears. However, when there is a change that occurs and stays, it should be investigated. If the next scheduled dental visit is several months away, a special appointment with the dentist or a physician should be made. Dentists should tell their patients, particularly older ones, how to undertake a regular self-exam of the lips between check-ups.

Treatment team

A physician who specializes in oncology, the study and treatment of cancer, will probably take the lead on treatment. A surgeon will remove the cancer. Not all oncologists are surgeons, so it is likely that the team will include a medical oncologist, who coordinates treatment, as well as a surgical oncologist, who performs the surgery.

Because surgery on the lip can interfere with eating and talking, most teams include a nutritionist and a speech pathologist. Scars and alterations of facial features can produce changes in **body image**, and a psychiatrist or social worker may participate in the team to help a patient cope with such changes. It is possible that a dentist or oral surgeon will also play a role. Nurses who administer **chemotherapy** and monitor the status of patients will be involved, as will radiation technicians and a radiation oncologist. If reconstruction of a lip is necessary because of the amount of tissue removed or the size of a scar, a plastic surgeon will be added to the team.

Clinical staging, treatments, and prognosis

The ability to see a suspicious area on the lips and to detect lip cancer early combine to form the staging process. (One inch equals 2.5 cm.)

- Stage I: The cancer is less than one inch in diameter and has not spread.
- Stage II: The cancer is up to approximately two inches in diameter and has not spread.
- Stage III: The cancer is either larger than two inches or has spread to a lymph node on the side of the neck that matches the primary location of the lip cancer. The lymph node is enlarged, but not much more than an inch.
- Stage IV: One or more of several things can occur. There may be a spread of cancer to the mouth or to the areas around the lip, more than one lymph node with cancer, or **metastasis** (spread) to other parts of the body.

The outlook for recovery from lip cancer is very good if it is diagnosed early. For stage I and stage II cancers, surgery to remove the cancer or radiation treatment of the affected area is sometimes all that is required to produce a cure. Decisions about which method to use depend on many factors, but the size of the tumor and the tolerance a patient has for radiation or chemotherapy are particularly important. The larger the tumor, the more urgent is its removal. Smaller tumors can be treated with radiation or other methods in an effort to shrink them before surgery. In some cases, surgery might be avoided. For stage III cancer with lymph node involvement, the cancerous lymph nodes are also removed.

Chemotherapy may be used at any stage, but it is particularly important for stage IV cancer. In some cases, chemotherapy is used before surgery, just as radiation is, to try to eliminate the cancer without cutting, or at least to make it smaller before it is cut out (excised). After surgery, **radiation therapy** and chemotherapy are both used to treat patients with stage IV lip cancer, sometimes in combination.

There are many new and promising types of treatment for lip cancer. For example, heat kills some cancer cells, and a treatment known as **hyperthermia** uses heat to eliminate cancer in some patients.

Because lip cancers are well-studied and often successfully treated, the best practices for dealing with the cancer, or a suspected cancer, are specific. In the case of how to extract and study tissue to determine whether a suspicious growth is malignant (biopsy), size is an extremely useful guide.

It is possible to take tissue from a suspected lip cancer for examination, or biopsy, by simply piercing and extracting tissue with a large, hollow needle. The technique is called a punch biopsy. However, the method is not recommended for any tumor that is thicker than about one-sixteenth of an inch. For thicker tumors, a tissue sample is better taken by cutting into the tumor, that is, making an incision.

Squamous cell carcinoma on lip. *(Custom Medical Stock Photo. Reproduced by permission.)*

The success with identifying lip cancer early and eliminating it means that it is not a big killer. Only 4 in 2.5 million people die from lip cancer each year, or about 112 individuals in the entire United States population. In contrast, cancers in the oral cavity, including on the tongue, cause more than 8,000 deaths in the United States each year.

Alternative and complementary therapies

Because there seems to be some link between a chronic absence of vitamins A and C in the diet and lip cancer, some complementary therapies promote taking massive amounts of the vitamins, or megavitamins. The value of such therapy has not been demonstrated. In order to avoid possible side effects or harmful interactions with standard cancer treatment, patients should always notify their treatment team of any over-the-counter or herbal remedies that they are taking.

Coping with cancer treatment

The doctor and patient should discuss the need for a way to communicate if speech is impaired after surgery. A pad and pencil may be all that is needed for a short interval. If there will be a long period of speech difficulty, patients should be ready with additional means, such as TYY phone service.

A change in appearance after the removal of a lip cancer can lead to concerns about body image, and social interaction may suffer. A support group can help. Discussions with a social worker, loved ones, or other patients who have undergone similar treatment can be of major benefit.

If a significant portion of lip is removed, speech therapy may be necessary to relearn how to make certain

KEY TERMS

Biopsy—A procedure in which a tissue sample is taken from the body for examination.

Epithelial tissue—The collection of cells that form coverings for the surfaces of the body.

Immunity—Ability to resist the effects of agents, such as bacteria and viruses, that cause disease.

Lymph node—A concentration of lymphatic tissue and part of the lymphatic system that collects fluid from around the cells and returns it to the blood vessels, and helps with the immune response.

Squamous cells—Flat epithelial cells, which usually make up the outer layer of epithelial tissue, the layer farthest away from the surface the epithelium covers.

QUESTIONS TO ASK THE DOCTOR

- Is this cancer curable?
- What is the stage of the cancer?
- What is the likelihood the cancer will recur?
- Is there a clinical trial in which I should participate?

sounds. Scars and alterations of the lips usually can be reduced or hidden entirely with the techniques available from plastic surgery, so any alteration in appearance because of lip cancer is typically transient.

Reconstruction of the lip will help with appearance, but it might not make it easier to talk, especially if muscle tissue is removed during the surgery to eliminate the cancer. In many cases, the reconstruction process actually damages more muscle and sensory tissue. New methods of **reconstructive surgery** are being developed to avoid such an outcome. Some of these newer methods involve grafts of skin and muscle taken from the forearm or the area of the cheek near the angle of the jawbone. In general, reconstruction of the lower lip is more difficult than reconstruction of the upper lip.

Appetite may be affected before, during and after treatment. Before treatment, the presence of a tumor can interfere with the tasting of food, and food might not seem as appealing as it once did. During treatment, particularly radiation treatment, the area of the lips and mouth might be sore and make eating difficult. After treatment, a loss of sensation in the part of the lip affected can reduce appetite. A nutritionist can help with supplements for those who experience significant **weight loss** and who do not have an appetite.

Clinical trials

The Cancer Information Service at the National Institutes of Health offers information about **clinical trials** that are looking for volunteers. The service can be reached at <http://cancertrials.nci.nih.gov> or (800) 422-6237.

Prevention

The best preventive measures are minimizing sun exposure and avoiding tobacco and alcohol. Eating plenty of fruits and vegetables is a good measure. Even though the importance of fruits and vegetables is not proven to prevent lip cancer, overall fruits and vegetables are demonstrated cancer-fighters. Any precaution that is taken against contracting human immunodeficiency virus (HIV), which causes AIDS, is also likely to reduce the chance of developing lip cancer.

Special concerns

Certain diseases can mimic a possible lip cancer. They must be ruled out if a suspicious spot is found. This is particularly true in areas where diseases that cause lesions, or sores, on the lips are found. One such disease is *histoplasmosis capsulatum*, which is caused by a fungus. It sometimes produces an ulcer, or lesion, on the lip that leads to suspicion of lip cancer.

Sometimes lip cancer cannot be cured. It may keep recurring. It may also metastasize, particularly to the lungs. But overall, lip cancer is considered highly curable. Talking openly with the physician in charge of care is important in order for the patient to understand the course of the disease and be prepared to make decisions.

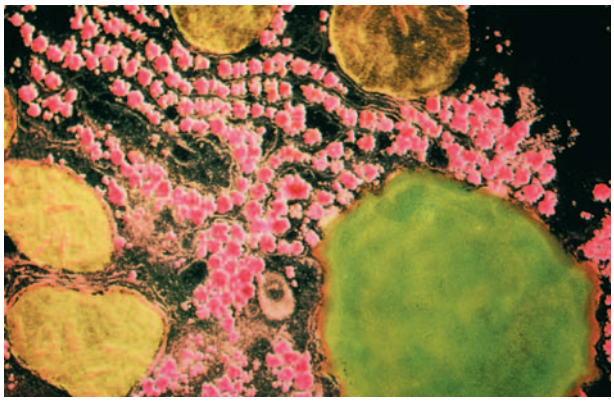
Liver biopsy

Definition

A liver **biopsy** is a medical procedure performed to obtain a small piece of liver tissue for diagnostic testing. Liver biopsies are sometimes called percutaneous liver biopsies, because the tissue sample is obtained by going through the patient's skin.

Purpose

A liver biopsy is usually done to diagnose a tumor, or to evaluate the extent of damage that has occurred to the liver because of chronic disease. Biopsies are often performed to identify abnormalities in liver tissues after **imaging studies** have failed to yield clear results.



A false-color scanning electron micrograph (SEM) of hepatocyte cells of the liver that secrete bile. *(Photograph by John Bavosi. Custom Medical Stock Photo. Reproduced by permission.)*

A liver biopsy may be ordered to evaluate any of the following conditions or disorders:

- jaundice
- cirrhosis
- hemochromatosis, which is a condition of excess iron in the liver
- repeated abnormal results from liver function tests
- unexplained swelling or enlargement of the liver
- primary cancers of the liver, such as hepatomas, cholangiocarcinomas, and angiosarcomas
- metastatic cancers of the liver

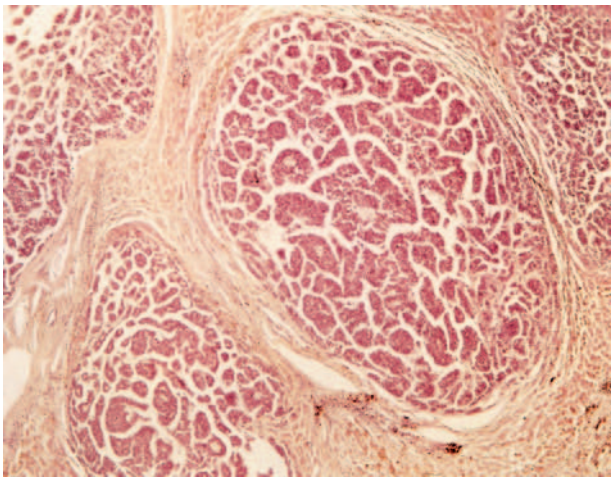
Precautions

Some patients should not have percutaneous liver biopsies. They include patients with any of the following conditions:

- a platelet count below 60,000
- a longer-than-normal prothrombin time
- a liver tumor that contains a large number of blood vessels
- a history of unexplained bleeding
- a watery (hydatid) cyst
- an infection in either the cavity around the lungs, or the diaphragm

Description

Percutaneous liver biopsy is done with a special hollow needle, called a Menghini needle, attached to a



Light micrograph of a section through a primary carcinoma from a human liver. Healthy liver cells are normally arranged in roughly hexagonal structures called lobules. In this cancerous liver, the lobules are disintegrating, and abnormal fibrous tissue has proliferated around them. *(Copyright John Burbridge, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

KEY TERMS

Biopsy—A procedure where a piece of tissue is removed from a patient for diagnostic testing.

Menghini needle—A special needle used to obtain a sample of liver tissue.

Percutaneous biopsy—A biopsy in which a needle is inserted and a tissue sample removed through the skin.

Prothrombin time—A blood test that determines how quickly a person's blood will clot.

Vital signs—A person's essential body functions, usually defined as the pulse, body temperature, and breathing rate.

suction syringe. Doctors who specialize in the digestive system or liver will sometimes perform liver biopsies. But in most cases, a radiologist (a doctor who specializes in x rays and imaging studies) performs the biopsy. The radiologist will use **computed tomography** scan (CT scan) or ultrasound to guide the choice of the site for the biopsy.

An hour or so before the biopsy, the patient may be given a sedative to help relaxation. He or she is then asked to lie on the back with the right elbow to the side and the right hand under the head. The patient is instructed to lie as still as possible during the procedure. He or she is warned to expect a sensation resembling a punch in the right shoulder, but to hold still in spite of the momentary feeling.

The doctor marks a spot on the skin where the needle will be inserted and thoroughly cleanses the right side of the upper abdomen with an antiseptic solution. The patient is then given an anesthetic at the biopsy site.

The needle with attached syringe is inserted into the patient's chest wall. The doctor then draws the plunger of the syringe back to create a vacuum. At this point the patient is asked to take a deep breath, exhale the air and hold their breath at the point of complete exhalation. The needle is inserted into the liver and withdrawn quickly, usually within two seconds or less. The negative pressure in the syringe draws or pulls a sample of liver tissue into the biopsy needle. As soon as the needle is withdrawn, the patient can breathe normally. Pressure is applied at the biopsy site to stop any bleeding, and a bandage will be placed over it. The entire procedure takes 10 to 15 minutes. Test results are usually available within a day.

Preparation

Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen are known to thin the blood and interfere with clotting. These medications should be avoided for at least a week before the biopsy. Four to eight hours before the biopsy, patients should stop eating and drinking.

The patient's blood will be tested prior to the biopsy to make sure that it is clotting normally. Tests will include a platelet count and a prothrombin time. Doctors will also ensure that the patient is not taking any other medications, such as blood thinners like Coumadin, that might affect blood clotting.

Aftercare

Liver biopsies are outpatient procedures in most hospitals. After the biopsy, patients are usually instructed to lie on their right side for about two hours. This provides pressure to the biopsy site and helps prevent bleeding. A nurse will check the patient's vital signs at regular intervals. If there are no complications, the patient is sent home within about four to eight hours.

Patients should arrange to have a friend or relative take them home after discharge. Bed rest for a day is recommended, followed by a week of avoiding heavy work or strenuous exercise. The patient can resume eating a normal diet.

Some mild soreness in the area of the biopsy is normal after the anesthetic wears off. Irritation of the muscle

QUESTIONS TO ASK THE DOCTOR

- Which medications should I stop taking before the biopsy?
- How soon can I return to my normal activities after the biopsy?
- How soon will I get my results?

that lies over the liver can also cause mild discomfort in the shoulder for some patients. Tylenol can be taken for minor soreness, but aspirin and NSAIDs are best avoided. Patients should call their doctor if they have severe pain in the abdomen, chest or shoulder, difficulty breathing, or persistent bleeding. These signs may indicate that there has been leakage of bile into the abdominal cavity, or that air has been introduced into the cavity around the lungs.

Risks

The risks of a liver biopsy are usually very small. When complications do occur, over 90% are apparent within 24 hours after the biopsy. The most significant risk is internal bleeding. Bleeding is most likely to occur in elderly patients, in patients with cirrhosis, or in patients with a tumor that has many blood vessels. Other complications from percutaneous liver biopsies include the leakage of bile or the introduction of air into the chest cavity (pneumothorax). There is also a small chance that an infection may occur, or an internal organ such as the lung, gallbladder, or kidney could be punctured.

Normal results

After the biopsy, the liver sample is sent to the pathology laboratory for study under a microscope. A normal (negative) result would find no evidence of cancer or other disease in the tissue sample.

Abnormal results

Changes in liver tissue that are visible under the microscope indicate abnormal results. Possible causes for the abnormality include the presence of a tumor, or a disease such as hepatitis.

Liver cancer

Definition

Liver cancer is a relatively rare form of cancer but has a high mortality rate. Liver cancers can be classified into two types. They are either primary, when the cancer starts in the liver itself, or metastatic, when the cancer has spread to the liver from some other part of the body.

Description and demographics

Primary liver cancer

Primary liver cancer is a relatively rare disease in the United States, representing about 2% of all malignancies and 4% of newly diagnosed cancers. Hepatocellular **carcinoma** (HCC) is the fifth most common cancer in the world as of 2004. It is much more common outside the United States, representing 10% to 50% of malignancies in Africa and parts of Asia. Rates of HCC in men are at least two to three times higher than for women. In high–risk areas (East and Southeast Asia, sub-Saharan Africa), men are even more likely to have HCC than women.

According to the American Cancer Society, 18,920 people in the United States will be diagnosed with primary liver cancer in 2004, and 14,270 persons will die from the disease. The incidence of primary liver cancer has been rising in the United States and Canada since the mid-1990s, most likely as a result of the rising rate of hepatitis C infections.

TYPES OF PRIMARY LIVER CANCER In adults, most primary liver cancers belong to one of two types: hepatomas, or hepatocellular carcinomas (HCC), which start in the liver tissue itself; and cholangiomas, or cholangiocarcinomas, which are cancers that develop in the bile ducts inside the liver. About 80% to 90% of primary liver

cancers are hepatomas. In the United States, about five persons in every 200,000 will develop a hepatoma (70% to 75% of cases of primary liver cancers are HCC). In Africa and Asia, over 40 persons in 200,000 will develop this form of cancer (more than 90% of cases of primary liver are HCC). Two rare types of primary liver cancer are mixed-cell tumors and Kupffer cell **sarcomas**.

One type of primary liver cancer, called a hepatoblastoma, usually occurs in children younger than four years of age and between the ages of 12 and 15. Unlike liver cancers in adults, hepatoblastomas have a good chance of being treated successfully. Approximately 70% of children with hepatoblastomas experience complete cures. If the tumor is detected early, the survival rate is over 90%.

Metastatic liver cancer

The second major category of liver cancer, metastatic liver cancer, is about 20 times more common in the United States than primary liver cancer. Because blood from all parts of the body must pass through the liver for filtration, cancer cells from other organs and tissues easily reach the liver, where they can lodge and grow into secondary tumors. Primary cancers in the colon, stomach, pancreas, rectum, esophagus, breast, lung, or skin are the most likely to metastasize (spread) to the liver. It is not unusual for the metastatic cancer in the liver to be the first noticeable sign of a cancer that started in another organ. After cirrhosis, metastatic liver cancer is the most common cause of fatal liver disease.

Causes and symptoms

Risk factors

The exact cause of primary liver cancer is still unknown. In adults, however, certain factors are known to place some individuals at higher risk of developing liver cancer. These factors include:

- Male sex.
- Age over 60 years.
- Ethnicity. Asian Americans with cirrhosis have four times as great a chance of developing liver cancer as Caucasians with cirrhosis, and African Americans have twice the risk of Caucasians. In addition, Asians often develop liver cancer at much younger ages than either African Americans or Caucasians.
- Exposure to substances in the environment that tend to cause cancer (carcinogens). These include: a substance produced by a mold that grows on rice and peanuts (aflatoxin); thorium dioxide, which was once used as a contrast dye for x rays of the liver; vinyl chloride, used in manufacturing plastics; and cigarette smoking.
- Use of oral estrogens for birth control.
- Hereditary hemochromatosis. This is a disorder characterized by abnormally high levels of iron storage in the body. It often develops into cirrhosis.
- Cirrhosis. Hepatomas appear to be a frequent complication of cirrhosis of the liver. Between 30% and 70% of hepatoma patients also have cirrhosis. It is estimated that a patient with cirrhosis has 40 times the chance of developing a hepatoma than a person with a healthy liver.
- Exposure to hepatitis viruses: Hepatitis B (HBV), Hepatitis C (HCV), Hepatitis D (HDV), or Hepatitis G (HGV). It is estimated that 80% of worldwide HCC is associated with chronic HBV infection. In Africa and most of Asia, exposure to hepatitis B is an important factor; in Japan and some Western countries, exposure to hepatitis C is connected with a higher risk of developing liver cancer. In the United States, nearly 25% of patients with liver cancer show evidence of HBV infection. Hepatitis is commonly found among intravenous drug abusers. The increase in HCC incidence in the United States is thought to be due to increasing rates of HBV and HCV infections due to increased sexual promiscuity and illicit drug needle sharing. The association between HDV and HGV and HCC is unclear as of the early 2000s.

Symptoms of liver cancer

The early symptoms of primary, as well as metastatic, liver cancer are often vague and not unique to liver disorders. The long period between the beginning of the tumor's growth and the first signs of illness is the major reason why the disease has a high mortality rate. At the time of diagnosis, patients are often fatigued, with **fever**, abdominal pain, and loss of appetite (anorexia). They may look emaciated and generally ill. As the tumor enlarges, it stretches the membrane surrounding the liver (the capsule), causing pain in the upper abdomen on the right side. The pain may extend into the back and shoulder. Some patients develop a collection of fluid, known as **ascites**, in the abdominal cavity. Others may show signs of bleeding into the digestive tract. In addition, the tumor may block the ducts of the liver or the gall bladder, leading to jaundice. In patients with jaundice, the whites of the eyes and the skin may turn yellow, and the urine becomes dark–colored.

Diagnosis

Physical examination

If the doctor suspects a diagnosis of liver cancer, he or she will check the patient's history for risk factors and pay close attention to the condition of the patient's abdo-

men during the physical examination. Masses or lumps in the liver and ascites can often be felt while the patient is lying flat on the examination table. The liver is usually swollen and hard in patients with liver cancer; it may be sore when the doctor presses on it. In some cases, the patient's spleen is also enlarged. The doctor may be able to hear an abnormal sound (bruit) or rubbing noise (friction rub) if he or she uses a stethoscope to listen to the blood vessels that lie near the liver. The noises are caused by the pressure of the tumor on the blood vessels.

Laboratory tests

Blood tests may be used to test liver function or to evaluate risk factors in the patient's history. Between 50% and 75% of primary liver cancer patients have abnormally high blood serum levels of a particular protein (alpha-fetoprotein or AFP). The AFP test, however, cannot be used by itself to confirm a diagnosis of liver cancer, because cirrhosis or chronic hepatitis can also produce high alpha–fetoprotein levels. Tests for alkaline phosphatase, bilirubin, lactic dehydrogenase, and other chemicals indicate that the liver is not functioning normally. About 75% of patients with liver cancer show evidence of hepatitis infection. Again, however, abnormal liver function test results are not specific for liver cancer.

Imaging studies

Imaging studies are useful in locating specific areas of abnormal tissue in the liver. Liver tumors as small as an inch across can now be detected by ultrasound or **computed tomography** scan (CT scan). Imaging studies, however, cannot tell the difference between a hepatoma and other abnormal masses or lumps of tissue (nodules) in the liver. A sample of liver tissue for **biopsy** is needed to make the definitive diagnosis of a primary liver cancer. CT or ultrasound can be used to guide the doctor in selecting the best location for obtaining the biopsy sample.

Chest x rays may be used to see whether the liver tumor is primary or has metastasized from a primary tumor in the lungs.

Liver biopsy

Liver biopsy is considered to provide the definite diagnosis of liver cancer. A sample of the liver or tissue fluid is removed with a fine needle and is checked under a microscope for the presence of cancer cells. In about 70% of cases, the biopsy is positive for cancer. In most cases, there is little risk to the patient from the biopsy procedure. In about 0.4% of cases, however, the patient develops a fatal hemorrhage from the biopsy because some tumors are supplied with a large number of blood vessels and bleed very easily.

Laparoscopy

The doctor may also perform a **laparoscopy** to help in the diagnosis of liver cancer. First, the doctor makes a small cut in the patient's abdomen and inserts a small, lighted tube called a laparoscope to view the area. A small piece of liver tissue is removed and examined under a microscope for the presence of cancer cells.

Clinical staging

Currently, the pathogenesis of HCC is not well understood. It is not clear how the different risk factors for HCC affect each other. In addition, the environmental factors vary from region to region.

Treatment

Treatment of liver cancer is based on several factors, including the type of cancer (primary or metastatic); stage (early or advanced); the location of other primary cancers or metastases in the patient's body; the patient's age; and other coexisting diseases, including cirrhosis. For many patients, treatment of liver cancer is primarily intended to relieve the pain caused by the cancer but cannot cure it.

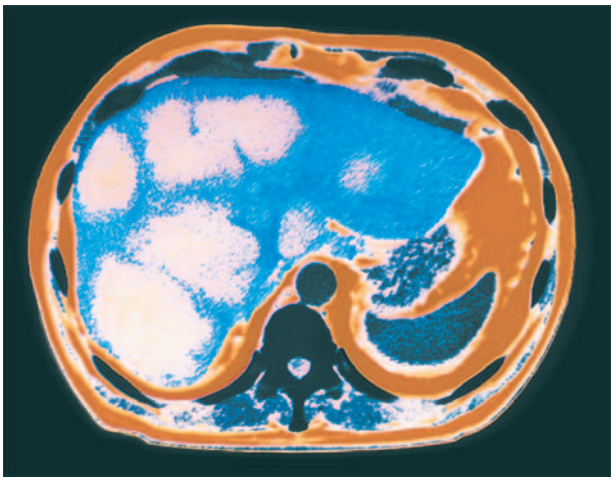
Surgery

Few liver cancers in adults can be cured by surgery because they are usually too advanced by the time they are discovered. If the cancer is contained within one lobe of the liver, and if the patient does not have either cirrhosis, jaundice, or ascites, surgery is the best treatment option. Patients who can have their entire tumor removed have the best chance for survival. Unfortunately, only about 5% of patients with metastatic cancer (from primary tumors in the colon or rectum) fall into this group. If the entire visible tumor can be removed, about 25% of patients will be cured. The operation that is performed is called a partial hepatectomy, or partial removal of the liver. The surgeon will remove either an entire lobe of the liver (a **lobectomy**) or cut out the area around the tumor (a wedge resection).

A newer technique that is reported to be safe and effective is laparoscopic radiofrequency ablation (RFA). RFA is a technique in which the surgeon places a special needle electrode in the tumor under guidance from MRI or CT scanning. When the electrode has been properly placed, a radiofrequency current is passed through it, heating the tumor and killing the cancer cells. RFA can be used to treat tumors that are too small or too inaccessible for removal by conventional open surgery.

Chemotherapy

Some patients with metastatic cancer of the liver can have their lives prolonged for a few months by



Colored computed tomography (CT) scan of axial section through the abdomen showing liver cancer. The vertebra appears dark blue, the liver is large and appears light blue, and the light patches on the liver are the cancerous tumors. *(Copyright Department of Clinical Radiology, Salisbury District Hospital, Science Source/Photo Researchers, Inc. Photo reproduced by permission.)*

chemotherapy, although cure is not possible. If the tumor cannot be removed by surgery, a tube (catheter) can be placed in the main artery of the liver and an implantable infusion pump can be installed. The pump allows much higher concentrations of the cancer drug to be carried to the tumor than is possible with chemotherapy carried through the bloodstream. The drug that is used for infusion pump therapy is usually **floxuridine** (FUDR), given for 14-day periods alternating with 14-day rests. Systemic chemotherapy can also be used to treat liver cancer. The medications usually used are 5-fluorouracil (Adrucil, Efudex) or **methotrexate** (MTX, Mexate). Systemic chemotherapy does not, however, significantly lengthen the patient's survival time.

Radiation therapy

Radiation therapy is the use of high-energy rays or x-rays to kill cancer cells or to shrink tumors. Its use in liver cancer, however, is only to give short-term relief from some of the symptoms. Liver cancers are not sensitive to radiation, and radiation therapy will not prolong the patient's life.

Liver transplantation

Removal of the entire liver (total hepatectomy) and liver transplantation can be used to treat liver cancer. However, there is a high risk of tumor recurrence and metastases after transplantation. In addition, most patients have cancer that is too far advanced at the time of diagnosis to benefit from liver transplantation.

Other therapies

Other therapeutic approaches include:

- Hepatic artery embolization with chemotherapy (chemoembolization).
- Alcohol ablation via ultrasound-guided percutaneous injection.
- Ultrasound-guided cryoablation.
- Immunotherapy with **monoclonal antibodies** tagged with cytotoxic agents.
- Gene therapy with retroviral vectors containing genes expressing cytotoxic agents.

Alternative and complementary therapies

Many patients find that alternative and complementary therapies help to reduce the stress associated with illness, improve immune function, and boost spirits. While there is no clinical evidence that these therapies specifically combat disease, such activities as biofeedback, relaxation, therapeutic touch, massage therapy and guided imagery have no side effects and have been reported to enhance well-being.

Several other healing therapies are sometimes used as supplemental or replacement cancer treatments, such as antineoplastons, cancell, cartilage (bovine and shark), laetrile, and mistletoe. Many of these therapies have not been the subject of safety and efficacy trials by the National Cancer Institute (NCI). The NCI has conducted trials on cancell, laetrile, and some other alternative therapies and found no anticancer activity. These treatments have varying effectiveness and safety considerations. (Laetrile, for example, has caused deaths and is not available in the U.S.) Patients using any alternative remedy should first consult their doctors in order to prevent harmful side effects or interactions with traditional cancer treatment.

Prognosis

Liver cancer has a very poor prognosis because it is often not diagnosed until it has metastasized. Fewer than 10% of patients survive three years after the initial diagnosis; the overall five-year survival rate for patients with hepatomas is around 4%. Most patients with primary liver cancer die within six months of diagnosis, usually from liver failure; fewer than 5% are cured of the disease. Patients with liver cancers that metastasized from cancers in the colon live slightly longer than those whose cancers spread from cancers in the stomach or pancreas.

As of 2004, African American and Hispanic patients have much lower 5-year survival rates than Caucasian patients. It is not yet known, however, whether cultural

KEY TERMS

Aflatoxin—A substance produced by molds that grow on rice and peanuts. Exposure to aflatoxin is thought to explain the high rates of primary liver cancer in Africa and parts of Asia.

Alpha-fetoprotein—A protein in blood serum that is found in abnormally high concentrations in most patients with primary liver cancer.

Cirrhosis—A chronic degenerative disease of the liver, in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Cryoablation—A technique for removing cancerous tissue by killing it with extreme cold.

Hepatitis—A viral disease characterized by inflammation of the liver cells (hepatocytes). People infected with hepatitis B or hepatitis C virus are at an increased risk for developing liver cancer.

Metastatic cancer—A cancer that has spread to an organ or tissue from a primary cancer located elsewhere in the body.

Radiofrequency ablation—A technique for removing a tumor by heating it with a radiofrequency current passed through a needle electrode.

differences as well as biological factors may be partly responsible for the variation in survival rates.

Coping with cancer treatment

Side effects of treatment, nutrition, emotional well-being, and other issues are all parts of coping with cancer. There are many possible side effects for a cancer treatment that include:

- constipation
- delirium
- fatigue
- fever, chills, sweats
- nausea and vomiting
- mouth sores, dry mouth, bleeding gums
- pruritus (itching)
- affected **sexuality**
- sleep disorders

Anxiety, **depression**, feelings of loss, post-traumatic stress disorder, affected sexuality, and substance abuse are all possible emotional side-effects. Patients should seek out a support network to help them through treatment. Loss of appetite before, during, and after a treatment can also be of concern. Other complications of coping with cancer treatment include fever and pain.

Clinical trials

As of 2004, the National Cancer Institute is sponsoring 55 **clinical trials** of treatments for primary liver cancer in adults and 13 trials for treatments of primary liver cancer in children. These trials allow researchers to investigate new types of radiation therapy and chemotherapy, new drugs and drug combinations, biological therapies, ways of combining various types of treatment for liver cancer, side effect reduction, and quality of life. Information on clinical trials can be acquired from the National Cancer Institute at <http://www.nci.nih.gov> or (800) 4-CANCER.

Prevention

There are no useful strategies at present for preventing metastatic cancers of the liver. Primary liver cancers, however, are 75% to 80% preventable. Current strategies focus on widespread vaccination for hepatitis B, early treatment of hereditary hemochromatosis (a metabolic disorder), and screening of high-risk patients with alpha-fetoprotein testing and ultrasound examinations.

Lifestyle factors that can be modified in order to prevent liver cancer include avoidance of exposure to toxic chemicals and foods harboring molds that produce aflatoxin. Most important, however, is avoidance of alcohol and drug abuse. Alcohol abuse is responsible for 60–75% of cases of cirrhosis, which is a major risk factor for eventual development of primary liver cancer. Hepatitis is a widespread disease among persons who abuse intravenous drugs.

See also Alcohol consumption; CT-guided biopsy; Hepatic arterial infusion; Immunologic therapy.

Lobectomy

Definition

A lobectomy is the removal of a lobe of one of the organs, usually referring to the brain, the lung, or the liver.

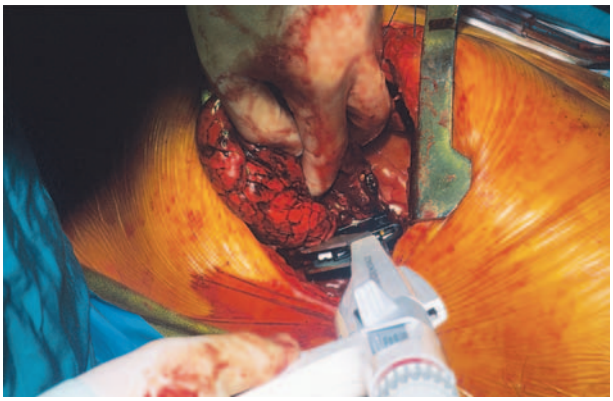
Purpose

Lobectomies are usually performed to prevent the spread of cancer from one part of an organ to other parts or to other parts of the body. Lobectomies also are performed on patients with severe seizure disorders (such as some forms of epilepsy) to prevent further seizures. However, there are differences in each of the three organs on which lobectomies may be performed.

Description

The brain

Each lobe of the brain performs a different function, and when part of the brain is removed, it does not grow back. However, other parts of the brain can take over some, or all, of the function of the missing part of the brain. Depending on the part of the brain removed, the effects may be quite severe, or nearly nonexistent.



Left upper lobectomy. A surgeon is using a stapling device to ligate (tie or bind) the left upper bronchus. The lobar veins and arteries have already been ligated. *(Custom Medical Stock Photo. Reproduced by permission.)*

The most commonly referenced brain lobectomy in the medical literature is the removal of the temporal lobe. Temporal lobectomy usually is performed to prevent debilitating seizures. Seizures are commonly caused by temporal lobe epilepsy, but can also be caused by brain tumors in the temporal lobe. Thus, lobectomy of the temporal lobe in patients with a temporal lobe tumor reduces or eliminates seizures, and has the beneficial side effect of removing the tumor mass.

The lung

Lobectomies of the lung also are called pulmonary lobectomies. Each part of the lung performs the same function: it exchanges oxygen for carbon dioxide in the blood. There are many different lobes of the lung, however, and some lobes exchange more oxygen than others. Lobes of the lung do not regenerate after they are removed. Therefore, removal of a large portion of the lung may cause a person to need oxygen or ventilator support for the rest of his or her life. However, removal of a small portion of the lung may result in very little change to the patient's quality of life. A test (a quantitative ventilation/perfusion scan, or quantitative V/Q scan) may be used before surgery to help determine how much of the lung can safely be removed.

The outcome of lung lobectomies also depends on the general health of the entire lung; emphysema and smoking would have a negative impact on the health of a patient's lung. The surgeon may perform the surgery with video assistance and special tools to decrease pain and speed patient recovery following surgery.

The liver

A lobectomy of the liver is also called a hepatic lobectomy. The liver plays a major role in digestion, in the transformation of food into energy, and in filtering and storing blood. It processes nutrients and drugs, produces bile, controls the level of glucose (sugar) in the blood, detoxifies blood, and regulates blood clotting. Unlike the brain and the lung, the liver may regrow, or regenerate, after part of the liver has been removed. In addition, since every part of the liver performs the same functions, the liver is the organ whose function is least likely to be severely affected by lobectomy, in the long term, because it regenerates. However, as the liver is central to the body's functions, removal of too much of the liver at once may result in coma or death.

Precautions

Brain lobectomies should not be performed unless the patient has been unable to control seizures through medication. Additionally, the seizures must be caused by a single, relatively small, localized part of the brain that can be resected without severe damage. Lung lobectomies should only be performed on patients with early stage non-small cell **carcinoma** of the lung, or as part of a combination of therapies at later stages. Since even a "complete removal" of the tumor does not result in an overwhelming survival rate after five years, other therapies also may be considered. Small cell cancer of the lung does not respond to surgical intervention. Patients with liver disease that is too extensive may need a liver transplant rather than a liver lobectomy. Patients with blood clotting problems, either due to chemotherapeutic agents or for other reasons, should have these problems addressed before surgery.

Preparation

Before surgery, patients should not take aspirin or ibuprofen for one week. Patients also should consult their physician about any blood-thinning medications such as coumadin or **warfarin**. The night before surgery, patients will usually be asked not to eat or drink after a certain time.

Aftercare

Each surgery offers different aftercare challenges. Patients may need to be hospitalized for some time after the operation. Patients with portions of their brain removed may require rehabilitation of a physical, mental, or emotional nature depending on the portion of the brain that has been removed. Patients who have had portions of their lungs removed probably will require a tube in their chest to drain fluid, and may require a machine to help them breathe. They also may require oxygen, either on a temporary or permanent basis. Patients who have had hepatic lobectomies also may have drainage tubes, and may also have initial dietary restrictions. Physicians

QUESTIONS TO ASK THE DOCTOR

- What benefits can I expect from this operation?
- What are the risks of this operation?
- What are the normal results of this operation?
- What happens if this operation doesn't go as planned?
- What is the expected recovery time?

should be consulted for the specifics of aftercare in each individual situation.

Risks

Specific risks vary from surgery to surgery and should be discussed with a physician. In general, any surgery requiring a general anesthetic may, uncommonly, result in death. Improperly performed brain surgery may result in permanent brain damage. Depending on the surgeon and the size of the tissue removed, patients may be at risk for some types of brain damage. As previously mentioned, patients having part of a lung removed may have difficulty breathing and may require the use of oxygen. Patients also may experience infection (**pneumonia**), or blood clots. Liver resection (surgery) may result in the following complications: coma, slow return of normal bowel function, and biliary leakage.

Normal results

Most patients who undergo temporal lobectomy experience few or no seizures after surgery (some estimates range from about 70% to about 90% success rate). Unfortunately, lung lobectomy is not as successful. 50% of cancer patients with completely removable stage I non-small cell cancer of the lung survive five years after the procedure. If the cancer has progressed beyond this stage, or if the cancer is not completely removable, the chances for survival drop significantly. The results of liver resection vary. The possible outcomes of each surgical type should be discussed with the patient's physician. Generally, the less severe the cancer, and the less tissue that needs to be removed, the better the outcome.

Abnormal results

Abnormal results vary from operation to operation and should be discussed thoroughly with the patient's physician before surgery. Patients who undergo temporal lobectomy may, rarely, die as a result of the operation (a complication in less than 1% of patients). Patients also may have problems with their vision, or problems with speech. Abnormal results from the removal of part of the lung could include pneumonia or blood clots (which may result in stroke, heart attack, or other problems) after the surgery. Also, a small percentage of patients undergoing lung lobectomy die during or soon after the surgery. The percentage of patients who suffer death varies from about 3% to 6% depending on the amount of lung tissue removed. Finally, abnormal outcomes from liver resection can include coma, death, and problems with liver function.

Lomustine

Definition

Lomustine is one of the anticancer (antineoplastic) drugs in a class called alkylating agents. It is available under the brand name CeeNU. Another commonly used name is CCNU.

Purpose

Lomustine is primarily used to treat brain tumors and **Hodgkin's disease**, which is a type of cancer that affects the lymph nodes and spleen.

Description

Lomustine chemically interferes with the synthesis of genetic material (DNA and RNA) of cancer cells, which prevents these cells from being able to reproduce and continue the growth of the cancer.

Recommended dosage

Lomustine is taken orally (in pill form). The dosage is typically 100 to 130 mg per square meter of body surface area once every 6 weeks. Lomustine should be taken on an empty stomach just prior to bedtime to prevent possible nausea and/or vomiting. Patients should avoid alcohol one hour before and shortly after taking lomustine.

Precautions

Lomustine can cause an allergic reaction in some people. Patients with a prior allergic reaction to lomustine should not take this drug.

Lomustine can cause harm to the fetus if a woman is taking this drug during pregnancy. Women of childbearing potential should use appropriate contraceptive measures to prevent pregnancy while on lomustine. There have been reports of infertility in men taking this drug due to testicular damage.

It is not known if lomustine is excreted in breast milk. Because of the potential of severe adverse effect, it is recommended that breastfeeding women should discuss with their physician the risk versus benefit of breastfeeding while taking lomustine.

Side effects

Common side effects of lomustine include nausea and/or vomiting, as well as an increased susceptibility to infection due to decreased production in the cells that fight infections. Patients should avoid crowds or exposure to any individuals who may have infections. Also, an increased risk of bleeding can occur due to decreased production of the platelets that are involved with the blood clotting process.

Less common side effects that may also occur include loss of appetite (anorexia), **diarrhea**, temporary hair loss (alopecia), and skin rash.

A doctor should be consulted immediately if the patient experiences any of the following effects:

- black, tarry or bloody stools
- blood in the urine
- confusion
- persistent cough

KEY TERMS

Antineoplastic—A drug that prevents the growth of a neoplasm by interfering with the maturation or proliferation of the cells of the neoplasm.

Neoplasm—New abnormal growth of tissue.

Hodgkins disease—A disease characterized by enlargement of the lymph nodes and spleen.

- fever and chills
- sore throat
- red spots on the skin
- shortness of breath
- unusual bleeding or bruising

Interactions

Lomustine should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician.

Paul A. Johnson, Ed.M.

Loperamide *see* **Antidiarrheal agents**

Lorazepam

Definition

Lorazepam is a tranquilizing drug used in managing anxiety, **nausea and vomiting**, insomnia, and seizures.

Purpose

Lorazepam decreases anxiety. Doctors may order it to treat muscle spasms that may accompany severe pain. Lorazepam may also be given with other drugs to help control nausea and vomiting associated with cancer treatment. It may be given just prior to the administration of **chemotherapy** to decrease the chances of nausea and vomiting. Patients experiencing difficulty sleeping may receive lorazepam. It is sometimes given prior to surgery or other procedures to help the patient relax, feel drowsy, and decrease his or her memory about the procedure.

Description

Lorazepam depresses the central nervous system when taken at the recommended dose.

Recommended dosage

Lorazepam may be given by mouth, injected into a muscle or administered through a vein. Patients should take the smallest dose possible that relieves symptoms. The dose should be adjusted based on the patient's reaction to the drug. Between 0.5 mg and 1 mg of Lorazepam may be given every six to eight hours to aid in controlling treatment-related nausea and vomiting. When given prior to chemotherapy to decrease the risk of this side effect, 2 mg is usually administered 30 minutes before treatment. An additional 2 mg may be given every four hours as needed. To control anxiety, 1 mg to 3 mg at two to three times per day is the typical dose. For sleep, patients may take from 2 mg to 4 mg at bedtime. Older or debilitated adults may be given 0.5 mg to 2 mg per day in divided doses. If a dose is missed, the patient should take it as soon as possible, but patients should not take two pills at the same time. This drug may be taken with or without food.

In 2004, a company called Intranasal Technology, Ltd. received a patent to develop a nasal form of lorazepam. By delivering the drug through the nose (nasal passages), its developers showed it could work faster with fewer side effects. Intranasal Technology was developing a small, inexpensive, manually operated, disposable device to administer the lorazepam.

Precautions

Lorazepam, like other drugs of this type, can create physical and mental dependence. Patients should not take more than the amount ordered and should not suddenly stop taking this medication. The amount taken should gradually be decreased, then discontinued. If the drug is abruptly stopped, the patient may experience agitation, irritability, difficulty sleeping, convulsions, and other withdrawal symptoms.

Patients allergic to this type of anti-anxiety drug should not take lorazepam. Those with narrow-angle glaucoma, pre-existing **depression** of the central nervous system, severe uncontrolled pain, or severe decrease in blood pressure should avoid taking it. This drug should be used cautiously in patients with kidney or liver disease, **myasthenia gravis**, lung disease, alcohol intoxication, or anyone with a history of drug abuse. This drug should not be given to children under 12. Children between 12 and 18 may receive the drug by mouth, but not through a vein. Pregnant women and those trying to become pregnant should not take lorazepam. This drug has been associated with fetal malformations when taken during the first three months of pregnancy. Patients taking this drug should not breast feed their infants.

KEY TERMS

Hallucinations—Seeing or hearing things that are not present.

Tranquilizer—In pharmacology, a drug that calms and relieves anxiety.

Side effects

Drowsiness and sleepiness are common and expected effects of lorazepam. Patients should not drive or operate machinery or appliances while taking this drug. Patients older than 50 years of age may experience greater and longer sedation after receiving lorazepam. These effects may subside with continued use or if the dose is reduced. Patients may experience difficulty walking or fall easily for up to eight hours after receiving an injection of lorazepam, and should ask for assistance when walking. The effects of an injection may impair performance and driving ability for 24 to 48 hours. The impairments may last longer in older patients and those taking other central nervous system depressants, such as pain medication.

Lorazepam may also make patients feel dizzy, weak, unsteady, or clumsy. Less frequently, they may also feel depressed, disoriented, nauseous, or agitated while taking this drug. Other side effects include headache, difficulty sleeping, rash, yellowing eyes, vision changes, and hallucinations. Redness and pain may occur at the injection site. Patients may experience high or low blood pressure and partial blockage of the airway after an injection of lorazepam. Nausea, vomiting, dry mouth, and constipation may occur. Sex drive may decrease, but this side effect is reversible. Patients should alert their physician to any side effects of confusion, depression, excitation, depression, nightmares, impaired coordination, changes in personality, changes in urinary pattern, chest pain, heart palpitations, or any other side effects.

Interactions

Alcohol and other central nervous system depressants can increase the drowsiness associated with this drug. Some over-the-counter medications depress the central nervous system. The herbal remedies kava and valerian may increase the effects of this type of drug. Patients should check with the doctor before starting any new medication. A patient's tolerance for alcohol will be diminished. Patients should refrain from drinking alcoholic beverages when taking lorazepam and for 24 to 48 hours after receiving an injection before a procedure.

When lorazepam is administered in a muscle or vein, it may interact with **scopolamine**, causing drowsiness, odd behavior, and hallucinations.

Loss of appetite *see* **Anorexia**

Low molecular weight heparins

Definition

Low molecular weight heparins (LMWHs) belong to a class of medications known as blood thinners. They are used to stop blood clots from forming and growing.

Purpose

LMWHs are used to prevent and treat blood clots in persons undergoing certain types of surgery, recent heart attack, severe chest pain caused by disease of heart vessels usually from fat deposits (unstable angina), and people who have blood clots in their veins (also known as deep vein thrombosis or DVT) or lungs (also known as pulmonary embolism or PE). As of 2001, there are three drugs that belong to the class of LMWHs: enoxaparin, dalteparin, and tinzaparin. All three have the same mechanism of action, but differ in their doses, structures, and Food and Drug Administration (FDA) indicated uses.

Many cancer patients can become prone to hypercoagulation, or overactive thickening and clotting of the blood. This makes the patient more likely to experience deep vein thrombosis, possibly leading to death.

Description

LMWHs only became available in the mid-1990s, with enoxaparin (Lovenox) being the first and most studied drug in its class. Dalteparin (Fragmin) was the second LMWH to become available and tinzaparin (Innohep) is the latest addition to this class. These medicines work by inhibiting certain clotting factors in the blood (Factor Xa and thrombin) and preventing blood clots from forming and getting bigger.

LMWHs are closely related to **heparin**, which is one of the oldest blood thinners available. These drugs have an advantage over heparin in that they have longer duration in the body, more predictable effects after a given dose, require less blood tests to check for their effectiveness and side effects, and do not have to be given in the hospital setting only. LMWHs have been found to be safe and effective in blood clot prevention after general surgery, orthopedic surgery, neurosurgery, multiple trauma, hip fracture, certain types of stroke, unstable angina, heart attack and treatment DVT and PE. These drugs are usually given with **warfarin** (Coumadin) for treatment of blood clots and with aspirin for prevention of complications after heart attack or angina attack. Besides their use for blood clot prevention and treatment, there have been some research studies in animals and humans to suggest that they may prevent cancer by decreasing the blood supply needed for the tumor to grow. The effects of LMWHs on patients with cancer and blood clots are being investigated. In 2004, clinical trails suggested that LMWHs might interfere with tumor growth and cancer spread, but further study was needed.

Recommended dosage

Administration

These medicines are given by injection beneath the skin (subcutaneous injection) and should not be injected directly into the vein or muscle. Injections can be given around the navel, upper thigh or buttock. The injection site should be changed daily. Massaging of the site before injection with an ice cube can decrease excessive bruising.

Doses and indications differ between three medicines. These drugs can not be used interchangeably for one another.

Adults

PREVENTION OF BLOOD CLOTS AFTER ORTHOPEDIC SURGERY The usual dose of tinzaparin is 50 units per kg daily starting two hours before surgery and continuing for 7–10 days. Doses of 75 units per kg per day have also been studied.

PREVENTION OF BLOOD CLOTS AFTER HIP OR KNEE REPLACEMENT SURGERY Doses vary between different agents. The usual enoxaparin dose is 30 mg every 12 hours starting 12–24 hours after surgery in patients undergoing hip or knee surgery. Alternatively, 40 mg once a day with the first dose given approximately 12 hours before surgery can be used in patients undergoing hip replacement surgery. The average duration of the initial phase of treatment is 7–10 days (up to 14 days). After the initial phase, 40 mg once a day for three weeks is recommended.

For people undergoing hip replacement surgery, 5,000 units of dalteparin are given 10–14 hours before surgery, then 5,000 units 4–8 hours after surgery, followed by 5,000 units daily. The therapy is usually continued for five to ten days (up to 14 days). A physician should be consulted for alternative dosing regimens.

PREVENTION OF DVT IN PATIENTS AT HIGH RISK FOR BLOOD CLOTS AFTER ABDOMINAL SURGERY. Enoxaparin is usually given at a dose of 40 mg once daily with the first dose given two hours before surgery for seven to ten days, up to 12 days.

In patients who are at moderate to high risk of blood clots, the usual dose of dalteparin is 2,500 units daily generally given for five to ten days. The first dose should be given one to two hours before surgery. In patients who are at high to very high risk of blood clots (those with cancer or history of DVT or PE) 5,000 units are given on the evening before surgery, followed by 5,000 units/day for five to ten days. A physician should be consulted for alternative dosing schedules.

Tinzaparin is usually dosed at 3,500 units daily starting two hours before surgery and continuing for seven to ten days.

TREATMENT OF DVT WITH OR WITHOUT PE Enoxaparin doses of 1 mg per kg twice a day are given when people are treated at home. People who are treated in the hospital can be given 1 mg per kg twice a day or 1.5 mg per kg at the same time once a day. Warfarin is usually given to finish treatment and the two drugs overlap for about 72 hours until good response to warfarin is confirmed by blood tests.

Tinzaparin is usually dosed at 175 units per kg daily for six days or until good response to warfarin is confirmed by blood tests.

UNSTABLE ANGINA OR HEART ATTACK In patients who are also getting aspirin the usual dose of enoxaparin is 1 mg per kg every 12 hours for a minimum of two days (usually two to eight days).

The usual dose of dalteparin in people who are also getting aspirin is 120 units per kg (up to a maximum 10,000 units) every 12 hours. Treatment should continue until the patient is stable for five to eight days.

Children

TREATMENT OF DVT WITH OR WITHOUT PE Children younger than two months of age should receive enoxaparin 1.5 mg per kg every 12 hours. Children older than two months of age should receive enoxaparin 1 mg per kg every 12 hours. A physician will do a blood test four to six hours after the dose to check for effectiveness.

PREVENTION OF BLOOD CLOTS The usual dose of enoxaparin is 0.75 mg per kg every 12 hours for children younger than two months and 0.5 mg per kg every 12 hours for children older than two months of age. A physician will do a blood test four to six hours after the dose to check for effectiveness.

Precautions

The use of LMWHs should be avoided in persons undergoing any procedure involving spinal puncture or anesthesia. Using these medicines before these procedures has caused severe bruising and bleeding into the spine and can lead to paralysis.

The use of these medicines should be avoided in patients with allergies to LMWHs, heparin, or pork products, allergies to sulfites or benzyl alcohol, people with active major bleeding, and people with a history of heparin-induced low blood platelet count (also known as heparin-induced **thrombocytopenia** or HIT).

LMWHs should be used with caution in the following persons:

- people with bleeding disorders
- people with a history of recent stomach ulcers
- people who recently had brain, spine, or eye surgery
- people on other blood thinners (such as warfarin, aspirin, ibuprofen, naproxen) because of increased risk of bleeding
- people with kidney or liver disease (the dose of LMWHs may need to be decreased)
- breast-feeding mothers (it is not known if these medicines cross into breast milk)
- women who are pregnant, unless benefits to the mother outweigh the risks to the baby

A doctor should be contacted immediately if any of these symptoms develop:

- tingling, weakness, numbness or pain
- blood in the urine or stool
- itching, swelling, skin rash, trouble breathing
- unusual bleeding or bruising

A physician may perform blood tests during therapy with LMWHs to prevent side effects. Blood tests to check for effectiveness of these medicines are usually not needed, except in children, people with kidney disease, and overweight persons.

Side effects

The most common side effects of LMWHs include irritation and pain at the injection site, easy bruising and

KEY TERMS

Deep vein thrombosis—Also known as DVT, a condition in which a blood clot (thrombus) formed in one part of the circulation, becomes detached and lodges at another point (usually in one of the veins of the legs or arms). People may feel pain, redness, and swelling at the site where the blood clot lodges in. This condition is treated with blood thinning drugs such as LMWHs, heparin, or warfarin.

Pulmonary embolism—Also known as PE, a condition in which a blood clot usually formed in of the leg veins becomes detached and lodges in the lung artery or one of its branches. Patients may be coughing up blood and experience trouble breathing. This condition is treated with blood thinning drugs such as LMWHs, heparin, or warfarin.

bleeding, **fever**, increase in liver enzyme tests usually without symptoms, and allergic reactions. Severe painful erection sometimes requiring surgery has been reported with tinzaparin in some patients. LMWHs can lower platelet counts, which may necessitate discontinuation.

Interactions

LMWHs should be used with caution in people on other oral blood thinners (aspirin, non-steroidal anti-inflammatory drugs, warfarin, and ticlopidine) because of increased risk of bleeding. If using both drugs together is necessary, the patients must be closely monitored.

Lumbar puncture

Definition

Lumbar puncture (LP) is the technique of using a needle to withdraw cerebrospinal fluid (CSF) from the spinal canal. CSF is the clear, watery liquid that protects the central nervous system from injury and cushions it from the surrounding bone structure. It contains a variety of substances, particularly glucose (sugar), protein, and white blood cells from the immune system.

Purpose

Lumbar puncture, or spinal tap, is used to diagnose some malignancies, such as certain types of brain cancer and leukemia, as well as other medical conditions that affect the central nervous system. It is sometimes used to assess patients with certain psychiatric symptoms and conditions.

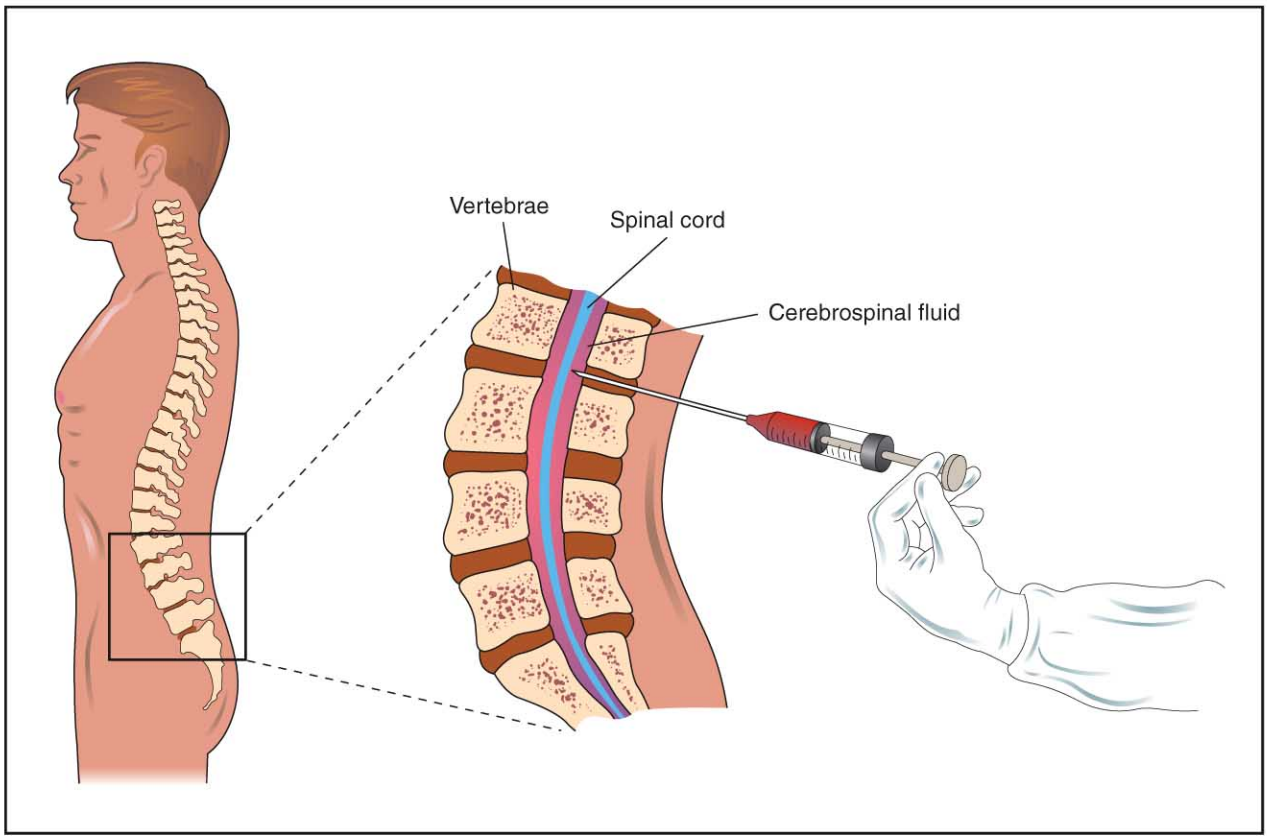
It is also used for injecting **chemotherapy** directly into the CSF. This type of treatment is called intrathecal therapy. Other medical conditions diagnosed with lumbar puncture include:

- viral and bacterial meningitis
- syphilis, a sexually transmitted disease
- bleeding (hemorrhaging) around the brain and spinal cord
- multiple sclerosis, a disease that affects the myelin coating of the nerve fibers of the brain and spinal cord
- Guillain-Barré syndrome, an inflammation of the nerves

Precautions

In some circumstances, a lumbar puncture to withdraw a small amount of CSF for analysis may lead to serious complications. Lumbar puncture should be performed only with extreme caution, and only if the benefits are thought to outweigh the risks, in certain conditions. For example, in people who have blood clotting (coagulation) or bleeding disorders or who are on anticoagulant treatment, lumbar puncture can cause bleeding that can compress the spinal cord. The term for this condition is spinal subdural hematoma, and it is a rare complication. However, it is of concern to some cancer patients whose low platelet counts (**thrombocytopenia**) make them more susceptible to bleeding. In some cases, these patients are given a platelet transfusion prior to lumbar puncture, but this procedure is still under investigation. A 1984–88 study, supported in part by the National Cancer Institute, researched the risk of lumbar puncture on children with acute lymphoblastic leukemia (ALL). No serious lumbar puncture complications were observed in this study of over 5,000 children.

Lumbar puncture has been shown to be less precise than some other methods in monitoring intracranial fluid pressure. A transducer provides more accurate information about changes in the flow of blood and cerebrospinal fluid within the brain.



During a lumbar puncture, or spinal tap, the physician inserts a hollow thin needle in the space between two vertebrae of the lower back and slowly advances it toward the spine. The cerebrospinal fluid pressure is then measured and some fluid is withdrawn for laboratory analysis. *(Electronic Illustrators Group.)*

A traumatic lumbar puncture (TLP) occurs when a blood vessel is inadvertently ruptured during the procedure. If this happens as part of a diagnostic leukemia workup, there is the potential of contaminating the CSF specimen that has been removed with leukemia cells, causing a false positive test result.

If there is a large brain tumor or other mass, removal of CSF can cause pressure shifts within the brain (herniation), causing compression of the brain stem and other vital structures, and leading to irreversible brain damage or death. These problems are easily avoided by checking blood coagulation through a blood test and by doing a **computed tomography** scan (CT) or **magnetic resonance imaging** (MRI) scan before attempting the lumbar puncture. In addition, a lumbar puncture procedure should never be performed at the site of a localized skin infection on the lower back because the infection may be introduced into the CSF and may spread to the brain or spinal cord.

Description

In a lumbar puncture, the area of the spinal column used to obtain the CSF sample is in the lumbar spine, or lower section of the back. In rare instances, such as a spinal fluid blockage in the middle of the back, a doctor may perform a spinal tap in the neck. The lower lumbar spine (usually between the vertebrae known as L4–5) is preferable because the spinal cord stops near L2, and a needle introduced below this level will miss the spinal cord and encounter only nerve roots, which are easily pushed aside.

A lumbar puncture takes about 15–30 minutes. Patients can undergo the test in a doctor's office, laboratory, or outpatient hospital setting. Sometimes it requires an inpatient hospital stay. If the patient has severe osteoarthritis of the spine, is extremely uncooperative, or obese, it may be necessary to introduce the spinal needle using x-ray guidance.

In order to get an accurate sample of cerebrospinal fluid, it is critical that a patient is in the proper position. The spine must be curved to allow as much space as possible between the lower vertebrae, or bones of the back, for the doctor to insert a lumbar puncture needle between the vertebrae and withdraw a small amount of fluid. The most common position is for the patient to lie on his or

KEY TERMS

Acute lymphoblastic leukemia (ALL)—A type of leukemia, also called acute lymphocytic leukemia, primarily in children, affecting lymphocytes.

Encephalitis—An inflammation or infection of the brain and spinal cord caused by a virus or as a complication of another infection.

Guillain-Barré syndrome—An inflammation involving nerves that affects the extremities. The inflammation may spread to the face, arms, and chest.

Immune system—Protects the body against infection.

Intrathecal therapy—Injecting chemotherapy directly into the CSF using lumbar puncture.

Manometer—A device used to measure fluid pressure.

Meningitis—An infection or inflammation of the membranes or tissues that cover the brain and spinal cord, and caused by bacteria or a virus.

Multiple sclerosis—A disease that destroys the covering (myelin sheath) of nerve fibers of the brain and spinal cord.

Spinal canal—The cavity or hollow space within the spine that contains cerebrospinal fluid.

Thrombocytopenia—Reduced platelet levels.

Vertebrae—The bones of the spinal column. There are 33 along the spine, with five (called L1–L5) making up the lower lumbar region.

her side with the back at the edge of the exam table, head and chin bent down, knees drawn up to the chest, and arms clasped around the knees. (Small infants and people who are obese may need to curve their spines in a sitting position.) People should talk to their doctors if they have any questions about their position because it is important to be comfortable and to remain still during the entire procedure. In fact, the doctor will explain the procedure to the patient (or guardian) so that the patient can agree in writing to have it done (informed consent). If the patient is anxious or uncooperative, a short-acting sedative may be given.

During a lumbar puncture, the doctor drapes the back with a sterile covering that has an opening over the puncture site and cleans the skin surface with an antiseptic solution. Patients receive a local anesthetic to minimize any pain in the lower back.

The doctor inserts a thin hollow needle in the space between two vertebrae of the lower back and slowly advances it through ligamentous tissues toward the spine. A steady flow of clear cerebrospinal fluid, normally the color of water, will begin to fill the needle as soon as it enters the spinal canal. The doctor measures the cerebrospinal fluid pressure with a special instrument called a manometer and withdraws several vials of fluid for laboratory analysis. The amount of fluid collected depends on the type and number of tests needed to diagnose a particular medical disorder.

In some cases, the doctor must remove and reposition the needle. This occurs when there is not an even flow of fluid, the needle hits bone or a blood vessel, or the patient reports sharp, unusual pain.

Preparation

Patients can go about their normal activities before a lumbar puncture. Experts recommend that patients relax before the procedure to release any muscle tension, since the lumbar puncture needle must pass through muscle tissue before it reaches the spinal canal. A patient's level of relaxation before and during the procedure plays a critical role in the test's success. Relaxation may be difficult for those patients who face frequent lumbar punctures, such as children with leukemia. In these cases, it is especially important for the child to receive psychological support before and after each procedure. It may be helpful to praise a child who remained still and quiet during the procedure, and to remind the child of his or her good behavior before the next lumbar puncture.

Aftercare

After the procedure, the doctor covers the site of the puncture with a sterile bandage. Patients must avoid sitting or standing and remain lying down for as long as six hours after the lumbar puncture. They should also drink plenty of fluids to help prevent lumbar puncture headache, which is discussed in the next section.

Risks

The most common side effect of lumbar puncture is a headache. This problem occurs in 10–20% of adult patients and in up to 40% of children. It is caused by decreased CSF pressure related to a small leak of CSF through the puncture site. These headaches usually are a dull pain, although some people report a throbbing sensation. A stiff neck and nausea may accompany the headache. A lumbar puncture headache typically begins within a few hours to two days after the procedure and usually persists a few days, although it can last several weeks or months.

QUESTIONS TO ASK THE DOCTOR

- What is the purpose of my lumbar puncture?
- What aftercare will be needed?
- Will lumbar puncture be used for chemotherapy, and if so, how often will I receive treatments?
- What are the risks for diagnostic procedures or treatments through lumbar puncture?
- What do the test results mean?
- What techniques are suggested to relax children before and after a lumbar puncture?

In some cases, the headache can be prevented by lying flat for an hour after the lumbar puncture, and taking in more fluids for 24 hours after the procedure. Since an upright position worsens the pain, lying flat also helps control the pain, along with prescription or non–prescription pain relief medication, preferably one containing caffeine. In rare cases, the puncture site leak is "patched" using the patient's own blood. People may also experience back pain. Headaches and backaches appear to be more common in adolescents than in younger children, and more common in girls than in boys.

Patients who receive anticancer drugs through lumbar puncture sometimes have **nausea and vomiting**. Intrathecal **methotrexate** can cause mouth sores. Some of these symptoms may be relieved by anti-nausea drugs prescribed by the physician.

In a very few cases, lumbar puncture in infants can lead to such complications as paraplegia. These complications are associated with the smaller size of the infant's central nervous system and increased difficulty in avoiding certain parts of the spinal cord when performing an LP.

People should talk to their doctors about complications from a lumbar puncture. In most cases, this procedure is safe and effective. Some patients experience pain, difficulty urinating, infection, or leakage of cerebrospinal fluid from the puncture site after the procedure.

Normal results

Normal CSF is clear and colorless. It may be straw or yellow–colored if there is excess protein, which may occur with cancer or inflammation. It may be cloudy in infections; blood–tinged if there was recent bleeding; or yellow to brown (xanthochromic) if caused by an older instance of bleeding.

A series of laboratory tests analyze the CSF for a variety of substances to rule out cancer or other medical disorders of the central nervous system. The following are normal values for commonly tested substances:

- CSF pressure: 50–180 mmH_2O
- Glucose: 40–85 mg/dL
- Protein: 15–50 mg/dL
- Leukocytes (white blood cells) total less than 5 per mL
- Lymphocytes (specific type of white blood cell): 60–70%
- Monocytes (a kind of white blood cell): 30–50%
- Neutrophils (another kind of white blood cell): none

Normally, there are no red blood cells in the CSF unless the needle passes though a blood vessel on route to the CSF. If this is the case, there should be more red blood cells in the first tube collected than in the last.

Abnormal results

A lumbar puncture is sometimes used as part of a diagnostic cancer workup. Abnormal test result values in the pressure or any of the substances found in the cerebrospinal fluid may suggest a number of medical problems including a tumor or spinal cord obstruction; hemorrhaging or bleeding in the central nervous system; infection from bacterial, viral, or fungal microorganisms; or an inflammation of the nerves. If there is a tumor in the meninges (membranes around the brain and spinal cord), the CSF may have higher protein levels, lower glucose levels, and a mild increase in lymphocytes (pleocytosis). It is important for patients to review the results of a cerebrospinal fluid analysis with their doctor and to discuss any treatment plans.

Lumpectomy

Definition

A lumpectomy is a type of surgery for **breast cancer**. It is considered "breast-conserving" surgery because in a lumpectomy, only the malignant tumor and a surrounding margin of normal breast tissue are removed. Lymph nodes in the armpit (axilla) also may be removed. This procedure is called **lymph node dissection**.

Purpose

Lumpectomy is a surgical treatment for newly diagnosed breast cancer. It is estimated that at least 50% of women with breast cancer are good candidates for this procedure. The location, size, and type of tumor are of primary importance when considering breast cancer surgery options. The size of the breast is another factor the surgeon considers when recommending surgery. The patient's psychological outlook, as well as her lifestyle and preferences, should also be taken into account when treatment decisions are made.

The extent and severity of a cancer is evaluated or "staged" according to a fairly complex system. Staging considers the size of the tumor and whether the cancer has spread to other areas, such as the chest wall, the lymph nodes, and/or to distant parts of the body. Women with early stage breast cancers are usually better candidates for lumpectomy. In most cases, a course of **radiation therapy** after surgery is part of the treatment. **Chemotherapy** or antiestrogens also may be prescribed.

Many studies have compared the survival rates of women who have had removal of a breast (**mastectomy**) with those who have undergone lumpectomy and radiation therapy. The data demonstrate that for women with comparable stages of breast cancer, survival rates are similar between the two groups, but the risk of the cancer recurring in the breast is slightly higher with lumpectomy. A 2003 study confirmed that younger women who have lumpectomies have a higher risk of tumor recurrence than those who have mastectomies.

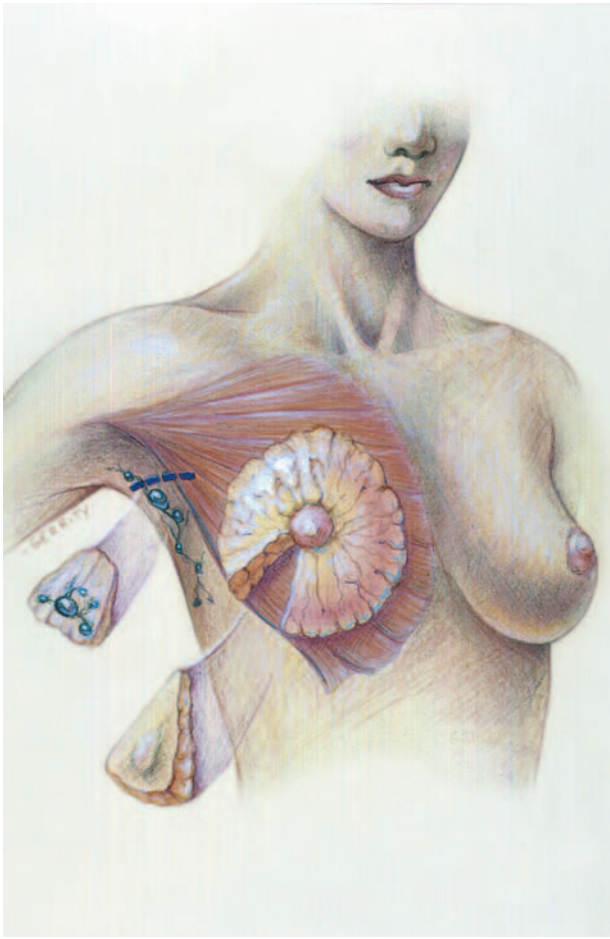
In some instances, women with later stage breast cancer may be able to have lumpectomy. Chemotherapy may be administered before surgery to decrease tumor size and the chance of spread in selected cases.

Precautions

A number of factors may prevent or prohibit a breast cancer patient from having a lumpectomy. The tumor itself may be too large or located in an area where it would be difficult to remove with good cosmetic results. Sometimes several areas of cancer are found in one breast, so the tumor cannot be removed as a single lump. A cancer that has already attached itself to nearby structures, such as the skin or the chest wall, needs more extensive surgery.

Certain medical or physical circumstances also may eliminate lumpectomy as a treatment option. Sometimes lumpectomy may be attempted, but the surgeon is unable to remove the tumor with a sufficient amount of normal tissue surrounding it. This may be termed "persistently positive margins," or "lack of clear margins," referring to the margin of unaffected tissue around the tumor. Lumpectomy is not used for women who have had a previous lumpectomy and have a recurrence of the breast cancer.

The need for radiation therapy after lumpectomy makes this surgery medically unacceptable for some women. For instance, radiation therapy cannot be



Lumpectomy is one form of breast cancer treatment in which the tumor and surrounding tissue is removed, thus preserving the breast. This illustration also shows the removal of the lymph nodes. *(Photograph by Peg Gerrity. Reproduced by permission.)*

administered to pregnant women because it may injure the fetus. If, however, delivery would be completed prior to the need for radiation, pregnant women may undergo lumpectomy. Women with collagen vascular disease, such as lupus erythematosus or scleroderma, would experience scarring and damage to their connective tissue if exposed to radiation treatments. A woman who has already had therapeutic radiation to the chest area for other reasons cannot have additional exposure for breast cancer therapy.

Some women may choose not to have a lumpectomy for other reasons. They may strongly fear a recurrence of breast cancer, and may consider a lumpectomy too risky. Others feel uncomfortable with a breast that has had a cancer, and they experience more peace of mind with the entire breast removed.

The need for radiation therapy may also be a barrier due to non-medical concerns. Some women simply fear this type of treatment and choose more extensive surgery so that radiation will not be required. The commitment of time, usually five days a week for six weeks, may not be acceptable for others. This may be due to financial, personal, or job-related constraints. Finally, in geographically isolated areas, a course of radiation therapy may require lengthy travel, and perhaps unacceptable amounts of time away from family and other responsibilities.

Description

Lumpectomy is an imprecise term. Any amount of tissue, from 1% to 50% of the breast, may be removed and called a lumpectomy. Breast conservation surgery is a frequently used synonym for lumpectomy. Partial mastectomy, quadrantectomy, segmental excision, wide excision, and tylectomy are other, less commonly used names for this procedure.

A lumpectomy is frequently done in a hospital setting (especially if lymph nodes are to be removed at the same time), but specialized outpatient facilities are sometimes preferred. The surgery is usually done while the patient is under general anesthesia. Local anesthetic with additional sedation may be used for some patients. The tumor and surrounding margin of tissue is removed and sent to the pathologist. The surgical site is closed.

If axillary lymph nodes were not removed in a prior biopsy, a second incision is made in the armpit. The fat pad that contains lymph nodes is removed from this area and is also sent to the pathologist for analysis. This portion of the procedure is called an axillary lymph node dissection; it is critical for determining the stage of the cancer. Typically, 10 to 15 nodes are removed, but the number may vary. Surgical drains may be left in place in either location to prevent fluid accumulation. The surgery may last from one to three hours.

The patient may stay in the hospital one or two days, or return home the same day. This generally depends on the extent of the surgery and the medical condition of the patient, as well as physician and patient preferences. A woman usually goes home with a small bandage. The inner part of the surgical site usually has dissolvable stitches. The skin may be sutured or stitched; or the skin edges may be held together with steristrips, which are special thin, clear pieces of tape.

Preparation

Routine preoperative preparations, such as having nothing to eat or drink the night before surgery, are typically ordered for a lumpectomy. Information about expected outcomes and potential complications is also part of preparation for lumpectomy, as it is for any surgical procedure. It is especially important that women

know about sensations they might experience after the operation, so the sensations are not misinterpreted as signs of further cancer or poor healing.

If the tumor is not able to be felt (not palpable), a pre-operative localization procedure is needed. A fine wire, or other device, is placed at the tumor site, using **x ray** or ultrasound for guidance. This is usually done in the radiology department of a hospital. The woman is most often sitting up and awake, although some sedation may be administered.

Aftercare

After a lumpectomy, patients are usually cautioned against lifting anything that weighs more than five pounds for several days. Other activities may be restricted (especially if the axillary lymph nodes were removed) according to individual needs. Pain is often enough to limit inappropriate motion. Women are often instructed to wear a well-fitting support bra both day and night for approximately one week after surgery.

Pain is usually well controlled with prescribed medication. If it is not, the patient should contact the surgeon, as severe pain may be a sign of a complication, which needs medical attention. A return visit to the surgeon is normally scheduled approximately ten days to two weeks after the operation. Studies have shown that women improve their survival rates after lumpectomy if they stop smoking.

Radiation therapy is usually started as soon as feasible after lumpectomy. Other additional treatments, such as chemotherapy or hormone therapy, may also be prescribed. The timing of these is specific to each individual patient.

Risks

The risks are similar to those associated with any surgical procedure. Risks include bleeding, infection, asymmetry, anesthesia reaction, or unexpected scarring. A lumpectomy also may cause loss of sensation in the breast. The size and shape of the breast will be affected by the operation. Fluid can accumulate in the area where tissue was removed, requiring drainage.

If lymph node dissection is performed, there are several potential complications. A woman may experience decreased feeling in the back of her armpit. She may also experience other sensations, including numbness, tingling, or increased skin sensitivity. An inflammation of the arm vein, called phlebitis, can occur. There may be injury to the nerves controlling arm motion.

KEY TERMS

Lymph node—A small mass of tissue in the form of a knot or protuberance. They are the primary source of lymph fluid, which serves in the body's defense by removing toxic fluids and bacteria.

Approximately 2% to 10% of patients develop lymphedema (swelling of the arm) after axillary lymph node dissection. This swelling of the arm can range from mild to very severe. It can be treated with elastic bandages and specialized physical therapy, but it is a chronic condition, requiring continuing care. Lymphedema can arise at any time, even years after surgery.

A new technique often eliminates the need for removing many axillary lymph nodes. **Sentinel lymph node mapping** and **biopsy** is based on the idea that the condition of the first lymph node in the network, which drains the affected area, can predict whether the cancer may have spread to the rest of the nodes. It is thought that if this first, or sentinel, node is cancer-free, there is no need to look further. Many patients with early-stage breast cancers may be spared the risks and complications of axillary lymph node dissection as the use of this approach continues to increase.

Normal results

When lumpectomy is performed, it is anticipated that it will be the definitive surgical treatment for breast cancer. Other forms of therapy, especially radiation, are often prescribed as part of the total treatment plan. A 2003 study reported that radiation of the entire breast produces better results than radiation of part of the breast. The expected outcome after lumpectomy and radiation is no recurrence of the breast cancer, however, women who have had lumpectomies, particularly those who were young at the time of treatment, should continue to see their physicians for regular breast cancer check-ups, since the cancer can recur.

Abnormal results

An unforeseen outcome of lumpectomy may be recurrence of the breast cancer, either locally or distally (in a part of the body far from the original site). Recurrence may be discovered soon after lumpectomy or years after the procedure. For this reason, it is important for patients to be regularly and closely monitored by their physicians. A 2003 report showed that magnetic resonance imaging (MRI) is accurate in detecting any cancer left in the breast after lumpectomy. Women should

continue to have regular mammograms. While the scar tissue from lumpectomy and radiation therapy can make mammograms less comfortable, a special cushion was approved by the U.S. Food and Drug Administration in 2003 that reduces discomfort in women who have had breast conserving surgery.

Lung cancer, non-small cell

Definition

Non-small cell lung cancer (NSCLC) is a disease in which the cells of the lung tissues grow uncontrollably and form tumors.

Description

There are two kinds of lung cancers, primary and secondary. Primary lung cancer starts in the lung itself, and is divided into small cell lung cancer and non-small cell lung cancer. Small cell lung cancers are shaped like an oat and called oat-cell cancers; they are aggressive, spread rapidly, and represent 20% of lung cancers. Non-small cell lung cancer represents almost 80% of all primary lung cancers. Secondary lung cancer is cancer that starts somewhere else in the body (for example, the breast or colon) and spreads to the lungs.

The lungs

The lungs are located along with the heart in the chest cavity. The lungs are not simply hollow balloons but have a very organized structure consisting of hollow tubes, blood vessels and elastic tissue. The hollow tubes, called bronchi, are highly branched, becoming smaller and more numerous at each branching. They end in tiny, blind sacs made of elastic tissue called alveoli. These sacs are where the oxygen a person breathes in is taken up into the blood, and where carbon dioxide moves out of the blood to be breathed out.

Normal healthy lungs are continually secreting mucus that not only keeps the lungs moist, but also protects the lungs by trapping foreign particles like dust and dirt in breathed air. The inside of the lungs is covered with small hairlike structures called cilia. The cilia move in such a way that mucus is swept up out of the lungs and into the throat.

Lung cancer

Most lung cancers start in the cells that line the bronchi, and can take years to develop. As they grow larger they prevent the lungs from functioning normally. The tumor can reduce the capacity of the lungs, or block the movement of air through the bronchi in the lungs. As a result, less oxygen gets into the blood and patients feel short of breath. Tumors may also block the normal movement of mucus up into the throat. As a result, mucus builds up in the lungs and infection may develop behind the tumor. Once lung cancer has developed, it frequently spreads to other parts of the body.

The speed at which non-small cell tumors grow depends on the type of cells that make up the tumor. The following three types account for the vast majority of non-small cell tumors:

- Adenocarcinomas are the most common and often cause no symptoms. Frequently they are not found until they are advanced.
- Squamous cell carcinomas usually produce symptoms because they are centrally located and block the lungs.
- Undifferentiated large cell and giant cell carcinomas tend to grow rapidly, and spread quickly to other parts of the body.

Demographics

Worldwide, lung cancer is the most common cancer in males, and the fifth most common cancer in women. The worldwide mortality rate for patients with lung cancer is 86%. In the United States, lung cancer is the leading cause of death from cancer among both men and women. The World Health Organization estimates that the worldwide mortality from lung cancer will increase to three million by the year 2025. Of those three million deaths, almost two and a half million will result from non-small cell lung cancer.

The American Cancer Society (ACS) estimates that 173,770 Americans will develop lung cancer in 2004, 93,110 men and 80,660 women. Of these patients, 160,440 will die of the disease.

The incidence of lung cancer is beginning to fall in developed countries. This may be a result of antismoking campaigns. In developing countries, however, rates continue to rise, which may be a consequence of both industrialization and the increasing use of tobacco products.

Causes and symptoms

Causes

Tobacco smoking accounts for 87% of all lung cancers. Giving up tobacco can prevent most lung cancers. Smoking **marijuana cigarettes** is considered another risk factor for cancer of the lung. Second-hand smoke also contributes to the development of lung cancer among nonsmokers.

Certain hazardous materials that people may be exposed to in their jobs have been shown to cause lung cancer. These include asbestos, coal products, and radioactive substances. Air pollution may also be a contributing factor. Exposure to radon, a colorless, odorless gas that sometimes accumulates in the basement of homes, may cause lung cancer in a tiny minority of patients. In addition, patients whose lungs are scarred from other lung conditions may have an increased risk of developing lung cancer.

Symptoms

Lung cancers tend to spread very early, and only 15% are detected in their early stages. The chances of early detection, however, can be improved by seeking medical care at once if any of the following symptoms appear:

- a cough that does not go away
- chest pain
- shortness of breath
- recurrent lung infections, such as bronchitis or pneumonia
- bloody or brown-colored spit or phlegm (sputum)
- persistent hoarseness
- significant **weight loss** that is not due to dieting or vigorous exercise; **fatigue** and loss of appetite (anorexia)
- unexplained fever

Although these symptoms may be caused by diseases other than lung cancer, it is important to consult a doctor to rule out the possibility of lung cancer.

If lung cancer has spread to other organs, the patient may have other symptoms such as headaches, bone fractures, pain, bleeding, or blood clots.

Diagnosis

Physical examination and diagnostic tests

The doctor will first take a detailed medical history and assess risk factors. During a complete physical examination the doctor will examine the patient's throat to rule out other possible causes of hoarseness or coughing, and will listen to the patient's breathing and chest sounds.

If the doctor has reason to suspect lung cancer, particularly if the patient has a history of heavy smoking or occupational exposure to irritating substances, a chest **x ray** may be ordered to see if there are any masses in the lungs. Special imaging techniques, such as **computed tomography** (CT) scans or **magnetic resonance imaging** (MRI), may provide more precise information about the size, shape, and location of any tumors.

Sputum analysis

Sputum analysis is a noninvasive test that involves microscopic examination of cells that are coughed up from the lungs. This test can diagnose at least 30% of lung cancers, even if tumors are not visible on chest x rays. In addition, the test can detect cancer in its very early stages, before it spreads to other regions. The sputum test does not provide any information about the location of the tumor.

Lung biopsy

Lung **biopsy** is the most definitive diagnostic tool for cancer. It can be performed in three different ways. **Bronchoscopy** involves the insertion of a slender, lighted tube, called a bronchoscope, down the patient's throat and into the lungs. This test allows the doctor to see the tubes inside the lungs, and to obtain samples of lung tissue. If a needle biopsy is to be performed, the location of the tumor is first identified using a computerized tomography (CT) scan or magnetic resonance imaging (MRI). The doctor then inserts a needle through the

chest wall and collects a sample of tissue from the tumor. In the third procedure, known as surgical biopsy, the chest wall is opened up and a part of the tumor, or all of it, is removed. A doctor who specializes in the study of diseased tissue (a pathologist) examines the tumor to identify the cancer's type and stage.

Treatment team

The treatment team for patients with non-small cell lung cancer will depend on which treatment strategy is followed. For patients who are treated surgically, a thoracic surgeon will perform the procedure. These surgeons specialize in operating inside the chest cavity. Patients who require **radiation therapy** will be seen by a radiation oncologist. Patients who need **chemotherapy** will see a hematologist or oncologist. Both are doctors who specialize in cancer treatment. Chemotherapy is usually administered by oncology nurses that specialize in caring for cancer patients.

Clinical staging, treatments, and prognosis

Staging

Treatment for non-small cell lung cancer depends primarily on the stage of the cancer. Staging is a process that tells the doctor if the cancer has spread and the extent of its spread. The most commonly used treatments are surgery, radiation therapy, and chemotherapy.

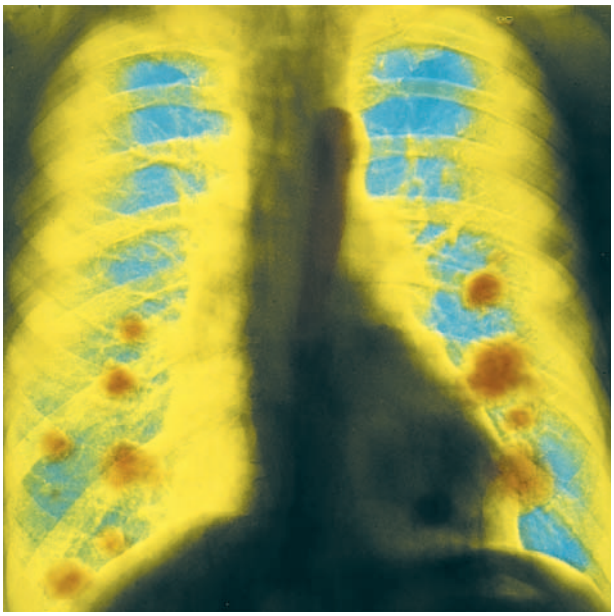
Non-small cell lung cancer has six stages:

- Occult **carcinoma**. Cancer cells have been found in the sputum, but no tumor has yet been found.
- Stage 0. A small group of cancerous cells have been found in one location.
- Stage I. The cancer is only in the lung and has not spread anywhere else.
- Stage II. The cancer has spread to nearby lymph nodes.
- Stage III. The cancer has spread to more distant lymph nodes, and/or other parts of the chest like the diaphragm.
- Stage IV. The cancer has spread to other parts of the body.

Surgery

Surgery is the standard treatment for the earlier stages of non-small cell lung cancer. The surgeon will decide on the type of surgery, depending on how much of the lung is affected. There are three different types of surgical procedures:

- Wedge resection is the removal of a small part of the lung.



False-color chest x ray showing evidence of cancerous masses (orange shadows) in both lungs. *(Copyright CNRI, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

- Lobectomy is the removal of one lobe of the lung. (The right lung has three lobes and the left lung has two lobes.)
- Pneumonectomy is the removal of an entire lung.

Lung surgery is a major procedure and patients can expect to experience pain, weakness in the chest, and shortness of breath. Air and fluid collect in the chest after surgery. As a result, patients will need help to turn over, cough, and breathe deeply. Patients should be encouraged to perform these activities because they help get rid of the air and fluid and speed up recovery. It can take patients several months before they regain their energy and strength.

Radiotherapy

Patients whose cancer has progressed too far for surgery (Stages III and IV) may receive radiotherapy. Radiotherapy involves the use of high-energy rays to kill cancer cells. It is used either by itself or in combination with surgery or chemotherapy. The amount of radiation used depends on the size and the location of the tumor.

Radiation therapy may produce such side effects as fatigue, skin rashes, upset stomach, and **diarrhea**. Dry or sore throats, difficulty in swallowing, and loss of hair (alopecia) in the treated area are all minor side effects of

radiation. These may disappear either during the course of the treatment or after the treatment is over.

Chemotherapy

Chemotherapy is also given to patients whose cancer has progressed too far for surgery. Chemotherapy is medication that is usually given intravenously to kill cancer cells. These drugs enter the bloodstream and travel to all parts of the body, killing cancer cells that have spread to different organs. Chemotherapy is used as the primary treatment for cancers that have spread beyond the lung and cannot be removed by surgery. It can also be used in addition to surgery or radiation therapy.

Chemotherapy for NSCLC has made significant advances since the early 1980s in improving the patient's quality of life as well as length of survival. Newer cytotoxic (cell-killing) agents developed in the 1990s, such as the taxanes, are typically combined with either cisplatin or carboplatin as first-line therapy for non-small cell lung cancer.

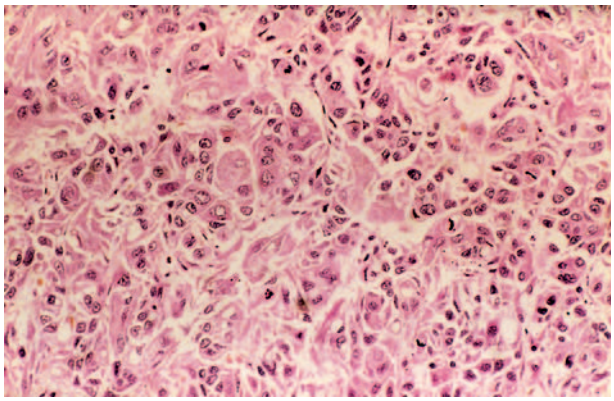
Newer drugs for lung cancer developed since 2000 include gefinitib (Iressa) and pemetrexed (Alimta). The FDA approved gefinitib in May 2003 as a treatment for patients with NSCLC who have not responded to platinum-based or taxane chemotherapy. It is taken by mouth and works by inhibiting an enzyme involved in the growth of tumor cells. Pemetrexed, which is given by injection, was approved by the FDA in February 2004 for the treatment of mesothelioma, a type of lung cancer caused by exposure to asbestos fibers. However, the drug appears to be effective in treating other types of lung cancer as well.

Chemotherapy is also used as palliative treatment for non-small cell lung cancer. Palliative refers to any type of therapy that is given to relieve the symptoms of a disease but not to cure it.

Chemotherapy for non-small cell lung cancer often has severe side effects, including **nausea and vomiting**, hair loss, anemia, weakening of the immune system, and sometimes **infertility**. Most of these side effects end when the treatment is over. Other medications can be given to lessen the unpleasant side effects of chemotherapy.

Prognosis

The prognosis for non-small cell lung cancer is better if the disease is found early, and removed surgically. For patients whose disease is caught in Stage I, the survival rate five years after surgery ranges from 60% to 80%. Up to 55% of Stage II patients are alive after five years, but only about 30% of Stage III patients survive five years. Unfortunately, 85% of patients already have at least Stage III cancer by the time they are diagnosed. Many of these patients have disease that is too advanced for surgery. Despite treatment with radiotherapy and chemotherapy, the five-year survival for patients with inoperable disease is extremely low.



Large-cell anaplastic carcinoma of the lung. *(Copyright Biophoto Associates, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Alternative and complementary therapies

Because non-small cell lung cancer has a poor prognosis with conventional medical treatment, many patients are willing to try complementary and alternative therapies. These therapies are used to try to reduce stress, ease side effects and symptoms, or control disease. Two treatments sometimes used are shark cartilage and mistletoe. Although shark cartilage is thought to interfere with the tumor's blood supply, **clinical trials** have so far been inconclusive. Mistletoe is a poisonous plant that has been shown to kill cancer cells in the laboratory. Again, however, clinical trials with cancer patients have been inconclusive.

Patients who decide to try complementary and alternative therapies should tell their doctors. Some of these therapies may interfere with conventional treatment.

Coping with cancer treatment

The side effects associated with treatment of non-small cell lung cancer can be severe. Patients should ask their doctors about medications to treat nausea and vomiting, and other side effects. It is particularly important to eat a nutritious diet and to drink plenty of fluids. In addition, most patients report feeling very tired and should get plenty of rest.

KEY TERMS

Bronchi—The tubes that carry air into the lungs.

Lymph—Clear fluid containing white blood cells that is collected from the tissues of the body and flows in vessels called the lymphatic system.

Lymph node—Small oval-shaped filters in the lymphatic system that trap bacteria and other unwanted particles to ensure their removal from the body.

Palliative—Referring to any type of treatment that is given to relieve the symptoms of a disease rather than to cure it.

Respiratory distress—A condition in which patients with lung disease are not able to get enough oxygen.

QUESTIONS TO ASK THE DOCTOR

- What type of lung cancer do I have?
- Has the cancer spread?
- What are the treatment options?
- Is there a clinical trial I can participate in?
- What is my prognosis?

Patients should consider joining local support groups with people who are coping with the same experiences. Many people with cancer find they can share thoughts and feelings with group members that they do not feel comfortable sharing with friends or family. Support groups are also a good source of information about coping with cancer.

Clinical trials

Patients diagnosed with non-small cell lung cancer should discuss participating in clinical trials with their doctor. There are many clinical trials currently underway that are investigating all different stages of the disease. These trials are studying various new treatment options including:

- Chemotherapy with new drugs, and combinations of drugs
- Courses of chemotherapy prior to surgery
- Radiotherapy after surgery
- Chemotherapy and radiotherapy in combination

Information on open clinical trials is available on the Internet from the National Cancer Institute at <http://cancertrials.nci.nih.gov>.

Prevention

The best way to prevent lung cancer is not to start smoking or to quit smoking. Secondhand smoke from other people's tobacco should also be avoided. Appropriate precautions should be taken when working with cancer-causing substances (carcinogens). Testing houses for the presence of radon gas, and removing asbestos from buildings have also been suggested as preventive strategies.

Special concerns

Respiratory distress

Patients who are having difficulty breathing because of non-small cell lung cancer are often unable to get enough oxygen and suffer from respiratory distress. These patients may begin breathing more quickly and wheezing. Patients will usually be given oxygen and medications such as morphine that will help them breathe more easily.

Follow-up

Regular checkups after treatment for non-small cell lung cancer are extremely important. Patients who have been treated for lung cancer should report any health problems to their doctor immediately to ensure quick treatment if the cancer has returned.

Lung cancer, small cell

Definition

Small cell lung cancer is a disease in which the cells of the lung tissues grow uncontrollably and form tumors.

Description

Lung cancer is divided into two main types: small cell and non-small cell. Small cell lung cancer is the least common of the two, accounting for only about 20% of all lung cancers. In the past, the disease was called oat cell cancer because, when viewed under a microscope, the cancer cells resemble oats. This type of lung cancer grows quickly and is more likely to spread to other organs in the body.

The lungs are located along with the heart in the chest cavity. The lungs are not simply hollow balloons, but have a very organized structure consisting of hollow tubes, blood vessels, and elastic tissue. The hollow tubes, called bronchi, are multi-branched, becoming smaller and more numerous at each branching. They end in tiny, blind sacs made of elastic tissue called alveoli. These sacs are where the oxygen a person breathes in is taken up into the blood, and where carbon dioxide moves out of the blood to be breathed out.

Normal, healthy lungs are continually secreting mucus that not only keeps the lungs moist, but also protects the lungs by trapping foreign particles like dust and dirt in breathed air. The inside of the lungs is covered with small, hair-like structures called cilia. The cilia move in such a way that mucus is swept up out of the lungs and into the throat.

Small cell lung tumors usually start to develop in the central bronchi. They grow quickly and prevent the lungs from functioning at their full capacity. Tumors may block the movement of air through the bronchi in the lungs. As a result, less oxygen gets into the blood and patients feel short of breath. Tumors may also block the normal movement of mucus into the throat. As a result, mucus builds up in the lungs and infection may develop behind the tumor.

Demographics

Lung cancer is a growing global epidemic. Worldwide, lung cancer is the second most common cancer among both men and women and is the leading cause of cancer death in both sexes. The worldwide mortality rate for patients with lung cancer is 86%. Of the 160,000 deaths from lung cancer that occur annually in the United

States, about 40,000 are caused by small cell lung cancer. Although there are differences in mortality rates between ethnic groups, this is mainly due to differences in smoking habits.

Causes and symptoms

Causes

Tobacco smoking accounts for nearly 90% of all lung cancers. The risk of developing lung cancer is increased for smokers who start at a young age, and for those who have smoked for a long time. The risk also increases as more **cigarettes** are smoked, and when cigarettes with higher tar content are smoked. Smoking **marijuana** cigarettes is also a risk factor for lung cancer. These cigarettes have a higher tar content than tobacco cigarettes.

Certain hazardous materials that people may be exposed to in their jobs have been shown to cause lung cancer. These include asbestos, coal products, and radioactive substances. Air pollution may also be a contributing factor. Exposure to radon, a colorless, odorless gas that sometimes accumulates in the basement of homes, may cause lung cancer in some patients. In addition, patients whose lungs are scarred from other lung conditions may have an increased risk of developing lung cancer.

Although the exact cause of lung cancer is not known, people with a family history of lung cancer appear to have a slightly higher risk of contracting the disease.

Symptoms

Small cell lung cancer is an aggressive disease that spreads quickly. Symptoms depend on the tumor's location within the lung, and on whether the cancer has spread to other parts of the body. More than 80% of small cell lung cancer patients have symptoms for only three months or less, and few cases are detected early. The following symptoms are the most commonly reported by small cell lung cancer patients at the time of their diagnosis:

- a cough that does not go away
- chest pain
- shortness of breath and wheezing
- persistent hoarseness
- **fatigue** and loss of appetite (anorexia). Although some patients may experience bloody spit or phlegm, this symptom is more commonly seen in patients with other types of lung cancer.

Small cell tumors often press against a large blood vessel near the lungs called the superior vena cava (SVC), causing a condition known as SVC syndrome. This condition may cause patients to retain water, cough, and have shortness of breath. Because small cell lung cancer often spreads quickly to the bones and central nervous system, patients may also have **bone pain**, headaches, and seizures.

Diagnosis

If lung cancer is suspected, the doctor will take a detailed medical history that checks both symptoms and risk factors. During a complete physical examination, the doctor will examine the patient's throat to rule out other possible causes of hoarseness or coughing, and listen to the patient's breathing and the sounds made when the patient's chest and upper back are tapped. A chest **x ray** may be ordered to check for masses in the lungs. Special imaging techniques, such as **computed tomography** (CT) scans or **magnetic resonance imaging** (MRI), may provide more precise information about the size, shape, and location of any tumors.

Sputum analysis involves microscopic examination of the cells that are either coughed up from the lungs, or are collected through a special instrument called a bronchoscope. The sputum test does not, however, provide any information about the location of the tumor and must be followed by other tests.

Lung **biopsy** is the most definitive diagnostic tool for cancer. It can be performed in several different ways. The doctor can perform a **bronchoscopy**, which involves the insertion of a slender, lighted tube, called a bronchoscope, down the patient's throat and into the lungs. In addition to viewing the passageways of the lungs, the doctor can use the bronchoscope to obtain samples of the lung tissue. In another procedure known as a needle biopsy, the location of the tumor is first identified using a CT scan or MRI. The doctor then inserts a needle through the chest wall and collects a sample of tissue from the tumor. In the third procedure, known as surgical biopsy, the chest wall is opened up and a part of the tumor, or all of it, is removed for examination.

Treatment team

Small cell lung cancer patients are usually treated with a combination of **chemotherapy** and radiotherapy. Patients will usually see an oncologist (cancer specialist) who will supervise their chemotherapy, while a radiation oncologist will supervise their radiotherapy. Oncology nurses that specialize in caring for cancer patients usually administer chemotherapy. The few patients who undergo surgery will see a thoracic surgeon who specializes in operating in the chest cavity.

Clinical staging, treatments, and prognosis

Staging

Staging procedures are important in lung cancer because they tell doctors whether patients have disease only in their lungs, or whether the cancer has spread to other parts of the body. To establish the cancer stage, doctors have to perform various tests. These may include **bone marrow aspiration and biopsy**, CT scans of the chest and abdomen, MRI scans of the brain, and radionuclide bone scans. All of these tests determine the extent to which the cancer has spread. Once the stage is determined, doctors can decide on a course of treatment, and can have a better idea of the patient's prognosis.

Unlike other types of lung cancer, the staging of small cell lung cancer is relatively simple. This is because approximately 70% of patients already have metastatic disease when they are diagnosed, and small differences in the amount of tumor found in the lungs do not change the prognosis. Small cell lung cancer is usually divided into three stages:

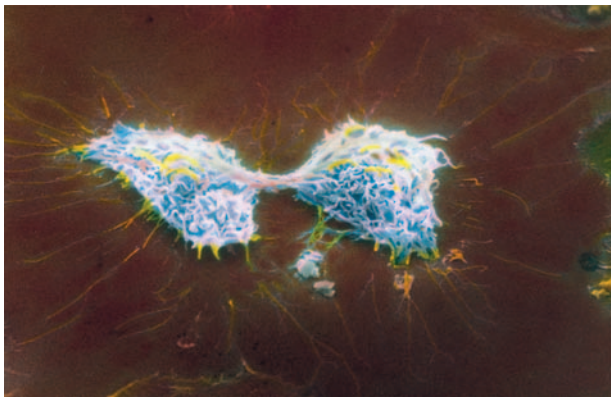
- Limited stage: The cancer is found only in one lung and in lymph nodes close to the lung.
- Extensive stage: The cancer has spread beyond the lungs to other parts of the body.
- Recurrent stage: The cancer has returned following treatment.

Treatment

Without treatment, small cell lung cancer has the most aggressive clinical course of any type of pulmonary tumor, with median survival from diagnosis of only 2–4 months. Compared with other cell types of lung cancer, small cell lung cancer has a greater tendency to be widely disseminated by the time of diagnosis, but is much more responsive to chemotherapy and irradiation.

Treatment of small cell lung cancer depends on whether the patient has limited, extensive, or recurrent disease. Treatment usually involves radiotherapy and chemotherapy. Surgery is rarely used for this type of lung cancer because the tumor is usually too advanced.

Patients with limited-stage disease are usually treated with chemotherapy. Combinations of two or more drugs have a better effect than treatment with a single drug. Up to 90% of patients with this stage of disease will respond to chemotherapy. The chemotherapy most commonly prescribed is a combination of the drugs **etoposide** (Vepesid) and **cisplatin** (Platinol). Combining chemotherapy with chest radiotherapy and/or occasionally surgery has also prolonged survival for limited-stage patients.



Lung cancer cells dividing. *(Custom Medical Stock Photo. Reproduced by permission.)*

In addition to chest radiotherapy, some patients are also treated with **radiation therapy** to the brain, even if no cancer is found there. This treatment, called prophylactic cranial irradiation (PCI), is given to prevent tumors from forming in the brain. The combination of etoposide and cisplatin chemotherapy with chest radiation therapy and PCI has increased the two-year survival of limited-stage small cell lung cancer patients to almost 50%.

Combinations of different chemotherapy agents are also used for treating extensive-stage small cell lung cancer. However, compared with limited-stage patients, the percentage of extensive-stage patients who respond to therapy is lower. Commonly used drug combinations include **cyclophosphamide** (Cytoxan), **doxorubicin** (Adriamycin), and **vincristine** (Oncovin), or etoposide and cisplatin. The addition of radiation therapy to chemotherapy does not improve survival in these patients. However, radiation therapy is used for the palliative (pain relief) treatment of symptoms of metastatic lung cancer, particularly brain and bone tumors.

Patients who have recurrent small cell lung cancer often become resistant to chemotherapy. These patients are treated with palliative radiotherapy. Their doctors may also recommend that they take part in clinical trials of a new therapy. Patients whose relapse occurs more than six months after their initial treatment, however, may still respond to traditional chemotherapy.

Prognosis

Small cell lung cancer is a very aggressive disease. Without treatment, limited-stage patients will survive for three to six months, while extensive-stage patients will survive six to 12 weeks. However, small cell lung cancer is much more responsive to chemotherapy and radiation therapy than other types of lung cancer. Among patients treated with chemotherapy, 70–90% have a major response to treatment.

A normal lung (left) and the lung of a cigarette smoker (right). *(Photograph by A. Glauberman, National Audubon Society Collection/ Photo Researchers, Inc. Reproduced by permission.)*

Survival in patients responding to therapy is four to five times longer than in patients without treatment. In addition, two years after the start of therapy, about 10% of patients remain free of disease. In general, women tend to have a better prognosis than men. Patients whose disease has spread to the central nervous system or liver have a much worse prognosis. Although the overall survival at five years is 5% to 10%, survival is higher in patients with limited stage disease. About 70% of patients who are disease free after two years do not relapse. After five to 10 disease-free years, relapses are rare.

Alternative and complementary therapies

Many cancer patients have tried using shark cartilage to treat their disease. Shark cartilage is thought to interfere with the tumor's blood supply. A clinical trial using this treatment in lung cancer patients is ongoing. Information on this and other alternative treatments is available on the Internet from the National Center for Complementary and Alternative Medicine.

Patients who decide to try complementary and alternative therapies should tell their doctor. Some of these therapies may interfere with conventional treatment.

Coping with cancer treatment

The side effects associated with treatment of small cell lung cancer can be severe. Patients should ask their doctor about medications to treat **nausea and vomiting** and other side effects. It is particularly important to eat a nutritious diet and to drink plenty of fluids. In addition, most patients report feeling very tired and should get plenty of rest.

Clinical trials

Most of the improvements in the survival of patients with small cell lung cancer are the result of **clinical trials**. Ongoing trials are investigating new chemotherapy and radiotherapy regimens. In addition, entirely new types of therapy, such as gene therapy and biological therapy, are now being tested. Patients with a lung cancer diagnosis should ask their doctor about participating in a clinical trial.

KEY TERMS

Bronchi—Hollow tubes that carry air into the lungs.

PCI—A type of radiotherapy that is used to prevent tumors from growing in the brain.

Radionuclide bone scan—A test that tells if cancer has spread to the bones.

Superior vena cava (SVC) syndrome—A condition seen in lung cancer patients where the tumor presses against a large blood vessel and causes various symptoms.

Information on open clinical trials is available on the Internet from the National Cancer Institute at <http://cancertrials.nci.nih.gov>.

Prevention

The best way to prevent lung cancer is either not start smoking, or quit smoking. Secondhand smoke from other people's tobacco should also be avoided. Appropriate precautions should be taken when working with substances that can cause cancer (carcinogens). Testing houses for the presence of radon gas, and removing asbestos from buildings have also been suggested as preventive strategies.

Special concerns

Small cell lung cancer can cause several hormonal disorders. About 40% of patients begin to secrete an anti-diuretic hormone at the wrong time. This hormone causes the body to retain water, which may result in the patient experiencing confusion, seizures, or coma. Less common are the development of **Cushing's syndrome** and the **Eaton-Lambert syndrome**. Symptoms of Cushing's syndrome include obesity, severe fatigue, high blood pressure, backache, high blood sugar, easy bruising, and bluish-red stretch marks on the skin. Eaton-Lambert syndrome is a neuromuscular disorder that causes muscle weakness, fatigue, and a tingling sensation on the skin. All of these hormonal disorders usually diminish after the lung tumor is successfully treated.

See also Smoking cessation; Superior vena cava syndrome.

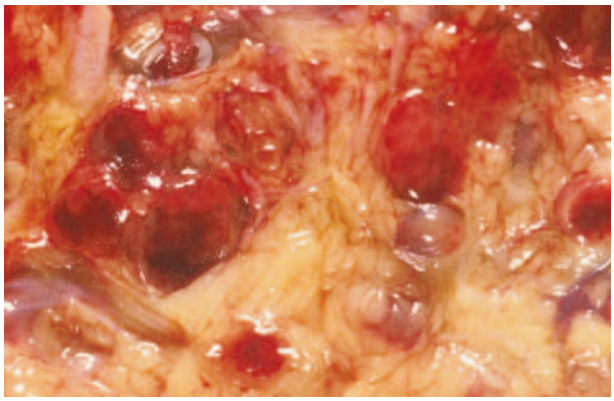
Lymph node biopsy

Definition

A lymph node biopsy is a procedure in which all or part of a lymph node is removed and examined to determine if there is cancer within the node.



Close-up view of normal lymph nodes and fatty tissue. *(Custom Medical Stock Photo. Reproduced by permission.)*

Purpose

The lymph system is the body's primary defense against infection. It consists of the spleen, tonsils, thymus, lymph nodes, lymph vessels, and the clear, slightly yellow fluid called lymph. These components produce and transport white blood cells called lymphocytes and macrophages that rid the body of infection. The lymph system is also involved in the production of antibodies. Antibodies are proteins that fight bacteria, viruses, and other foreign materials that enter the body.

The lymph vessels are similar to veins, only instead of carrying blood as veins do, they circulate lymph to most tissues in the body. Lymph nodes are about 600 small, bean-shaped collections of tissue found along the lymph vessel. They produce cells and proteins that fight infection, and clean and filter lymph. Lymph nodes are sometimes called lymph glands, although they are not true glands. When someone talks about having swollen glands, they are actually referring to lymph nodes.

Normal lymph glands are no larger than 0.5 in (1.3 cm) in diameter and are difficult to feel. However, lymph nodes can enlarge to greater than 2.5 in (6 cm) and can become sore. Most often the swelling is caused by an infection, but it can also be caused by cancer.

Cancers can metastasize (spread) through the lymph system from the site of the original tumor to distant parts of the body where secondary tumors are formed. The purpose of a lymph node biopsy is to determine the cause of the swelling and/or to see if cancer has begun to spread through the lymph system. This information is important in staging the cancer and devising a treatment plan.

Precautions

Women who are pregnant should inform their doctor before a lymph node biopsy, although pregnancy will not affect the results.

Description

There are three kinds of lymph node biopsy. **Sentinel lymph node mapping** and biopsy is a promising new technique that is discussed in its own entry. Fine needle aspiration (FNA) biopsy, often just called needle biopsy, is done when the lymph node of interest is near the surface of the body. A hematologist (a doctor who specializes in blood diseases) usually performs the test. In FNA biopsy, a needle is inserted through the skin and into the lymph node, and a sample of tissue is drawn out of the node. This material is preserved and sent to the laboratory for examination.

Advantages of a needle biopsy are that the test is minimally invasive. Only a local anesthetic is used, the procedure generally takes less than half an hour, and there is little pain afterwards. The disadvantage is that cancer may not be detected in the small sample of cells removed by the needle.

Open lymph node biopsy is a surgical procedure. It is done by a surgeon under general anesthesia on lymph nodes in the interior of the body and under local anesthesia on surface lymph nodes where FNA biopsy is considered inadequate. Once there is adequate anesthesia, the surgeon makes a small cut and removes either the entire lymph node or a slice of tissue that is then sent to the laboratory for examination. Results in both kinds of biopsies take one to three days.

Open biopsy can be advantageous in that it is easier to detect and identify the type of cancer in a large piece of tissue. Also, lymph nodes deep in the body can be sampled. Disadvantages include a longer recovery time, soreness at the biopsy site for several days, and the use of deeper anesthesia, increasing the risks to the patient. The procedure is done in a hospital or outpatient surgery center and takes about an hour, with additional time to recover from general anesthesia.

Preparation

No particular preparation is necessary for a needle biopsy. For an open biopsy, patients need standard preoperative blood tests and other tests to evaluate general health. The doctor should be informed about any medications (prescription, non-prescription, or herbal) the patient is taking, as well as past bleeding problems or allergies to medication or anesthesia.

KEY TERMS

Lymph nodes—Small, bean-shaped organs located throughout the lymphatic system. The lymph nodes store special cells that can trap cancer cells or bacteria that are traveling through the body in lymph. Also called lymph glands.

Lymphocytes—Small white blood cells that bear the major responsibility for carrying out the activities of the immune system; they number about 1 trillion.

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Spleen—An organ located at the left side of the stomach that acts as a reservoir for blood cells and produces lymphocytes and other products involved in fighting infection.

Thymus—An organ near the base of the neck that produces cells that fight infection. It is at its largest at puberty, then declines in size and function during adult life.

Tonsils—Small masses of tissue at the back of the throat.

Aftercare

Little aftercare is needed in a needle biopsy other than a bandage to keep the biopsy site clean. Patients who have general anesthesia for an open biopsy often feel drowsy and tired for several days following the procedure, and should not plan to drive home after biopsy. The incision site must be kept clean and dry, and a follow-up visit to check on healing is usually necessary.

Risks

There are few risks associated with lymph node biopsy. The main risks are excessive bleeding (usually only in people with blood disorders) and allergic reaction to general anesthesia (rare). Occasionally the biopsy site becomes infected.

Normal results

Normal lymph nodes are small and flat. When examined under the microscope, they show no signs of cancer or infection.

Abnormal results

Abnormal lymph nodes are usually enlarged and contain cancerous (malignant) cells and/or show signs of infection.

QUESTIONS TO ASK THE DOCTOR

- What kind of biopsy are you going to do?
- What will this tell me about my cancer?
- If you are doing an open biopsy, will you be removing any other structures at the same time?
- If you are, how will that affect my recovery from the operation?

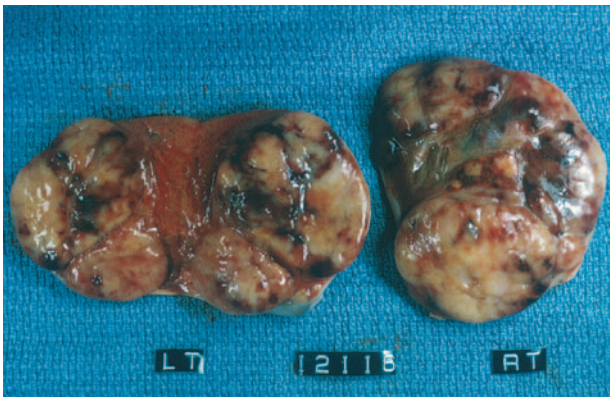
Lymph node dissection

Definition

Lymph node dissection (lymphadenectomy) is the surgical removal of lymph nodes in order to assess the spread of cancer.

Purpose

The lymph system is the body's primary defense against infection. It consists of the spleen, tonsils, thymus, lymph nodes, lymph vessels, and the clear, slightly yellow fluid called lymph. These components produce and transport cells and proteins that help rid the body of infection.



Diseased lymph nodes. *(Custom Medical Stock Photo. Reproduced by permission.)*

The lymph vessels are similar to veins, only instead of carrying blood as veins do, they circulate lymph to tissues in the body. There are about 600 small, bean-shaped collections of tissue found along the lymph vessels. These are called lymph nodes. They produce cells and proteins that fight infection. They also clean and filter foreign cells, such as bacteria or cancer cells, out of the lymph.

Cancer cells can break off from the original tumor and metastasize (spread) through the lymph system to distant parts of the body, where secondary tumors are formed. The purpose of a lymph node dissection is to remove the lymph nodes that have trapped cancer cells so that the extent of spread can be determined. Lymph node dissection is done for many different types of cancers, including cancers of the head and neck, breast, prostate, testes, bladder, colon, and lung.

About 200 lymph nodes are in the head and neck and another 30 to 50 are in the armpit. More are located in the groin area. Lymph nodes are sometimes called lymph glands, although they are not true glands. When someone talks about having swollen glands, they are referring to swollen lymph nodes.

Normally lymph nodes are no larger than 0.5 in (1.3 cm) in diameter and are difficult to feel. However, when lymph nodes trap bacteria or cancer cells, they can increase in size to greater than 2.5 in (6 cm). Most often, hot and painful swollen nodes are caused by trapped bacteria. Swollen lymph nodes caused by cancer are usually painless.

Precautions

This operation usually will not be performed if the cancer has already metastasized to another site. In this case, removing the lymph nodes will not effectively contain the cancer. As with any surgery, women who are pregnant should inform their doctors before a lymph node dissection.

Description

Lymph node dissection is usually done by a surgeon in a hospital setting, under general anesthesia. An incision is made and tissue is pulled back to reveal the lymph nodes. The surgeon is guided in what to remove by the location of the original cancer. Sample lymph nodes may be sent to the laboratory for examination. If the excised nodes do contain malignant cells, this would indicate that the cancer has spread beyond the original site, and recommendations can then be made regarding further therapy.

Preparation

Tests may be done before the operation to determine the location of the cancer and which nodes should be removed. These tests may include lymph node biopsies, CT (**computed tomography**) scans, and MRI scans. In addition, standard pre-operative blood and liver function tests are performed. The patient will meet with an anesthesiologist before the operation, and should notify the anesthesiologist about all drug allergies and all medication (prescription, non-prescription, or herbal) that he or she is taking.

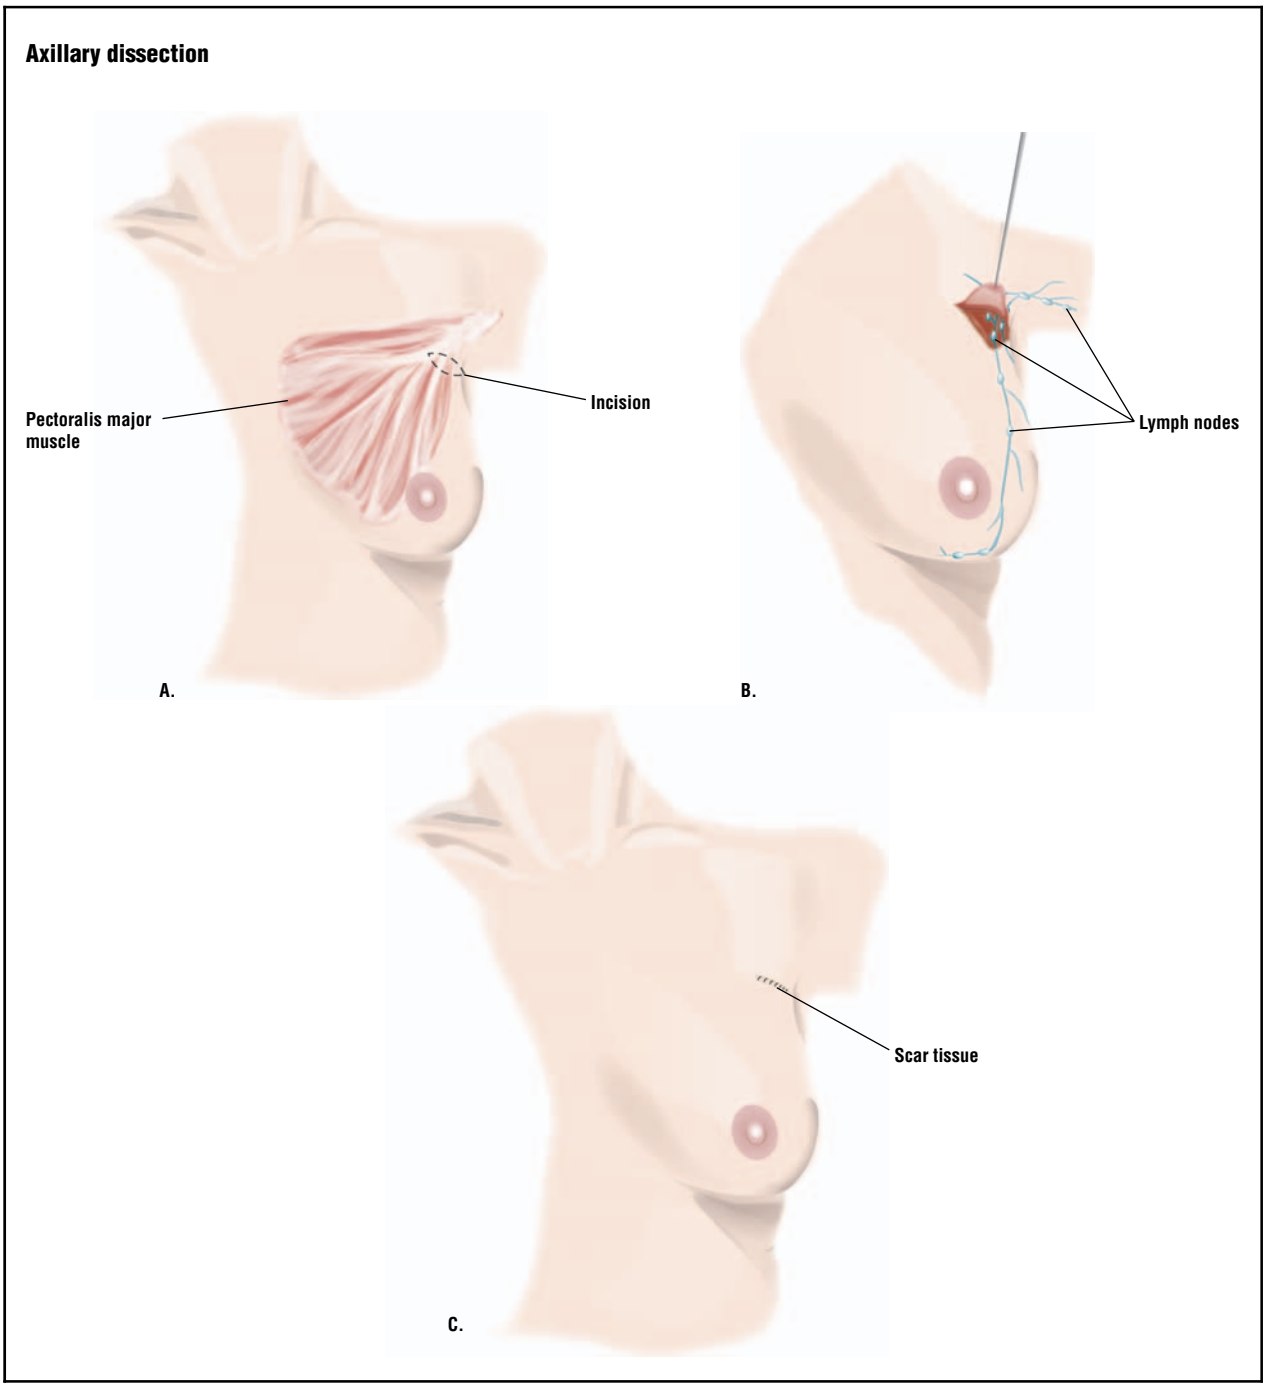
Aftercare

How long a person stays in the hospital after lymph node dissection depends on how many lymph nodes were removed, their location, and whether surgery to remove the primary tumor or other structures was performed at the same time. Drains are inserted under the skin to remove the fluid that accumulates after the lymph nodes have been removed, and patients are usually able to return home with the drains still in place. Some patients are able to leave the same day or the day following the procedure.

An accumulation of lymph fluid that causes swelling, a condition known as lymphedema, is the most feared side effect of lymph node dissection. If swelling occurs, patients should consult their doctors immediately. Swelling may indicate that a new tumor is blocking a lymph vessel, or that a side effect of lymph node dissection is present. Treatment for lymphedema in people with cancer is different than treatment of lymphedema that arises from other causes. In cancer patients, it is essential to alleviate swelling without spreading cancer cells to other parts of the body, therefore an oncologist (cancer specialist) should be consulted before beginning any treatment.

Risks

People who have lymph nodes removed are at increased risk of developing lymphedema, which can



(Illustration by Argosy Publishing. Reproduced by permission of The Gale Group.)

occur in any part of the body where lymph accumulates in abnormal quantities. When the amount of fluid exceeds the capacity of the lymph system to move it through the body, it leaks into the tissues and causes them to swell. Removing lymph nodes and lymph vessels through lymph node dissection increases the likelihood that the capacity of the lymph transport system will be exceeded.

Lymphedema can occur days or weeks after lymph node dissection. **Radiation therapy** also increases the chance of developing lymphedema, so those people who have radiation therapy following lymph node dissection are at greatest risk of experiencing this side effect. Lymphedema slows healing, causes skin and tissue damage, and when left untreated can result in the

KEY TERMS

Computed tomography (CT or CAT) scan—Using x rays taken from many angles and computer modeling, CT scans help determine the size and location of tumors and provide information on whether they can be surgically removed.

Magnetic resonance imaging (MRI)—MRI uses magnets and radio waves to create detailed cross-sectional pictures of the interior of the body.

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Metastasize—Spread of cells from the original site of the cancer to other parts of the body where secondary tumors are formed.

QUESTIONS TO ASK THE DOCTOR

- How will you determine which lymph nodes should be removed?
- How should I prepare for this procedure?
- Are there precautions I can take to help prevent lymphedema?
- How will lymph node dissection affect my daily life?
- Will you be removing anything else besides lymph nodes during this operation?
- About how long will I have to stay in the hospital?
- Will having my lymph nodes removed increase my chances of getting infections?

development of hard or fibrous tissue. People with lymphedema are also at risk for repeated infection, because pools of lymph in the tissues provide a perfect spot for bacteria to grow. In severe cases, untreated lymphedema can develop into a rare form of cancer called lymphangiosarcoma.

Other risks associated with lymph node dissection are the same as for all major surgery: potential bleeding, infection, and allergic reaction to anesthesia.

Normal results

Normal lymph nodes are small and flat and show no cancerous cells under the microscope.

Abnormal results

Abnormal lymph nodes are enlarged and show malignant cells when examined under the microscope.

See also Lymph node biopsy; Radical neck dissection.

Lymphangiogram, lymph node angiogram
see Lymphangiography

Lymphangiography

Definition

Lymphangiography is a type of diagnostic testing technique in which x rays (called lymph node angiograms) and the injection of a contrast medium (a substance that provides a contrast between the tissue or organ being filmed and the medium) are used to visualize lymphatic circulation and the lymph nodes.

Purpose

The lymphatic system consists of tissues, organs, and vessels that aid in circulating body fluids and defending the body from damage by foreign substances such as viruses, bacteria, or fungi. However, certain cancers may also spread through the lymphatic system. Thus, lymphangiography is sometimes used to:

- diagnose the presence or spread of tumors, lymphatic cancer (lymphoma), and other cancers

- distinguish primary lymphedema (when swelling in the lymphatic system arises from missing or impaired lymphatic vessels) from secondary lymphedema (swelling caused by damaged lymph vessels or lymph nodes that have been removed)
- localize tumors for surgical removal
- assess the effectiveness of **chemotherapy** and **radiation therapy** in treating problems associated with metastatic (spreading) cancer

Although the results of lymphangiography are considered reliable, additional tests, studies, and clinical observations are necessary to determine a precise diagnosis. By itself, lymphangiography misses cancer in about 20% of cases. One of the major drawbacks of lymphangiography is its failure to fill certain lymphatic channels and groups of lymph nodes—a failure that may be due to infection, injury, or tumor spread. When this filling failure occurs, certain segments of the lymphatic system in the abdomen and pelvis cannot be visualized; thus, metastatic disease can be neither confirmed nor ruled out.

Since the late 1990s, conventional lymphangiography (using an iodine oil-based contrast agent) has been used almost exclusively for the staging of urologic pelvic and testicular malignancies. The test may demonstrate metastases within lymph nodes of normal size that are missed on computed tomography (CT) imaging. Technical innovations in nuclear diagnostics and computer imaging largely replaced lymphangiography with simpler, safer, and more reliable techniques of visualizing the lymphatic system (such as lymphangioscintigraphy, or isotope lymphography).

False-color lymphangiogram of the abdomen of a person suffering from lymphoma. *(Copyright Mehau Kulyk, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Precautions

Because of the possibility of an adverse reaction to the contrast medium, lymphangiography is usually not administered to patients with lung problems, heart disease, or severe kidney or liver disease.

Individuals with allergies to shellfish, iodine, or dye used in other diagnostic tests may receive steroids or antihistamines before the test to decrease the risk of allergic reactions.

Description

Lymphangiography testing may be done on an inpatient or outpatient basis. A sedative may be given to help the patient relax. After the skin of each foot is cleaned with an antiseptic, a blue indicator dye (which does not show up on x rays) is injected between the first, second, and third toes of each foot. The dye spreads into the lymphatic system in about 15 to 30 minutes. The thin, bluish lines that appear on the top of each foot delineate the lymphatic vessels. Next, a local anesthetic is injected, and a small incision is made into one of the larger blue lines in each foot. A needle or catheter (a thin flexible tube) is inserted into a vessel in each foot, and an oil-based contrast medium (such as Ethiodol) is injected at a slow, steady rate. A feeling of pressure may occur as the contrast medium is injected, but the patient must lie still to avoid dislodging the needle.

A fluoroscope (a device consisting of a fluorescent screen on which the shadows of objects that come between the screen and an attached x-ray apparatus can be viewed) is used to monitor the progress of the contrast medium as it spreads slowly (taking about 60 to 90 minutes) through the lymphatic system, traveling up the legs, into the groin, and along the back of the abdominal cavity. After the contrast agent is injected, the catheter is removed and the incisions are stitched and bandaged. Then x rays are taken of the legs, pelvis, abdomen, and chest areas. The following day, an additional set of x rays is obtained.

KEY TERMS

Contrast medium—A substance that provides a contrast between the tissue or organ being filmed and the medium.

Lymph node—A rounded, encapsulated body consisting of an accumulation of lymphatic tissue; found in lymphatic vessels.

Lymphoma—A type of lymphatic cancer.

Metastases—Cancer cells that have spread from the primary site of malignancy to another location in the body.

QUESTIONS TO ASK THE DOCTOR

- What is the purpose of the test?
- How long will the test take?
- Will I be sedated or get anesthesia before the test?
- Is there anything special I need to do before the test?
- Can I drive myself home after testing?
- When will I get the results?

After the test, the patient's skin, feces, and urine may have a bluish tint for two to three days (until the marker dye disappears), and there may be some discomfort behind the knees and in the groin area. Test results are reported to the doctor or patient from a few hours to a few days after the procedure.

Preparation

There is usually no special preparation needed before lymphangiography—such as restrictions in diet, activity, or medication intake. However, some facilities may require a clear liquid diet for a specified period of time before the test. In addition, for comfort reasons, patients may be asked to empty their bladders before testing. A patient undergoing lymphangiography (or a close family member) must sign a consent form before the test is administered.

Aftercare

After testing, the patient's blood pressure, pulse, breathing status, and temperature are monitored at regular intervals until they are stable. Any lung complications are noted, such as hoarseness or shortness of breath, chest pain, low blood pressure, low-grade **fever**, and blueness of lips and nailbeds due to clotting of the dye.

Bedrest for at least 24 hours following the test is recommended, with feet elevated to help reduce swelling at the incision sites. The incision sites may be sore for several days, and ice packs may be applied to these sites to further reduce swelling. The patient should also inspect the incision sites for infection. Sterile dressings should remain in place for two days, and the incision sites should be kept dry until after the sutures are removed (7 to 10 days after the test).

Risks

There is a risk of infection or bleeding caused by introducing the needle or tube through the skin or an allergic reaction—usually not serious— to the contrast medium. There is also a slight risk of oil embolism (obstruction of a blood vessel) due to the oil-based contrast medium. The contrast medium eventually seeps from the lymphatic channels into the general circulation, where it may travel to, and lodge in, the lungs.

There is some radiation exposure involved in the procedure. Although pregnant women and children are particularly sensitive to these risks, physicians may order the procedure when the benefits appear to outweigh the risks.

Normal results

Normal test results indicate no anatomical or functional abnormalities.

Abnormal results

Abnormal results may indicate:

- filariasis (a tropical disease caused by worms living in the lymphatic system)
- Hodgkin's or non-Hodgkin's lymphoma (cancers of the lymphatic system)
- inflammation
- metastatic cancer
- primary lymphedema
- retroperitoneal tumors (tumors lying outside of the peritoneum—the membrane lining the abdominal cavity)
- trauma

Lymphocyte immune globulin

Definition

Lymphocyte **immune globulin** is a drug used to suppress the immune system. Lymphocyte immune globulin is also known by the generic name anti-thymocyte globulin (ATG) and the brand names Atgam and Thymoglobulin. Atgam first received FDA approval in 1981 and Thymoglobulin in 1999. As of 2001, no generic preparations are available.

Purpose

Lymphocyte immune globulin is used to treat aplastic anemia and to prevent rejections during **bone marrow transplantation**. This drug has also been used experimentally to treat advanced **non-Hodgkin's lymphomas** and cutaneous T-cell lymphomas.

Description

This drug suppresses the immune system by slowing down T cells, cells critical in immunity. Without them, the immune system is essentially paralyzed. Lymphocyte immune globulin contains antibodies that attach to T cells and prevent them from working properly. This drug also decreases the number of T cells in the blood.

Lymphocyte immune globulin is made by vaccinating an animal with immature human T cells, then collecting the antibodies made against them. Atgam is made in horses and Thymoglobulin in rabbits.

Atgam is labeled for use only in kidney transplantation and aplastic anemia, and Thymoglobulin is specifically approved only for kidney transplantation. The effectiveness of either drug for treating aplastic anemia in cancer patients, however, is unknown.

Lymphocyte immune globulin is often used off-label to treat graft-versus-host disease (GVHD) after bone marrow transplantation. The drug has been beneficial for GVHD patients in some studies, but its effectiveness has not been conclusively demonstrated. In some **clinical trials**, it is also being used to prepare the patient's body for bone marrow transplantation. This drug produces short partial remissions of some lymphomas in published experiments.

Recommended dosage

The usual dose of Atgam in adults is 10–30 mg/kg (1 kilogram is 2.2 pounds). Doses of 5–25 mg/kg have been given to a few children. Thymoglobulin, which is about 10 times stronger, has a recommended dose of 1–1.5 mg/kg in adults. Typically these drugs are given daily or every other day for several days or weeks. They are injected into the blood over several hours, under close supervision in the hospital or clinic.

Precautions

Patients should not take Atgam if they are allergic to horse proteins or Thymoglobulin if they are allergic to rabbit proteins. Patients should tell their doctors about any current or previous blood cell problems and about all their prescription and over-the-counter drugs.

Lymphocyte immune globulin can make infections more serious. Patients should check with their doctors if they have any symptoms of an infection, such as chills, **fever**, or sore throat. They should also avoid people with contagious diseases and anyone recently vaccinated with an oral polio vaccine. The drug decreases the effectiveness of vaccinations given just before or during treatment. Some types of **vaccines** are not safe to receive while taking this drug.

Lymphocyte immune globulin does not interact with any specific foods. However, patients should check with their doctor for specific recommendations for eating and drinking before the treatment.

Patients should be careful in planning their activities, as this drug can cause dizziness.

Side effects

Thymoglobulin and Atgam have very similar side effects. However, Thymoglobulin is approximately twice as likely to decrease the number of white blood cells and three times as likely to result in malaise. Dizziness is much more common with Atgam. Other numerous side effects caused by both drugs include:

- Chills or fever in most patients
- Risk of developing an infection, which has been seen in up to 30% of patients, and sepsis in approximately 10%
- Risk of bleeding, due to **thrombocytopenia** (seen in 30–45% of patients)
- Rarely, anemia or the destruction of white blood cells other than T cells
- Pain, swelling, and redness where the drug is injected (minimized by injecting the drug into the faster-moving blood in a large vein)
- Allergic reactions (Serious allergic reactions can cause difficulty breathing, swelling of the tongue, a drop in blood pressure, or pain in the chest, sides, or back. Severe allergic reactions are potentially life-threatening, but rare; milder allergic reactions can result in **itching**, hives, or rash. Skin tests are often done to predict the likelihood of an allergic reaction, but are not foolproof.)
- Serum sickness, an immune reaction against the drug (Can result in fever, chills, muscle and joint aches, rash, blurred vision, swollen lymph nodes, or kidney problems; serum sickness is common when lymphocyte immune globulin is used alone for aplastic anemia, but fairly rare when it is combined with other drugs that suppress immunity.)
- Headaches, pain in the abdomen, **diarrhea**, nausea or vomiting, fluid retention, weakness, rapid heartbeats, or an abnormal increase in blood potassium (these side effects develop in more than a fifth of all patients during treatment)
- Uncommon side effects such as kidney damage, high blood pressure, heart failure, lethargy, abnormal sensations such as prickling in the skin, seizures, pulmonary edema, and adult respiratory distress syndrome
- Risk of developing **lymphoma** or leukemia, if the immune system is greatly suppressed for a long time

Side effects in pregnant or nursing women

The effects of this drug on an unborn child are unknown. Doctors are not sure if this drug reaches breast milk.

KEY TERMS

Adult respiratory distress syndrome (ARDS)—A lung disease characterized by widespread lung abnormalities, fluid in the lungs, shortness of breath, and low oxygen levels in the blood.

Antibodies—Proteins made by the immune system that attach to targeted molecules and cells.

Aplastic anemia—Failure of the bone marrow to make enough blood cells.

Blood cells—Cells found in the blood, including red blood cells that carry oxygen, white blood cells that fight infections, and platelets that help the blood to clot.

Bone marrow—A group of cells and molecules found in the centers of some bones. It makes all of the cells found in the blood, including the cells involved in immunity.

Graft-vs-host disease (GVHD)—A disease that develops when immune cells in transplanted bone marrow attack the body.

Immune system—The cells and organs that defend the body against infections.

Pulmonary edema—A disease characterized by excessive fluid in the lungs and difficulty breathing.

Sepsis—An infection that has spread into the blood.

Serum sickness—A type of allergic reaction against blood proteins. Serum sickness develops when the immune system makes antibodies against proteins that are not normally found in the body.

Skin test—A test used to diagnose allergies.

T lymphocyte or T cell—A type of white blood cell. Helper T cells aid other cells of the immune system, while cytotoxic T cells destroy abnormal body cells, including those that have been infected by a virus.

Thrombocytopenia—Too few platelets in the blood.

Methods of preventing or reducing side effects

Drugs such as antihistamines, acetaminophen, and **corticosteroids** can prevent or decrease some side effects, including fevers, chills, and allergic reactions. **Antibiotics** may help to prevent infections.

Interactions

Combining this drug with other medications that suppress the immune system (including **chemotherapy**) can severely suppress immunity. Drugs that slow blood clotting, such as aspirin, can increase the risk of bleeding. Any drug that reduces the symptoms of an infection, including aspirin and acetaminophen, can increase the risk that a serious infection will go undetected.

Lymphoma

Definition

Lymphoma is the name of a diverse group of cancers of the lymphatic system, a connecting network of glands, organs and vessels whose principle cell is the lymphocyte.

Description

When lymphoma occurs, cells in the lymphatic system grow abnormally. They divide too rapidly and grow without any order or control. Too much tissue is formed and tumors begin to grow. Because there is lymph tissue in many parts of the body, the cancer cells may involve the liver, spleen, or bone marrow.

Two general types of lymphoma are commonly recognized: **Hodgkin's disease** or Hodgkin's lymphoma (HD), and Non-Hodgkin's lymphoma (NHL). The two are distinguished by cell type. These differ significantly in respect of their natural histories and their response to therapy. Hodgkin's disease tends to be primarily of nodal origin. **Non-Hodgkin's lymphomas**, unlike HD, can spread beyond the lymphatic system.

M

Magnetic resonance imaging

Definition

Magnetic resonance imaging (MRI) is one of the newest, and perhaps most versatile, medical imaging technology available. Doctors can get highly refined images of the body's interior without surgery using MRI. By using strong magnets and pulses of radio waves to manipulate the natural magnetic properties in the body, this technique makes better images of organs and soft tissues than those of other brain scanning technologies. MRI is particularly useful for imaging the brain and spine, as well as the soft tissues of joints and the interior structure of bones, as well as the liver. The entire body is visible with MRI, and the technique poses few known health risks.

Purpose

MRI was developed in the 1980s. Its technology has been developed for use in magnetic resonance **angiography** (MRA), magnetic resonance spectroscopy (MRS), and, more recently, magnetic resonance cholangiopancreatography (MRCP). MRA was developed to study blood flow, whereas MRS can identify the chemical composition of diseased tissue and produce color images of brain function. MRCP is evolving into a potential noninvasive alternative for the diagnostic procedure **endoscopic retrograde cholangiopancreatography** (ERCP).

Advantages

DETAIL MRI creates precise images of the body based on the varying proportions of magnetic elements in different tissues. Very minor fluctuations in chemical composition can be determined. MRI images have greater natural contrast than standard x rays, computed tomography scan (CT scan), or ultrasound, all of which depend on the differing physical properties of tissues. This sensitivity allows MRI to distinguish fine variations in tissues deep within the body. It is also particularly useful for spotting and distinguishing diseased tissues (tumors and other lesions) early in their development. Often, doctors prescribe an MRI scan to more fully investigate earlier findings of other imaging techniques.

SCOPE The entire body can be scanned, from head to toe and from the skin to the deepest recesses of the brain. Moreover, MRI scans are not obstructed by bone, gas, or body waste, which can hinder other imaging techniques. (Although the scans can be degraded by motion such as breathing, heartbeat, and bowel activity.) The MRI process produces cross-sectional images of the body that are as sharp in the middle as on the edges, even of the brain through the skull. A close series of these two-dimensional images can provide a three-dimensional view of the targeted area. Along with images from the cross-sectional plane, the MRI can also provide images sagitally (from one side of the body to the other, from left to right for example), allowing for a better three-dimensional interpretation, which is sometimes very important for planning a surgical approach.

SAFETY MRI does not depend on potentially harmful ionizing radiation, as do standard **x ray** and computer tomography scans. There are no known risks specific to the procedure, other than for people who might have metal objects in their bodies.

Despite its many advantages, MRI is not routinely used because it is a somewhat complex and costly procedure. MRI requires large, expensive, and complicated equipment; a highly trained operator; and a doctor specializing in radiology. Generally, MRI is prescribed only when serious symptoms or negative results from other tests indicate a need. Many times another test is appropriate for the type of diagnosis needed.

Uses

Doctors may prescribe an MRI scan of different areas of the body.

BRAIN AND HEAD MRI technology was developed because of the need for brain imaging. It is one of the few imaging tools that can see through bone (the skull)

and deliver high quality pictures of the brain's delicate soft tissue structures. MRI may be needed for patients with symptoms of a brain tumor, stroke, or infection (like meningitis). MRI may also be needed when cognitive or psychological symptoms suggest brain disease (like Alzheimer's or Huntington's diseases, or multiple sclerosis), or when developmental retardation suggests a birth defect. MRI can also provide pictures of the sinuses and other areas of the head beneath the face. In adult and pediatric patients, MRI may be better able to detect abnormalities than compared to computed tomography scanning.

SPINE Spinal problems can create a host of seemingly unrelated symptoms. MRI is particularly useful for identifying and evaluating degenerated or herniated spinal discs. It can also be used to determine the condition of nerve tissue within the spinal cord.

JOINT MRI scanning is most commonly used to diagnose and assess joint problems. MRI can provide clear images of the bone, cartilage, ligament, and tendon that comprise a joint. MRI can be used to diagnose joint injuries due to sports, advancing age, or arthritis. MRI can also be used to diagnose shoulder problems, such as a torn rotator cuff. MRI can also detect the presence of an otherwise hidden tumor or infection in a joint, and can be used to diagnose the nature of developmental joint abnormalities in children.

SKELETON The properties of MRI that allow it to see through the skull also allow it to view the inside of bones. Accordingly, it can be used to detect bone cancer, inspect the marrow for leukemia and other diseases, assess bone loss (osteoporosis), and examine complex fractures.

HEART AND CIRCULATION MRI technology can be used to evaluate the circulatory system. The heart and blood flow provides a good natural contrast medium that allows structures of the heart to be clearly distinguished.

THE REST OF THE BODY Whereas computed tomography and ultrasound scans satisfy most chest, abdominal, and general body imaging needs, MRI may be needed in certain circumstances to provide better pictures or when repeated scanning is required. The progress of some therapies, like liver cancer therapy, needs to be monitored, and the effect of repeated x-ray exposure is a concern.

Precautions

MRI scans and metal

MRI scanning should not be used when there is the potential for an interaction between the strong MRI magnet and metal objects that might be imbedded in a patient's body. The force of magnetic attraction on certain types of metal objects (including surgical steel) could move them within the body and cause serious injury. Metal may be imbedded in a person's body for several reasons.

MEDICAL People with implanted cardiac pacemakers, metal aneurysm clips, or who have broken bones repaired with metal pins, screws, rods, or plates must tell their radiologist prior to having an MRI scan. In some cases (like a metal rod in a reconstructed leg), the difficulty may be overcome.

INJURY Patients must tell their doctors if they have bullet fragments or other metal pieces in their body from old wounds. The suspected presence of metal, whether from an old or recent wound, should be confirmed before scanning.

OCCUPATIONAL People with significant work exposure to metal particles (e.g., working with a metal grinder) should discuss this with their doctors and radiologists. The patient may need prescan testing—usually a single, regular x ray of the eyes to see if any metal is present.

Chemical agents

Chemical agents designed to improve the picture or allow for the imaging of blood or other fluid flow during MRA may be injected. In rare cases, patients may be allergic to, or intolerant of, these agents, and these patients should not receive them. If these chemical agents are to be used, patients should discuss any concerns they have with their doctor and radiologist.

Side effects

The potential side effects of magnetic and electric fields on human health remain a source of debate. In particular, the possible effects on an unborn baby are not well known. Any woman who is, or may be, pregnant, should carefully discuss this issue with her doctor and radiologist before undergoing a scan.

As with all medical imaging techniques, obesity greatly interferes with the quality of MRI.

Description

In essence, MRI produces a map of hydrogen distribution in the body. Hydrogen is the simplest element known, the most abundant in biological tissue, and one that can be magnetized. It will align itself within a strong magnetic field, like the needle of a compass. The earth's magnetic field is not strong enough to keep a person's hydrogen atoms pointing in the same direction, but the

superconducting magnet of an MRI machine can. This comprises the magnetic part of MRI.

Once a patient's hydrogen atoms have been aligned in the magnet, pulses of very specific radio wave frequencies are used to knock them back out of alignment. The hydrogen atoms alternately absorb and emit radio wave energy, vibrating back and forth between their resting (magnetized) state and their agitated (radio pulse) state. This comprises the resonance part of MRI.

The MRI equipment records the duration, strength, and source location of the signals emitted by the atoms as they relax and translates the data into an image on a television monitor. The state of hydrogen in diseased tissue differs from healthy tissue of the same type, making MRI particularly good at identifying tumors and other lesions. In some cases, chemical agents such as gadolinium can be injected to improve the contrast between healthy and diseased tissue.

A single MRI exposure produces a two-dimensional image of a slice through the entire target area. A series of these image slices closely spaced (usually less than half an inch) makes a virtual three-dimensional view of the area.

Magnetic resonance spectroscopy (MRS) is different from MRI because MRS uses a continuous band of radio wave frequencies to excite hydrogen atoms in a variety of chemical compounds other than water. These compounds absorb and emit radio energy at characteristic frequencies, or spectra, which can be used to identify them. Generally, a color image is created by assigning a color to each distinctive spectral emission. This comprises the spectroscopy part of MRS. MRS is still experimental and is available only in a few research centers.

Doctors primarily use MRS to study the brain and disorders like epilepsy, Alzheimer's disease, brain tumors, and the effects of drugs on brain growth and metabolism. The technique is also useful in evaluating metabolic disorders of the muscles and nervous system.

Magnetic resonance angiography (MRA) is another variation on standard MRI. MRA, like other types of angiography, looks specifically at fluid flow within the blood (vascular) system, but does so without the injection of dyes or radioactive tracers. Standard MRI cannot make a good picture of flowing blood, but MRA uses specific radio pulse sequences to capture usable signals.

The technique is generally used in combination with MRI to obtain images that show both vascular structure and flow within the brain and head in cases of stroke, or when a blood clot or aneurysm is suspected.

MRI technology is also being applied in the evaluation of the pancreatic and biliary ducts in a new study called magnetic resonance cholangiopancreatography (MRCP). MRCP produces images similar to that of endoscopic retrograde cholangiopancreatography (ERCP), but in a non-invasive manner. Because MRCP is new and still very expensive, it is not readily available in most hospitals and imaging centers.

Regardless of the exact type of MRI planned, or area of the body targeted, the procedure involved is basically the same. In a special MRI suite, the patient lies down on a narrow table and is made as comfortable as possible. Transmitters are positioned on the body and the table moves into a long tube that houses the magnet. The tube is as long as an average adult lying down, and is open at both ends. Once the area to be examined has been properly positioned, a radio pulse is applied. Then a two-dimensional image corresponding to one slice through the area is made. The table then moves a fraction of an inch and the next image is made. Each image exposure takes several seconds and the entire exam will last anywhere from 30 to 90 minutes. During this time, the patient must remain still as movement can distort the pictures produced.

Depending on the area to be imaged, the radio-wave transmitters will be positioned in different locations.

- For the head and neck, a helmet-like covering is worn on the head.
- For the spine, chest, and abdomen, the patient will be lying on the transmitters.
- For the knee, shoulder, or other joint, the transmitters will be applied directly to the joint.

Additional probes will monitor vital signs (like pulse, respiration, etc.) throughout the test.

The procedure is somewhat noisy and can feel confining to many patients. As the patient moves through the tube, the patient hears a thumping sound. Sometimes, music is supplied via earphones to drown out the noise. Some patients may become anxious or feel claustrophobic while in the small, enclosed tube. Patients may be reassured to know that throughout the study, they can communicate with medical personnel through an intercom-like system.

Recently, open MRIs have become available. Instead of a tube open only at the ends, an open MRI also has opening at the sides. Open MRIs are preferable for patients who have a fear of closed spaces and become anxious in traditional MRI machines. Open MRIs can also better accommodate obese patients, and allow parents to accompany their children during testing.

If the chest or abdomen is to be imaged, the patient will be asked to hold his to her breath as each exposure is made. Other instructions may be given to the patient as needed. In many cases, the entire examination will be performed by an MRI operator who is not a doctor. However, the supervising radiologist should be available to consult as necessary during the exam, and will view and interpret the results sometime later.

Preparation

In some cases (such as for MRI brain scanning or MRA), a chemical designed to increase image contrast may be given immediately before the exam. If a patient suffers from anxiety or claustrophobia, drugs may be given to help the patient relax.

The patient must remove all metal objects (watches, jewelry, eye glasses, hair clips, etc.). Any magnetized objects (like credit and bank machine cards, audio tapes, etc.) should be kept far away from the MRI equipment because they can be erased. The patient cannot bring any personal items such as a wallet or keys into the MRI machine. The patient may be asked to wear clothing without metal snaps, buckles, or zippers, unless a medical gown is worn during the procedure. The patient may be asked not to use hair spray, hair gel, or cosmetics that could interfere with the scan.

Aftercare

No aftercare is necessary, unless the patient received medication or had a reaction to a contrast agent. Normally, patients can immediately return to their daily activities. If the exam reveals a serious condition that requires more testing or treatment, appropriate information and counseling will be needed.

Risks

MRI poses no known health risks to the patient and produces no physical side effects. Again, the potential effects of MRI on an unborn baby are not well known. Any woman who is, or may be, pregnant, should carefully discuss this issue with her doctor and radiologist before undergoing a scan.

Normal results

A normal MRI, MRA, MRS, or MRCP result is one that shows the patient's physical condition to fall within normal ranges for the target area scanned.

KEY TERMS

Angiography—Any of the different methods for investigating the condition of blood vessels, usually via a combination of radiological imaging and injections of chemical tracing and contrast agents.

Gadolinium—A very rare metallic element useful for its sensitivity to electromagnetic resonance, among other things. Traces of it can be injected into the body to enhance the MRI pictures.

Hydrogen—The simplest, most common element known in the universe. It is composed of a single electron (negatively charged particle). It is the nuclear proton of hydrogen that makes MRI possible by reacting resonantly to radio waves while aligned in a magnetic field.

Ionizing radiation—Electromagnetic radiation that can damage living tissue by disrupting and destroying individual cells. All types of nuclear decay radiation (including x rays) are potentially ionizing. Radio waves do not damage organic tissues they pass through.

Magnetic field—the three-dimensional area surrounding a magnet, in which its force is active. During MRI, the patient's body is permeated by the force field of a superconducting magnet.

Radio waves—Electromagnetic energy of the frequency range corresponding to that used in radio communications, usually 10,000 cycles per second to 300 billion cycles per second. Radio waves are the same as visible light, x rays, and all other types of electromagnetic radiation, but are of a higher frequency.

Abnormal results

Generally, MRI is prescribed only when serious symptoms or negative results from other tests indicate a need. There often exists strong evidence of a condition that the scan is designed to detect and assess. Thus, the results will often be abnormal, confirming the earlier diagnosis. At that point, further testing and appropriate medical treatment is needed. For example, if the MRI indicates the presence of a brain tumor, an MRS may be prescribed to determine the type of tumor so that aggressive treatment can begin immediately without the need for a surgical biospy.

Male breast cancer

Definition

Male **breast cancer** is a malignant tumor that forms in a man's breast.

Description

Breast cancer is rare in men, but can be serious and fatal. Many people believe that only women can get breast cancer, but men have breast tissue that also can develop cancer. When men and women are born, they have a small amount of breast tissue with a few tubular passages called ducts located under the nipple and the area around the nipple (areola). By puberty, female sex hormones cause breast ducts to grow and milk glands to form at the ends of the ducts. But male hormones eventually prevent further breast tissue growth. Although male breast tissue still contains some ducts, it will have only a few—or no—lobules. Near the breasts of men and women are axillary lymph nodes. These are underarm small structures shaped like beans that collect cells from lymphatic vessels. Lymphatic vessels carry lymph, a clear fluid that contains fluid from tissues, cells from the immune system, and various waste products throughout the body. The axillary lymph nodes are important to breast cancer patients, as they play a role in the spread and staging of breast cancer.

Breast cancer is much more common in women, mostly because women have many more breast cells that can undergo cancerous changes and because women are exposed to the effects of female hormones.

Infiltrating ductal **carcinoma** is the most common type of breast cancer in men. It is a type of **adenocarcinoma**, or a type of cancer that occurs in glandular tissue. Infiltrating ductal carcinoma starts in a breast duct and spreads beyond the cells lining the ducts to other tissues in the breast. Once the cancer begins spreading into the breast, it can spread to other parts of the body. This distant spread is called **metastasis**. When breast cancer metastasizes to other areas of the body, it can cause serious, life-threatening consequences. For example, breast cancer might spread to the liver or lungs. About 80% to 90% of all male breast cancers are infiltrating ductal carcinomas.

Ductal carcinoma in situ (DCIS) is not common; it accounts for about 10% of all male breast cancers. It also is an adenocarcinoma. In situ cancers remain in the immediate area where they began, so DCIS remains confined to the breast ducts and does not spread to the fatty tissues of the breast. This means it is likely found early. DCIS also may be called intraductal carcinoma.

Other types of breast cancer are very rare in men. Adenocarcinomas that are lobular (forming in the milk glands or lobules) only occur in about 2% of male breast cancer cases because men normally do not have milk gland tissues. Inflammatory breast cancer, a serious form of breast cancer in which the breast looks red and swollen and feels warm, also occurs rarely. Paget's disease of the nipple, a type of breast cancer that grows from the ducts beneath the nipple onto the nipple's surface, only accounts for about 1% of female breast cancers. However, slightly more men have this form of breast cancer than women. Sometimes, Paget's disease is associated with another form of breast cancer.

Although not a form of cancer, but a benign condition, gynecomastia is important to mention. It is the most common of all male breast disorders and can be associated with male breast cancer in a rare condition called Klilnefelter's syndrome. Gynecomastia most often occurs in teenage boys when their hormones change during puberty. Older men also may experience the condition when their hormone balance changes as they age. Gynecomastia is an increase in the amount of breast tissue, or breast tissue enlargement. If a man has Klinefelter's syndrome, he can develop gynecomastia and increased risk of breast cancer.

Demographics

Breast cancer in men is rare, accounting for less than 1% of all breast cancers. Still, about 1,450 American men were diagnosed with the disease and 470 men died from it in 2004. Although studies show the number of breast cancer cases in women has decreased in the United States and Europe since the 1960s, the number of breast cancer cases in men have not decreased, but remained stable or slightly increased.

The rate of increase in cases begins and steadily rises at age 50 for men. However, the average age for male breast cancer is between 60 and 70 years old, with a median age of 67 years. Men often are diagnosed at a later stage than women.

Causes and symptoms

Scientists do not know what causes most cases of male breast cancer. However, excellent progress is being made in genetic research and in understanding how genes instruct cells to grow, divide, and die. For example, researchers have now mapped all of the genes in the human body. Genes are part of the body's DNA, which is the chemical that instructs the cells. When DNA or genes carry defects (mutations), they activate changes in the cells, such as rapid cell division, that lead to cancer. Some genes, called tumor suppression genes, cause cells to die. Scientists have identified some genetic mutations that are risk factors for breast cancer. In other cases, environmental, or outside, factors are thought to increase a man's risk for breast cancer.

Mutations of at least two versions of a tumor suppressor gene (BRCA1 and BRCA2) have been identified as causes of breast cancer in women. In men, the BRCA2 mutation is considered responsible for about 15% of breast cancers. Men can inherit genes from either parent. Studies have shown that BRCA1 also may increase a man's risk for breast cancer, but its role is less certain. These mutations have been shown to increase other cancers in men, including **prostate cancer**. Klinefelter's syndrome is a rare genetic cause of breast cancer in men. It results from inheriting an additional X chromosome.

Several other factors also may cause male breast cancer. Some conditions, such as the liver disease cirrhosis, can cause an imbalance in a man's hormones, producing high levels of the female hormone estrogen, which can lead to breast cancer. Exposure to some substances such as high amounts of radiation may contribute to male breast cancer. A 2004 report studied why a cluster of breast cancer cases occurred among a small group of men who worked in the basement office of a multi-story office building. The study linked their breast cancer to exposure to high magnetic fields from a nearby electrical switchgear room in their work space.

Many men do not realize they can develop breast cancer; they ignore the symptoms. The most common symptom is a mass, or lump in the chest area, particularly around the nipple. The lump will be firm, not tender or

painful. Other signs that may warn of male breast cancer include:

- Skin dimpling or puckering
- Changes in the nipple, such as drawing inward (retraction)
- Nipple discharge of any kind
- Redness or scaling of the nipple or breast skin
- Abnormal swelling (or lump) of the breast, nipple, or chest muscle
- Prolonged rash or irritation of the nipple, which may indicate Paget's disease

Diagnosis

Physicians follow the same steps for diagnosing breast cancer in men as in women, except that routine screening of breast cancer is not done in men. Once symptoms are noticed, however, physicians will proceed in the same way. The physician will conduct a thorough medical history and examination, including questions that may identify risk factors for breast cancer, such as male or female relatives with the disease. The medical history also helps gather details on possible symptoms for breast cancer.

The physician also performs a clinical breast examination. This helps locate and study a lump or suspicious area. The physician will feel (palpate) a mass to get an idea of its size, texture, likely location and relation to surrounding skin, muscles and tissues. At this point, the physician already will begin to look for signs that the cancer may have spread to other organs and to the lymph nodes. The physician will palpate lymph nodes and the liver, for instance, to see if they are enlarged.

The next step in diagnosis usually is a diagnostic mammogram. **Mammography** is an x ray of the breast. Mammograms are performed by radiologic technologists who take special training in the procedure. Mammograms are evaluated by radiologists, physicians who receive medical training specifically in interpreting **x rays**. If the initial mammogram shows suspicious findings, the radiologist may order magnification views to more closely look at the suspicious area. Mammograms can accurately show the tissue in the breast, even more so in men than women, because men do not have dense breasts or benign cysts in their breasts that interfere with the diagnosis.

The radiologist also might recommend an ultrasound to follow up on suspicious findings. Ultrasound often is used to image the breasts. Also known as sonography, the technique uses high-frequency sound waves to take pictures of organs and functions in the body. Sound wave echoes can be converted by computer to an image and displayed on a computer screen. Ultrasound does not use radiation. A technologist will perform the ultrasound; it will be evaluated by the radiologist.

Biopsies, which involve removing a sample of tissue, are the only definite way to tell if a mass is cancerous. At one time, surgical biopsies were the only option, requiring removal of all or a large portion of the lump in a more complicated procedure. Today, fine-needle aspiration **biopsy** and core biopsies can be performed. In fine-needle aspiration biopsy, a thin needle is inserted to withdraw fluid from the mass. The physician may use ultrasound or other imaging guidance to locate the mass if necessary. The fluid is tested in a laboratory under a special microscope to determine if it is cancerous.

A core biopsy is similar, but involves removing a small cylinder of tissue from the mass through a slightly larger needle. Core biopsy may require local anesthesia. These biopsy techniques usually can be performed in a physician office or outpatient facility. The cells in biopsy samples help physicians determine if the lump is cancerous and the type of breast cancer. A tissue sample also may be used for assigning a grade to the cancer and to test for certain proteins and receptors that aid in treatment and prognosis decisions.

If there is discharge from the nipple, the fluid also may be collected and analyzed in a laboratory to see if cancer cells are present in the fluid.

Diagnosis of breast cancer spread may require additional tests. For example, a **computed tomography** (CT) scan may be ordered to check organs such as the liver or kidney for possible metastasized cancer. A chest x ray can initially check for cancer spread to the lungs. Bone scans are nuclear medicine procedures that look for areas of diseased bone. **Magnetic resonance imaging** (MRI) has been increasingly used in recent years as a follow-up study to mammograms when findings are not clear. However, for metastatic breast cancer, they are more likely to be ordered to check for cancer in the brain and spinal cord. **Positron emission tomography** (PET) scans also have become more common in recent years.

Treatment team

The treatment team for male breast cancer normally consists of a primary care physician, a medical oncologist (cancer specialist) and if **radiation therapy** is used, a radiation oncologist. Many other staff also are involved. For instance, special oncology nurses help

guide patients through their care and recovery. Radiation therapists are specially trained technologists who deliver the radiation therapy treatments prescribed by the radiation oncologist.

Clinical staging, treatments, and prognosis

A technique called sentinel **lymph node biopsy** may be the first step in staging. The sentinel node is the first one the cancer cells are likely to reach, so it is the first one checked for cancerous cells. Using a radioactive substance and blue dye injected into the area around the tumor, physicians can track the path of the cells and stage the cancer. The technique has been used for many years on women with breast cancer; research in 2004 showed it worked well for predicting lymph node status in men as well.

Staging

Cancer staging systems help physicians compare treatments and research and identify patients for **clinical trials**. Most of all, they help physicians determine treatment and prognosis for individual patients by describing how severe a patient's cancer is in relation to the primary tumor. The most common system used for cancer is the American Join Committee on Cancer (AJCC) TNM system, which bases staging largely on the spread of the cancer. T stands for tumor and describes the tumor's size and spread locally, or within the breast and to nearby organs. The letter N stands for lymph nodes and describes the cancer's possible spread to and within the lymph node system. In some descriptions below, the cancer may have been found by sentinel node biopsy as microscopic disease in nodes that are in the breasts (rather than the armpits). For simplification, these findings have been grouped with the axillary lymph nodes. M stands for metastasis to note if the cancer has spread to distant organs. Further letters and numbers may follow these three letters to describe number of lymph nodes involved, approximate tumor sizes, or other information. The following is a summary of breast cancer stages:

Stage 0: Tis, N0, M0: Ductal carcinoma in situ (DCIS). This is the earliest and least invasive form of breast cancer; the cancer cells are located within a duct and have not invaded surrounding fatty tissue.

Stage I: T1, N0, M0: The tumor is less than 1 in. in diameter (2 cm or less) and has not spread to lymph nodes or distant organs.

Stage IIA: T0, N1, M0/T2, NO, MO: No tumor is found or the tumor is smaller than 2 cm and cancer is found in one to three axillary lymph nodes (even if no tumor is found), or the tumor is between 2 and 5 cm in diameter but has not spread to the axillary lymph nodes. The cancer has not spread to distant organs.

Stage IIIB: T2, N1, M0/T3, NO, MO: The tumor is between 2 and 5 cm in diameter and has spread to one to three axillary lymph nodes or the tumor is larger than 5 cm, has not grown into the chest wall or spread to the lymph nodes or distant organs.

Stage IIIA: T0-2, N2, M0/T3, N1, MO: The tumor is smaller than 5 cm in diameter and has spread to four to nine axillary lymph nodes or the tumor is larger than 5 cm and has spread to one to nine axillary lymph nodes. The cancer has not spread to distant organs.

Stage IIIB: T4, N0-2, M0: The tumor has grown into the chest wall or the skin and may have spread to no lymph nodes or as many as nine lymph nodes. Cancer has not spread to distant sites.

Stage IIIC: T0-4, N3, MO: The tumor is any size, has spread to 10 or more axillary lymph nodes or to one or more lymph nodes under or above the collarbone (clavicle) on the same side as the breast tumor. The cancer has not spread to distant organs.

Inflammatory breast cancer: Classified as stage III, unless it has spread to distant organs or lymph nodes not near the breast (which would classify it as Stage IV).

Stage IV: T0-4, N0-3, M1: Regardless of the tumor's size, the cancer has spread to distant organs, such as the liver, bones, or lung, or to lymph nodes far from the breast.

Treatment

If the axillary lymph nodes were identified as containing cancer at the time of the sentinel lymph node biopsy, they will be removed in an axillary dissection. Sometimes, this is done at the time of the biopsy.

For Stage I, surgery often is the only treatment needed for men. Women often have lumpectomies, which remove as little surrounding breast tissue as possible, to preserve some of their breast shape. For men, this is less of a concern, and **mastectomy**, or surgical removal of the breast, is performed in 80% of all male breast cancers. Men with Stage I tumors larger than 1 cm may receive additional (adjuvant) **chemotherapy**.

Men with Stage II breast cancer also usually receive a mastectomy. If they have cancer in the lymph nodes, they probably will receive adjuvant therapy. Those with estrogen receptor-positive tumors may receive hormone therapy with **tamoxifen**. The treatment team may recommend adjuvant radiation therapy if the cancer has spread to nearby lymph nodes and/or to the skin.

Stage III breast cancer requires mastectomy followed by adjuvant therapy with tamoxifen when hormones are involved. Most patients with Stage III disease also will require chemotherapy and radiation therapy to the chest wall.

Men with Stage IV breast cancer will require systemic therapy, or chemotherapy and perhaps hormonal therapy that works throughout the body to fight the cancer in the breast, as well as the cancer cells that have spread. Patients also may receive immunotherapy to help patients fight infection following chemotherapy. Radiation and surgery also may be used to relieve symptoms of the primary cancer and areas where the cancer may have spread. The treatment team also may have to diagnose specific treatments for the metastatic cancers, depending on their sites.

If male breast cancer recurs in the breast or chest wall, it can be treated with surgical removal and followed by radiation therapy. An exception is recurrence in the same area, where additional radiation therapy can damage normal tissue. Recurrence of the cancer in distant sites is treated the same as metasteses found at the time of diagnosis.

Prognosis

Prognosis for male breast cancer varies, depending on stage. Generally, prognosis is poorer for men than for women, because men tend to show up for diagnosis when their breast cancer has reached a later stage. The average five-year survival rate for Stage I cancers is 96%. For Stage II, it is 84%. Stage III cancers carry an average five-year survival rate of 52%, and by Stage IV, the rate drops to 24%.

Alternative and complementary therapies

Many alternative and complementary therapies can help cancer patients relax and deal with pain, though none to date have been shown to treat or prevent male breast cancer. For example, traditional Chinese medicine offers therapies that stress the importance of balancing energy forces. Many studies also show that guided imagery, prayer, meditation, laughter, and a positive approach to cancer can help promote healing. Early studies have shown that soy and flaxseed may have some preventive properties for breast cancer. However, these trials have been conducted in women. When looking for these therapies, cancer support groups suggest asking for credible referrals and working with the medical treatment team to coordinate alternative and complementary care.

Coping with cancer treatment

It is difficult for some men to accept and cope with a breast cancer diagnosis, since it is a relatively rare and unexpected disease among men. It is important that men work closely with their treatment team to talk about the their concerns and to carefully follow all instructions for care. Support groups and family support are critical in coping with a breast cancer diagnosis.

Eating a nutritious diet, stopping use of tobacco, and limiting use of alcohol, can help in recovery from breast cancer. Beginning a regular exercise program when the treatment team recommends also helps.

KEY TERMS

Lymph node—One of a number of small, bean-shaped structures that run along the lymphatic system of vessels. The lymph nodes trap cancer cells, along with other cells and fluids.

Malignant—Causing worsening or death. Malignant tumors can invade other tissues and organs and spread to other areas of the body.

Clinical trials

Research currently is underway to test various chemotherapy combinations for male breast cancer at different stages. A clinical trial also is underway to investigate a vaccine for treating patients with metastatic breast cancer. The National Institutes of Health list clinical trials by disease type, including those for which they are recruiting patients. Choosing to participate in a clinical trial is a decision that involves the patient, family, and treatment team.

Prevention

Some forms of male breast cancer cannot be prevented. But detecting the cancer at an early stage can prevent serious complications, such as spread to distant organs. Men who have a history of breast cancer in their family should pay particular attention to the symptoms of breast cancer and seek immediate medical evaluation. Physicians may be able to test the blood of men with family history for presence of the BRCA2 gene so they may more carefully watch for early signs of breast cancer. Avoiding exposure to radiation also may help present some male breast cancers.

Special concerns

Men should remember that there are important difference between male and female breast cancers. Some experts say that specific guidelines and instructions for men with breast cancer are noticeably lacking, so men

QUESTIONS TO ASK YOUR DOCTOR

- What type of breast cancer do I have?
- How far has my cancer advanced; what stage is it in?
- What treatments are most appropriate for my type and stage of breast cancer? Which treatment or treatments do you recommend and why?
- How can I prepare for my breast cancer treatment? What side effects can I expect from each treatment?
- Is there anything I can do to keep the cancer from recurring or signs to watch for?

should not be afraid to ask questions or to push a physician for more information when he suspects he might have a suspicious lump or finding in his breast.

Malignant fibrous histiocytoma

Definition

Malignant fibrous histiocytoma (MFH), although rare, is the most common abnormal growth of soft tissue (sarcoma) in adults.

Description

MFH occurs as a painless mass most commonly in the skin, arms, legs, kidneys, or the pancreas. More rarely MFH may occur in the bones, heart, breasts, or inside the skull.

When MFHs spread (metastasize) to other organs, the most common site is the lung, but **metastasis** to local lymph nodes and to bone have also been reported.

MFHs tend to be slow growing and slow to metastasize.

Local recurrence of MFH after surgery to remove the initial tumor is common because MFHs grow along the fat layers that separate different layers of soft tissue. Often, an MFH is not completely removed because it has crossed, undetected, from one fat layer to another neighboring layer.

Demographics

MFHs are diagnosed in six of every one million people each year. MFHs can occur in people of any age, but they are extremely rare in children.

MFHs occur in a slightly higher frequency in Caucasians than in people of African descent or Asians. No relationship of MFHs appear to exist to any geographic region. Males are affected in slightly higher numbers than are females.

MFHs of the skin are seen almost exclusively in sun-exposed areas of the skin in elderly patients.

People affected with certain genetic diseases, such as neurofibromatosis, have a higher incidence of MFHs than unaffected people.

MFHs of the bone are seen almost exclusively in people who have a pre-existing skeletal disorder such as Paget disease or fibrous dysplasia of bone.

Causes and symptoms

The cause, or causes, of MFHs are not known. An elevated risk for the development of MFHs has been linked to the chemical phenoxyacetic acid found in herbicides; to clorphenols found in wood preservatives; and to exposure to asbestos. People who have been exposed to high doses of radiation are also more prone to develop MFHs than the remainder of the population. Research is ongoing to determine if there is a genetic cause of MFHs.

The only direct symptom of MFHs is the presence of an abnormal mass, but some patients may also experience:

- abnormally high levels of a certain type of white blood cells (eosinophils) in the blood
- low blood sugar (hypoglycemia)
- fever
- abnormal liver function tests

Diagnosis

Prior to removal, MFHs are extremely difficult to distinguish from the other forms of soft tissue sarcoma. The definitive diagnosis of MFH usually occurs after a tumor has been surgically removed. This diagnosis is accomplished by conducting microscopic examinations on the tumor.

Treatment team

Treatment for MFHs is mostly surgical or observational. Surgeries to remove MFHs are generally performed by orthopedic surgeons. MFHs rarely require any chemotherapies or radiation therapies, however, when these treatments are called for they are directed by a medical oncologist and administered by health care personnel who specialize in these fields.

KEY TERMS

Liver function tests (LFTs)—Blood tests that measure the blood serum levels of several enzymes produced by the liver.

Sarcoma—A form of cancer that arises from within the supportive tissues, such as bone, cartilage, fat, or muscle.

Clinical staging, treatments, and prognosis

MFHs are divided into three grades based on the appearance of the tissue within the tumor. Low grade tumors may closely resemble the surrounding normal tissue. Intermediate and high grade tumors may have little resemblance to normal tissue.

Additionally, MFHs are divided into two clinical stages based on size. Stage one MFHs are those tumors that are under 5 centimeters (2 inches) in diameter. Stage two MFHs are those tumors larger than 5 centimeters (2 inches) in diameter.

A treatment plan is determined after the grade and stage of the tumor has been established. High and intermediate grade tumors generally, regardless of the stage, are surgically removed. Low grade, stage one, tumors may be observed for development to a higher grade or stage rather than removed if it is determined that the risks of anesthetic and surgery outweigh the risk of the tumor to the individual patient.

Stage one MFHs are generally removed by wide local excision. This technique involves the surgical removal of the tumor and an area of healthy surrounding tissue that is approximately the same size as the tumor itself.

Stage two MFHs require wide surgical excision with the removal of wider margins of healthy tissue than those margins removed in the excision of smaller tumors. In some instances, stage two MFHs may require **amputation**.

Post-operative treatment of MFH patients may include **chemotherapy** or **radiation therapy**, especially in cases of MFH of the bones and in cases of metastasis to the lungs.

In cases of large MFHs, the patient may undergo radiation treatments prior to surgery in an attempt to shrink the size of the tumor prior to excision.

As of 2000, overall survival from MFH was approximately 75% five-year disease-free survival. The prognosis is generally poorer if:

QUESTIONS TO ASK THE DOCTOR

- Which type of MFH do I have?
- What is the size of my tumor?
- Will I require chemotherapy or radiation treatments to shrink my tumor prior to its removal?
- What is the likelihood of my type of MFH coming back?
- How often should I seek follow-up examinations?

- the disease has metastasized to the lungs or bones
- complete tumor removal is not accomplished, or is not possible
- the patient is of an advanced age
- the tumor is large
- the location of the tumor is somewhere other than the arms or legs
- the tumor is located deep in the body, rather than superficially

Alternative and complementary therapies

There are no effective alternative treatments for MFHs other than surgical removal with or without chemotherapy or radiation treatments.

Coping with cancer treatment

Most patients who undergo wide local excision to remove their tumors can resume their normal activities within a few days of the operation.

The loss of a limb may produce feelings of grief that are similar to that felt upon the death of a spouse or close family member. Patients who must undergo amputation to remove their cancer may require extended psychological care to help them to deal with this grief and to help them develop a new, healthy, **body image**. These patients may also require extended physical therapy to learn to operate without the missing limb or to learn to use a prosthetic device.

Clinical trials

There were 40 **clinical trials** underway, in early 2001, aimed at the treatment of MFHs and other soft tissue **sarcomas**. More information on these trials, including contact information, may be found by conducting a clinical trial search at the website of the National Cancer Institute, CancerNet <http://cancernet.nci.nih.gov/trialsrch.shtml>.

Prevention

Because the causes of MFHs are not known, there is no known prevention.

Special concerns

Repeat surgery may be necessary for MFHs because these tumors sometimes redevelop. Careful monitoring by the medical team will be required.

MALT lymphoma

Definition

MALT lymphomas are solid tumors that originate from cancerous growth of immune cells that are recruited to secretory tissue such as the gastrointestinal tract, salivary glands, lungs, and the thyroid gland.

Description

The digestive tract is generally not associated with lymphoid tissue, with the exception of small collections of lymphocytes such as Peyer's patches. A specific kind of white blood cell, B lymphocytes, can accumulate in response to infections of the digestive tract and other secretory tissues, or as a result of autoimmune conditions such as Sjögren's syndrome. When the growth of these lymphocytes is maintained through continued infection or autoimmune disease, a malignant cell can arise and replace the normal lymphocytes. These lymphomas, derived from mucosa-associated lymphoid tissue (MALT), most commonly arise in the stomach. Their growth seems to be dependent upon continuous stimulation of the immune system by an infectious agent, such as

H. pylori, or some other entity, termed an antigen, that the body recognizes as foreign. This antigen-driven growth permits these tumors to be treated by eliminating the stimulus that generated the original, normal **immune response**. In the stomach they are associated, in greater than 90% of all cases, with the bacteria called *Helicobacter pylori (H. pylori)*. This bacteria is also associated with peptic stomach irritation, ulcers, and gastric cancer. MALT lymphomas are generally indolent, that is, they grow slowly and cause little in the way of symptoms. Those MALT lymphomas that arise in the stomach in response to *H. pylori* infections are generally successfully treated with **antibiotics**, which eliminate the bacteria.

Demographics

MALT lymphomas occur at a frequency of about 1.5 per 100,000 people per year in the United States and account for about 10% of all **non-Hodgkin's lymphomas**. The frequency varies among different populations. For example, in parts of Italy the frequency of MALT lymphomas is as high as 13 per 100,000 people per year. This can in part be attributed to different rates of infection with *H. pylori*. However, other hereditary, dietary, or environmental factors are almost certainly involved.

Causes and symptoms

The majority of MALT lymphomas appear to be the result of infectious agents, most commonly *H. pylori* in the stomach. It is not known if infectious agents also cause MALT lymphomas outside of the stomach. In some cases, such as in the thyroid, MALT lymphomas seem to arise in patients who have autoimmune diseases, which make their immune systems treat their own tissue as foreign or antigenic. It is believed that there must be additional factors, in addition to infection or autoimmunity, that influence the development of MALT lymphomas. For example, in the United States, where infections with *H. pylori* are quite common, less than 1 in 30,000 people who have *H. pylori* in their stomachs develop MALT lymphomas. In addition, individuals who develop MALT lymphomas are more likely to develop other forms of cancer. This would suggest that there might be genetic factors predisposing individuals to develop MALT lymphomas or other tumors in response to environmental or infectious agents.

In general, patients have stomach pain, ulcers, or other localized symptoms, but rarely do they suffer from systemic complaints such as **fatigue** or **fever**.

Diagnosis

The indolent nature of most MALT lymphomas means that the majority of patients are diagnosed at early stages with relatively nonspecific symptoms. In the case of gastric MALT lymphomas, the physician will then have a gastroenterologist perform an endoscopy to examine the interior of the stomach. MALT lymphomas are then recognized as areas of inflammation or ulceration within the stomach. It is unusual for masses recognizable as tumors to be seen upon examination. Definitive diagnosis of MALT lymphoma requires a **biopsy**, in which a bit of tissue is removed from the stomach or other involved site. Examination of this tissue by a pathologist is the first step in distinguishing among the possible diagnoses of inflammation, indolent lymphoma, or a more aggressive form of cancer, such as gastric cancer or a rapidly growing non-Hodgkin's lymphoma. The pathologist evaluates the type of lymphoid cells that are present in the biopsy to establish the nature of the lesion. In addition, it is essential that the pathologist determine whether the lymphoma has grown beyond the borders of the mucosa, which lines the stomach or other gland.

KEY TERMS

Antigen—A foreign substance that leads to an immune response, including the production of antibodies by B cells.

Autoimmune disease—A condition in which an individual's immune system reacts to their own tissues, viewing self components as if they were foreign antigens.

Bone marrow biopsy—A procedure in which cellular material is removed from the pelvis or breastbone and examined under a microscope to look for the presence of abnormal blood cells characteristic of specific forms of leukemia and lymphoma.

Indolent lymphoma (also called low-grade)—Cancerous growths of lymphoid tissue that progress slowly to more aggressive forms of cancer.

Lymphoid tissue—Sites within the body that produce cells of the immune system, including lymph nodes, bone marrow, and the thymus.

Clinical staging, treatments, and prognosis

The best staging system to employ for MALT lymphomas is still the subject of discussion. However, it is standard practice that patients diagnosed with MALT lymphomas should be evaluated in a similar manner to individuals with nodal lymphomas, the more common type of lymphoma that originates at sites within the lymphoid system. These procedures include a complete

QUESTIONS TO ASK THE DOCTOR

- When will I know the results of the biopsies?
- Where does the lymphoma seem to be growing? Is there any evidence that it has spread?
- Does the pathology report indicate that this lymphoma is indolent? Will you treat me with antibiotics? Do you think chemotherapy or radiation is needed? Why?
- How long will I take the antibiotics or undergo chemotherapy before I am re-examined to see if the lymphoma is in remission?

history and physical, blood tests, chest x rays, and bone marrow biopsy. This evaluation will permit the oncologist to determine if the disease is localized or if it has spread to other sites within the body.

In general, the prognosis for patients with MALT lymphomas is good, with overall five-year survival rates that are greater than 80%. The features that are most closely related to the outlook for newly diagnosed individual patients are: whether the **primary site** is in the stomach or is extra-gastric; if the disease has spread beyond the initial location; and whether the histologic evaluation of the initial tumor biopsies is consistent with a low-grade, slowly growing lesion, as compared to a high-grade lesion that is more rapidly growing. In general, the histologic grade is the most important feature, with high-grade lesions requiring the most aggressive treatment.

Treatment of MALT lymphomas differs from that of most lymphomas. In the most common type of MALT lymphomas—low-grade lesions originating in the stomach—treatment with antibiotics to eliminate *H. pylori* leads to complete remissions in the majority of patients. The effectiveness of this treatment is indistinguishable from surgery, **chemotherapy**, **radiation therapy**, or a combination of surgery with drugs or irradiation. Approximately one-third of patients in this group have evidence of disseminated disease, where lymphoma cells are detected at sites in addition to the gastric mucosa. The response of these patients to antibiotic treatment is not significantly different from that for individuals with localized disease. For both groups a complete remission is achieved in about 75% of patients, who remain, on average, free of disease for about five years.

Patients with MALT lymphomas arising outside of the digestive tract also have good prognoses. Effective treatment for these lymphomas has been achieved with local radiation, chemotherapy, and/or interferons. Surgery followed by chemotherapy or radiation is also effective with nongastrointestinal MALT lymphomas. Overall these patients have five-year survival rates greater than 90%.

While the outlook for patients with MALT lymphomas is good, difficulties in diagnosis and staging have left the optimal treatment a matter of continued study. This is an especially open question for those patients who fail to respond to antibiotic therapy, or whose disease recurs. It may be the case that in these patients, the MALT lymphoma may have already progressed to a point where high-grade lesions, not observed in the original biopsies, were resistant to the initial treatment. The best treatment for these patients remains to be established. In general, these patients are treated with chemotherapy in a similar manner to patients with other types of lymphoma. Given the success of antibiotics, and the good prognosis for gastric MALT lymphomas in general, no sufficient body of evidence exists to determine the best chemotherapy for patients who fail to achieve a complete and lasting remission upon initial treatment. At present, a chemotherapeutic regime designated CHOP includes the anti-cancer drugs **cyclophosphamide**, **doxorubicin**, **vincristine**, and prednisone. Similar drug combinations are being used for patients whose MALT lymphomas do not respond to antibiotic treatment.

Clinical trials are underway and mostly concentrate upon optimizing treatment of gastric MALT lymphomas that involve *H. pylori*. The aspects of treatment being addressed are the most effective antibiotics and the use of antacids to modulate irritation in the stomach. These protocols have been designed to follow the natural history of gastric lymphomas and to establish the biological features that predict treatment response to antibiotics and duration of remission.

Prevention

There are currently no commonly accepted means to prevent MALT lymphomas. While the *H. pylori* infections are associated with this and other gastric disease, the eradication of *H. pylori* in asymptomatic individuals is not currently recommended for prevention of MALT lymphomas or stomach cancer.

Mammography

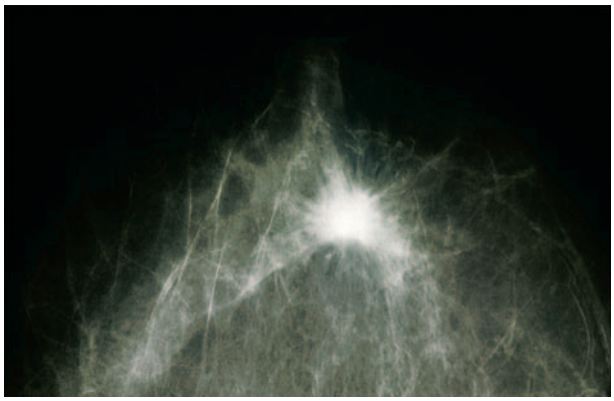
Definition

Mammography is the study of the breast using **x ray**. The actual test is called a mammogram. There are two types of mammograms. A screening mammogram is ordered for women who have no problems with their breasts. It consists of two x-ray views of each breast. A diagnostic mammogram is for evaluation of new abnormalities or of patients with a past abnormality requiring follow-up (i.e. a woman with **breast cancer** treated with **lumpectomy**). Additional x rays from other angles or special views of certain areas are taken.

Purpose

The purpose of screening mammography is breast cancer detection. A **screening test**, by definition, is used for patients without any signs or symptoms in order to detect disease as early as possible. Many studies have shown that having regular mammograms increases a woman's chances of finding breast cancer in an early stage, when it is more likely to be curable. It has been estimated that a mammogram may find a cancer as much as two years before it can be felt. The American Cancer Society, American College of Radiology, American College of Surgeons and American Medical Association recommend annual mammograms for every woman beginning at age 40.

Screening mammograms are not usually recommended for women under age 40 who have no special risk factors and a normal physical breast examination. Below age 40, breasts tend to be "radiographically dense," which means it is difficult to see many details. In 2003, a new technique that introduces radiographic contrast into digital mammograms was proving useful at improving visibility of breast cancer in younger women. Screening mammograms can detect cancers in their earliest stages and greatly reduce mortality, particularly among women age 40 to 69. In fact, a study in 2003 found that women age 40 and older who had annual screening mammograms had better breast cancer prognoses because their cancers were diagnosed at earlier stages than women who had mammograms less often.



A mammogram of the right breast of a 72-year-old woman reveals carcinoma. *(Custom Medical Stock Photo. Reproduced by permission.)*

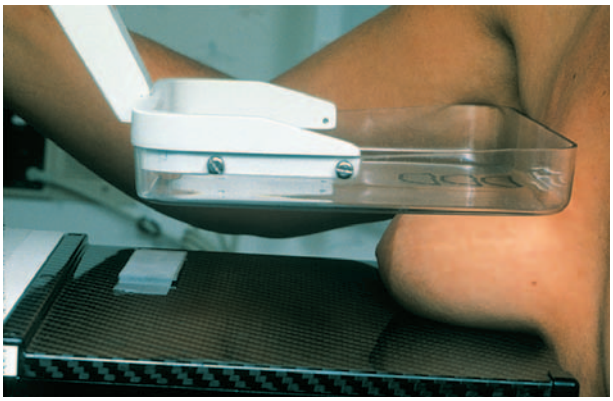
Some women are at increased risk for developing breast cancer, such as those with multiple relatives who have the disease. The 2003 American Cancer Society guidelines stated that women at increased risk might benefit from earlier screening mammograms and more frequent intervals for screening. However, the society suggested that evidence was not strong enough at that time to support making specific recommendations concerning screening examinations.

Diagnostic mammography is used to evaluate an existing problem, such as a lump, discharge from the nipple, or unusual tenderness in one area. The cause of the problem may be definitively diagnosed from this study, but further investigation using other methods often is necessary. This test is also used to evaluate findings from screening mammography tests.

Description

A mammogram may be offered in a variety of settings. Hospitals, outpatient clinics, physician's offices, or other facilities may have mammography equipment. In the United States, since October 1, 1994, only places certified by the U.S. Food and Drug Administration (FDA) are legally permitted to perform, interpret, or develop mammograms.

In addition to the usual paperwork, a woman will be asked to fill out a form seeking information relevant to her risk of breast cancer and special mammography needs. The woman is asked about personal and family history of cancer, details about menstruation, child bearing, birth control, breast implants, other breast surgery, age, and hormone replacement therapy. Information



Mammogram. Breast compressed with compression paddle. *(Copyright SIU, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

about Breast Self Examination (BSE) and other breast health issues are usually available at no charge.

At some centers, a technologist may perform a physical examination of the breasts before the mammogram. Whether or not this is done, it is essential for the patient to tell the technologist about any lumps, nipple discharge, breast pain, or other concerns.

Clothing from the waist up is removed and a hospital gown or similar covering is put on. The woman stands facing the mammography machine. The technologist exposes one breast and places it on a plastic or metal film holder about the size of a placemat. The breast is compressed as flat as possible between the film holder and a rectangle of plastic (called a paddle), which presses down onto the breast from above. The compression should only last a few seconds, just enough to take the x ray. Good compression can be uncomfortable, but it is necessary to ensure the clearest view of all breast tissues.

Next, the woman is positioned with her side toward the mammography unit. The film holder is tilted so the outside of the breast rests against it, and a corner touches the armpit. The paddle again holds the breast firmly as the x ray is taken. This procedure is repeated for the other breast. A total of four x rays, two of each breast, are taken for a screening mammogram. Additional x rays, using special paddles, different breast positions, or other techniques are usually taken for a diagnostic mammogram.

The mammogram may be seen and interpreted by a radiologist right away, or it may not be reviewed until later. If there are any questionable areas or an abnormality, extra x rays may be recommended. These may be taken during the same appointment. More commonly, especially for screening mammograms, the woman is called back on another day for these additional films.

KEY TERMS

Breast biopsy—A procedure in which suspicious tissue is removed and examined by a pathologist for cancer or other disease. The breast tissue may be obtained by open surgery or through a needle.

Radiographically dense—Difficult to see details of breast tissue on x ray.

A screening mammogram usually takes approximately 15 to 30 minutes. A woman having a diagnostic mammogram can expect to spend up to an hour at the mammography facility.

The cost of mammography varies widely. Many mammography facilities accept "self referral." This means women can schedule themselves without a physician's referral. However, some insurance policies do require a doctor's prescription to ensure payment. Medicare will pay for annual screening mammograms for all women with Medicare who are age 40 or older and a baseline mammogram for those age 35 to 39.

A digital mammogram is performed in the same way as a traditional exam, but in addition to the image being recorded on film, it is viewed on a computer monitor and stored as a digital file.

Preparation

The compression or squeezing of the breast for a mammogram is a concern for some women, but necessary to render a quality image. Even with concerns about pain, a 2003 study said that three-fourths of women reported the pain associated with a mammogram as four on a 10-point scale. Mammograms should be scheduled when a woman's breasts are least likely to be tender. One week after the menstrual period is usually best. The MQSA regulates equipment compression for consistency and performance.

Women should not put deodorant, powder, or lotion on their upper body on the day the mammogram is performed. Particles from these products can get on the breast or film holder and may look like abnormalities on the mammogram film.

Aftercare

No special aftercare is required.

Risks

The risk of radiation exposure from a mammogram is considered virtually nonexistent. Experts are unani-

QUESTIONS TO ASK THE DOCTOR

- What do the results mean?
- If there is something abnormal, shouldn't we immediately find out what it is?
- What future care will I need?

mous that any negligible risk is far outweighed by the potential benefits of mammography.

Some breast cancers do not show up on mammograms, or "hide" in dense breast tissue. A normal (or negative) study is not a guarantee that a woman is cancer-free. Mammograms find about 85% to 90% of breast cancers.

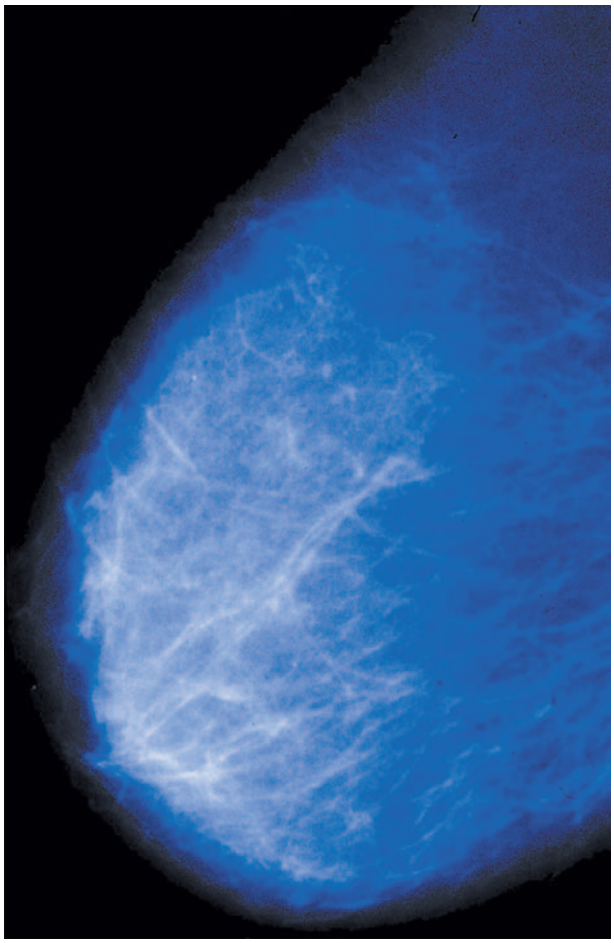
"False positive" readings are also possible, and 5% to 10% of mammogram results indicate the need for additional testing, most of which confirms that no cancer is present.

Normal results

A mammography report describes details about the x ray appearance of the breasts. It also rates the mammogram according to standardized categories, as part of the Breast Imaging Reporting and Data System (BIRADS) created by the American College of Radiology (ACR). A normal mammogram may be rated as BIRADS 1 or negative, which means no abnormalities were seen. A normal mammogram may also be rated as BIRADS 2 or benign findings. This means that one or more abnormalities were found but are clearly benign (not cancerous), or variations of normal. Some kinds of calcification, lymph nodes, or implants in the breast might generate a BIRADS 2 rating. A BIRADS 0 rating indicates that the mammogram is incomplete and requires further assessment.

Abnormal results

Many mammograms are considered borderline or indeterminate in their findings. BIRADS 3 means an abnormality is present and probably (but not definitely) benign. A follow-up mammogram within a short interval of six months is suggested. This helps to ensure that the abnormality is not changing, or is "stable." This stability in the abnormality indicates that a cancer is probably not present. If the abnormality were a cancer, it would have grown in the interval between mammograms. Some women are uncomfortable or anxious about waiting and may want to consult with their doctor about a having a biopsy. BIRADS 4 means suspicious for cancer. A biopsy is usually recommended in this case. BIRADS 5 means an abnormality is highly suggestive of cancer. The suspicious area should be biopsied.



Color-enhanced mammogram of the left breast of a 73-year-old woman showing normal tissue. *(Copyright SIU, Science Source/Photo Researchers, Inc. Photo reproduced by permission.)*

Often, screening mammograms are followed up with additional imaging. The reasons are numerous; they may mot mean the radiologist suspects a cancerous lesion, only that he or she cannot make a clear diagnosis from the screening mammogram views. The most common imaging methods are additional views on the mammogram, sometimes called magnification views, and ultrasound. In recent years, some patients have received magnetic resonance imaging (MRI) of the breast. A new technique called dual-energy contrast enhanced digital subtraction mammography is reported to find cancers that may be missed by conventional mammography. It may be ordered in the future as a follow-up study.

Mantle cell lymphoma

Definition

Mantle cell lymphoma (MCL) is a rare type of non-Hodgkin's lymphoma characterized under the microscope by expansion of the mantle zone area of the lymph node with a homogeneous (structurally similar) population of malignant small lymphoid cells. These cancerous cells have slightly irregular nuclei and very little cytoplasm, and are mixed with newly made normal lymphocytes (white blood cells) that travel from the bone marrow to the lymph nodes and spleen. Unlike normal lymphocytes, they do not mature properly and become cancerous instead.

Description

The body's immune system produces two types of lymphocytes or white blood cells: the B cells which are made in the bone marrow and the T cells which are made in the thymus. Both types of cells are found in the lymph, the clear liquid that bathes tissues and circulates in the lymphatic system. Lymphomas are cancers that occur in this lymphatic system and B-Cell lymphomas—also called non-Hodgkin's lymphomas—include follicular lymphomas, small non-cleaved cell lymphomas (Burkitt's lymphomas), marginal zone lymphomas (MALT lymphomas), small lymphocytic lymphomas, large cell lymphomas and also mantle cell lymphomas.

Mantle cell lymphoma accounts for 5% to 10% of all lymphomas diagnosed and 5% of B-cell lymphomas. There are three subsets of MCL cells: the mantle zone type, the nodular type, and the blastic or blastoid (immature) type. These various types often occur together to some degree, and approximately 30% to 40% of diagnoses are of mixed mantle and nodular type. As MCL develops further, the non-cancerous mantle centers also become invaded by cancerous cells. In about 20% of these cases, the cells become larger, and of the blastic type.

Extensive debates are ongoing concerning the grade of this cancer. European classification used to classify it as a low-grade cancer because it is initially slow-growing, while American classification considered it intermediate based on patients' shorter average survival rate. The combined European-American classification (REAL), is still discussing the status of mantle cell lymphoma. This is due to the mixed nature of MCL cells. Blastic type-MCL seems to be considered as a high-grade cancer because it spreads at about the rate of other lymphomas belonging to that category. The studies currently attempting to describe the precise nature of these cells will be key to any general agreement that is finally reached.

Demographics

Mantle cell lymphoma is rare in persons under the age of 50. It is most often seen in men aged 50–70 years. Out of 1,000 persons diagnosed with MCL, approximately 33% will be women. This cancer has the shortest average survival of all lymphoma types.

Causes and symptoms

The cause of MCL is unknown. Many of its symptoms are shared by other lymphomas as well and patients generally complain of **fatigue**, **anemia**, low grade fevers, **night sweats**, **weight loss**, rashes, digestive disturbances, chronic sinus irritation, recurrent infections, sore throat, shortness of breath, muscle and bone aches and edema.

More specific symptoms include spleen enlargement (in about 60% to 80% of cases), particularly with nodu-

lar-type MCL. Swollen lymph nodes are an early-stage symptom, even though the general health of the patient is good. Mild anemia is also common. Some patients also report lower back pain, and burning pain in the legs and testicles. As MCL becomes more advanced, the lymph nodes increase in volume, and the general symptoms become more pronounced.

In the end stage of MCL, neurologic symptoms appear, indicating that the MCL has spread to the central nervous system.

Diagnosis

MCL is very similar to several other lymphoma types and special care must be taken with the diagnosis. It should not be made from blood or bone marrow specimens alone. It is believed that immunologic tests are required to make the correct diagnosis. Immunophenotyping is one such test, it is used to determine what kind of surface molecules are present on cells, and thus, the exact type of lymphoma from a tissue sample. The Lymphoma Research Foundation of America recommends that several opinions be sought from recognized mantle cell experts to confirm the accuracy of the diagnosis.

At the time of diagnosis, mantle cell lymphoma has usually spread into other tissues such as the lymph nodes, spleen, bone marrow (up to 90% of cases), or to Waldeyer's ring (the ring of adenoid, palatine and lingual tonsils at the back of the mouth) or to the gastrointestinal tract. MCL can also spread to the colon, in which case it is diagnosed as multiple lymphomatous polyposis.

Treatment team

Depending on the type of MCL and stage of the cancer, the treatment team may include a radiation oncologist, a medical oncologist, a surgeon and a neurologist.

Clinical staging, treatments, and prognosis

There is no formal staging system for mantle cell lymphoma and no standard treatment has yet been adopted for MCL patients. Patients have been treated with surgery, radiation, single drug or combination **chemotherapy** and stem cell transplants. CHOP is one of the most common chemotherapy regimens for treating MCL. It derives its name from the combination of drugs used: **Cyclophosphamide** (cytoxan, neosar), adriamycin (**doxorubicin** or Hydroxydoxorubicin), **vincristine** (Oncovin), and Prednisone.

There is no cure for mantle cell lymphoma. As with other slow-growing lymphomas, spontaneous remissions have been reported, but only partial, lasting a year at the most. All mantle cell lymphoma experts agree that the long-term prognosis of MCL patients receiving conventional treatment is poor, and that there is an urgent need for new, improved therapies.

Alternative and complementary therapies

Because MCL is a cancer of the lymphatic system, immunologic therapies are often used, or combined with the more conventional radiation and chemotherapy treatments. Immunological therapies take advantage of the body's immune system. The immune system is a network of specialized cells and organs that defends the body against foreign invaders (antigens) by producing special ''defense'' proteins, an example of which are the antibodies. These substances recognize and attach to the antigens, usually found on the surface of cells and destroy them. There are reports of immunological therapies being used for MCL using interferon, one such natural substance produced by the body in response to a virus. Numerous studies show that **interferons** can stimulate the immune system to fight the growth of cancer, but there has not yet been enough evidence produced to see it emerge as a strong candidate for MCL treatment.

Other immunological therapies based on **monoclonal antibodies** (MABs or MOABs) have recently emerged, such as Rituxan (**rituximab**). MABs work on cancer cells in the same way natural antibodies work, by identifying and binding to the target cells, alerting other cells in the immune system to the presence of the cancer cells. MABs are very specific for a particular antigen, meaning that one designed for a B-cell lymphoma will not work on T-cell lymphomas. MABs used alone may enhance a patient's **immune response** to the cancer but they are thought to be more efficient when combined to another form of therapy, such as a chemotherapeutic drug. This way, the cancer is attacked on two fronts: chemical attack from the chemotherapy and immune response attack stimulated by the MAB.

Coping with cancer treatment

It is important to have a caregiver system when receiving medical treatment for MCL, and it is just as important to have a network of support for coping with the non-medical aspects of the cancer. Friends, relatives, coworkers and health professionals all can provide help, as well as the national cancer associations, some specifically addressing the needs of lymphoma patients. Please refer to the Resources section at the end of this entry for contact information.

KEY TERMS

Anemia—A condition caused by a reduction in the amount of red blood cells produced by the bone marrow. Its symptoms are general weakness and lack of energy, dizziness, shortness of breath, headaches, and irritability.

Antibody—A protein (immunoglobulin) produced by plasma cells (mature B cells) to fight infections in the body. They are released into the circulatory system in response to specific antigens and thus target those antigens that induced their production.

Antigen—An antigen is any substance which elicits an antibody response. As such, they are substances that stimulate a specific immune response of the body and are capable of reacting with the products of that response. Antigens may be foreign chemical substances or proteins located on the surface of viruses, bacteria, toxins, tumors and other infectious agents.

B-Cell lymphocyte—A type of lymphocyte (white blood cell). B cells react to the presence of antigens by dividing and maturing into plasma cells.

B-cell lymphomas—Non-Hodgkin's lymphomas that arise from B cells.

Blood cell—Cellular component of blood. There are three general types: white blood cells, red blood cells, and platelets, all which are produced in the bone marrow.

Cytoplasm—The organized complex of organic and inorganic substances external to the nuclear membrane of a cell.

DNA—Deoxyribonucleic acid are nucleic acids that are the part of the cell nucleus that contains and controls all genetic information.

Edema—Swelling of a body part caused by an abnormal buildup of fluids.

Gene—The specific site on a chromosome, consisting of protein and DNA responsible for the transmittal and determination of hereditary characteristics.

Gene therapy—The use of genes to treat cancer and other diseases.

Immune system—The system within the body, consisting of many organs and cells, that recognizes and fights foreign cells and disease.

Lymph—A milky white liquid responsible for carrying the lymphocytes in the lymphatic vessels.

Lymphatic system—Tissues and organs such as the bone marrow, spleen, thymus and lymph nodes that produce and store cells to fight infection and disease. Also includes the lymphatic vessels that carry lymph.

Lymphocyte—A type of white blood cell that defends the body against infection and disease. Lymphocytes are found in the bloodstream, the lymphatic system, and lymphoid organs. The two main types of lymphocytes are the B cells (produced in the bone marrow) and the T cells (produced in the thymus).

Lymphoma—Cancers that starts in the lymphatic system. Lymphomas are classified into two categories: Hodgkin's Disease and the non-Hodgkin's lymphomas.

Monoclonal antibody—An antibody raised against a specific antigen. Monoclonal antibodies are being used to target chemotherapy or radioactive substances directly to cancer cells.

Non-Hodgkin's lymphomas—Lymphomas characterized by different types of cancerous lymphatic cells, excluding those characterized by Hodgkin's disease.

Remission—A complete or partial disappearance of the signs and symptoms of cancer, usually in response to treatment.

Stem cell—Primitive cell found in the bone marrow and in the blood stream. Stem cells become different types of mature blood cells, thus enabling them to rejuvenate the circulatory and immune systems.

Stem cell transplant—Treatment procedure by which young blood stem cells are collected from the patient (autologous) or another matched donor (allogeneic). High-dose chemotherapy and/or radiation is given, and the stem cells are reinserted into the patient to rebuild his or her immune system.

Clinical trials

Clinical trials addressing the needs of MCL patients are very recent because the mantle cell lymphoma subtype has only recently been defined. There are now several trials being carried out in the United States specifically for mantle cell. Some other trials designed for patients with lymphomas may also accept mantle cell patients. Ongoing trials in this area are cheifly concerned with investigating monoclonal antibodies. Information regarding clinical trials can be obtained through the Clinical Trials web site listed at the end of this entry.

The following clinical protocols are specifically designed for MCL patients:

- The MD Anderson Protocol (high-dose chemotherapy with or without stem cell transplant)
- Rituxan, by itself or with CHOP
- Bexxar
- Oncolym
- Flavopiridol
- Phenylacetate

Prevention

Because the cause of MCL is unknown, no prevention measures can be recommended.

Special concerns

Special concerns that apply to lymphoma patients may also apply to MCL patients. Because MCL is a cancer that usually involves chemotherapy and **radiation therapy**, it can be severely damaging to organ function and long-term resistance. In addition to the immediate side effects of these treatments, other effects appear after treatment is completed, one of which, called Post-Cancer Fatigue (PCF), is often seen with lymphoma patients. This is fatigue that persists after treatment and can sometimes be extreme. The medical team will be able to offer the best advice to deal with PCF.

Mastectomy

Definition

Mastectomy is the surgical removal of the breast for the treatment or prevention of **breast cancer**.

Purpose

Mastectomy is performed as a surgical treatment for breast cancer. The severity of a breast cancer is evaluated according to a complex system called staging. This takes into account the size of the tumor and whether it has spread to the lymph nodes, adjacent tissues, and/or distant parts of the body. A mastectomy usually is the recommended surgery for more advanced breast cancers. Women with earlier stage breast cancers, who might also have breast-conserving surgery (**lumpectomy**), may choose to have a mastectomy. In the United States, approximately 50,000 women a year undergo mastectomy.

The size, location, and type of tumor are important considerations when choosing the best surgery to treat breast cancer. The size of the breast is also an important factor. A woman's psychological concerns and lifestyle choices should also be considered when making a decision.

There are many factors that make a mastectomy the treatment of choice for a patient. Large tumors are difficult to remove with good cosmetic results. This is especially true if the woman has small breasts. Sometimes multiple areas of cancer are found in one breast, making removal of the whole breast necessary. The surgeon is sometimes unable to remove the tumor with a sufficient amount, or margin, of normal tissue surrounding it. In this situation, the entire breast needs to be removed. Recurrence of breast cancer after a lumpectomy is another indication for mastectomy.

Radiation therapy is almost always recommended following a lumpectomy. If a woman is unable to have radiation, a mastectomy is the treatment of choice. Pregnant women cannot have radiation therapy for fear of harming the fetus. A woman with certain collagen vascular diseases, such as systemic lupus erythe-

matosus or scleroderma, would experience unacceptable scarring and damage to her connective tissue from radiation exposure. Any woman who has had therapeutic radiation to the chest area for other reasons cannot tolerate additional exposure for breast cancer therapy.

The need for radiation therapy after breast-conserving surgery may make mastectomy more appealing for nonmedical reasons. Some women fear radiation and choose the more extensive surgery so radiation treatment will not be required. The commitment of time, usually five days a week for six weeks, may not be acceptable for other women. This may be due to financial, personal, or job-related factors. In geographically isolated areas, a course of radiation therapy may require lengthy travel and perhaps unacceptable amounts of time away from family or other responsibilities.

Some women choose mastectomy because they strongly fear recurrence of the breast cancer, and lumpectomy seems too risky. Keeping a breast that has contained cancer may feel uncomfortable for some patients. They prefer mastectomy, so the entire breast will be removed.

The issue of prophylactic or preventive mastectomy, or removal of the breast to prevent future breast cancer, is controversial. Women with a strong family history of breast cancer and/or who test positive for a known cancer-causing gene may choose to have both breasts removed. Patients who have had certain types of breast cancers that are more likely to recur may elect to have the unaffected breast removed. Although there is some evidence that this procedure can decrease the chances of developing breast cancer, it is not a guarantee. It is not possible to be certain that all breast tissue has been removed. There have been cases where breast cancers have occurred after both breasts have been removed.

Studies have shown that women who choose preventive mastectomy generally are satisfied with their choice, but also believe they lacked enough information before deciding, particularly about the surgery, genetic testing, and breast reconstruction. A study released in 2003 concerning women who underwent radical mastectomy of one breast and chose surgical removal of the other breast as a preventive measure found that 83% were highly satisfied with their decision.

Precautions

The decision to have mastectomy or lumpectomy should be carefully considered. It is important that the woman be fully informed of all the potential risks and benefits of each surgical treatment before making a choice.

Description

There are several types of mastectomies. The radical mastectomy, also called the Halsted mastectomy, is rarely performed today. It was developed in the late 1800s, when it was thought that more extensive surgery was most likely to cure cancer. A radical mastectomy involves removal of the breast, all surrounding lymph nodes up to the collarbone, and the underlying chest muscle. Women were often left disfigured and disabled, with a large defect in the chest wall requiring skin grafting, and significantly decreased arm sensation and motion. Unfortunately, and inaccurately, it is still the operation many women picture when the word mastectomy is mentioned.

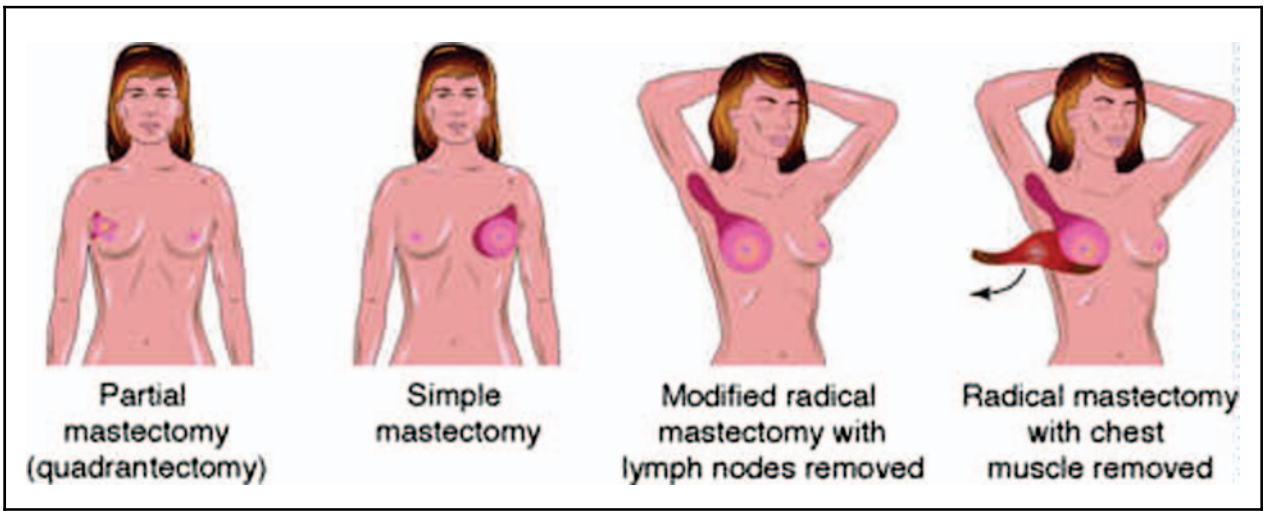
Surgery that removes breast tissue, nipple, an ellipse of skin, and some axillary or underarm lymph nodes, but leaves the chest muscle intact, is usually called a modified radical mastectomy. This is the most common type of mastectomy performed today. The surgery leaves a woman with a more normal chest shape than the older radical mastectomy procedure, and a scar that is not visible in most clothing. It also allows for immediate or delayed breast reconstruction.

In a simple mastectomy, only the breast tissue, nipple, and a small piece of overlying skin are removed. If a few of the axillary lymph nodes closest to the breast are also taken out, the surgery may be called an extended simple mastectomy.

There are other variations on the term mastectomy. A skin-sparing mastectomy uses special techniques that preserve the patient's breast skin for use in reconstruction, although the nipple is still removed. Total mastectomy is a confusing expression, as it may be used to refer to a modified radical mastectomy or a simple mastectomy. In 2003, surgeons reported on a new technique that spared the nipple in many women with early stage breast cancer.

Many women choose to have breast reconstruction performed in conjunction with the mastectomy. The reconstruction can be done using a woman's own abdominal tissue, or using saline-filled artificial expanders, which leave the breast relatively flat but partially reconstructed. Additionally, there are psychological benefits to coming out of the surgery with the first step to a reconstructed breast. Immediate reconstruction will add time and cost to the mastectomy procedure, but the patient can avoid the physical impact of a later surgery.

A mastectomy is typically performed in a hospital setting, but specialized outpatient facilities sometimes are used. The surgery is done under general anesthesia. The type and location of the incision may vary according to plans for reconstruction or other factors, such as old



There are four types of mastectomies: partial mastectomy, or lumpectomy, in which the tumor and surrounding tissue is removed; simple mastectomy, where the entire breast and some axillary lymph nodes are removed; modified radical mastectomy, in which the entire breast and axillary lymph nodes are removed; and the radical mastectomy, where the entire breast, axillary lymph nodes, and chest muscles are removed. *(Illustration by Electronic Illustrators Group.)*

scars. As much breast tissue as possible is removed. Approximately 10 to 20 axillary lymph nodes are usually removed. All tissue is sent to the pathology laboratory for analysis. If no immediate reconstruction is planned, surgical drains are left in place to prevent fluid accumulation. The skin is sutured and bandages are applied.

The surgery may take from two to five hours. Patients usually stay at least one night in the hospital, although outpatient mastectomy is increasingly performed for about 10% of all patients. Insurance usually covers the cost of mastectomy. If immediate reconstruction is performed, the length of stay, recovery period, insurance reimbursement, and fees will vary. In 1998, the Women's Health and Cancer Rights Act required insurance plans to cover the cost of breast reconstruction in conjunction with a mastectomy procedure.

Preparation

Routine preoperative preparations, such as not eating or drinking the night before surgery, typically are ordered for a mastectomy. On rare occasions, the patient also may be asked to donate blood in case a blood transfusion is required during surgery. The patient should advise the surgeon of any medications she is taking. Information regarding expected outcomes and potential complications also should be part of preparation for a mastectomy, as for any surgical procedure. It is especially important that women know about sensations they might experience after surgery, so they are not misinterpreted as a sign of poor wound healing or recurrent cancer.

Aftercare

In the past, women often stayed in the hospital at least several days. Now many patients go home the same day or within a day or two after their mastectomies. Visits from home care nurses can sometimes be arranged, but patients need to learn how to care for themselves before discharge from the hospital. Patients may need to learn to change bandages and/or care for the incision. The surgical drains must be attended to properly; this includes emptying the drain, measuring fluid output, moving clots through the drain, and identifying problems that need attention from the doctor or nurse. If the drain becomes blocked, fluid or blood may collect at the surgical site. Left untreated, this accumulation may cause infection and/or delayed wound healing.

After a mastectomy, activities such as driving may be restricted according to individual needs. Pain is usually well controlled with prescribed medication. Severe pain may be a sign of complications, and should be reported to the physician. A return visit to the surgeon is usually scheduled seven to 10 days after the procedure.

Exercises to maintain shoulder and arm mobility may be prescribed as early as 24 hours after surgery. These are very important in restoring strength and promoting good circulation. However, intense exercise should be avoided for a time after surgery in order to prevent injury. The specific exercises suggested by the physician will change as healing progresses. Physical therapy is an integral part of care after a mastectomy, aiding in the overall recovery process.

KEY TERMS

Axillary—Located in or near the armpit.

Lymphedema—Swelling caused by an accumulation of fluid from faulty lymph drainage.

Mastectomy, modified radical— Total mastectomy with axillary lymph node dissection, but with preservation of the pectoral muscles.

Mastectomy, radical—Removal of the breast, pectoral muscles, axillary lymph nodes, and associated skin and subcutaneous tissue.

Mastectomy, simple—Removal of only the breast tissue, nipple and a small portion of the overlying skin.

QUESTIONS TO ASK THE DOCTOR

- What are my options for degree of treatment? Is it advisable to consider lumpectomy instead of a mastectomy procedure?
- What are the cosmetic implications of this surgery? What are my options for reconstruction?
- How soon after the procedure will I be able to return to normal activities?
- Is there a support group in the area where I could talk with other women who have undergone this procedure?

Emotional care is another important aspect of recovery from a mastectomy. A mastectomy patient may feel a range of emotions including **depression**, negative self-image, grief, fear and anxiety about possible recurrence of the cancer, anger, or guilt. Patients are advised to seek counseling and/or support groups and to express their emotions to others, whether family, friends, or therapists. Assistance in dealing with the psychological effects of the breast cancer diagnosis, as well as the surgery, can be invaluable for women.

Measures to prevent injury or infection to the affected arm should be taken, especially if axillary lymph nodes were removed. There are a number of specific instructions directed toward avoiding pressure or constriction of the arm. Extra care must be exercised to avoid injury, to treat it properly if it occurs, and to seek medical attention promptly when appropriate.

Additional treatment for breast cancer may be necessary after a mastectomy. Depending on the type of tumor, lymph node status, and other factors, **chemotherapy**, radiation therapy, and/or hormone therapy may be prescribed.

Risks

Risks that are common to any surgical procedure include bleeding, infection, anesthesia reaction, or unexpected scarring. After mastectomy and axillary **lymph node dissection**, a number of complications are possible. A woman may experience decreased feeling in the back of her armpit or other sensations including numbness, tingling, or increased skin sensitivity. Some women report phantom breast symptoms, experiencing **itching**, aching, or other sensations in the breast that has been removed. There may be scarring around where the lymph nodes were removed, resulting in decreased arm mobility and requiring more intense physical therapy.

Approximately 10% to 20% of patients develop lymphedema after axillary lymph node removal. This swelling of the arm, caused by faulty lymph drainage, can range from mild to very severe. It can be treated with elevation, elastic bandages, and specialized physical therapy. Lymphedema is a chronic condition that requires continuing treatment. This complication can arise at any time, even years after surgery. A new technique called **sentinel lymph node mapping** and **biopsy** can eliminate the need for removing many lymph nodes.

Normal results

A mastectomy is performed as the definitive surgical treatment for breast cancer. The goal of the procedure is that the breast cancer is completely removed and does not recur.

Abnormal results

An abnormal result of a mastectomy is the incomplete removal of the breast cancer or a recurrence of the cancer. Other abnormal results include long-lasting (chronic) pain or impairment that does not improve after several months of physical therapy.

Matrix metalloproteinase inhibitors

Definition

Matrix metalloproteinases are a class of enzymes that can break down proteins, such as collagen and gelatin. Since these enzymes require zinc or calcium atoms to function, they are referred to as metalloproteinases. Matrix metalloproteinases function in tumor cell invasion and **metastasis**, wound healing, and angiogenesis (supplying the tumor with blood). They are normally found in the spaces between cells (extracellular) in tissues and are involved in degrading extracellular matrix proteins like collagens and gelatins. The extracellular matrix compartments are the primary barriers to tumor growth and spread. Matrix metalloproteinase inhibitors are selective inhibitors of matrix metalloproteinases. These agents inhibit tumor metastasis and angiogenesis.

Description

Matrix metalloproteinases have been linked to cancers such as breast, ovarian, colorectal, and lung. Synthetic matrix metalloproteinase inhibitors are being explored for use in **cancer prevention** and treatment because of their demonstrated antimetastatic and antiangiogenic properties. Matrix metalloproteinase inhibitors include compounds such as: Marimastat (BB-2516), COL-3, BAY 12-9566, and KB-R7785. Marimastat (BB-2516) was the first orally bioavailable matrix metalloproteinase inhibitor to enter **clinical trials** in the field of oncology. Developing nontoxic, orally active, MMP inhibitors is important because these compounds will likely need chronic administration in combination with other therapies.

Crystal Heather Kaczkowski, MSc.

Mechlorethamine

Definition

Mechlorethamine is a **chemotherapy** medicine used to treat cancer by destroying cancerous cells. Mechlorethamine is marketed as the brand name Mustargen. It is also commonly known as nitrogen mustard.

Purpose

Mechlorethamine is approved by the Food and Drug Administration (FDA) to treat **Hodgkin's disease** and **non-Hodgkins' lymphomas**. It is also approved for certain types of leukemia, malignant lymphomas, and lung cancer. Mechlorethamine has been used to relieve symptoms caused by a build up of cancerous fluid in the lungs, abdomen, and around the heart.

Description

Mechlorethamine is one of the first chemotherapy drugs discovered to have an effect on cancer cells. **Clinical trials** with this agent began in the 1940s. Mechlorethamine is a member of the group of chemotherapy drugs known as alkylating agents. Alkylating agents interfere with the genetic material (DNA) inside the cancer cells, more specifically through cross-linking DNA strands, and prevent them from further dividing and growing more cancer cells. Mechlorethamine is commonly combined with other chemotherapy agents to treat cancer.

Recommended dosage

A mechlorethamine dose can be determined using a mathematical calculation that measures a person's body surface area (BSA). This number is dependent upon a patient's height and weight. The larger the person, the

greater the body surface area. BSA is measured in the units known as square meter (m^2). The body surface area is calculated and then multiplied by the drug dosage in milligrams per square meter (mg/m^2). This calculates the actual dose a patient is to receive.

Mechlorethamine is a yellowish liquid that is injected directly into a vein over a period of one to five minutes. It can also be applied onto the skin as an ointment for certain conditions.

Mechlorethamine is combined with other chemotherapeutic drugs **vincristine** (oncovin), **procarbazine**, and prednisone for treatment of Hodgkin's disease. The dose of mechlorethamine used in this regimen is 6 mg per square meter on day 1 and day 8 of a treatment cycle. This regimen is referred to as MOPP, and was one the initial regimens that caused a breakthrough in the treatment of Hodgkin's disease.

Mechlorethamine can also be infused into certain compartments in the body where cancerous fluid has accumulated. The dose for this treatment is based on a patient's weight in kilograms (1 kilogram is 2.2 pounds). Mechlorethamine is given at a dose of 0.2 to 0.4 mg per kilogram of body weight, infused directly into the area where the fluid is building up.

KEY TERMS

Anemia—A red blood cell count that is lower than normal.

Antidote—A drug given to reverse the negative effects of another drug.

Chemotherapy—Specific drugs used to treat cancer.

Deoxynucleic acid (DNA)—Genetic material inside of cells that carries the information to make proteins that are necessary to run the cells and keep the body functioning smoothly.

Food and Drug Administration (FDA)—The government agency that oversees public safety in relation to drugs and medical devices, and gives the approval to pharmaceutical companies for commercial marketing of their products.

Intravenous—To enter the body through a vein.

Metastatic—Cancer that has spread to one or more parts of the body.

Neutropenia—A white blood cell count that is lower than normal.

Precautions

Patients should notify their doctors if they have had any previous allergic reactions to chemotherapy treatment or if they have received **radiation therapy**.

Blood counts should be monitored regularly while on mechlorethamine therapy. During a certain time period after receiving mechlorethamine, there may be an increased risk of getting infections. Caution should be taken to avoid unnecessary exposure to crowds and people with infections.

Patients who may be pregnant or are trying to become pregnant should tell their doctors before receiving mechlorethamine. Chemotherapy can cause men and women to become sterile, or unable to have children.

Patients should check with their doctors before receiving live virus **vaccines** while on chemotherapy.

Patients should increase their intake of fluids while on this medication.

Side effects

One of the most common side effects from receiving mechlorethamine is **nausea and vomiting**. The nausea and vomiting can begin within one hour from receiving the drug. Patients will be given **antiemetics** before and after receiving mechlorethamine to help prevent or decrease this side effect.

A common side effect from taking mechlorethamine is low blood cell counts (**myelosuppression**). When the white blood cell count is lower than normal (**neutropenia**), patients are at an increased risk of developing **fever** and infections. The platelet blood count can also be decreased. Platelets are blood cells in the body that cause clots to form to stop bleeding. When the platelet count is low, patients are at an increased risk for bruising and bleeding. Low red blood cell counts (**anemia**), make people feel tired, dizzy, and lacking in energy.

Less common side effects from mechlorethamine include **diarrhea**, loss of appetite (anorexia), mouth sores, liver problems, metallic taste in the mouth, fever, ringing in the ears or hearing loss, and inflammation at the injection site. Allergic reactions have been reported, some of them severe anaphylactic reactions.

Damage to nerves and nervous system tissues is uncommon with mechlorethamine therapy. However, some reports do exist of nerve damage that has resulted in numbness and tingling in the hands and feet.

Mechlorethamine can cause skin reactions. When applied on top of the skin, the area can become red, swollen, brown colored, itchy, and have a burning sensation.

Hair loss (**alopecia**), irritation, and change of color of the vein where the drug was injected can occur. If the drug is not given directly into the vein, or is accidentally injected into surrounding areas of tissue, an antidote must be administered to that area as soon as possible. The area will become painful, gray-colored, and the tissue will begin to die. This is considered a severe reaction, and medical personnel must be notified immediately.

Interactions

Radiation therapy along with mechlorethamine administration can cause severe damage to the bone marrow.

Nancy J. Beaulieu, R.Ph., B.C.O.P.

Meclizine

Definition

Meclizine is an antihistamine commonly used to control nausea, vomiting and dizziness. It is known by the over-the-counter name Bonine. In the United States, the prescription brand name is Antivert.

Purpose

Meclizine may be given to help control **nausea and vomiting** that often occurs with cancer treatment, other medical conditions, or motion sickness. It is also used as part of palliative care for patients with terminal cancer.

More recently, meclizine has been reported to be effective in the treatment of panic disorder.

Description

Meclizine acts as a central nervous system depressant. It is believed its therapeutic actions occur due to the drug's drying effects and its ability to depress conduction of nerve messages in the inner ear. Meclizine begins working about one hour after ingestion. It continues being effective for eight to 24 hours.

Recommended dosage

The dosage to control nausea and vomiting associated with cancer treatment is 25 mg to 50 mg, every eight to 12 hours. When used to manage dizziness, patients generally take 25 mg to 100 mg daily in divided doses. Patients should not double up on this medication if a dose is missed.

Precautions

Patients with glaucoma, an enlarged prostate, bladder or bowel obstructions, or asthma or other breathing difficulties should discuss with the doctor the risks and benefits associated with this drug before taking it. Those who have experienced an allergic reaction to meclizine should not take it. The FDA recommends that youngsters under age 12 should not take this drug, except under the direction of a physician. Pregnant women and those trying to become pregnant should not take this medication. Animal reproductive studies have shown some deformities at elevated doses. Women who are breastfeeding should discuss this medication with their doctors prior to taking it.

Side effects

Meclizine may cause drowsiness and **fatigue**. Drowsiness is the most common adverse reaction. Alcohol and other central nervous system depressants, such as pain medication and tranquilizers, may increase this effect. Patients should refrain from drinking alcoholic beverages, and avoid driving or operating machinery or appliances when taking this drug. Less frequently, the drug also may produce the opposite effect. Excitability, nervousness, restlessness, mood enhancement and difficulty sleeping may develop. Rarely, it may cause a patient to see or hear things that are not present (hallucinations). Despite being used to treat nausea and vomiting, it may produce this effect. It may also cause constipation, **diarrhea**, an upset stomach or a poor appetite (anorexia). Other side effects include frequent or difficult urination, incomplete emptying of the bladder, low blood pressure, a rapid heart rate or palpitations. It may cause vision changes, a dry nose and throat, ringing in the ears, and a rash or hives. Some of the side effects may be more pronounced in older adults.

Side effects may decrease as the body adjusts to the medication. Ice chips or sugarless hard candy or gum may help relieve the dry mouth. If the feeling of a dry mouth persists for more than two weeks, the doctor should be notified.

Interactions

Central nervous system depressants, including alcohol, may increase drowsiness associated with meclizine. Pain medications, other antihistamines, seizure

KEY TERMS

Antihistamine—Agent that blocks or counteracts the action of histamine, which is released during an allergic reaction.

Palliative—Referring to treatments that are intended to relieve pain and other symptoms of disease but not to cure.

medications, sleeping pills and muscle relaxants can depress the central nervous system. Taking this drug with some medications used to treat **depression** may increase the risk of side effects. Patients should inform the doctor of all medications being taken. Patients should not start or stop any drugs without the approval of the doctor. The herbal supplement henbane may increase some of meclizine's side effects, including dry mouth and difficulty urinating.

Mediastinal tumors

Definition

A mediastinal tumor is a growth in the central chest cavity (mediastinum), which separates the lungs and contains the heart, aorta, esophagus, thymus, and trachea. Mediastinal tumors are also known as neoplasms of the mediastinum.

Description

Growths that originate in the mediastinum are called primary mediastinal tumors. Most of them are composed of reproductive (germ) cells or develop in thymic, neurogenic (nerve), lymphatic, or mesenchymal (soft) tissue.

Secondary (metastatic) mediastinal tumors originate in the lung, stomach, esophagus, and trachea, and spread through the lymphatic system to the chest cavity.

Although still relatively rare, malignant mediastinal tumors are becoming more common. Usually diagnosed in patients between 30 and 50 years old, they can develop at any age and arise from any tissue that exists in or passes through the chest cavity.

The mediastinum is traditionally divided into superior, anterior, middle, and posterior compartments, and is also described as having anterosuperior, middle, and posterior divisions. Boundaries of these divisions are not fixed, and they frequently overlap.

The anterosuperior compartment contains a vein and the thymus gland, superior vena cava, aortic arch, and thyroid gland. More than half (54%) of mediastinal tumors in adults and 43% of those in children occur in the anterosuperior compartment.

The middle mediastinum contains the pericardium, heart, nerves of the diaphragm (phrenic nerves), trachea, main bronchial stem, and lung hila. Twenty percent of adult mediastinal tumors and 18% of those in children occur in this division.

The posterior mediastinum contains the sympathetic chain, vagus nerve (which controls the heart, larynx, and gastrointestinal tract), thoracic duct (which drains lymph from the abdomen, legs, and left side of the head and chest), descending thoracic aorta, and the esophagus. Slightly more than one fourth (26%) of adult mediastinal tumors and 40% of those in children occur in the posterior mediastinum.

Each of these compartments also contains lymph nodes and fatty tissue.

Types of cancers

Anterior mediastinal tumors

The most common anterior mediastinal tumors are thymomas, teratomas, lymphomas, and thyroid tissue that has become enlarged or displaced (ectopic).

THYMOMAS The cause of most adult mediastinal tumors and 15% of those in children, thymomas almost always form at the spot where the heart and great vessels meet. These tumors usually develop between the ages of 40 and 60.

About half of the people who have thymomas do not have any symptoms. Between 35 and 50% experience symptoms of **myasthenia gravis**, such as

- weakness of the eye muscles
- drooping of one or both eyelids (ptosis)
- fatigue

Early treatment of these slow-growing tumors is very effective. Most are benign, but thymomas can metastasize and should always be considered cancerous.

TERATOMAS Most common in young adults, teratomas are made up of embryonic (germ) cells that did not develop normally and do not belong in the part of the body where the tumor is located. Found along the center of the body between the skull and kidneys, teratomas account for:

- 10%–15% of primary mediastinal tumors
- 70% of **germ cell tumors** in children
- 60% of germ cell tumors in adults

Teratomas may be solid or contain cysts. Malignant teratomas usually develop between the ages of 30 and 40, and almost all (90%) of them occur in men.

At least 90% of patients with these tumors experience:

- chest pain
- cough
- fever
- shortness of breath

These symptoms may not appear until the tumor has grown very large.

LYMPHOMAS These tumors account for 10–20% of anterior mediastinal tumors. Although lymphomas are the second most common mediastinal tumor in children, they are usually diagnosed between the ages of 30 and 40. Nonsclerosing **Hodgkin's disease** causes most adult mediastinal lymphomas.

Some patients with lymphomas do not have symptoms. Others cough or experience chest pain.

THYROID TUMORS Most mediastinal thyroid tumors grow out of goiters and occur in women between the ages of 50 and 60. About 75% of these tumors extend to the windpipe (trachea). The rest extend behind it.

Mediastinal thyroid tumors are encapsulated and do not metastasize.

Middle mediastinal tumors

Tumors of the middle mediastinum include lymphomas, mesenchymal tumors, and carcinomas.

MESENCHYMAL TUMORS Also called soft tissue tumors, mesenchymal tumors originate in connective tissue within the chest cavity. These tumors account for about 6% of primary mediastinal tumors. More than half (55%) of them are malignant.

The most common mesenchymal tumors are lipomas, liposarcomas, fibromas, and fibrosarcomas.

Posterior mediastinal tumors

Tumors of the posterior mediastinum include: neurogenic tumors, mesenchymal tumors, and endocrine tumors.

NEUROGENIC TUMORS Representing 19–39% of mediastinal tumors, neurogenic tumors can develop at any age. They are most common in young adults.

Adult neurogenic tumors are usually benign. In children, they tend to be malignant and tend to metastasize before symptoms appear.

MALIGNANT SCHWANNOMAS Also known as malignant sheath tumors, malignant sarcomas, and neurosarcomas, these tumors develop from the tube (sheath) enclosing the peripheral nerves that transmit impulses from the central nervous system (CNS) to muscles and organs.

Usually large and painful, these rare, aggressive tumors may invade the lungs, bones, and aorta.

NEUROBLASTOMAS The most common malignant tumors of early childhood, neuroblastomas generally occur before the age of two. These tumors usually develop in the adrenal glands, neck, abdomen, or pelvis.

Neuroblastomas often spread to other organs. Most patients have symptoms that relate to the part of the body the tumor has invaded. Likelihood of survival is greatest in patients who are less than a year old and whose tumor has not spread.

Symptoms

About 40% of people who have mediastinal tumors do not have any symptoms. When symptoms exist, they usually result from pressure on an organ that the tumor has invaded, and indicate that the tumor is malignant.

The symptoms most commonly associated with mediastinal tumors are:

- chest pain
- cough
- shortness of breath

A person who has a mediastinal tumor may be hoarse, cough up blood (**hemoptysis**), or have:

- fatigue
- difficulty swallowing (dysphagia)
- night sweats
- systemic lupus erythematosus
- inflamed muscles (polymyositis)
- ulcerative colitis
- rheumatoid arthritis
- thyroid problems (thyroiditis, thyrotoxicosis,)
- fever
- glandular disorders (panhypopituitarism, adenopathy)
- high blood pressure
- low blood sugar (hypoglycemia)
- breast development in males (gynecomastia)
- wheezing
- vocal cord paralysis
- heart problems (**superior vena cava syndrome**, pericardial tamponade, arrhythmias)
- neurologic abnormalities
- weight lossand other immune, autoimmune, and endocrine system disorders.

Blood disorders associated with these tumors include abnormally high levels of calcium (**hypercalcemia**), abnormally low numbers of:

- circulating blood cells (cytopenia)
- normal red blood cells (pernicious anemia)
- antibodies (hypogammaglobulinemia)and an inability to produce red blood cells (red-cell aplasia).

Diagnosis

Imaging studies

Routine x rays often detect mediastinal tumors. Doctors use **computed tomography** (CT) scans of the chest to determine tumor size and location, extent of disease, the tumor's relationship to nearby organs and tissues, and whether the tumor contains cysts or areas of calcification.

Magnetic resonance imaging (MRI) is more effective at clarifying the relationship between a tumor and nearby blood vessels, but is far more costly and time-consuming than CT scanning.

Other tests

Injecting radioactive substances into the patient's blood (radioimmunoassay) enables doctors to measure levels of hormones and other substances a tumor secretes and identify specific tumor types, evaluate the effectiveness of therapy, and monitor possible tumor recurrence.

Invasive procedures

Imaging studies play the most important role in initial diagnosis of mediastinal tumors, but before doctors can determine the most effective treatment for any tumor, they must know what kind of cells it contains.

Although invasive diagnostic procedures have been largely replaced by less invasive techniques (such as CT-guided percutaneous needle **biopsy**), some patients still require surgery.

MEDIASTINOSCOPY Performed under general anesthesia, this relatively simple procedure enables doctors to accurately diagnose 80–90% of mediastinal tumors, and 95–100% of anterior mediastinal tumors.

Mediastinoscopy is especially useful in providing the large tissue specimens needed to diagnose lymphomas.

MEDIASTINOTOMY Doctors perform mediastinotomy by using a lighted tube to:

- examine the center of the chest and nearby lymph nodes
- remove tissue for biopsy
- determine whether cancer has spread from the spot where it originated. Similar to mediastinoscopy, this procedure begins with a small incision next to the breastbone, rather than in the patient's neck.

Mediastinotomy also enables doctors to examine the lymph nodes closest to the heart and lungs. Cancer that originates in the left upper lobe of the lung often spreads to these nodes.

THORACOTOMY Although some surgeons still perform this procedure to diagnose mediastinal tumors, thoracoscopy may be used instead in certain situations. In a **thoracotomy**, the physician gains access to the chest cavity by cutting through the chest wall. Thoracotomy allows for study, examination, treatment, or removal of any organs in the chest cavity. Tumors and metastatic growths can be removed, and a biopsy can be taken, through the incision. Thoracotomy also gives access to the heart, esophagus, diaphragm, and the portion of the aorta that passes through the chest cavity.

THORACOSCOPY This 100% accurate, minimally invasive procedure is performed under general anesthesia. Enabling the surgeon to view the entire mediastinum, **thoracoscopy** may be used when a mediastinal tumor touches the mediastinal pleura. However, this procedure has limited applications.

Thoracoscopy cannot be performed on a patient who has thick scar tissue.

Treatment

Doctors use surgery, radiation, and single-agent or combination **chemotherapy** to treat mediastinal tumors.

Thymomas

A patient whose **thymoma** is surgically removed (resected) has the best chance of survival. To lessen the likelihood of new tumors developing (reseeding), surgeons do not recommend biopsy, and try to remove the tumor without puncturing the capsule that encloses it.

RADIATION Thymomas respond well to radiation, which is used:

- to treat all stages of disease
- before or after surgical resection
- to treat recurrent disease.

The course of treatment lasts three to six weeks. The most common complications of **radiation therapy** are formation of scar tissue in the lungs (pulmonary fibrosis), inflammation of the pericardium (pericarditis), and inflammation of the spinal cord (myelitis).

CHEMOTHERAPY The use of chemotherapy to treat invasive thymomas is becoming more common. One or more drugs may be administered before or after surgery. Synthetic hormones (**corticosteroids**) can reverse the progression of tumors that do not respond to chemotherapy.

Teratomas

Teratomas are removed surgically. Chemotherapy and radiation are not used to treat these tumors. The prospect for long-term cure is excellent, and these tumors rarely recur.

Lymphomas

These tumors do not require surgery, except to make the diagnosis. Doctors treat them with chemotherapy and radiation.

Thyroid tumors

Doctors generally treat thyroid tumors with surgical resection, chemotherapy, and/or radiation.

Mediastinal tumors

Cancer type	Occurs in
Thymomas	Anterior mediastinum, almost always form where heart and major vessels meet
Teratomas	Anterior mediastinum, along the center of the body between the skull and kidneys
Lymphomas	Anterior and middle mediastinum
Thyroid tumors	Thyroid (anterior mediastinum)
Mesenchymal tumors (soft tissue tumors)	Middle mediastinum
Carcinomas	Middle mediastinum
Neurogenic tumors (developing in nerve cells)	Posterior mediastinum
Malignant schwannomas	Posterior mediastinum
Neuroblastomas	Posterior mediastinum

Fibrosarcomas

Fibrosarcomas cannot usually be resected and do not respond well to chemotherapy.

Malignant schwannomas

Multiagent chemotherapy is used to treat these aggressive tumors, which tend to recur following surgery. The 5-year survival rate is 75%.

Neuroblastomas

Because these tumors sometimes regress spontaneously, doctors may postpone treatment if the patient has no symptoms or the tumor is not growing.

In other cases, doctors remove these tumors even before symptoms appear. Risks associated with removing these tumors from the spinal canal include:

- injury to the spinal cord or anterior spinal artery
- uncontrolled bleeding in the spinal canal
- decreased blood supply (ischemia) to tissues and organs.

See also CT-guided biopsy; Fibrosarcoma; Neuroblastoma; Thyroid cancer.

Mediastinoscopy

Definition

Mediastinoscopy is a surgical procedure that allows physicians to view areas of the mediastinum, the cavity behind the breastbone that lies between the lungs. The organs in the mediastinum include the heart and its vessels, the lymph nodes, trachea, esophagus, and thymus.

Mediastinoscopy is most commonly used to detect or stage cancer. It is also ordered to detect infection, and to confirm diagnosis of certain conditions and diseases of the respiratory organs. The procedure involves insertion of an endotracheal (within the trachea) tube, followed by a small incision in the chest. A mediastinoscope is inserted through the incision. The purpose of this equipment is to allow the physician to directly see the organs inside the mediastinum, and to collect tissue samples for laboratory study.

Purpose

Mediastinoscopy is often the diagnostic method of choice for detecting **lymphoma**, including **Hodgkin's disease**. The diagnosis of sarcoidosis (a chronic lung disease) and the staging of lung cancer can also be accomplished through mediastinoscopy. Lung cancer staging involves the placement of the cancer's progression into stages, or levels. These stages help a physician study cancer and provide consistent definition levels of cancer and corresponding treatments. The lymph nodes in the mediastinum are likely to show if lung cancer has spread beyond the lungs. Mediastinoscopy allows a physician to observe and extract a sample from the nodes for further study. Involvement of these lymph nodes indicates diagnosis and stages of lung cancer.

Mediastinoscopy may also be ordered to verify a diagnosis that was not clearly confirmed by other methods, such as certain radiographic and laboratory studies. Mediastinoscopy may also aid in certain surgical biopsies of nodes or cancerous tissue in the mediastinum. In fact, the surgeon may immediately perform a surgical procedure if a malignant tumor is confirmed while the patient is undergoing mediastinoscopy, thus combining the diagnostic exam and surgical procedure into one operation when possible.

Although still performed in 2001, advancements in **computed tomography** (CT) and **magnetic resonance imaging** (MRI) techniques, as well as the new developments in **ultrasonography**, have led to a decline in the use of mediastinoscopy. In addition, better results of fine-needle aspiration (drawing out fluid by suction) and core-needle **biopsy** (using a needle to obtain a small tissue sample) investigations, along with new techniques in **thoracoscopy** (examination of the thoracic cavity with a lighted instrument called a thoracoscope) offer additional options in examining mediastinal masses. Mediastinoscopy may be required, however, when these other methods cannot be used or when the results they provide are inconclusive.

Precautions

Because mediastinoscopy is a surgical procedure, it should only be performed when the benefits of the exam's findings outweigh the risks of surgery and anesthesia. Patients who previously had mediastinoscopy should not receive it again if there is scarring present from the first exam.

Several other medical conditions, such as impaired cerebral circulation, obstruction or distortion of the upper airway, or thoracic aortic aneurysm (abnormal dilation of the thoracic aorta) may also preclude mediastinoscopy. Anatomic structures that can be compressed by the mediastinoscope may complicate these pre-existing medical conditions.

Description

Mediastinoscopy is usually performed in a hospital under general anesthesia. An endotracheal tube is inserted first, after local anesthesia is applied to the throat. Once the patient is under general anesthesia, a small incision is made usually just below the neck or at the notch at the top of the breastbone. The surgeon may clear a path and feel the patient's lymph nodes first to evaluate any abnormalities within the nodes. Next, the physician will insert the mediastinoscope through the incision. The scope is a narrow, hollow tube with an attached light that allows the surgeon to see inside the area. The surgeon can insert tools through the hollow tube to help perform biopsies. A sample of tissue from the lymph nodes or a mass can be extracted and sent for study under a microscope or on to a laboratory for further testing.

In some cases, analysis of the tissue sample which shows malignancy will suggest the need for immediate surgery while the patient is already prepared and under anesthesia. In other cases, the surgeon will complete the visual study and tissue extraction and stitch the small incision closed. The patient will remain in the surgery recovery area until it is determined that the effects of anesthesia have lessened and it is safe for the patient to leave the area. The entire procedure should take about an hour, not counting preparation and recovery time. Studies have shown that mediastinoscopy is a safe, thorough,

KEY TERMS

Endotracheal—Placed within the trachea, also known as the windpipe.

Hodgkin's disease—A malignancy of lymphoid tissue found in the lymph nodes, spleen, liver, and bone marrow.

Lymph nodes—Small round structures located throughout the body; contain cells that fight infections.

Pleural space—Space between the layers of the pleura (membrane lining the lungs and thorax).

Sarcoidosis—A chronic disease characterized by nodules in the lungs, skin, lymph nodes and bones; however, any tissue or organ in the body may be affected.

Thymus—An unpaired organ in the mediastinal cavity that is important in the body's immune response.

QUESTIONS TO ASK THE DOCTOR

- Why do I need this test?
- Is the test dangerous?
- How do I prepare for the test?
- How long will the test take?
- Will I get general or local anesthesia?
- How soon will I get my test results?

and cost-effective diagnostic tool with less risk than some other procedures.

Preparation

Patients are asked to sign a consent form after having reviewed the risks of mediastinoscopy and known risks or reactions to anesthesia. The physician will normally instruct the patient to fast from midnight before the test until after the procedure is completed. A physician may also prescribe a sedative the night before the exam and before the procedure. Often a local anesthetic will be applied to the throat to prevent discomfort during placement of the endotracheal tube.

Aftercare

Following mediastinoscopy, patients will be carefully monitored to watch for changes in vital signs or indications of complications of the procedure or the anesthesia. A patient may have a sore throat from the endotracheal tube, temporary chest pain, and soreness or tenderness at the site of incision.

Risks

Complications from the actual mediastinoscopy procedure are relatively rare—the overall complication rate in various studies has been 1.3–3.0%. However, the following complications, in decreasing order of frequency, have been reported:

- hemorrhage
- pneumothorax (air in the pleural space)
- recurrent laryngeal nerve injury, causing hoarseness
- infection
- tumor implantation in the wound
- phrenic nerve injury (injury to a thoracic nerve)
- esophageal injury
- chylothorax (chyle—a milky lymphatic fluid—in the pleural space)
- air embolism (air bubble)
- transient hemiparesis (paralysis on one side of the body)

The usual risks associated with general anesthesia also apply to this procedure.

Normal results

In the majority of procedures performed to diagnose cancer, a normal result involves evidence of small, smooth, normal-appearing lymph nodes and no abnormal tissue, growths, or signs of infection. In the case of lung cancer staging, results are related to the severity and progression of the cancer.

Abnormal results

Abnormal findings may indicate lung cancer, tuberculosis, the spread of disease from one body part to another, sarcoidosis (a disease that causes nodules, usually affecting the lungs), lymphoma (abnormalities in the lymph tissues), and Hodgkin's disease.

Medroxyprogesterone acetate

Definition

Medroxyprogesterone acetate (MPA) is used during cancer therapy to stop new cell growth in some cancers. It is also used outside of cancer treatment as a contraceptive. MPA is known by many different brand names in the United States including Amen, Depo-Provera, Provera, Prodasone, and Progeston.

Purpose

MPA is used to treat some advanced, hormone-responsive cancers of the breast, kidney, and lining of the uterus.

Description

MPA is a synthetic derivative of the female hormone progesterone. In healthy women, progesterone plays a major role in preparing the uterus for pregnancy. MPA has been approved by the Food and Drug Administration (FDA), and its use in cancer treatment is usually covered by insurance. Outside the area of cancer treatment, it is used to prevent pregnancy.

Exactly why MPA stops tumor growth is unclear. Many cancerous tumors are sensitive to hormones. It appears that MPA, in some way, changes the hormonal climate of the tumor so that cells stop responding to other hormones and proteins that would normally stimulate their growth. This drug cannot tell the difference between normal cells and cancer cells, so some normal cells are also killed during treatment. But since cancer cells generally grow more rapidly than normal cells, more cancer cells are killed. MPA is considered very effective and relatively non-toxic.

MPA is usually given to women whose **breast cancer** has returned or whose cancer does not respond to **tamoxifen** or **toremifene**. Both drugs are antiestrogens, or agents that antagonize the actions of estrogen. For these women, it is an alternative to the new aromatase inhibiting drugs (anastrozole, letrozole, or aromasin). Aromatase is one of the enzymes involved in steroid biosynthesis. In **endometrial cancer** (cancer of the uterus), MPA is sometimes used when cancer has spread (metastasized) beyond the uterus or is inoperable.

Recommended dosage

MPA comes as tablets or as a liquid that is given as an intramuscular injection. For breast cancer, it is usually given as a tablet once a day at the same time each day. Occasionally, MPA is given in divided doses that are spaced evenly throughout the day. For kidney and uterine cancer, MPA is usually given as a shot once a week at first, then later once a month.

By 2001, **clinical trials** were underway testing the use of MPA in women with both breast and endometrial cancer. The selection of clinical trials underway changes frequently. Current information on clinical trials and where they are being held is available by entering the search term "medroxyprogesterone acetate" at the following web sites:

- National Cancer Institute <http://cancertrials.nci.nih.gov> or (800) 4-CANCER
- National Institutes of Health Clinical Trials <http://clinicaltrials.gov>
- Center Watch: A Clinical Trials Listing <http://www.centerwatch.com>

Precautions

People taking MPA daily should take it at the same time each day. The time of day is unimportant, but the regular spacing of the dose is important.

Women taking MPA should not get pregnant. It is believed that MPA causes birth defects in babies born to mothers who are taking this drug during the first four months of pregnancy.

Side effects

The number and severity of side effects vary widely among people. Not only is it dependent on each person's

KEY TERMS

Endometrial cancer—Cancer of the uterus.

Food and Drug Administration (FDA)—The government agency that oversees public safety in relation to drugs and medical devices, and gives the approval to pharmaceutical companies for commercial marketing of their products.

own unique body chemistry, side effects vary with the type of cancer, the health of the patient, and the other drugs being given. There is no way to predict who will experience side effects of MPA.

Among the more common side effects are:

- increased appetite and weight gain
- nausea
- swelling and fluid retention in the hands, legs, and breast
- breakthrough vaginal bleeding
- muscle cramps
- fatigue
- emotional or mood changes
- headaches

A less common, but serious, side effect is the development of blood clots that can lead to heart attack or stroke. People who have a history of clotting problems are not good candidates for using MPA.

Interactions

Aminoglutethimide (Cytadren: an inhibitor of steroid biosynthesis), when given with MPA, decreases the effectiveness of MPA.

Medulloblastoma

Definition

Medulloblastoma is a solid, cancerous tumor originating in the cerebellum of the brain. It is also known as a primitive neuroendocrine tumor.

Description

Medulloblastoma is the most common cancerous brain tumor of childhood. It accounts for 20% to 25% of all childhood tumors. Medulloblastomas can occur soon after birth and into puberty, but most tumors occur either before age ten or sometime in the late teens or early twenties. If these tumors are left untreated, they can spread to other areas of the brain and to the spine.

Medulloblastomas occur in the area of the brain known as the cerebellum. The cerebellum, located in the back of the brain above the neck, is the area of the brain responsible for controlling and integrating movement. A person could move his or her muscles without the aid of the cerebellum, but those movements would be clumsy and disorganized. Medulloblastoma tumors in the cerebellum can cause loss of functioning of the cerebellum, leading to this uncoordinated movement, called cerebellar ataxia.

If medulloblastomas are not detected early, they may spread cancer throughout the brain or spinal cord. If the cancer spreads to the spinal cord, a child may begin experiencing severe back pain, difficulty walking, and the inability to control bladder and bowel functions.

Demographics

As stated earlier, medulloblastoma is a childhood cancer, occurring mainly in the first ten years of life. About half of all medulloblastomas occur in children aged five or younger. Boys tend to develop the tumors more than girls at a rate of approximately two to one. There are no current studies comparing the incidence of medulloblastoma between different racial and ethnic groups.

Causes and symptoms

Besides being male, there are no other known risk factors for medulloblastoma. This type of tumor can occur in association with two rare types of genetically linked family cancer syndromes. Gorlin's syndrome and Turcot's syndrome. Gorlin's syndrome is caused by a defect in a gene known as PTC located on chromosome 9. This defect can cause medulloblastoma as well as cancers of the skin and ovary. Turcot's syndrome is caused by a defective gene known as APC, and can present with cancer of the intestinal tract as well as medulloblastoma. It should again be stated that both of these syndromes are quite rare and only account for a fraction of medulloblastoma cases seen and reported.

Medulloblastoma can present in many ways. In infants, symptoms of the tumor can include an unusual increase in head size, vomiting, irritability, and lethargy. Since all infants generally have these symptoms at one

time or another, it can be difficult for a parent or even a health care worker to recognize the initial presentation of medulloblastoma in babies and toddlers.

In older children and teenagers, medulloblastoma can present the same as in infants or much differently. Non-specific symptoms such as **nausea and vomiting**, headache, and vague visual disturbances can be the first sign of a tumor in the cerebellum. Other, more striking signs can be double vision, sudden difficulty writing, and problems walking and moving that worsen over time.

Diagnosis

The diagnosis of medulloblastoma is made with both clinical observation and **imaging studies**. If a parent has noticed some of the signs and symptoms listed above, then a visit to a pediatrician is certainly warranted. During the office visit, various specialized neurological tests will be done to see if there is any sign of a problem in the cerebellum or surrounding brain structures.

If there are indications of a tumor, then imaging studies can be done to see if a tumor can be detected. The two types of imaging studies done to detect medulloblastoma are **magnetic resonance imaging** (MRI) and computed tomography (CT) scan. The MRI uses a high-strength magnetic field to visualize the brain, and is very useful for detecting medulloblastomas. The CT scan uses **x-ray** images reconstructed by computer. Like the MRI, a CT scan is also useful for detecting brain tumors as well as tumors that may have spread to the spine.

Treatment team

The treatment of medulloblastoma is optimally carried out in a medical center that has experience in treating this often difficult-to-treat cancer. Treatment and treatment planning is usually carried out by a multidisciplinary team of cancer specialists, including a pediatric oncologist (a doctor specializing in the treatment of **childhood cancers**), a pediatric neurosurgeon (a doctor specializing in childhood brain surgery), as well as a pediatric neurologist and radiation oncologist (a doctor specializing in the use of radiation to treat cancer).

Clinical staging, treatment, and prognosis

The staging of childhood brain tumors has become important to the selection of treatment plans, as well as giving information to make a more accurate prognosis. For medulloblastoma, there are four stages defined, as follows:

- T1: the tumor is less than 3 cm in diameter.
- T2: the tumor is greater than 3 cm in diameter and has invaded one other brain structure in addition to the cerebellum.
- T3: the tumor has invaded two other brain structures besides the cerebellum.
- T4: the tumor has spread down into the midbrain or upper spinal cord.

The treatment options for medulloblastoma have changed significantly over the past few decades. The first treatment option for medulloblastoma was surgery, and this is still the most common treatment. Surgeons try to remove the entire tumor, although this is sometimes not possible. After the surgery is completed, further treatment will depend upon whether or not the child has been placed in an "average risk" or "high risk" group. An average-risk child is defined as three years or older, with the tumor initially confined to the cerebellum with little to no tumor left after surgery. A high-risk child is defined as a child under three years of age, with the tumor initially spread into other areas of the brain besides the cerebellum, and with some of the tumor remaining in the brain after surgery.

Children in the average-risk group will often have radiation therapy applied to the area in their brain where the medulloblastoma tumor was, especially if the surgeon was not able to remove all of the tumor. Using radiation on children younger than three years may result in the child having growth retardation along with learning disabilities.

Because of the possible side effect of radiation, especially in children younger than three years of age, the use of certain medications called **chemotherapy** is being used more frequently for medulloblastoma. Researchers have found that medulloblastoma tumors are highly sensitive to chemotherapy, giving hope that chemotherapy can be used instead of radiation, especially for children at average risk. For children at high risk, the current recommendation is to use both radiation and chemotherapy, since this combination has been shown to improve overall survival rates for high-risk children.

In 1930, the anticipated survival rate for a child with medulloblastoma after surgery was less than 2%. Today, with the use of better surgical techniques, radiation, and chemotherapy, the prognosis for children in the average risk group has increased to a 60% survival rate over a five-year period. Children in the high-risk group do not fare as well, having a 30% to 35% survival rate over a five-year period.

KEY TERMS

Ataxia—The inability to perform voluntary, coordinated muscular movements.

Cerebellum—The portion of the brain lying superior to the spinal cord, involved in coordinating voluntary muscular movements.

Chemotherapy—The application of certain medicinal chemicals to treat specific diseases, including cancer.

Radiation therapy—The use of high-energy ionizing radiation in the treatment of cancerous tumors.

Alternative and complementary therapies

Alternative and complementary therapies are those that fall outside the scope of traditional, first-line therapies such as surgery, chemotherapy and radiation. Complementary therapies are meant to supplement those traditional therapies with the objective of relieving symptoms. Alternative therapies are nontraditional, unproven attempts to cure the disease.

Common complementary therapies used in many types of cancer include aromatherapy, massage, meditation, music therapy, prayer, and certain forms of exercise. These therapies have the objective of reducing anxiety and increasing a patient's feeling of well-being.

Numerous alternative therapies exist in cancer treatment. Plant extracts, **vitamins**, protein therapies, and natural substances such as mistletoe and shark cartilage have all been touted as cancer-fighting remedies. However, some alternative therapies, such as Laetrile, can produce dangerous side effects and have shown no anticancer activity in **clinical trials**. Patients interested in alternative therapies should consult their doctors to ensure that the products are safe, especially for children, and do not interfere with regular cancer treatment.

Coping with cancer treatment

During treatment, a child's health will be followed by the team of physicians involved. Those physicians will be able to monitor the child for any side effects from the treatments, especially if the child is receiving chemotherapy. The most frequent side effects of chemotherapy can include nausea and vomiting, **diarrhea**, **fatigue**, and hair loss (alopecia). With medications, physicians can often treat some of the side effects, especially nausea, vomiting, and diarrhea.

Cancer treatment can be especially frightening for a young child. Family support is critical, and parents should consult their physicians about any organizations in the area that can help their child cope with the effects of medulloblastoma and its treatment.

Clinical trials

There are many clinical trials being done to help better the treatment options for medulloblastoma. Some of the most promising ones are studies in which peripheral stem cell transplantation is used. This is a technique in which certain cells in the body known as stem cells are used to replace other, depleted cells, such as the immune cells and blood cells that are destroyed when chemotherapy is used. It is hoped that with stem cell use, physicians will be able to use higher doses of chemotherapy in order to destroy the medulloblastoma cancer.

Prevention

There are currently no known ways to prevent medulloblastoma. Those who have the very rare genetic disorders which predisposes them to medulloblastoma, Gorlin's and Turcot's syndrome, should be especially aware of any signs or symptoms of medulloblastomas. Children of parents with these genetic disorders should have routine screening done by a pediatrician for any signs of a brain tumor.

Megestrol acetate

Definition

Megestrol acetate is used to treat unexplained **weight loss** during cancer therapy and to stop new cell growth in some cancers. Megestrol acetate is also known by the brand name Megace.

Purpose

Megestrol acetate is used to treat some advanced hormone-responsive cancers of the breast, kidney, and uterus. It is also used in larger doses to help reverse weight loss for which there is no other treatable cause.

Description

Megestrol acetate is a synthetic derivative of the female hormone progesterone. In healthy women, progesterone plays a major role in preparing the uterus for pregnancy. It has been approved by the Food and Drug Administration (FDA), and its use is usually covered by insurance.

Exactly why megestrol acetate stops tumor growth is unclear. Many tumors are sensitive to hormones. It appears that megestrol acetate, in some way, changes the hormonal climate of the tumor so that cells stop responding to other hormones and proteins that would normally stimulate their growth. This drug cannot tell the difference between normal cells and cancer cells, so some normal cells are also killed during treatment. But since cancer cells grow more rapidly than normal cells, more cancer cells are killed.

Megestrol acetate has another independent use in cancer treatment. In high doses, it is used to counteract weight loss that does not occur for any other treatable reason. Megestrol acetate appears to bring about weight gain through increased fat storage.

Recommended dosage

Megestrol acetate comes in both liquid and tablet form. To treat weigh loss, the standard dosage is a single dose given in the morning with breakfast. Many clinical studies are underway to examine the best use of megestrol acetate in severe weight loss. Most of these studies are for people who are losing weight because they suffer with AIDS. However, the selection of **clinical trials** underway changes frequently. Current information on what clinical trials are available and where they are being held can be found by entering the search term "megestrol acetate" at the following websites:

- National Cancer Institute <http://cancertrials.nci.nih.gov> or (800) 4-CANCER
- National Institutes of Health Clinical Trials <http://clinicaltrials.gov>
- Center Watch: A Clinical Trials Listing <http://www.centerwatch.com>

To reduce tumor growth, the dose of megestrol acetate is individualized, and depends on the type of cancer, the patient's body weight and general health, what other drugs are being given, and the way the cancer responds to hormones. A standard dose of Megace to treat **breast cancer** is 160 mg/day divided into four doses. A standard dose for **endometrial cancer** (cancer of the uterus) is 40–320 mg/day in divided doses. Treatment normally continues for about two months.

Precautions

Women taking megestrol acetate should not get pregnant. Megestrol acetate is believed to cause birth defects in babies born to mothers who are taking the drug. A patient assistance program is available through Bristol Meyer Squibb, the manufacturer of this drug at (800) 332-2056.

KEY TERMS

Food and Drug Administration (FDA)—The government agency that oversees public safety in relation to drugs and medical devices, and gives the approval to pharmaceutical companies for commercial marketing of their products in the United States.

Hormone—A chemical released by a gland that travels through the circulatory system and affects only the tissues at a distance from its release point that have receptors for the chemical.

Progesterone—A female hormone that prepares the uterus for pregnancy.

Side effects

Megestrol acetate has several rare but serious side effects. Some people have been reported to develop **Cushing's syndrome**. This is a hormonal imbalance in which people (usually women) develop fatty deposits in the face and neck, lose bone mass (osteoporosis), stop menstruating, develop diabetes, high blood pressure, and other signs of fluid and salt (electrolyte) imbalances.

Other common side effects of megestrol acetate include:

- worsening of diabetic symptoms
- pain in the chest or abdomen
- infection
- sarcoma (tumors of the skin or connective tissue)
- irregular heartbeat
- fluid retention
- breakthrough vaginal bleeding
- blood clots in legs or lungs
- nausea or constipation
- dry mouth or increased salivation
- abnormal white blood cell count
- confusion or abnormal thinking
- emotional and psychological changes
- rash, **itching**, abnormal sweating, or skin disorders
- cough, sore throat, lung disorders
- hair loss (alopecia)
- uncontrolled urination or urinary tract infection
- male impotence

Interactions

No specific interactions with other pharmaceuticals have been reported in people using megestrol acetate. However, many drugs interact with nonprescription (over-the-counter) drugs and herbal remedies as well as prescription drugs. Patients should always tell their health care providers about all remedies they are taking. Patients should also mention if they are on a special diet such as low salt or high protein.

Tish Davidson, A.M.

Melanoma

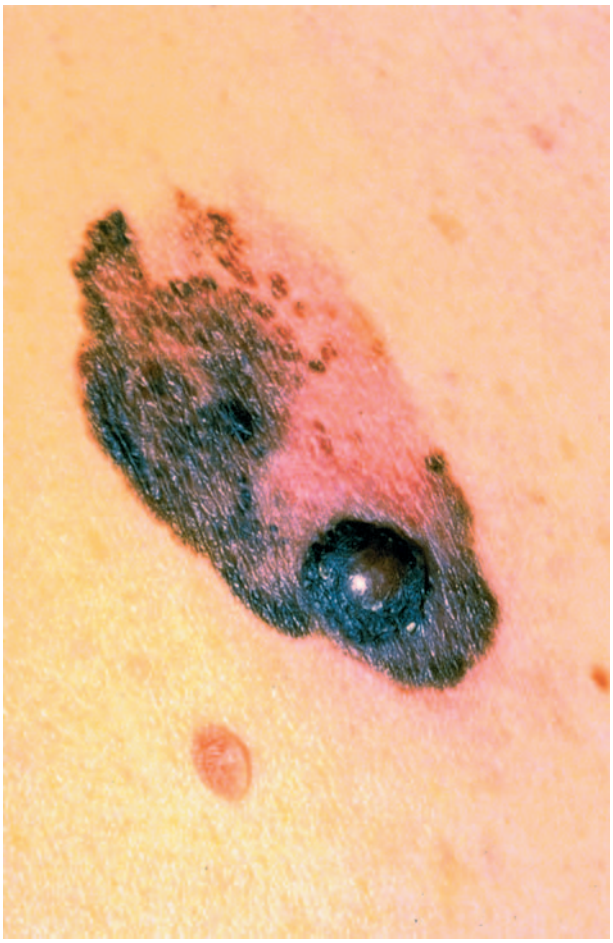
Definition

Malignant melanoma is a type of cancer arising from the melanocyte cells of the skin. The melanocytes are cells in the skin that produce the pigment melanin. Malignant melanoma develops when the melanocytes no longer respond to normal control mechanisms of cellular growth and are capable of invasion locally or spread to other organs in the body (**metastasis**), where again they invade and compromise the function of that organ.

Description

Melanocytes, embryologically derived from the neural crest, are distributed in the epidermis and thus are found throughout the skin. They produce a brown pigment known as melanin and are responsible for racial variation in skin color and also the color of moles. Malignant degeneration of the melanocyte gives rise to the tumor, melanoma, of which there are four subtypes. These are: superficial spreading, nodular, lentigo maligna, and acral lentiginous melanomas, accounting for 70%, 15% to 30%, 4% to 10%, and 2% to 8% of cases, respectively. Malignant melanoma may develop anywhere on the body. In men, it is most common on the trunk. In women, it is most common on the back or legs. The subtype also may influence where the tumor develops; lentigo melanoma is more common on the face while acral lentiginous melanoma is more common on the palms of the hand, soles of the feet, or in the nail beds.

The locally invasive characteristic of this tumor involves vertical penetration through the skin and into the dermis and subcutaneous (under-the-skin) tissues of the malignant melanocytes. With the exception of the nodular variety of melanoma, there is often a phase of



A close-up image of a malignant melanoma on a patient's back. *(Custom Medical Stock Photo. Reproduced by permission.)*

radial or lateral growth associated with these tumors. Since it is the vertical growth that characterizes the malignancy, the nodular variant of melanoma carries the worst prognosis. Fortunately, the superficial spreading type is most common.

The primary tumor begins in the skin, often from the melanocytes of a pre-existing mole. Once it becomes invasive, it may progress beyond the site of origin to the regional lymph nodes or travel to other organ systems in the body and become systemic in nature.

The lymph is the clear, protein-rich fluid that bathes the cells throughout our body. Lymph will work its way back to the bloodstream via small channels known as lymphatics. Along the way, the lymph is filtered through cellular stations known as nodes, thus they are called lymph nodes. Nearly all organs in the body have a primary lymph node group filtering the tissue fluid, or lymph, that comes from that organ. Different areas of the skin have different primary nodal stations. For the leg, they are in the groin. For the arm, the armpit or axilla. For the face, it is the neck. Depending where on the torso the tumor develops, it may drain into one groin or armpit, or both.

Cancer, as it invades in its place of origin, may also work its way into blood vessels. If this occurs, it provides yet another route for the cancer to spread to other organs of the body. When the cancer spreads elsewhere in the body, it has become systemic in extent and the tumor growing elsewhere is known as a metastasis.

Untreated, malignant melanoma follows a classic progression. It begins and grows locally, penetrating vertically. It may be carried via the lymph to the regional nodes, known as regional metastasis. It may go from the lymph to the bloodstream or penetrate blood vessels, directly allowing it a route to go elsewhere in the body. When systemic disease or distant metastasis occur, melanoma commonly involves the lung, brain, liver, or occasionally bone. The malignancy causes death when its uncontrolled growth compromises vital organ function.

Demographics

In the United States, malignant melanoma will account for 5% of malignancies in men and 4% in women, being the sixth most common cancer in men and the seventh in women. There will be 553,400 total cancer deaths in the United States. Malignant melanoma will account for 7,800 for an incidence of 1.5% of total deaths related to cancer.

The incidence of primary cutaneous malignant melanoma has been steadily increasing, possibly related to increase of sun exposure. Currently, the risk is about 13 per 100,000 of the population. It affects all age groups but is most commonly seen in patients between 30 and 60 years of age.

Sun exposure definitely increases risk of developing melanoma. The melanocytes are part of the integument's photoprotective mechanism; in response to sunlight, they produce melanin that has a protective role from the sun's ultraviolet rays. For Caucasians, the amount of melanin present in the skin is directly related to sun exposure. However, it is not so much the total sun exposure that seems important, rather it is the history of sunburn, (especially if severe or at an early age), that correlates with the increased risk. On this basis populations of fair-skinned people living in areas of high sun exposure such as the southwest United States or Australia are subject to increased risk. Malignant melanoma also affects non-Caucasians—though sun exposure probably does not

play a role—at a rate of 10% that of Caucasians. The most common form of melanoma in African Americans is acral lentiginous melanoma.

Malignant melanoma may arise in the skin anywhere on the body. It is estimated that 50% to 70% develop spontaneously while the remainder start in a pre-existing mole.

Causes and symptoms

The predisposing causes to the development of malignant melanoma are environmental and genetic. The environmental factor is excessive sun exposure. There are also genetically transmitted familial syndromes with alterations in the CDKN2A gene, which encodes for the tumor-suppressing proteins p16 and p19. In 2003, a group of Swedish researchers reported that 63 out of a group of 71 melanoma patients, or 89% of the group, had mutations in either the NRAS or the BRAF gene. The researchers found that these mutations occur at an early point in the development of melanoma and remain as the tumor progresses.

As of early 2003, some researchers think there may be two pathways to malignant melanoma, one involving exposure to sunlight and the other with melanocyte proliferation triggered by other factors. This hypothesis is based on the difference in distribution of moles on the body between patients who develop melanomas on the face and neck, and those who develop melanomas on the trunk.

A small percentage of melanomas arise within burn scar tissue. As of 2003, researchers do not fully understand the relationship between deep burns and an increased risk of skin cancer.

As mentioned previously, melanin production in fair-skinned people is induced by sun exposure. An exposure substantial enough to result in a mild sunburn will be followed by melanin producing a tan that may last a few weeks. Both ultraviolet radiation and damaging oxygen radicals caused by sun exposure may damage cells, particularly their DNA. It is suspected that this damage induces mutations that result in the development of malignant melanoma. Though these mutations are alterations of the genome causing the melanoma, they are environmentally induced and account for sporadic or spontaneous cases of this disease.

A positive family history of one or two first-degree relatives having had melanoma substantially increases the risk on a genetic basis. A family tendency is observed in 8% to 12% of patients. There is a syndrome known as the dysplastic (atypical) nevus syndrome that is characterized by atypical moles with bothersome clinical features in children under age 10. Such individuals have to be observed closely for the development of malignant melanoma. Chromosome 9p has been identified as being involved in familial predisposition. There are mutations in up to 50% of familial melanoma patients of the tumor-suppressing gene CDKN2A. The actual number of moles increases risk, but the size of the moles needs be considered. Those with 10 larger moles of over 1 cm (0.4 in.) are at more risk than those with a higher number (50–99) of smaller moles. Finally, when a child is born with a

KEY TERMS

Adjuvant therapy—Therapy administered to patients who are at risk of having microscopic untreated disease present but have no manifestations

Dermis—The deeper portion or layer of the skin

Dysplastic nevus syndrome—A familial syndrome characterized by the presence of multiple atypical appearing moles, often at a young age

Epidermis—The superficial layer of the skin

Genome—Composed of DNA, the genome is the genetic makeup of the cell

Immunotherapy—Therapy using biologic agents that either enhance or stimulate normal immune function

Integument—The skin

Lymph node dissection—Surgical removal of an anatomic group of lymph nodes

Lymphedema—Swelling of an extremity following surgical removal of the lymph nodes draining that extremity

Melanocyte—Cells derived from the neural crest that are in the skin and produce the protein pigment melanin

Metastasis—A tumor growth or deposit that has spread via lymph or blood to an area of the body remote from the primary tumor

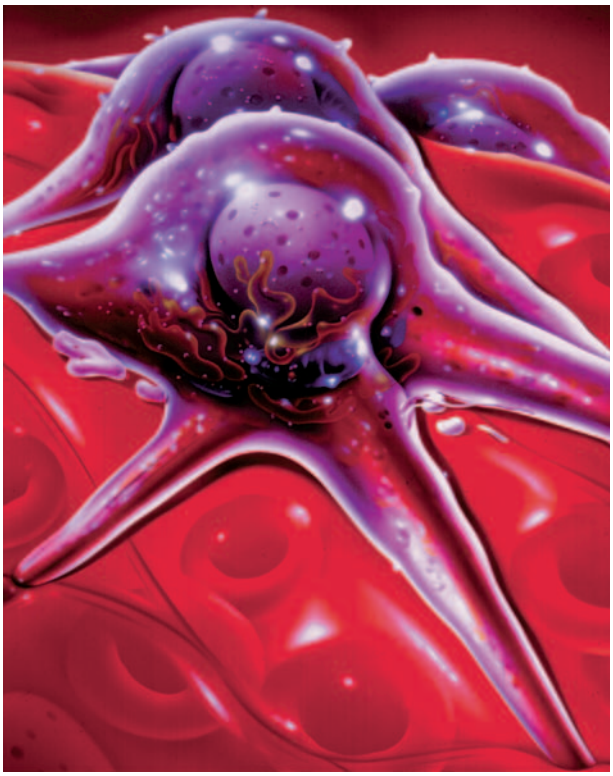
Nevus—A mole

Resection—The act of removing something surgically

Skin appendages—Structures related to the integument such as hair follicles and sweat glands

Systemic disease—Used to refer to a patient who has distant metastasis

Variegation—Patchy variation



Melanoma. *(Photo Researchers, Inc. Reproduced by permission.)*

large congenital mole, careful observation for change is appropriate because of increased risk.

An excellent way of identifying changes of significance in a mole is the ABCDE rule:

- Assymetry
- Border irregularity
- Color variegation
- Diameter exceeding 6 mm (0.24 in.)
- Elevation above surrounding tissue.

Notice that three of the criteria refer to variability of the lesion (color variegation refers to areas of light color and black scattered within the mole). Thus small, uniform regular lesions have less cause for concern. It is important to realize that change in a mole or the rapid development of a new one are very important symptoms.

Another summary of important changes in a mole is the Glasgow 7-point scale. The symptoms and signs below can occur anywhere on the skin, including the palms of the hands, soles of the feet, and also the nail beds:

- change in size
- change in shape
- change in color
- inflammation
- crusting and bleeding
- sensory change
- diameter more than 7 mm (0.28 in.)

In this scheme, change is emphasized along with size. Bleeding and sensory changes are relatively late symptoms.

Symptoms related to the presence of regional disease are mostly those of nodules or lumps in the areas containing the lymph nodes draining the area. Thus nodularity can be found in the armpit, the groin, or the neck if regional nodes are involved. There is also a special type of metastasis that can occur regionally with malignant melanoma; it is known as an in-transit metastasis. If the melanoma is spreading through the lymph system, some of the tumor may grow there, resulting in a nodule part way between the **primary site** and the original lymph node. These in-transit metastasis are seen both at the time of original presentation or later after primary treatment has been rendered, the latter being a type of recurrence.

Finally, in those who either are diagnosed with or progress to widespread or systemic disease, symptoms and signs are related to the affected organ. Thus neurologic problems, lung problems, or liver problems develop depending on the organ involved.

Diagnosis

None of the clinical signs or symptoms discussed above are absolute indications that a patient has malignant melanoma. The actual diagnosis is accomplished by **biopsy**, a procedure that removes tissue to examine under a microscope. It is important that the signs and symptoms are used to develop a suspicion of the diagnosis because the way the biopsy is performed for melanoma may be different than for other lesions of the skin.

When dealing with an early malignant melanoma, it is very important to establish the exact thickness of penetration of the primary tumor. Any biopsy that doesn't remove the full vertical extent of the primary is inadequate. Therefore, if a skin lesion is suspicious, full thickness excisional biopsy is the approach recommended. Shave biopsies and biopsies that remove only a portion of the suspect area are inappropriate. Often, in an early case, the excision involves just the suspicious lesion with minimal normal skin, but it should be a full vertical excision of the skin. If a melanoma is diagnosed, further treatment of this area will often be necessary but doesn't compromise outcome (prognosis). In some special areas of the body, minor modifications may be nec-

essary about initial total excision, but full thickness excision should always be the goal. (See staging, below.)

Once the diagnosis is obtained, careful examination of the patient for regional lymph node involvement should be done. A careful review to uncover any symptoms of widespread disease is also appropriate.

The more common patient has an early melanoma, and extensive testing is not usually warranted. Routine testing in this situation involves a complete blood count, a chest **x ray**, and determinations of blood enzymes including lactic dehydrogenase and alkaline phosphatase.

If the patient has signs or symptoms of more advanced disease, or if the lesion's depth of penetration is sizeable, further **imaging studies** may be appropriate. These would involve CAT scans of the abdomen, the chest, or regional nodal areas, or a CT or MRI of the brain.

Treatment team

The treatment of malignant melanoma is primarily surgical. Newer, more effective protocols involving the medical oncologist are being developed for the patient with systemic disease. **Radiation therapy** has a limited role in the treatment of melanoma, primarily that of helping to ease the effects of metastasis to the brain or sometimes the skeleton.

Clinical staging, treatments, and prognosis

The key to successful treatment is early diagnosis. Patients identified with localized, thin, small lesions (typified by superficial spreading subtype) nearly always survive. For those with advanced lesions, the outcome is poor in spite of progress in systemic therapy.

Clinical staging

Malignant melanoma is locally staged based on the depth of penetration through the skin and its appendages. There are two ways of looking at the depth of penetration. The Clarke system utilizes the layers of the dermis and the skin appendages present at that layer to identify the depth of penetration. The Breslow system uses the absolute measurement of depth. Though useful conceptually, the Clarke system is used less frequently because of the fact that skin is of different thickness in different regions of the body. The depth of penetration is much greater when the tumor reaches the subcutaneous fat when the skin involved is the back as opposed to the face. It turns out that the Breslow measurement is more reproducible and thus more useful; therefore, for purposes here, depth of penetration by absolute measurement (Breslow) is used in local staging.

Stage I and stage II have no involvement of the regional lymph nodes and are thus localized to the site of origin. These stages are subdivided on the basis of penetration. Stage Ia is 0.75 mm or less (1 mm = 0.04 in), and Stage Ib is 0.75 mm to 1.5 mm penetration. Stage IIa is 1.5 mm to 4.0 mm and Stage IIb is over 4.0 mm or into the subcutaneous fat. In stage III and IV, there is disease beyond the primary site. Stage III is defined by the presence of in-transit or regional nodal metastasis or both. Stage IV is defined by the presence of distant metastasis.

Treatments

Once the diagnosis of malignant melanoma has been established by biopsy and the stage has been identified using the results of the examination and studies, a treatment plan is developed. Melanoma is not cured unless it is diagnosed at a stage when it can be isolated and removed surgically. Considerations revolve around the extent of the local and regional nodal surgery for stages I through III. For stage IV patients, or those that are treated and then develop recurrence at distant sites, **chemotherapy** or immunotherapy is planned. Studies are in progress to improve the results from traditional chemotherapeutic regimens. Adjuvant therapy (auxiliary drug treatment used to make possibility of relapse less for those at high risk) is also considered.

Surgical therapy for the primary site is that of wide local removal of the skin including subcutaneous tissue surrounding the lesion. In the past, wide excisions were large and encompassed 2 in. of tissue in all directions wherever feasible. It has been shown that such wide local excisions are not necessary and the question has become how wide is necessary? Studies from the World Health Organization Melanoma Group and by the Melanoma Intergroup Committee in the United States have provided general guidelines based on the depth of penetration of the melanoma. These guidelines and anatomic considerations need to be kept in mind by the surgeon.

The next issue in primary management is whether or not the patient needs to have the regional lymph nodes removed in addition to treatment of the primary tumor. The problems associated with the resection of regional lymph nodes are those of lifelong edema or swelling in the extremity. Though it does not occur in all patients (5% to 20%, depending on the extremity and extent of the dissection), it can be a disabling symptom. Certainly, if it could be ascertained that there was disease in the nodes, resection (removal) would be appropriate. However, if there was no disease, the risk of edema should be avoided. In patients with no signs of regional disease, depth of penetration of the primary tumor helps guide the decision. If the tumor penetrates less than 1mm, dissection is not

usually done. If it is 1-2 mm, node dissection may be done at the time of primary treatment or the patient may be observed and only undergo **lymph node dissection** if the area later shows signs of disease. If the patient has enlarged lymph nodes or the depth of the tumor has led to the evaluation by CAT scan showing enlarged nodes, resection of the nodes will be considered. In the latter case, more extensive imaging of the lung, liver, or brain may be appropriate to be sure the patient doesn't already have stage IV disease.

Questions related to which patients should have resection of regional lymph nodes have led to an intermediary procedure known as sentinel lymph node mapping and biopsy. Intermediate thickness melanomas between 1 and 4 mm deep (0.04 and 0.16 in.) may have nodal involvement even if the exam and any other studies done are normal. If a radioisotope tracer or blue dye is injected into the area of the primary tumor, very shortly it will travel to the lymph nodes draining that area. These sentinel nodes are thus identifiable and are the most likely to harbor any regional metastatic disease. If these nodes alone are biopsied and are normal, the rest of the lymph node group can be spared. If they show microscopic deposits of tumor, then the full resection of the lymph node group may be completed. This procedure allows selection of those patients with intermediate thickness melanoma who will benefit from the regional lymph node dissection.

Patients with metastatic melanoma who do not respond well to other therapies may be candidates for treatment with **aldesleukin** (also called interleukin-2), a specific kind of biological response modifier that promotes the development of T cells. These cells are part of the lymphatic system and can directly interact with and fight cancer cells. Although interleukin is produced naturally in the body, its therapeutic form is developed via biotechnology in a laboratory setting. In some patients, this medication has helped shrink tumors. Side effects, however, can be severe, and range from flu-like symptoms to whole-body infection (sepsis) and coma.

Some patients, such as those with IIb or stage III melanoma, are at high risk for the development of recurrence after treatment. Although these patients are clinically free of disease after undergoing primary treatment, they are more likely to have some microscopic disease in the body that studies have not yet been able to identify. In an effort to decrease the rate of relapse, adjuvant therapy may be considered. Interferon alpha 2a is an agent that stimulates the immune system. This adjuvant therapy may slightly increase the duration of a patient's disease-free state and lengthen overall survival. However, interferon alpha 2a has high toxicity and patients may not tolerate the side effects.

Unfortunately, treatment for those patients who present with or go on to develop systemic disease usually fails; melanoma that has metastasized to the brain is particularly difficult to treat. The chemotherapeutic agent **dacarbazine**, or DTIC, seems to be the most active agent. Overall responses are noted in about 20% of patients, and they last only two to six months. Combination therapy may be an option. The regimen of DTIC + BCNU (**carmustine**) + **cisplatin** + **tamoxifen** delivers a response rate of 40%. Combining biologic or immunologic agents such as interferon with standard chemotherapeutic agents is under study and showing improved response rates, though toxicity is substantial and only the healthier, younger patients tolerate the treatment.

Some researchers are investigating the reasons why melanomas are so resistant to chemotherapy. One suggestion as of late 2003 is that the genes ordinarily responsible for apoptosis (cell self-destruction) do not function normally in melanomas. The development of new drugs to treat melanoma depends on a better understanding of the complex processes involved in apoptosis.

Prognosis

Almost all patients survive stage Ia malignant melanoma, and the suvivorship for stage I overall is more than 90%. Survival drops in stage IIa to about 65% at five years and is worse yet for stage IIb at slightly over 50%. Stage III has a survival rate at 5 years of 10% to 47%, depending on the size and number of regional nodes involved. Stage IV malignant melanoma is almost always a fatal disease.

Alternative and complementary therapies

Though radiation therapy has a minimal role in the primary treatment of malignant melanoma, for patients who have metastatic disease, radiation may be helpful. This is true in patients who have developed tumor deposits in areas such as the brain or the bone.

Coping with cancer treatment

For those with familial tendencies for malignant melanoma, genetic counseling may be appropriate. Psychological counseling may be appropriate for anyone having trouble coping with a potentially fatal disease. Local cancer support groups may be helpful and are often identified by contacting local hospitals or the American Cancer Society.

Clinical trials

Clinical trials are studies of new modes of therapy in an effort to improve results of treatment. For those

QUESTIONS TO ASK THE DOCTOR

- What stage of cancer do I have?
- Has the cancer spread? What tests will be used to determine this?
- What are my treatment options?
- Is adjuvant therapy really necessary in my case?
- What are the risks and side effects of these treatments?
- What medications can I take to relieve treatment side effects?
- Are there any clinical studies underway that would be appropriate for me?
- What effective alternative or complementary treatments are available for this type of cancer?
- How debilitating is the treatment? Will I be able to continue working?
- How will the treatment affect my sexuality?
- Are there any local support groups for melanoma patients?
- What is the chance that the cancer will recur?
- Is there anything I can do to prevent recurrence?
- How often will I have follow-up examinations?

wishing to find a trial related to their particular situation, the National Cancer Institute lists those available at: <http://cancernet.nci.nih.gov/trialsrch.shtml>.

In an attempt to develop a new type of immunotherapy, melanoma-specific **vaccines** are being developed. Antigens specific to melanoma cells and other tumor-associated antigens are being used to stimulate the body's own natural immune system to attack and kill the cells of malignant melanoma. Though experimental, this type of therapy offers hope and clinical trials are underway. In 2003 a team of researchers in New York reported that vaccines made from poxviruses show promise as a treatment for melanoma.

Prevention

Though it is difficult to prove that sunscreens statistically reduce the frequency of malignant melanoma at this time, most authorities recommend use as protection from ultraviolet light (considered a major factor in the development of melanoma.) Avoidance of severe sunburns is recommended.

Special concerns

Sub-ungal melanoma is a type of acral lentiginous melanoma that occurs in the nail beds. Any pigmented lesion in these areas needs evaluation. They are commonly mistaken for bruises or infection. The main concern is to know they exist so that proper evaluation is performed as early as possible.

Malignant melanoma may also involve the eye, as melanin-producing cells exist there also. Again, familiarity with these spots is important so that pigmented growths are not ignored but evaluated early.

Rarely, a patient presents with regional lymph node involvement, but the primary site of the tumor cannot be identified. The primary may not be producing pigment and is known as an amelanonic melanoma. Because these patients present with stage III disease, they do less well as a group overall.

Melphalan

Definition

Melphalan is an anticancer (antineoplastic) agent. It also acts as a suppressor of the immune system. It is available under the brand name Alkeran.

Purpose

Melphalan is primarily used to treat **ovarian cancer** and **multiple myeloma**, which is a type of cancer of the bone marrow. It is also used to treat cancers that have metastasized to the liver.

Although not specifically labeled for use in the treatment of these cancers, melphalan is also used in some patients with:

- breast cancer
- cancers of the blood and lymph system
- endometrial cancer
- malignant melanoma
- Waldenström's macroglobulinemia

More recently, melphalan has been used to prevent rejection of transplanted stem cells in the treatment of metastatic breast cancer and renal cell carcinoma.

Description

Melphalan is a nitrogen mustard derivative and belongs to the group of alkylating anticancer agents. It chemically interferes with the synthesis of genetic material (DNA and RNA) of cancer cells, which prevents these cells from being able to reproduce and continue the growth of the cancer.

Recommended dosage

Melphalan may be taken either orally in pill form or as an injection in liquid form. The dosage prescribed may vary widely depending on the patient, the cancer being treated, and whether or not other medications are also being taken.

A typical dosage for multiple myeloma is 6 mg per day for two to three weeks. After this initial dose, the drug is halted for up to 4 weeks, then resumed at a dose of 2 mg per day, depending on blood counts of the drug in the patient's blood test.

A typical dosage for ovarian cancer is 0.2 mg per kilogram (2.2 pounds) of body weight once per day for five days.

Precautions

Melphalan should be taken with food to minimize stomach upset. Melphalan should always be taken with plenty of fluids.

Melphalan can cause an allergic reaction in some people. Patients with a prior allergic reaction to melphalan should not take the drug.

KEY TERMS

Antineoplastic—A drug that prevents the growth of a neoplasm by interfering with the maturation or proliferation of the cells of the neoplasm.

Neoplasm—New abnormal growth of tissue.

Melphalan can cause serious birth defects if either the man or the woman is taking this drug at the time of conception, or if the woman is taking this drug during pregnancy. Also, male sterility is a possible side effect of melphalan. This sterility may either be temporary or permanent.

Because melphalan is easily passed from mother to child through breast milk, breastfeeding is not recommended while melphalan is being taken.

Melphalan suppresses the immune system and interferes with the normal functioning of certain organs and tissues. For these reasons, it is important that the prescribing physician is aware of any of the following preexisting medical conditions:

- a current case of, or recent exposure to, chicken pox
- herpes zoster (shingles)
- a current case, or history of, gout or kidney stones
- all current infections
- kidney disease

Because melphalan is such a potent immunosuppressant, patients taking this drug must exercise extreme caution to avoid contracting any new infections. They should do their best to:

- avoid any person with any type of infection
- avoid any person who has received a polio vaccine in the last two months
- avoid bleeding injuries, including those caused by brushing or flossing the teeth
- avoid contact of the hands with the eyes or nasal passages unless the hands have just been washed and have not touched anything else since this washing
- avoid contact sports or any other activity that could cause a bruising or bleeding injury

Side effects

There are no common side effects of melphalan. Side effects that may occur, however, include:

- increased susceptibility to infection
- nausea and vomiting
- diarrhea
- mouth sores
- skin rash, **itching**, or hives
- swelling in the feet or lower legs

A doctor should be consulted immediately if the patient experiences black, tarry, or bloody stools, blood in the urine, persistent cough, **fever** and chills, pain in the lower back or sides, painful or difficult urination, or unusual bleeding or bruising.

Interactions

Melphalan should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician. It is particularly important that the prescribing physician be aware of the use of any of the following drugs:

- amphotericin B
- antithyroid agents
- azathioprine
- chloramphenicol
- colchicine
- flucytosine
- ganciclovir
- interferons
- plicamycin
- probenecid
- sulfinpyrazone
- zidovudine
- any **radiation therapy** or **chemotherapy** medicines

Memory change

Description

Many people with cancer experience memory changes—such as mild forgetfulness, an inability to concentrate on more than one task, or more severe memory loss—after undergoing **chemotherapy** or radiation treatments. In other cases, as in a person with a brain tumor, the cancer itself may cause memory changes. Surgical interventions, particularly for brain cancer, may also lead to memory loss.

Causes

Studies show that patients experience trouble with memory and language skills after chemotherapy. Scientists are searching for the exact cause, but they believe the chemotherapy agents may be associated with this side effect. The drugs are designed to attack cancer cells, but often kill healthy cells in the process. Researchers are studying whether chemotherapy agents may be damaging healthy brain cells. Others believe the cancer itself may be responsible for the memory changes.

Similarly, **radiation therapy** also may cause people with cancer to lose some mental abilities, including memory. Physicians use radiation waves to penetrate cancer cells and stop them from growing. During the process, the rays may damage some healthy tissue. The severity of damage depends on the dose and duration of the radiation treatments. In some cases, cells killed by radiation can form a tumor-like mass in the brain, which can lead to memory loss. Children who undergo radiation treatments for a brain tumor may have developmental delays later in life.

Other side effects of cancer, such as **fatigue**, pain, and **depression**, may lead to memory impairment as a person struggles to cope with cancer. Living with constant pain, for example, takes a great deal of energy and can cause a person to become more distracted than usual. Sometimes, especially in elderly patients, it can be difficult to tell if the memory changes are caused by an existing dementia or the cancer treatment.

Treatments

Depending on the type and intensity of cancer treatment, memory difficulties may fade over time. Some people, however, will experience a permanent loss. Families can help by offering useful strategies, such as making lists of daily tasks, using a calendar or daily organizer, reducing stress, and encouraging the person to ask for help if disoriented.

Patients scheduled for radiation therapy should discuss their concerns about memory loss with their physician before the treatment begins. The radiologists may be able to control the dosage to minimize damage to healthy cells. For instance, many hospitals use a gamma knife for brain cancer treatment. The device allows radiation therapists to simultaneously attack a tumor with high-energy rays from several different angles. The gamma knife sends a concentrated dose to the tumor without damaging surrounding brain tissue.

Occupational therapists can assist people who find that cancer-related memory changes are interfering with their ability to work or perform normal activities. Many people learn helpful coping strategies from other cancer survivors by joining a support group. Since more damage occurs in younger patients, children who go through radiation therapy for brain tumors may need extra tutoring, or special education programs when they go to school.

Alternative and complementary therapies

Often, when physicians prescribe medication to ease a person's pain or depression, the patient's memory may improve as well. Researchers also are studying the ability of the herb *gingko biloba* to increase mental sharpness. Although it has not yet been proven to be completely effective, some people with memory loss find it helpful. Since gingko can cause circulatory problems, it is important to check with a doctor before taking it.

Meningioma

Definition

A meningioma is a benign tumor of the central nervous system that develops from cells of the meninges, the membranes that cover and protect the brain and spinal cord.

Description

The meninges

The delicate tissues of the brain and spinal cord are protected by a layer of bone and an inner covering called the meninges. The meninges are composed of three layers:

- dura mater
- arachnoid
- pia mater

The tough, thick dura mater forms the outer layer of the meninges and is attached to the bone of the skull and spinal cord. The arachnoid and pia mater layers are thinner and more delicate than the dura mater. The innermost pia mater layer is attached directly to the brain and spinal cord. Meningiomas arise from the middle arachnoid layer, and most remain attached to the dura mater by a dural tail.

Types of meningiomas

Meningiomas account for 15–20% of all brain tumors, and 25% of all spinal cord tumors. The World Health Organization (WHO) classifies meningiomas into 11 different categories according to their cell type. However, because there are so many different cell types and so much overlap between types, meningiomas are most often placed into three general categories, including benign, atypical, and malignant.

Benign meningiomas are by far the most common, accounting for more than 90% of all meningiomas. These tumors grow slowly and produce symptoms only if they become large enough to compress nearby brain tissue. In some patients, meningiomas can grow very large with almost no symptoms. This happens because the tumor has grown very slowly and has gradually compressed the brain over time. Meningiomas can also cause fluid to build up in the brain, and can sometimes block veins. They may also grow into nearby bone, causing the bone to become thicker.

Up to 7% of meningiomas are classified as atypical. These tumors grow more quickly than benign meningiomas and are more likely to be symptomatic. Malignant meningiomas are fast-growing aggressive tumors and are the most rare, accounting for only about 2% of all meningiomas. It is extremely unusual for meningiomas to metastasize to other organs. When they do, the lungs are the most common site.

Only about one tenth of meningiomas are found in the spine. These slow-growing tumors cause symptoms when they begin to compress the spinal cord. Spinal meningiomas usually grow in the spinal canal between the neck and the abdomen, and are almost always benign.

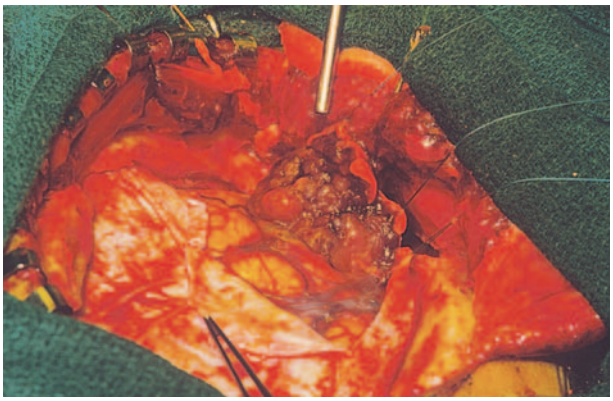
Demographics

Only one person in every 50,000 is diagnosed with a symptomatic meningioma annually. Most of these patients are women. Women develop brain meningiomas almost twice as often as men and spinal meningiomas four to five times more often than men. The disease usually strikes middle-aged and elderly patients. Men are most affected between the ages of 50 and 60 years, while women are most affected between the ages of 60 and 70 years. Atypical and malignant meningiomas are more common in men. Meningiomas do not occur very often in children.

Causes and symptoms

Causes

Although no single factor has been found that causes meningiomas, several risk factors are known. Some patients have developed a meningioma after being exposed to radiation. These patients tend to be younger than typical meningioma patients, and their tumors often grow more quickly. According to one study, the average age of patients with radiation-induced meningiomas is 38 years.



Brain surgery to remove an invasive meningioma. *(Custom Medical Stock Photo. Reproduced by permission.)*

There is also a genetic component to meningioma. Patients who suffer from neurofibromatosis, a rare genetic disease, often develop multiple meningiomas.

Since meningioma cells recognize the female sex hormone progesterone, some researchers believe that female sex hormones may play a role in the development of meningiomas. This possible link is still being investigated.

A group of researchers at the National Cancer Institute reported in 2004 that people in certain occupations have a higher than normal risk of developing meningiomas. These higher-risk occupations include auto body painting, industrial production supervision, teaching, business management, interior decorating and design, and career military service. Further research is needed to determine whether there is a common causal factor linking these different fields of work.

Symptoms

Up to 75% of meningiomas produce no symptoms because they grow slowly and remain small. Often, tumors are discovered only when patients are being investigated for an unrelated illness. When symptoms do appear, it results that the tumor has grown large enough to compress part of the brain or spinal cord.

Patients experience different symptoms depending on the location of the tumor. Most brain meningiomas are located either just below the top of the skull, or between the two hemispheres of the brain. If the tumor is located in these areas, symptoms include:

- headaches
- seizures
- dizziness
- problems with memory
- behavior changes
- protrusion of one or both eyeballs (exophthalmos)

More rarely, tumors are near sensory areas of the brain such as the optic nerve or close to the ears. Patients with these tumors experience vision or hearing losses.

Spinal meningiomas are usually found in the spinal column between the neck and the abdomen. The most common symptoms are:

- pain
- weakness and stiffness of the arms and legs
- episodes of partial paralysis

Diagnosis

Meningiomas are diagnosed using a painless noninvasive technique called **magnetic resonance imaging** (MRI). MRI works by exposing the patient to harmless radio waves and a magnetic field, which produce clear images of the brain and the spine that show the size and location of tumors. No special preparation is required for the test.

Diagnosis can also be made by **computed tomography** (CT) scan. The CT scan uses low-dose x rays to generate a picture of the inside of the body. Sometimes a dye is injected into the patient's vein to improve the visibility of tissues. If the meningioma has grown into nearby bone, a CT scan will show the extent of bone invasion better than MRI. Women who are pregnant, or who think they might be pregnant, should tell their doctors before having a CT scan.

Treatment team

The treatment team for a patient with a symptomatic meningioma may include a radiologist, a neurologist (specialist of the nervous system), and a neurosurgeon.

If surgery is necessary, a neurosurgeon will perform the procedure with the help of a surgical team. The team includes two or three nurses, and an anesthesiologist.

A small number of patients receive radiotherapy for their meningioma either because the tumor is too difficult to remove surgically, or because the surgeon had to leave some tumor behind. These patients will be referred to a radiation oncologist (specialist in giving radiation to cancer patients).

Clinical staging, treatments, and prognosis

Staging

Meningiomas are classified into three different grades depending upon the likelihood of recurrence and aggressive growth:

KEY TERMS

Benign tumor—A growth that is non-cancerous.

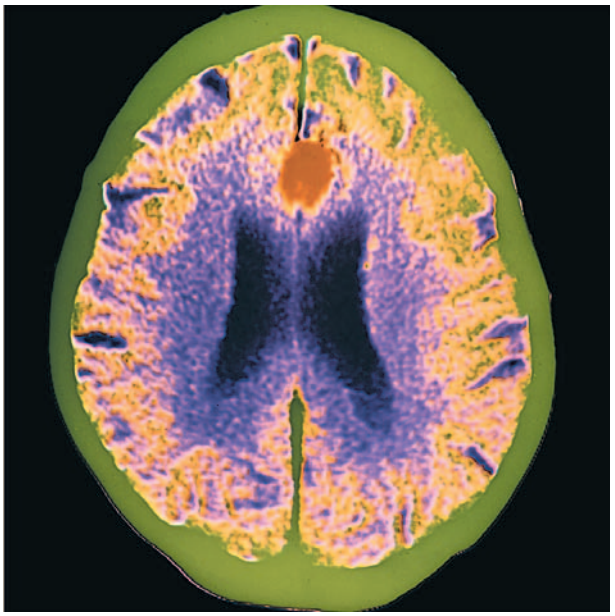
Computed tomography (CT) scan—A method of imaging the inside of the body using x rays.

Magnetic resonance imaging (MRI)—A method of imaging the inside of the body using radio waves and a magnetic field.

Meninges—Membranes that cover and protect both the brain and spinal cord.

Neurofibromatosis—A rare, genetic disease that causes tumors to grow in the nervous system.

Radiotherapy—The use of radiation to treat a medical condition.



Colored computed tomography (CT) scan of the brain showing a meningioma. At upper center is the tumor (red). The cerebrum is colored yellow and light purple. *(Copyright Department of Clinical Radiology, Salisbury District Hospital, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

- Grade I: Low risk of recurrence and slow growth
- Grade II: Greater likelihood of recurrence and/or aggressive growth
- Grade III: High recurrence rates and aggressive growth.

The vast majority of meningiomas are grade I. Atypical tumors are grade II, and malignant tumors are grade III.

Medical therapies

Medical treatment for meningiomas is necessary when tumors cause symptoms. Fortunately, only about a quarter of meningiomas become symptomatic. Most patients are cured by surgery.

The objective of surgery is to remove not only the entire meningioma, but also the tail that attaches the tumor to the meninges. If the tumor has grown into bone, the bone is removed, too. If the tumor is in a difficult location in the brain, the surgeon may leave some tumor behind in order to preserve brain tissue.

The prognosis following brain meningioma treatment is very good. For the few patients who are not cured, prognosis depends on how completely the tumor is removed. If some tumor is left behind, recurrence is more likely, particularly for patients with grade II or grade III meningiomas. Ten years after surgery, 7–20% of patients with benign grade I tumors have a recurrence. For patients with malignant grade III tumors, up to 78% have a recurrence. A second surgery is sometimes necessary for patients with recurrent tumors.

Spinal meningioma is the most successfully treated meningioma, and the most successfully treated of all spinal tumors. Most of these tumors are removed completely, and they rarely recur. Even patients with quite severe symptoms fully recover after surgery.

For the few patients who are inoperable (usually because of tumor location), **radiation therapy** can stop the growth of tumors. Recently, stereotactic radiosurgery has been successfully used. This procedure uses images of the patient's skull to construct a frame that allows precise aiming of radiation, thus minimizing harm to nearby healthy tissue. Another option is fractionated radiotherapy, which also delivers precise doses of radiation to very small areas of tissue.

Not every patient with a meningioma receives surgery or radiation. Asymptomatic patients with small or slow-growing tumors can receive periodic MRI tests to check tumor growth. Treatment may also not be necessary for patients with mild or minimal symptoms.

Alternative and complementary therapies

Unlike many other cancers, conventional medical treatment of meningioma has very high success rates. As a result, alternative therapies are not commonly used for these tumors.

QUESTIONS TO ASK THE DOCTOR

- Will I need to have surgery?
- Can I expect a full recovery after surgery?
- Will I need radiotherapy?
- How often will I need to return for an MRI or CT scan?
- How soon can I return to work after surgery?

Coping with cancer treatment

When first diagnosed with a meningioma, many patients experience anxiety, resulting in nervousness, sleepless nights, and even nausea. However, patients can often relieve many of their fears by learning more about the disease and its course of treatment. Nevertheless, about 21% of patients with meningiomas develop psychiatric disorders, most commonly depression or an anxiety disorder.

The majority of meningioma patients are treated with surgery alone. Surgery will involve a hospital stay of at least a week. Before going home, patients are usually given medications to help prevent pain and swelling. Once home, patients can expect to feel some headache pain, and will become tired easily. If headaches and weakness become worse, a doctor should be contacted. Patients should make sure they get plenty of rest and eat a balanced, nutritious diet. Most patients can begin to resume their normal activities in about six to eight weeks.

Clinical trials

Chemotherapy is seldom given to meningioma patients because surgery (and/or radiotherapy) is usually successful. For patients with tumors that do not respond to these treatments, however, chemotherapy is available within a clinical trial.

Clinical trials have investigated several drugs to treat patients whose meningioma recurs following failure of both surgery and radiotherapy. **Hydroxyurea**, a drug used to treat some other cancers, has been shown to slow the growth of meningioma cells. Studies of hydroxyurea continue. Some trials have explored the link between meningioma and female sex hormones. **Tamoxifen**, an anti-estrogen drug used to fight **breast cancer**, has produced disappointing results. Trials using RU-486, an anti-progesterone agent, are underway. Information on these and other open clinical trials is available on the Internet from the National Cancer Institute at <http://www.nci.nih.gov>.

Prevention

The most avoidable risk factor for the development of meningioma is exposure to radiation. Children exposed to small amounts of radiation in the 1950s to treat tinea captis, a fungal infection of the scalp, developed meningiomas at an unusually high rate. There is also a clear relationship between radiation dose and meningioma: the higher the radiation dose, the greater the probability of developing a meningioma.

Special concerns

The very elderly

In very elderly people, the symptoms of a meningioma can be very similar to normal aging. These patients typically experience difficulty with learning and remembering things as a result of the tumor. Headaches, a classic symptom of a meningioma, are not usually reported. Treatment of very elderly patients may be difficult if the patient is too frail for surgery.

Children

On the rare occasions that meningiomas are diagnosed in children, they tend to be large, fast growing, and located in unusual positions. Treatment for children is the same as for adults: complete tumor removal with surgery and/or radiotherapy.

Neurofibromatosis

Neurofibromatosis (NF) is actually two different genetic diseases: NF Type 1 and NF Type 2. NF Type 2 is the more rare of the two diseases, affecting only one in 40,000 individuals. These patients often develop multiple brain meningiomas. Although there is no cure for NF, meningioma tumors can be removed with surgery.

Meperidine

Definition

Meperidine, available as hydrochloride salt, is a narcotic analgesic, a classification term used to describe medications capable of producing a reversible **depression** of the central nervous system for pain control. Because of its potential for physical and psychological dependence, meperidine is a carefully controlled substance. It is commonly referred to by one of its brand names, Demerol.

Purpose

There are several possible indications for the administration of meperidine. It is commonly used for the relief of moderate to severe pain, particularly in obstetrics. Meperidine is also widely used preoperatively, and as an adjunct to anesthesia during surgery. Meperidine is not recommended for long-term management of chronic pain, such as pain caused by cancer, because of its potential for psychological and physical dependence.

Description

Meperidine is a synthetic compound that acts as an agonist—meaning it attaches to opioid receptors in the central nervous system and stimulates physiologic activity normally stimulated by naturally occurring substances such as endorphins (short for endogenous morphine). Meperidine acts much like morphine, although constipation, suppression of the cough reflex, and smooth muscle spasm are all reduced with meperidine.

Meperidine is available in a banana-flavored syrup, in a tablet, and in a liquid form for injection. Oral meperidine tends to be less effective than the injectable form. When taking the syrup, patients should dilute it with approximately one half glass of water to reduce temporary anesthesia to the mouth and tongue.

Recommended dosage

The recommended dosage of meperidine depends on the purpose for which it is prescribed, as well as the population in whom it is administered. For example, elderly patients, or patients with underlying medical problems that increase side effects or decrease drug metabolism, should generally be given reduced dosages. Meperidine can be taken orally, in tablet or syrup form, intravenously (directly into a vein), or by injection into the muscle (intramuscularly) or connective tissue (subcutaneously).

Generally, repeated doses administered to manage pain should be given by injection intramuscularly. The subcutaneous route is acceptable for occasional

KEY TERMS

Agonist—A drug that binds to cell receptors and stimulates activities normally stimulated by naturally occurring substances.

Endorphin—Short for endogenous morphine, it is a naturally occurring substance that binds to opioid receptors in the brain.

Narcotic analgesic—A classification of medications that relieves pain by temporarily depressing the central nervous system.

Opioid—A drug that possesses some properties characteristic of opiate narcotics but not derived from opium.

Patient controlled analgesic (PCA)—A device resembling an intravenous pump that allows patients to self-medicate within pre-established dosage parameters for pain control.

administration. When given intravenously, meperidine should be diluted and administered very slowly. When taken in conjunction with phenothiazine or other tranquilizers, the dose should be decreased by as much as a half. Specific dosages are as follows.

FOR RELIEF OF MODERATE TO SEVERE PAIN The recommended dosage for adults for pain relief is 50–150 mg every three to four hours by oral or intramuscular route. When given intravenously through a patient-controlled analgesia (PCA) device, an initial dose of 10 mg should be administered. The PCA should be programmed to administer between 1–5 mg every 6–10 minutes. If meperidine is given continuously through an intravenous line, the dose should be adjusted based on patient response to a range of 15–35 mg an hour. Children should be given 1–1.8 mg per kg (2.2 pounds) intramuscularly or subcutaneously.

FOR PREOPERATIVE MEDICATION Adults may be given 50–100 mg of meperidine intramuscularly, or subcutaneously 30–90 minutes prior to surgery. Children's dosages should be reduced to 1–2 mg per kg through the same routes.

For obstetric pain control. The recommended dosage for control of regular (not sporadic) pain in this setting is 50–100 mg every 1–3 hours intramuscularly or subcutaneously.

Precautions

Other patients who should avoid meperidine use include those with previous hypersensitivity to narcotics, or those with underlying respiratory problems. Meperidine, even in recommended therapeutic doses, can decrease the respiratory drive. Conditions such as asthma or chronic obstructive pulmonary disease may increase the likelihood of respiratory difficulty. Meperidine can also impair judgment, and should not be used in individuals engaging in activities that require alertness, such as driving.

Because its effects on a fetus are unknown, meperidine is not recommended in pre-labor stage pregnant women. Even in labor, when it may be indicated for pain control, meperidine may cause respiratory depression of the mother and her baby, particularly premature babies. Meperidine is excreted in breast milk, and, if needed, should be administered several hours before breastfeeding to minimize ingestion by the infant.

Side effects

The most common adverse effects of meperidine are lightheadedness, dizziness, sedation, nausea and/or vomiting, and sweating. Less common, but more severe, side effects include respiratory depression and abnormally low blood pressure.

Interactions

Individuals who are taking, or who have recently taken, drugs called monoamine oxidase (MAO) inhibitors (a class of antidepressants), should not be given meperidine. Reactions have been reported in this population that are characterized by a variety of signs and symptoms including respiratory distress, coma, abnormally low or abnormally high blood pressure, hyperexcitability, and even death. If administration of a narcotic is required, it should be given in small, gradually increasing test doses under careful supervision.

Adverse effects such as respiratory depression and decreased blood pressure are more common when meperidine is administered in conjunction with other narcotic analgesics, anesthetics, phenothiazines, sedatives, or any other type of drug that suppresses the central nervous system. Alcohol should also be avoided.

Tamara Brown, R.N.

Mercaptopurine

Definition

Mercaptopurine is a medicine used to prevent the formation and spread of cancer cells. Mercaptopurine is

also called 6-mercaptopurine or 6-MP, and is available under the brand name Purinethol.

Purpose

Mercaptopurine is used as part of the consolidation and maintenance treatment for **acute lymphocytic leukemia** (ALL) and **acute myelocytic leukemia** (AML).

Description

Mercaptopurine is an analog of purine, a component of DNA/RNA, and belongs to antimetabolites that prevent the biosynthesis, or utilization, of normal cellular metabolites. It has been used for several decades in combination with other **chemotherapy** drugs for the treatment of different types of acute adult and childhood leukemias (ALL and AML). It has also been shown to be effective for the treatment of inflammatory bowel disease (IBD) (which includes Crohn's disease and ulcerative colitis), certain types of arthritis, and polycythemia vera (above normal increase in red cells in the blood). Mercaptopurine helps to decrease the dose of steroids in patients with IBD, and to reduce their dependence on steroids to control symptoms of their disease. The medicine is taken up by red cells in the blood and works by decreasing the formation of certain genetic material (DNA and RNA) in patients with cancer and by altering the activity of the immune system in patients with IBD.

Recommended dosage

Doses vary between different chemotherapy protocols. The usual dose is 2.5 mg per kg (2.2 pounds) per day in adults and children (50 mg daily in an average 5-year old child or 100–200 mg daily in adults). The total daily dose is calculated to the nearest multiple of 25 mg and is given all at one time. Another way of dosing 6-MP is based on body surface area (BSA), and is usually 75 mg per square meter in children and 80–100 mg per square meter in adults.

Doses of 1.5–2.5 mg per kg per day is recommended for leukemia patients. For those patients with inflammatory bowel disease, doses of 1.5 mg per kg per day have been used in research studies.

Administration

This medicine is usually taken by mouth and should be given at the same time every day, preferably on an empty stomach (one hour before meals or two hours after meals). Children with leukemia should be taking this medicine at bedtime for maximum effectiveness. All patients should drink plenty of fluids (at least eight glasses of water per day) while taking this medication, unless otherwise directed by a physician.

Precautions

The use of 6-MP in pregnant women should be avoided whenever possible, especially during the first three months of pregnancy, as 6-MP can cause birth defects and spontaneous abortions.

As 6-MP can lower the body's ability to fight infections, patients are advised to avoid contact with people who have a cold, flu, or other infections.

Mercaptopurine should be used with caution in the following populations:

- people who had an allergic reaction to 6-MP in the past
- people at risk for pancreatitis (inflammation of the pancreas)
- breastfeeding mothers (it is not known if 6-MP crosses in to breast milk)
- people with liver or kidney disease
- people with gout (6-MP can exacerbate the symptoms of gout)
- people taking **allopurinol** for gout
- people with suppressed bone marrow (tissue filling the empty spaces inside the bone)

Patients are encouraged to stop taking 6-MP, and contact a physician immediately, if any of the following symptoms develop:

- fever, chills, or sore throat
- yellowing of the skin or eyes
- blood in the urine or stools
- black stools
- unusual bleeding or bruising
- stomach pain with nausea, vomiting, or loss of appetite

Patients taking 6-MP must see a physician before starting medication therapy, and also occasionally during therapy, to have blood tests for the monitoring of a complete blood count and kidney and liver functions.

Side effects

This is a very potent medicine that can cause serious side effects. These side effects include skin rash, nausea, vomiting, **diarrhea**, mouth sores, yellowing of the eyes or skin, clay-colored stools, dark urine, decreased ability to fight infections, pinpoint red dots on the skin, and darkening of the skin. Nausea and vomiting, diarrhea, and stomach pain are less common in children than in adults.

KEY TERMS

Consolidation therapy—A stage in treatment of acute lymphocytic leukemia (ALL) that follows induction of remission. The purpose of this stage is to eliminate remaining cancer cells that cannot be detected by usual methods.

Inflammatory bowel disease (IBD)—This disease can be divided into two types: Crohn's disease and ulcerative colitis. Patients with Crohn's disease can have inflammation of the full thickness of the walls of the entire gastrointestinal tract. In patients with ulcerative colitis, the inflammation is limited to the surface of the walls of the large intestine and rectum.

Leukemia—A type of cancer caused by a progressive increase in abnormal blood-forming cells of the bone marrow.

Maintenance therapy—The last stage in treatment of ALL. The purpose of this stage is to provide long-term exposure to lower doses of drugs and to give the immune system time to kill the leukemia cells.

Interactions

Mercaptopurine can decrease the effectiveness of blood thinners such as **warfarin** (Coumadin).

The drug can exacerbate the symptoms of gout. The anti-gout medication, allopurinol, can increase blood levels of 6-MP and increase the risk of its side effects. The dose of 6-MP needs to be decreased, or its use should be avoided, in patients taking allopurinol, which interferes with the degradation of 6-MP.

Risk of liver disease may be increased in patients taking both **doxorubicin** (a cancer chemotherapy drug) and 6-MP. Other medicines that decrease the function of the liver can cause increased toxicity with 6-MP. Patients should inform their doctor or pharmacist about all the prescription drugs and over-the-counter medications that they are taking.

Olga Bessmertny, Pharm.D.

Merkel cell carcinoma

Definition

Merkel cell carcinoma (MCC) is a rare form of cancer that develops on, or just beneath, the skin and in hair follicles. It is also known as neuroendocrine cancer of the skin or trabecular cancer.

Description

Merkel cells are cells that lie in the middle layers of the skin. They are named for their discoverer, a German professor of anatomy named Friedrich Sigmund Merkel (1845–1919). These cells are organized around hair follicles and are believed to act as some type of touch receptors. MCC begins in these cells.

MCC usually appears as firm shiny skin lumps, or tumors. These tumors are painless and can range in size from less than a quarter of an inch (0.6 cm) to over two inches (5.1 cm) in diameter. They may be red, pink, or blue. Tumors first appear on the head and neck in about 48% of cases, and less frequently on other sun-exposed parts of the body.

MCC is very aggressive, it spreads very rapidly, and it often invades other tissues and organs (metastasizes). The most common sites of **metastasis** of MCC are the lymph nodes, liver, bones, lungs, and brain. Metastasis to the lymph nodes generally occurs within seven to eight months after the first skin tumors appear. Nearly half of all people affected with MCC will develop systemic metastases within 24 months, and 67% to 74% of these people will die within five years.

Local recurrence of MCC after the removal of the primary tumor occurs in approximately one-third of all patients and is usually apparent within four months.

Several other names have been used to describe MCC, among these are: anaplastic carcinoma of the skin, apudoma, endocrine carcinoma of the skin, neuroendocrine carcinoma of the skin (NEC), primary small-cell carcinoma of the skin, primary undifferentiated carcinoma of the skin, and trabecular cell carcinoma. The two most commonly used names are MCC and NEC.

Demographics

MCC is seen almost exclusively (94% of known cases)in Caucasians. It affects males more often than females. Seventy-six percent of cases reported in the United States have been diagnosed in people older than 65, but MCC has also been seen in a child as young as seven and a woman as old as 97.

As of 2003, the National Cancer Institute (NCI) had compiled records of 1034 patients in the United States diagnosed with MCC. The number of new cases of MCC is expected to rise as the average life span continues to increase, exposure to the sun remains high, and MCC is recognized more often by medical practitioners.

Causes and symptoms

The cause of MCC has not been positively identified. As of the early 2000s, it is believed to be caused by the skin damage associated with exposure to ultraviolet light from the sun.

Some researchers believe that Merkel cell carcinoma may also be associated with immunodeficiency syndromes, as six of the 1043 patients recorded in the United States developed MCC after being diagnosed with chronic lymphocytic leukemia.

The only symptom of primary MCC is the appearance of the characteristic tumors in the skin. Lymph node metastases show enlarged, firm, lymph nodes in the region of the primary tumor. Other systemic metastases show as masses in the affected organs. The location of the primary tumor is not related to the location of these systemic metastases.

Diagnosis

The diagnosis of MCC is performed by examining and testing a **biopsy** of the tumor. MCC is difficult to differentiate from several other forms of abnormal tissue growth (neoplasms). This diagnosis cannot be made just by examining the tumor cells under a microscope. It is done by performing a variety of chemical tests on these cells. Testing must be performed to make sure this is not metastatic oat-cell (lung) cancer.

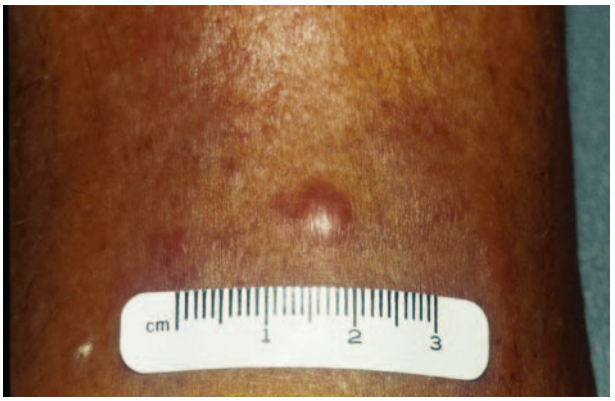
Treatment team

MCC is generally first identified by a microbiologist who examines a biopsy sample. Most MCC tumor removals are performed by dermatologists. Post-operative radiation treatments are generally ordered by the dermatologist and performed by a radiation therapist under the direction of a radiologist and/or a radiation physicist.

Because of the rapid and possibly invasive nature of MCC, patients are generally referred to a physician specializing in cancer (oncologist) to ensure that the disease has not spread to other parts of the body. Chemotherapy for MCC is considered investigational as of late 2003.

Clinical staging, treatments, and prognosis

MCC is classified into three clinical stages. Stage I MCC is defined as a disease that is localized to the skin. Stage II MCC is characterized by a spreading of the disease to the lymph nodes that are near the primary skin tumor or tumors. Stage III MCC is characterized by systemic metastases.



A Merkel cell tumor on a patient's leg. *(Custom Medical Stock Photo. Reproduced by permission.)*

Treatment of stage I MCC involves wide local excision and follow-up **radiation therapy**. Wide local excision is a procedure in which the tumor and a small area of the surrounding healthy tissue are surgically removed. Since MCC is so aggressive, all patients are considered to be at high risk for recurrence and metastasis. For this reason, all patients will undergo radiation therapy of the lymph nodes near the site of the primary tumor that was removed. A technique called lymphoscintigraphy is used to determine the precise location of the lymph nodes that are most likely to be affected.

Treatment of stage II MCC is the same as for stage I MCC with the additional removal of the affected lymph nodes.

Treatment of stage III MCC is generally **chemotherapy**. But, because the number of known cases of MCC is relatively small, there is no generally prescribed chemotherapy regimen. It has been treated with **etoposide**, cisplatin, and **fluorouracil** with varying degrees of success.

The prognosis for patients affected with MCC is generally poor. Half will have a recurrence within two years and one-third will develop systemic involvement (stage III). The average time span from diagnosis of stage III MCC to death is eight months. The two-year survival rate for people affected with MCC is approximately 50%. Factors that improve the patient's length of survival include location of the tumor on the limbs rather than the face; localization of the disease; and female sex.

Alternative and complementary therapies

Naturopathic remedies believed by some to be beneficial in the prevention of skin cancers include regular cleansing by fasting, enema, or herbal supplements. Many naturopaths also recommend a daily scrubbing of the skin with a sauna brush prior to bathing to increase circulation.

KEY TERMS

Merkel cells—Specialized cells of the skin that are located at the base of some hairs. These cells are believed to function as touch receptors. They are named for a nineteenth-century German professor of anatomy.

Metastasis—The migration of a cancer from its primary location to another, distant location in the body.

Neoplasm—Any new and abnormal growth of a tissue.

QUESTIONS TO ASK THE DOCTOR

- What stage is my cancer in?
- How long will my radiation therapy treatments last after the tumor is removed?
- What are the possible side effects of the particular radiation or chemotherapy treatments that I will receive?
- How often should I continue to be checked for possible recurrence of MCC?

Vitamins A, C, and E, as well as zinc, are believed by some to be essential supplements to a high fiber diet in the prevention of skin damage. However, these remedies have not been proven effective in treating Merkel cell tumors. Traditional medical treatments which have succeeded include surgery, radiation therapy, chemotherapy, and rare success with stem cell transplant.

Coping with cancer treatment

The radiation therapy necessary for follow-up treatment after MCC tumor removal can become stressful for some patients. Additionally, most of these cancers occur in the head and neck region, and their removal can be very disfiguring. It is important that all patients receive adequate counseling and other psychological support prior to and during such treatments.

Clinical trials

In late 2003, the National Cancer Institute was conducting three phase II studies of treatments for Merkel cell carcinoma: a study of antineoplaston therapy for MCC; a study of imatinib mesylate, a drug that blocks enzymes necessary for tumor growth; and a study of oblimersen, a drug that blocks the production of a crucial protein in cancer cells.

Prevention

Because MCC is believed, at least in some cases, to be caused by long-term exposure to ultraviolet light, it may possibly prevented by avoiding sun exposure when possible and by wearing a PABA containing sunscreen daily.

Special concerns

MCC is very aggressive and can metastasize quickly. For these reasons, medical treatment needs to be sought quickly when MCC is suspected. Recurrence of MCC, either on the skin or in the lymph nodes or other bodily organs, is quite common. Therefore, it is extremely important that all MCC patients, even if they believe that they have no symptoms, have follow-up examinations monthly for at least two years after they have finished their initial radiation treatments.

Mesna

Definition

Mesna is a medicine that helps protect the inside lining of the bladder from damage due to certain **chemotherapy** drugs. Mesna may also be referred to as 2-mercaptoethane sulfonate, sodium salt, or Mesnex (its brand name).

Purpose

Mesna is a medicine that is approved by the Food and Drug Administration (FDA) for use in combination with the chemotherapy drug **ifosfamide** to protect the bladder lining from irritation due to the chemotherapy. It has also been shown useful in protecting the bladder lining when used in combination with large doses of the chemotherapy drug **cyclophosphamide**. Irritation to the bladder lining can cause bleeding and this is referred to as hemorrhagic cystitis. Mesna is not administered to treat cancer.

Description

Mesna is a clear, colorless solution with a foul odor. It is usually administered intravenously through a vein to prevent bleeding of the inside lining of the bladder. Sometimes it can be given to a patient to mix in a beverage and drink. When ifosfamide and cyclophosphamide are given, they break down in the body and form a poisonous substance called acrolein. Acrolein concentrates in the bladder and causes irritation that can lead to severe bleeding from the bladder into the urine. When mesna is administered it also concentrates in the bladder and combines with the toxic acrolein to form a nontoxic substance that is removed from the body by urinating.

Recommended dosage

Mesna is usually administered through a vein over at least five minutes. This same drug can also be mixed with a beverage and taken by mouth (flavored drinks like grape juice, cola, and chocolate milk are good choices to hide the taste of the mesna).

The mesna dose depends on the amount of chemotherapy drugs, ifosfamide or cyclophosphamide, that a patient receives. The mesna dose can vary with the time frame the chemotherapy drugs are being administered. The standard mesna dose is equal to 20% of the total ifosfamide dose given at three separate time intervals through a vein infused over at least five minutes. The first dose is right before the ifosfamide, often referred to as hour 0. The second dose is four hours after the start of the infusion and the third dose is eight hours after the start of the infusion. Mesna is given in this way each day the ifosfamide is administered.

Mesna can be given at a dose of 100% (the same dose as the ifosfamide) of the ifosfamide. This mesna would be mixed directly with the ifosfamide in the same intravenous infusion bag. This type of dosing may or may not have the patient receive a small dose of mesna right before or after the ifosfamide infusion.

Precautions

Mesna can cause allergic reactions that range from a mild rash to severe life-threatening, full-body allergic reactions. Patients with a known previous allergic reaction to mesna or thiol-like medicines should tell their doctor before receiving mesna.

Mesna that contains the preservative benzyl alcohol must not be used in premature babies or infants and must be used with caution in older children.

Mesna should prevent most bleeding from the bladder, however patients may be asked to check their urine for traces of blood with a chemical strip that is dipped into the urine sample.

Side effects

Side effects due only to the mesna are uncommon and difficult to determine since the drug is not given alone. However in clinical studies mesna has been known to cause nausea and vomiting, **diarrhea**, abdominal pain, and a bad taste in the mouth. Other reported side effects include; headache, fatigue, pain in arms and legs, drop in blood pressure, and allergic reactions.

All side effects a patient experiences should be reported to his or her doctor.

KEY TERMS

Acrolein—A breakdown product of the chemotherapy drugs ifosfamide and cyclophosphamide that concentrates in the bladder and irritates the bladder lining and causes bleeding.

Bladder—Organ in the body that collects urine from the kidneys.

Chemotherapy—Specific drugs used to treat cancer.

Food and Drug Administration—A government agency that oversees public safety in relation to drugs and medical devices. The FDA gives the approval to pharmaceutical companies for commercial marketing of their products.

Hemorrhagic cystitis—Irritation of the bladder lining that causes bleeding.

Nontoxic—Does not cause harm.

Interactions

Mesna can cause a false positive test of the urine for ketone bodies. This may be most important in diabetic patients who routinely check their urine for ketones.

Nancy J. Beaulieu, RPh.,BCOP

Mesothelioma

Definition

Mesothelioma is a rare form of cancer. In mesothelioma, malignant cells are found in the sac lining of the chest (the pleura) or the abdomen (the peritoneum). The majority of people with mesothelioma have a history of jobs that exposed them to asbestos, an insulation material.

Description

In the chest and abdominal cavities, as well as in the cavity around the heart (pericardial sac), there is a layer of specialized cells called mesothelial cells. These cells also surround the outer surface of most internal organs. These cells form tissue called mesothelium.

The mesothelium performs a protective function for the internal organs by producing a lubricating fluid that permits the organs to move around. For example, this fluid makes it easier for the lungs to move inside the chest while a person breathes. The mesothelium of the abdomen is known as the peritoneum, and the mesothelium of the chest is called the pleura. The pericardium refers to the mesothelium of the pericardial cavity.

There are three primary types of malignant mesotheliomas:

- Epithelioid. About 50% to 70% of mesotheliomas are of this type and have the best outlook for survival.
- Sarcomatoid. Approximately 7% to 20% of cases are of this type.
- Mixed/biphasic. From 20% to 35% of mesothelioma cases fall into this category.

Approximately three-fourths of all mesotheliomas begin in the chest cavity and are known as pleural mesotheliomas. Peritoneal mesotheliomas begin in the abdomen, and make up around 10% to 20% of all cases. Mesotheliomas arising in the cavity around the heart are quite rare.

Demographics

Mesothelioma is a fairly rare form of cancer. According to the American Cancer Society, there are an estimated 2,000 to 3,000 new cases per year of the disease in the United States, but this figure seems to be rising. This rising figure is related to the widespread use of asbestos from the 1940s to the end of the 1970s. European researchers studying the disease expect deaths from mesothelioma to peak around the year 2020 and then drop off, because asbestos use has been cut back greatly since the early 1980s.

The average age of a person with mesothelioma is 50 to 70 years old. It affects men three to five times more often than women and is less common in African-Americans than in Caucasian Americans.

Causes and symptoms

The primary risk factor for developing mesothelioma is asbestos exposure. In the past, asbestos was used as a very effective type of insulation. The use of this material, however, has been declining since the link between asbestos and mesothelioma has become known. It is thought that when the fibers of asbestos are inhaled, some of them reach the ends of the small airways and penetrate into the pleural lining. There the fibers may directly harm mesothelial cells and eventually cause mesothelioma. If the fibers are swallowed, they can reach the abdominal cavity, where they can contribute to the formation of peritoneal mesothelioma.

Exposure to certain types of radiation as well as to a chemical related to asbestos known as zeolite has also been related to incidences of mesothelioma.

The early symptoms of mesothelioma are often ignored, because they may be caused by a variety of ailments. These symptoms include:

- pain in the lower back or at the side of the chest
- shortness of breath
- difficulty swallowing
- cough
- fever
- fatigue
- abdominal pain, **weight loss**, and **nausea and vomiting** (symptoms of peritoneal mesothelioma)

Diagnosis

A doctor should be seen if a person experiences shortness of breath, chest pain, or pain or swelling in the abdomen. If these symptoms are present, the doctor may order an **x ray** of the abdomen or chest. The doctor will do a complete physical examination and take a thorough medical history. Then, one or more of the following methods may be used to ascertain whether mesothelioma is present.

- Imaging tests. These tests may include x rays, **computed tomography** (CT scans), or **magnetic resonance imaging** (MRI) to allow the doctor to visualize the area in question. These studies will help determine the location, size, and extent of the cancer.
- **Pleural biopsy**. Diagnosing mesothelioma requires an adequate **biopsy** specimen. However, because mesothelioma usually arises from the lower part of the diaphragmatic and/or parietal pleura, obtaining enough tissue may be difficult. A simple, or closed, pleural biopsy involves the insertion of a needle into the chest cavity to obtain tissue from the pleural membrane for analysis. This technique is minimally invasive and normally requires only local anesthesia. This technique, however, may not provide adequate material for the necessary stains of the tissue to make a diagnosis of mesothelioma. Moreover, since the biopsy is not done under direct vision, the sample may not be exactly in the area of the tumor. If the diagnosis cannot be made with this relatively noninvasive technique, an adequate tissue sample usually can be obtained via an open pleural biopsy. In this approach, a surgeon makes an incision on the patient's side and goes into the pleural space. This method allows maximum exploration of the pleural membranes as well. However, the technique requires general anesthesia.
- **Thoracoscopy**. A thoracoscopy, which is a relatively new technique, allows the doctor to look directly into the chest (pleural) cavity at the tumor and during the same operation to also take a tissue sample for laboratory analysis. The thoracoscopy is performed by making a small incision into the chest and using a tiny video camera to inspect the region. The doctor can then use forceps to obtain a tissue biopsy. A **laparoscopy**, a similar operation, is used to obtain a biopsy of a peritoneal tumor.
- **Bronchoscopy**. A bronchoscopy, which examines the airways, or a **mediastinoscopy**, which looks at the lymph nodes in the chest, allows the doctor to look at the area using a lighted tube. Samples may be taken with a needle and sent to the lab to find out if cancer cells are present. However, bronchoscopy and mediastinoscopy are not that effective for diagnosing mesothelioma, as the disease is seldom found within the airways or the lymph nodes.
- Surgery. This lets the doctor obtain a larger tumor sample or, on occasion, the entire tumor.

Diagnosing mesothelioma is often difficult, even with tissue biopsies. Microscopically, mesothelioma is often difficult to distinguish from several other forms of cancer. For this reason, certain laboratory tests are performed to help correctly diagnose mesothelioma. Some of these tests involve using antibodies to distinguish lung cancer from mesothelioma. Sometimes the tissue samples must be viewed under an electron microscope in order to get the correct diagnosis.

Treatment team

A person with symptoms of mesothelioma will most likely seek help from a primary physician initially. During the diagnostic phase, various technicians will perform the **imaging studies**. A specially trained physician—a thoracic surgeon or, rarely, a pulmonologist—performs other diagnostic tests like pleural biopsy and thoracoscopy. A pathologist will view the tissue samples and make the tissue diagnosis. Following diagnosis, the patient will be offered some form of treatment, which may entail surgery, **radiation therapy**, **chemotherapy**, or a combination of these. The patient may receive care from a thoracic surgeon, an anesthesiologist, medical and radiation oncologists, and specially trained nurses who administer chemotherapy.

Clinical staging, treatments, and prognosis

The treatment and outlook for those with mesothelioma depends a great deal on the stage of their cancer. Because the most frequently occurring type of mesothelioma is pleural, and it is also the one most studied, it is

the only type for which a staging system exists. The following stages are based on a system known as the Butchart system, which divides mesothelioma into four stages:

- Stage I: Mesothelioma is found within the right or the left pleura and may also involve the lung, the pericardium, or the diaphragm on the same side.
- Stage II: In this stage, mesothelioma has spread to the chest wall or involves the esophagus, the heart, or the pleura on both sides. The lymph nodes in the chest may be involved as well.
- Stage III: Mesothelioma has gone through the diaphragm and into the lining of the abdominal cavity. Additional lymph nodes besides those in the chest may be involved.
- Stage IV: There is evidence that mesothelioma has spread through the bloodstream to distant organs or tissues.

Another system of staging mesothelioma is based on a TNM system (T=tumor, N=spread to lymph nodes, and M=metastasis). There are minor differences between this and the Butchart system. It is more detailed and precise, but the original Butchart system is still the one most often used to describe pleural mesotheliomas.

There are treatments available for all patients with malignant mesothelioma. The three kinds of treatment used are surgery, radiation therapy, and chemotherapy.

Surgery is a common treatment for mesothelioma. It is not an option unless the cancer is limited to one place and unless the person can withstand the surgery. During surgery, the physician may remove a portion of the lining of the chest (pleurectomy) or abdomen (peritonectomy) and some of the tissue surrounding it. Depending on the extent the disease has spread, a lung may also require removal (extrapleural **pneumonectomy**). Occasionally, a portion of the diaphragm is taken out as well. If treatment is not possible, other less invasive measures can be used to relieve the patient's symptoms. For example, a needle placed into the chest cavity (**thoracentesis**) can remove excess fluid in the chest. If recurrence of fluid causes symptoms, a nonsurgical or surgical method can be used to scar the lining of lung cavity and cause it to adhere to the lung. The procedure obliterates the pleural space and thus prevents the fluid from reaccumulating. (This procedure is called sclerosis or sclerotherapy.) These methods are called palliative, for they are not meant to cure the cancer but to improve symptoms.

Radiation therapy uses high-energy x rays to kill cancer cells and cause tumor shrinkage. It is rarely used as the primary treatment for pleural mesothelioma in those patients for whom surgery is not an option. It may also be used as an adjunct to surgery or as a method of alleviating various symptoms like trouble with swallowing, pain, and shortness of breath.

Chemotherapy involves the use of drugs to kill cancer cells. The most commonly used drugs are **doxorubicin**, **cisplatin**, and **methotrexate**. The medicines are delivered into a vein or taken by mouth. In the treatment of mesothelioma, they may also be injected directly into the chest or abdominal cavity. Chemotherapy may be given as the main treatment or may be an addition to surgery, depending on the type and stage of the cancer.

A new treatment being studied for early stages of mesothelioma confined to the chest is called intraoperative photodynamic therapy. This treatment uses special drugs that make cancer cells more sensitive to killing by a laser light. The drugs are given several days before surgery. During surgery, the special light is used to shine on the pleura.

By the time symptoms show up and mesothelioma is diagnosed, the disease is often advanced. The average survival period after diagnosis is about one year. If the cancer is found before it has spread and it is treated aggressively, about half of the patients will live two years, and approximately 20% will survive five years.

Alternative and complementary therapies

There are no proven effective alternative therapies for mesothelioma. Because the prognosis is often poor, many patients may be interested in trying other avenues of treat-

KEY TERMS

Asbestos—A group of naturally occurring fibrous minerals, found in soil and rocks around the world. These minerals are composed of magnesium, silicon, and other elements. Asbestos has been used as an insulating material since ancient times. Exposure to asbestos dust is the primary risk factor for developing mesothelioma.

ment. Patients should first consult with their physicians prior to trying any of these methods. There are many well-studied complementary treatments that may increase a patient's comfort and sense of well-being. These may include meditation to aid in relaxation, massage to decrease pain, and guided imagery to help prevent nausea.

Coping with cancer treatment

Coping with cancer treatment can be difficult and exhausting. It can be very helpful for the patient receiving therapy for mesothelioma to find a group of family and friends who can aid with household responsibilities, provide transportation, and give psychological support. The patient should not feel a need to rush back to normal activities after treatment is completed.

Clinical trials

A great deal of research is being performed in the area of mesothelioma. Much of the research is focused on finding out how asbestos changes the mesothelial cells to cause these cancers. In addition, new combinations of treatments are being tested, along with gene therapy. A variety of **clinical trials** are testing new chemotherapy drugs and immunotherapy. Some of these treatments use hormonelike substances called interleukins and **interferons** that activate the immune system.

Prevention

The best method of preventing mesothelioma is to avoid or limit exposure to asbestos. People who might experience asbestos exposure at work include miners, insulation manufacturers, construction workers, ship builders, and factory workers.

Special concerns

Mesothelioma is a serious disease with a poor long-term prognosis. Patients with this cancer should communicate their wishes regarding treatment to their family and physicians.

QUESTIONS TO ASK THE DOCTOR

- What type of mesothelioma do I have?
- Has my cancer spread beyond the primary site?
- What stage is my cancer in? What treatment options are there?
- What is my prognosis?
- Are there experimental therapies I may benefit from? Where are they being performed?

Metastasis

Definition

The ability to invade and metastasize are the defining characteristics of a cancer. Invasion refers to the ability of cancer cells to penetrate through the membranes that separate them from healthy tissues and blood vessels. Metastasis can refer either to the spread of cancer cells to other parts of the body, or to the condition produced by this spread. The English word metastasis (plural, metastases) comes from a Greek word that means "a change." The tumors produced by metastasis sometimes are called secondary tumors. metastasis is responsible for 90% of the deaths caused by cancer.

Description

Metastasis is a complex multi-step process that begins with changes in the genetic material of a cell (**carcinogenesis**) followed by the uncontrolled multiplication of altered cells. It continues with the development of

a new blood supply for the tumor (angiogenesis), invasion of the circulatory system, dispersal of small clumps of tumor cells to other organs or parts of the body, and the growth of secondary tumors in those sites.

Carcinogenesis and genetic mutations

The first step in cancer development is a change or mutation of the DNA in the chromosomes of a cell. Mutations can be triggered by a number of different factors, including:

- Environmental carcinogens. Ultraviolet radiation from the sun is known to cause skin cancer. Chemical carcinogens include tobacco smoke, asbestos, and benzene. Ionizing radiation from x-ray therapy or atomic fallout, or industrial exposure to uranium or thorium are also associated with an increased risk of cancer.
- Viruses. Infection by a virus containing an oncogene is known to cause cancer in experimental animals. In humans, such viruses as human immunodeficiency virus (HIV), human papillomavirus (HPV), hepatitis B or C viruses, and **Epstein-Barr virus** (EBV) have been linked to **Kaposi's sarcoma**, **anal cancer**, certain types of **lymphoma**, primary liver cancer, and cancers of the genitals.
- Chronic irritation and inflammation. Chronic irritation of the skin, or chronic inflammation of the bladder or bile ducts caused by certain intestinal parasites, have been linked to cancers of the skin, bladder, or pancreas.
- Chromosomal rearrangement or damage. Oncogenes are genes found in the chromosomes of tumor cells. Activation of oncogenes is associated with the conversion of normal cells into cancer cells. Oncogenes sometimes are activated by chromosomal rearrangements. The so-called Philadelphia chromosome, an abnormality that involves a transposition of genetic material between the long arms of human chromosomes 9 and 22, is found in about 80% of patients with chronic myelocytic leukemia.
- Loss of tumor suppressor genes. Another type of genetic alteration that can lead to cancer is the inactivation of anti-oncogenes, or tumor suppressor genes. Under normal circumstances, tumor suppressor genes act like a brake on cell growth and division. If these genes are altered or lost, oncogenes can stimulate cells to multiply uncontrollably without any opposition. In colorectal cancer, deletion of the DCC gene, which is a tumor suppressor gene located on the long arm of human chromosome 18, lowers the patient's chances of five-year survival by 30%.

Other mutations in a cell's DNA occur for reasons that are not yet fully understood.

Steps in the development of metastases

Cell alteration and replication

Most cancer cells originate within the epithelium, which is a layer of tissue that covers body surfaces and lines the inner surfaces of body cavities and blood vessels. Cancer cells in epithelial tissue are known to be genetically unstable and to have a high mutation rate. Most cancers, in fact, are the end result of multiple genetic alterations both in oncogenes and tumor suppressor genes. The activation of oncogenes is accompanied by the loss or deactivation of tumor suppressor genes, which means that one of the body's normal lines of defense against uncontrolled cell proliferation is disabled just when it is most needed.

Following these alterations in its genetic material, the cell replicates, or copies itself at a faster rate. In some instances, a mutation prevents the cell's apoptosis, or programmed self-destruction. Apoptosis, which is also sometimes called "cell suicide," normally occurs when a cell recognizes some damage to its DNA and dies. The protein produced by the p53 gene ordinarily encourages apoptosis in cells with defective DNA, but these cells are more likely to survive and replicate if the p53 gene has been altered or deactivated.

Breaking through the basement membrane

Once a cancer develops, the first stage in the development of metastasis is the tumor's penetration of the basement membrane, which separates epithelial tissue from underlying connective tissue. The basement membrane is a specialized layer of extracellular matrix, which is a mass of connective tissue fibers and proteins that support and nourish the body's connective tissues. Under normal circumstances, the extracellular matrix is a barrier that keeps cells from moving away from their sites of origin. Cancer cells, however, secrete several different types of enzymes that digest the proteins in the basement membrane. When the membrane has been sufficiently weakened, the tumor can push through it.

Angiogenesis

Angiogenesis is the process in which a tumor creates its own blood supply by releasing growth factors—particularly a substance called vascular endothelial growth factor, or VEGF—that attract vascular cells that begin to migrate toward the tumor. The vascular cells eventually form new blood vessels within the tumor. Angiogenesis is sometimes called vascularization, which means blood vessel formation. Angiogenesis is a significant step in the development of metastasis for two reasons: the formation of blood vessels in

the tumor supplies the tumor with nutrients that speed up its growth; these vessels also provide pathways for cancer cells to travel from the primary tumor to other organs. A similar process of vessel formation involves the lymph system.

Angiogenesis may occur at about the same time that the tumor breaks through the basement membrane, but it can also take place at an earlier point in the tumor's growth.

Invasion and embolization

After the tumor's new blood vessels have formed, individual cancer cells break off from the tumor and travel through these new vessels into the body's main circulatory system. These cells are sometimes called micrometastases. Even a small tumor can shed as many as a million cancer cells each day into the blood and lymph vessels. Most of these cells die soon after entering the blood stream or lymph vessels. Sometimes, however, the cancer cells may travel as small clumps of cells called emboli. A protein called fibrin, which ordinarily is formed when blood clots, surrounds each embolus. The fibrin appears to protect the embolus of cancer cells as it moves through the circulatory system, and may increase its chances for survival when it arrives in the capillaries (small blood vessels) that supply another organ or area of the body.

Extravasation and formation of secondary tumors

Extravasation refers to the cancer cell's breaking out through the wall of the capillary where it has been stopped and invading the tissue around the capillary. In order to extravasate, the tumor cell must attach itself to the wall of the capillary. Once it has attached itself, it can work its way through the tissue lining the blood vessel, the vessel wall itself, and the basement membrane covering the blood vessel. The tumor cell can then begin to replicate itself and start the process of angiogenesis, thus forming a metastasis or secondary tumor in its new location. The secondary tumor can eventually release its own cancer cells into the circulation and produce further metastases.

Most tumor cells do not survive in the blood stream long enough to extravasate and form metastases. The longer the cells are in the circulation, the more likely they are to die. The chances of a given tumor cell's surviving the journey and forming a metastasis in its new site have been variously estimated as one in 10,000 or as less than one in one million. Researchers have asked whether the tumor cells that do produce metastases are random survivors or whether they have special capacities for survival and reproduction. Recent studies indicate that cells from the same tumor vary in their metastatic potential; those that eventually form metastases have a higher degree of malignancy.

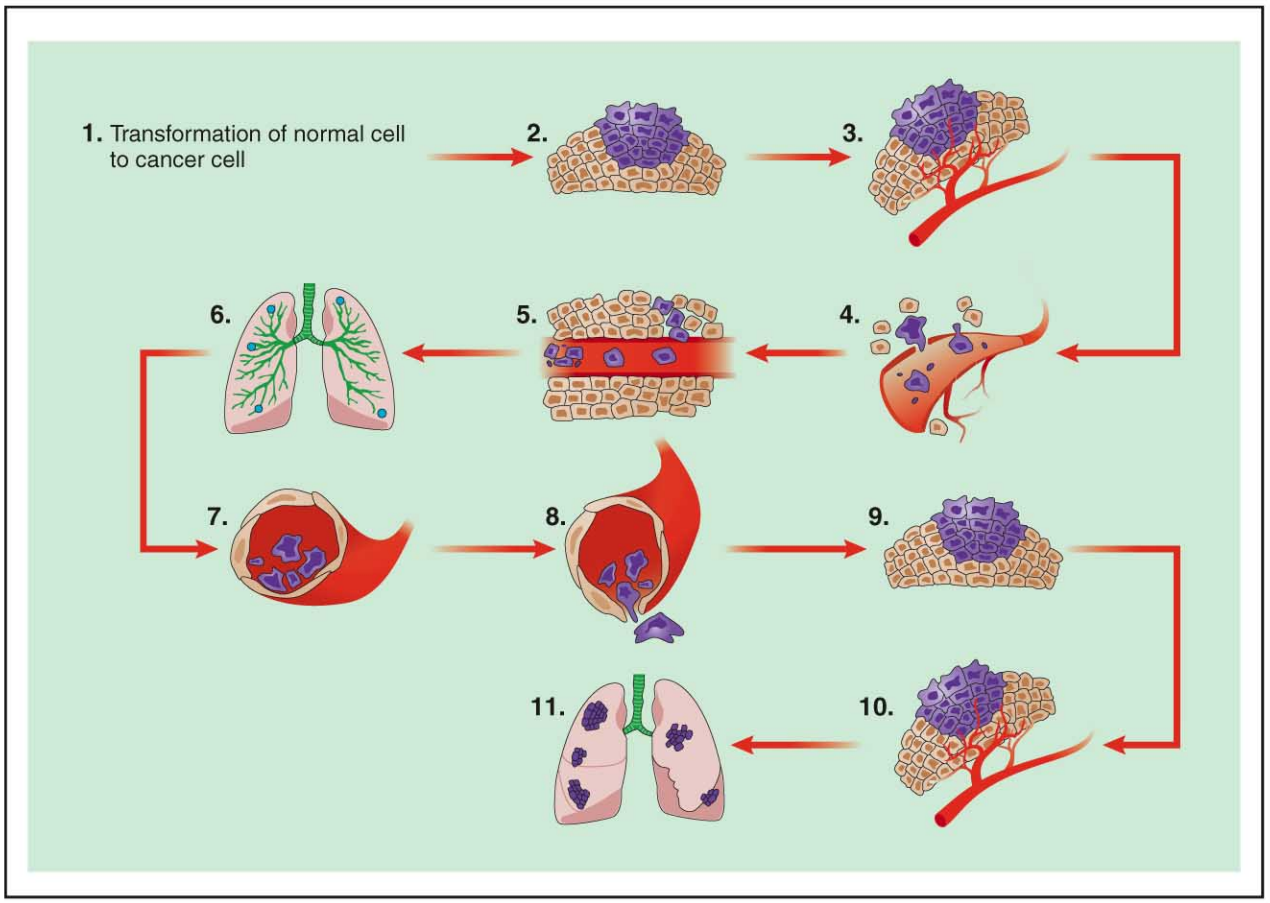
Diagnosis and monitoring of metastases

Some primary cancers, such as lung and ovarian cancers, begin to shed tumor cells that form metastases elsewhere in the body before the primary cancer is large enough to be detected by standard diagnostic techniques. Marker molecules that are given off by micrometastases circulating in the bloodstream can now be detected.

Tumor markers are substances produced either by tumors themselves or by the body in response to a tumor. The blood levels of tumor markers can be used to evaluate the recurrence or spread of cancer and the patient's response to treatment. Some commonly used tumor markers include: prostate-specific antigen (PSA) for **prostate cancer**; prostatic acid phosphatase (PAP) for prostate cancer that has metastasized, **testicular cancer** and leukemia; and CA 125 (Cancer antigen 125) for recurrence of **ovarian cancer**. It also detects cancers of the uterus, liver, pancreas, colon, cervix, lung, and digestive tract, as well as several others.

DNA analysis can be used to distinguish metastatic tumors from multicentric tumors. A multicentric cancer is one that appears simultaneously in several different



(1) A cell is transformed. (2) Cancerous cell proliferates and cells pile up to form a malignant tumor. (3) Angiogenesis: the tumor acquires a blood supply, which also allows (4) the cancer cells access into the circulatory system. (5) Cancer cells travel through the blood stream. (6) The cells stop in a capillary bed, and (7) adhere to the layer of cells that line the blood vessel. (8) The cells invade the essential, functional tissue of the organ surrounding the blood vessel. (9) In this new organ, cancer cells pile up to form secondary tumors, which (10) induce angiogenesis. (11) Metastases (secondary tumors) are now evident. *(Illustration by Argosy Publishing.)*

parts of the body, as distinct from cancers with primary and secondary (metastatic) tumors. Mutations in the p53 tumor suppressor gene have been used as "genetic fingerprints" to identify differences between multicentric and metastatic tumors.

Specific types of metastases

Brain

SYMPTOMS Metastatic tumors to the brain usually come to the doctor's attention in the same way as primary tumors—they cause increased pressure inside the head, disturbances of brain functions, or both. Common symptoms of brain metastases include headaches, seizures, loss of sensation or balance, or personality changes.

SOURCES The most common source of brain metastases is primary cancer of the lung. Other primary sources include malignant melanomas and cancers of the breast, kidney, or digestive tract.

DIAGNOSIS Secondary brain tumors are usually detected on (**computed tomography**) (CT) scans or (**magnetic resonance imaging**) (MRI) studies.

TREATMENT If the patient has only one secondary tumor in the brain, it is sometimes possible to remove it surgically and then treat with radiation. Otherwise, radiation is used by itself to treat the tumors. Steroids may be given to reduce or lower swelling of the brain, treating the headaches and other symptoms. **Chemotherapy** has only a limited role in treating brain metastases, because most chemotherapy drugs cannot cross the blood-brain barrier. However, intrathecal chemotherapy (chemotherapy drugs injected directly into the spinal fluid) can have a role in treating brain metastases. Patients with multiple metastases in the brain or widespread cancer elsewhere in the body have a poor prognosis. Treatments that are

still under evaluation include laser-assisted surgery and biological response modifiers.

Bone

SYMPTOMS Primary bone cancers are less common than bone metastases. Bone metastases, in fact, are a common cause of pain in many patients with late-stage cancer. Metastases in the spine can compress the spinal cord and damage the nervous system. Bone metastases also make bones more prone to fracture.

SOURCES Breast, lung, and prostate cancer are responsible for about 80% of bone metastases; over half of patients with these three types of primary cancer will develop bone metastases. Patients with lung cancer that has metastasized to bone live on average less than six months, but breast and prostate cancer patients may have lengthy periods of survival with bone metastases.

Bone metastases usually are caused by tumor cells carried through the bloodstream, and are typically multiple. About 70% of bone metastases occur in the ribs, spine, sacrum (lowest portion of spine, attached to pelvis), or head; most of the remainder occur in the long bones of the body.

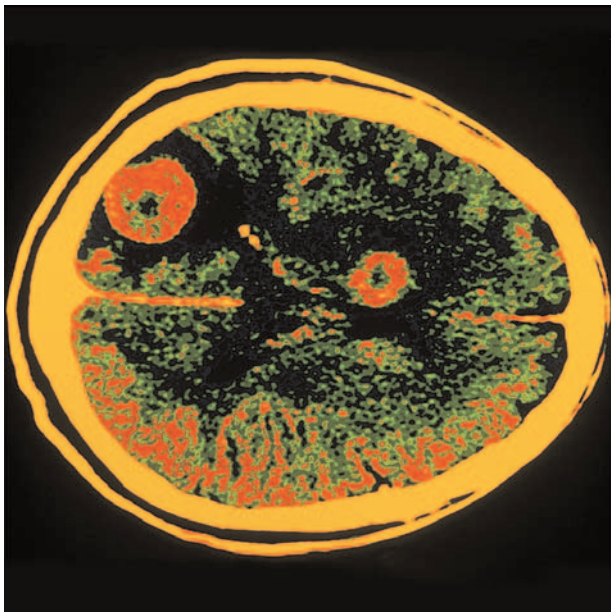
DIAGNOSIS Bone metastases usually are detected by bone scans, CT scans, or MRIs, and confirmed by a **biopsy**. In 2003, reports showed that positron emission tomography (PET) scans were effective in detecting certain types of bone mestasteses from lung and breast cancer and from lymphoma.

TREATMENT Bone metastases are treated with hormonal or systemic chemotherapy and/or **radiation therapy**. Metastases in the spine may require surgical removal of part of the vertebrae (laminectomy) followed by radiation treatment to prevent compression of the spinal cord. Surgery also may be performed if there is a risk of fracture.

As of May 2001, two new drugs show promise as treatments for bone metastases. One is a generic drug called clodronate, which is taken by mouth, and the other is a medication called Atrasentan. Atrasentan was tested on patients in advanced stages of bone metastases who were no longer responding to other forms of treatment.

Lung

SOURCES Metastatic tumors in the lungs may result either from primary cancer of the lung or from malignancies elsewhere in the body that spread to the lungs through the circulatory system or by direct extension. The incidence of metastatic cancer to the lung is six in 100,000 people. Almost any type of cancer can metastasize to the lung, but the most common tumors that spread to the lung are **breast cancer**, **sarcomas**, non-Hodgkin's lymphoma, **neuroblastoma**, and **Wilms' tumor**. Between 20% and 54% of patients dying of cancer are found to have metastases in the lungs.



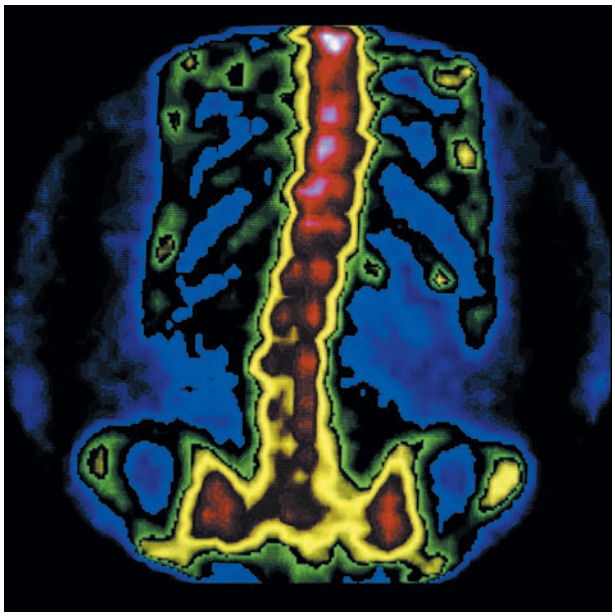
Computed tomography (CT) scan of 47-year-old female's brain showing adenocarcinoma of lung metastatic to brain. *(Copyright Scott/Brian Carmazine, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

DIAGNOSIS Diagnosis is usually the appearance of a group of masses on a chest **x ray**. Evaluation of lung metastases is first directed at diagnosing/locating the primary tumor.

TREATMENT Secondary lung cancers are treated primarily by appropriate systemic therapy for the primary tumor. Surgery for secondary lung tumors may be beneficial if there are four or less metastases. Surgical removal of tumors metastatic to the lung is usually performed only if: the primary tumor is treatable, all metastases can be removed, chemotherapy or other nonsurgical approaches cannot be used, and if there are no metastases elsewhere in the patient's body. If the primary cancer is a malignant **melanoma** and there is only one secondary tumor, surgery may be an option. (Surgery is usually not performed if the primary cancer is a malignant melanoma and there is more than one secondary tumor.) The five-year survival rate for surgical treatment of secondary tumors to the lung is 20%-35%.

Liver

The most common form of liver cancer is metastatic; in fact, metastases in the liver are often the first



False-color scintigram (bone scan) of the human spine and ribs, revealing secondary cancers (metastases) in the vertebrae (backbones), arising from a primary cancer of the prostate gland. *(Copyright CNRI, Science Source/ Photo Researchers, Inc. Reproduced by permission.)*

noticeable evidence of a primary cancer located elsewhere in the body. In the liver, finding multiple metastases is more common than finding a single tumor. The liver's important role within the circulatory system makes it a common stopping point for tumor emboli carried in the blood from other organs.

SOURCES The most common sites of primary tumors that metastasize to the liver are the lungs, breasts, colon, pancreas, and stomach.

DIAGNOSIS The diagnosis of metastatic liver cancer is usually difficult unless the patient's primary tumor is in advanced stages of disease. Ultrasound, CT scans, and liver function tests are used to screen patients with a known cancer for metastases in the liver, but the results are not fully reliable. A definitive diagnosis depends on biopsy of liver tissue.

TREATMENT Metastatic cancer to the liver is considered incurable. Systemic chemotherapy may temporarily shrink tumors in the liver and extend the patient's life span but does not cure the cancer. Radiation treatment may relieve pain but is not otherwise helpful. Some doctors may recommend surgical removal of liver metastases, particularly if the primary tumor is in the colon and there is a solitary metastasis, but others do not favor this approach. The five-year survival rate for surgical removal of liver metastases is 20%-30%.

Metastatic cancers of unknown primary origin

Between 0.5% and 7% of all cancers are carcinomas of unknown primary origin, or CUPs. The patient's history and physical examination should be analyzed for signs of breast, prostate, pelvic, rectal, and **gastrointestinal cancers**. The pattern of spread of a CUP may indicate whether the primary tumor is above or below the diaphragm; lung metastases are twice as common with primary tumors found to be above the diaphragm, while liver metastases are more common if the **primary site** is below the diaphragm.

Metastases of unknown primary origin are usually treated by chemotherapy—either cisplatin/carboplatin, **doxorubicin** or **paclitaxel**. In most cases, the patient's prognosis is poor; the average length of survival is three to four months, with fewer than 10% of patients surviving five years. Male sex and involvement of the liver are negative factors in the prognosis.

Treatment

Surgery

Surgery as a method of cancer treatment has limitations in the therapy of metastatic cancer. It is sometimes used to remove large secondary tumors that are causing pain or interfering with body functions. It also may offer a survival advantage over other therapies, as with limited metastases to the lung or liver.

Chemotherapy

Chemotherapy is frequently used to treat micrometastases that have entered the patient's bloodstream or lymphatic system. Systemic chemotherapy is the only type of treatment that can act at multiple sites simultaneously. Because of some chemotherapy drugs' side effects and risks (for example, **nausea and vomiting**, some drugs are implicated in causing some cancers), the likelihood of tumor responsiveness needs to be balanced with the patient's quality of life when selecting chemotherapy.

Radiation

Radiation therapy can be effective in the treatment of metastatic disease, especially for metastases to the brain and bones. It is limited, however, because it treats only a limited area. One complication that is possible with radiation therapy is that it has been associated with an increased rate of secondary cancers in patients who have been previously treated for malignancies. The risk is particularly high in patients who were treated with a combination of radiation and chemotherapy.

KEY TERMS

Angiogenesis—The process of forming new blood vessels that supply a tumor with nutrients and help to carry tumor emboli into the larger vessels of the circulatory system.

Apoptosis—The programmed self-destruction of a cell, which takes place when the cell detects some damage to its DNA. Apoptosis is sometimes called "cell suicide."

Basement membrane—A specialized layer of extracellular matrix that separates epithelial tissue from underlying connective tissue. Cancer cells must break through the basement membrane in order to migrate to other parts of the body and form metastases.

Embolus (plural, emboli)—A clump of tumor cells that breaks off from a primary tumor to travel through the circulatory system and lodge in a capillary in another part of the body. The process of forming emboli is called embolization.

Epithelium—The layer of tissue that covers body surfaces and lines the internal surfaces of body cavities, blood vessels, and hollow organs. Most cancer cells arise within epithelial tissue.

Extracellular matrix—A collection of connective tissue proteins and fibers that supports and nourishes body tissues. The extracellular matrix forms a physical barrier to the movement of tumor cells.

Extravasation—The process of reverse invasion in which tumor cells that have invaded the blood vessels and traveled to other organs force their way back out of the blood vessels and into the tissues surrounding their new site.

Micrometastasis (plural, micrometastases)—A term sometimes used to describe malignant tumor cells circulating in the blood or other metastases too small to be detected by a standard clinical examination.

Multicentric—A type of cancer that appears at several different sites in the patient's body simultaneously.

Oncogene—Any gene that is a factor in triggering the development of cancer. Oncogenes are mutated forms of proto-oncogenes, which are genes that promote the normal process of cell growth and division.

Replication—The process in which a cell duplicates or copies itself.

Tumor markers—Substances that occur in the blood, urine, or tissues of patients with certain types of cancer. Tumor markers may be produced either by the tumor itself or by the body in response to the tumor.

Tumor necrosis factor (TNF)—A protein that destroys cells showing abnormally rapid growth. TNF is used in immunotherapy to shrink tumors rapidly.

Tumor suppressor gene—A gene that encodes proteins that inhibit cell division and replication. Tumor suppressor genes are damaged or inactive in many types of cancer cells.

Vascular endothelial growth factor (VEGF)—A substance released by tumor cells that attracts vascular (blood vessel) cells to the tumor. The vascular cells then form new blood vessels within the tumor.

Vascularization—Another name for angiogenesis.

Immunotherapy

Immunotherapy, or immunologic therapy, is a modality, or method, of cancer treatment that is still in its experimental stages. It mobilizes the patient's own immune system to fight cancer cells. Immunotherapy is being evaluated in the treatment of metastatic melanoma, renal cell **carcinoma**, breast tumors, and other tumors. Some of the substances that are being tested in **clinical trials** are produced by the human body, while others are made in laboratories. The major categories of substances used in immunotherapy include:

- **Interferons**. Interferons are proteins produced by virus-infected cells that limit further reproduction of the virus and stimulate resistance to the infection.
- Interleukins. Interleukins are small proteins that promote the growth and activation of the body's white cells. Interleukin-2, known as IL-2 or **aldesleukin**, is approved for the treatment of metastatic melanoma and renal cell carcinoma.
- Tumor necrosis factor (TNF). TNF is a protein that was discovered in 1975. It destroys cells that show unusually rapid growth and stimulates the production of interleukins.

- **Monoclonal antibodies**. Monoclonal antibodies are antibodies produced in laboratory-grown cell clones in order to achieve greater abundance and uniformity than are found in antibodies produced in the body.
- **Vaccines**. Cancer vaccines are intended to stimulate the body's killer T cells (a specialized type of white blood cell) to attack tumor cells. Some vaccines being tested are made from relatively rare white blood cells called dendritic cells; others are made from genetically altered tumor cells.

Newer therapies for metastatic cancer

Recent advances in understanding the process of metastasis have led to some new approaches to treatment.

GENE THERAPY Some researchers are investigating ways to replace a mutated p53 tumor suppressor gene, or to inhibit an activated *ras* oncogene. Another approach involves the use of **angiogenesis inhibitors** to suppress metastatic tumors. An antibody to VEGF, called anti-VEGF, is presently being used in clinical trials for patients with late-stage colon, breast, and lung cancers. A second angiogenesis inhibitor that is being tested is endostatin.

Other researchers are studying substances that trigger apoptosis in defective cells or prevent the uncontrolled multiplication of tumor cells.

ISOLATED PERFUSION Isolated perfusion is the treatment of metastatic melanoma and sarcoma to the extremities by isolating the vasculature (blood vessels) of the affected extremity, and then delivering high doses of chemotherapeutic drugs directly to the area of metastatic disease. The limb is then flushed before re-establishing circulation. With this technique, it becomes possible to deliver doses of drugs regionally that would otherwise be very toxic or lethal if delivered systemically.

HYPERTHERMIA **Hyperthermia** is the use of therapeutic heat to treat cancers on and inside the body. The goal of hyperthermia is to shrink and destroy cancer without harming noncancerous cells. The treatment can be delivered directly to the tumor, to an area of the body, or to the whole body. Research has established that the effectiveness of some forms of radiation therapy and chemotherapy are enhanced when combined with hyperthermia. In 2001, the American Cancer Society acknowledged that hyperthermia could the cells of some cancers more responsive to treatment, but still considered the treatment experimental, especially in whole-body form. The National Institutes of Health are sponsoring ongoing clinical trials studying hyperthermia. Patients with extensive metastasis may not be good candidates for hyperthermia.

Alternative and complementary therapies

The National Center for Complementary and Alternative Medicine (NCCAM) is sponsoring new as well as ongoing trials of alternative treatments for metastatic cancer. One ongoing trial involves **PC-SPES**, a combination of eight Chinese herbs that is used to treat prostate cancer. Other trials are evaluating the use of herbal remedies to treat the side effects of chemotherapy. The National Cancer Institute (NCI) makes information about ongoing clinical trials available. Patients can contact the NCI or the NCCAM at the numbers and web sites listed below.

Methadone *see* **Opioids**

Methotrexate

Definition

Methotrexate is a **folic acid** derivative that interferes with folic acid metabolism (folate antagonist). It is a cytotoxic agent (a chemical that is directly toxic to cells) with multiple characteristics and may be described as an antimetabolite, antineoplastic, and immunosuppressant. In the United States, methotrexate is also recognized by the trade names Folex and Mexate, or the generic name amethopterin.

Purpose

Methotrexate is administered to cancer patients diagnosed with various malignancies. These conditions may include **breast cancer**, lung cancer, non-metastatic bone cancer, cancers associated with the head and neck, **acute lymphocytic leukemia**, meningeal leukemia, advanced **non-Hodgkin's lymphomas**, and uterine tumors. Certain other cancers may be treated with methotrexate as prescribed by the oncologist.

Description

Methotrexate was granted FDA approval in 1986. Methotrexate is a highly effective chemical compound that targets a specific enzyme required by cells for normal function. When this enzyme activity is blocked by methotrexate, certain processes within the cell are shut down and cell death results. The growth of some normal cells may be affected by methotrexate. However, because this is a process associated with actively dividing cells, the accelerated rate at which cancer cells grow and divide make them more susceptible to the effects of methotrexate. Methotrexate may be given as a single agent, often followed by **leucovorin** rescue. Methotrexate may also be administered in a combination regimen with steroids to produce and maintain rapid remission of certain cancers or as part of an adjuvant therapy regimen with **doxorubicin**, **cisplatin**, or the BCD combination of **bleomycin**, **cyclophosphamide**, and **dactinomycin**.

Recommended dosage

Methotrexate is available is both injectable and tablet form. The injectable form may be given intravenously (IV), intramuscularly (IM), or intrathecal (directly into the spinal fluid). The dose amount varies over a wide range for patients receiving methotrexate. The final dose and treatment cycle will be determined by the oncologist based on what the medication is being used for, what cancer type is being treated, whether methotrexate is being used as a single agent or in concert with other anticancer drugs, and the method by which the medication is being administered. It is extremely important to take methotrexate in the correct timetable prescribed by the oncologist. If a dose is missed, the patient should not take the missed dose at a later time, or double the next prescribed dose. Rather, the patient should maintain the schedule prescribed and notify the oncologist about the missed dose.

Precautions

To maximize treatment effects, patients receiving methotrexate should observe certain guidelines. Including any modifications given by the oncologist, these guidelines should include regular visits with the oncologist and laboratory testing for white blood cell count, kidney, liver, and bone marrow function. Avoid any immunizations not approved or prescribed by the oncologist. Avoid contact with individuals taking or that have recently taken oral polio vaccine, or individuals that have an active infection. When necessary wear a protective facemask. Avoid prolonged or direct exposure to sunlight, as some patients experience an increased sensitivity. Ask for specific instructions on oral hygiene procedures to reduce the risk of gum abrasion, and avoid touching the eye and nasal areas unless hands have been properly washed immediately prior to contact. To reduce bleeding and bruising complications, patients should exercise extreme caution when handling sharp instruments and decline participation in contact sports. Prior to treatment, the patient's medical history should be

KEY TERMS

Antimetabolite—Anti-cancer drugs which prevent cells from growing and dividing by blocking the chemical reactions required in the cell to produce DNA.

Antineoplastic—Agents that inhibit or prevent the development of cancers by stopping the maturation and proliferation of malignant cells.

BCD—The combined chemotherapy treatment of bleomycin, cyclophosphamide, and dactinomycin.

Cytotoxic—Chemicals that are toxic to cells, and prevent their reproduction or growth.

Hodgkin's lymphoma—A human malignant disorder of lymph tissue that appears to originate in a particular lymph node and later spreads to the spleen, liver, and bone marrow.

Immunosupressant—Any chemotherapeutic agent which also has the effect of suppressing the immune system.

Leucovorin—The antidote for high dose treatments of methotrexate.

Lymphocytic leukemia—An acute form of childhood leukemia characterized by the development of abnormal cells in the bone marrow and lymph cells found in blood-forming tissues.

Metastatic—Refers to the spread of a cancer from its place of origin to another site in the body.

Oncologist—A physician who specializes in the diagnosis and treatment of patients with cancer.

thoroughly reviewed to avoid complications that might arise from previous conditions such as gout, kidney stones or kidney disease, liver disease, chickenpox, shingles, intestinal blockage, colitis, immunosupression, stomach ulcers, mouth sores, or a history of allergic reactions to various drugs. The oncologist should also be made aware if the patient is pregnant or if there is the possibility the patient might be pregnant, or if the patient is a breast-feeding mother. Only prescribed medications or over the counter (OTC) drugs approved by the oncologist should be taken by a patient receiving methotrexate.

Side effects

The beneficial effects of methotrexate are usually accompanied by less desirable side effects. Side effects correlate in severity with dose amount and length of treatment. It is important to encourage the patient to discuss any presenting side effects. Some side effects do not require medical attention, but still cause the patient concern. Side effects that fall into this category may include loss of hair (alopecia) and appetite (anorexia), nausea or vomiting, skin rash with **itching**, pale skin tone, and the appearance of boils or acne. These side effects tend to diminish as the body adjusts to the therapy, or if they become bothersome, the oncologist may prescribe interventions. Side effects that should be reported immediately to the oncologist include mouth sores; back, lower side, joint or stomach pain; **fever** or chills; headaches; bloody or dark urine; drowsiness; dizziness; black tarry stools; bloody stools or vomit; **diarrhea**; redness or pinpoint red spots on the skin; swelling of the feet or lower legs; the development of a cough or hoarseness; and shortness of breath.

Interactions

Anti-inflammatory medications should be avoided while the patient is receiving methotrexate. These drugs elevate the effects of methotrexate to potentially harmful levels. **Vaccines** should be avoided due to the immunosuppression action of methotrexate, and alcohol should be avoided to reduce the risk of liver complications.

Jane Taylor-Jones, Research Associate, M.S.

Methylphenidate

Definition

Methylphenidate is a mild central nervous system stimulant. This drug is sold under the brand name Ritalin in the United States.

Purpose

Methylphenidate can be used to decrease sedation and lethargy from opioid pain medications. In addition, methylphenidate may improve the mood of a cancer patient suffering from feelings of **depression**, often raises a patient's energy level, and may improve his or her appetite. This drug is also used to treat attention deficit disorder in children and the sleep disorder narcolepsy.

Description

Exactly how methylphenidate acts in the brain is not clear. It is believed to trigger arousal systems or increase the release of brain chemicals. It produces added alertness.

Recommended dosage

How the patient responds to treatment will determine the recommended dose. The usual dose for adults when methylphenidate is ordered with opiate pain medication is 2.5 mg. to 15 mg., daily or twice per day. This drug should be taken exactly as directed. It can become habit-forming if taken in greater amounts or for longer periods than is necessary. Patients should take the last dose of the day before 6 P.M. to decrease sleep difficulties. Patients should not crush or break this medication. If a dose is missed, the patient should take it as soon as possible. Patients should not take two pills at the same time.

Precautions

Methylphenidate can produce physical and mental dependence. Patients should not suddenly stop taking it. A sudden discontinuation of the drug can cause withdrawal symptoms, including depression, paranoid feelings, thoughts of suicide, anxiety, agitation, and sleep disturbances.

Methylphenidate should not be given to patients with extreme anxiety, tension, agitation, severe depression, instability, or a history of alcohol or drug abuse. It is not indicated for use in those with Tourette's syndrome, people with tics, glaucoma, or some mental-health conditions. This drug should be used cautiously in patients with high blood pressure, those with a history of seizures, and women who are breastfeeding. Methylphenidate is not typically ordered for women during their childbearing years, unless the doctor determines that the benefits outweigh the risks. Methylphenidate should not be ordered for patients less than six years of age. Its safety has not been determined in this age group.

Side effects

The most common side effects are nervousness, sleep difficulties, a rapid heartbeat, and increased blood pressure. Reducing the dose or changing the time the drug is taken may reduce some side effects. Patients should discuss any adverse reactions with their doctors. Patients should receive regular blood pressure and pulse checks while on this drug. Methylphenidate also may cause dizziness, irritability, vision changes, drowsiness, and a poor appetite. Patients may experience chest pain, palpitations, joint pain, skin rash, and uncontrolled movements or speech. Patients may develop a rapid or irregular heartbeat, stomach upset, nausea, headache, blood in the urine or stools, muscle cramps, red dots on the skin, or bruises. Patients should not drive or operate machinery or appliances until they understand how this drug affects them. Patients should not drive if they become lightheaded or dizzy. Methylphenidate may cause irregularities in the makeup of the blood and produce changes in liver function. Patients should receive regular blood work.

At higher doses or with long-term use, patients may experience confusion, false beliefs, mood changes, hallucinations, feelings that they or their environment are not real, and **weight loss**.

KEY TERMS

Narcolepsy—Disorder that causes people to suddenly fall asleep

Opiate—Remedy containing or derived from opium, or any drug that induces sleep

Interactions

Several drugs may interfere with methylphenidate, including anticoagulants (blood thinners), and drugs to prevent seizures, combat depression and treat high blood pressure.

Debra Wood, R.N.

Methylprednisolone *see* **Corticosteroids**

Metoclopramide

Definition

Metoclopramide (Reglan, Octamide, Maxeran) is a drug used to prevent the **nausea and vomiting** caused by cancer **chemotherapy**, diabetic neuropathy, gastroesophageal reflux, and similar conditions. It has also been approved by the Food and Drug Administration (FDA) to treat the small bowel prior to intubation. Metoclopramide is one of the drugs most frequently used in palliative care for cancer patients.

Purpose

Nausea and vomiting are among the most common side effects of cancer chemotherapy. They are also among the most unpleasant and upsetting side effects for patients. If left untreated, persistent nausea and vomiting can lead to dehydration, dental decay, digestive abnormalities, and nutritional deficiencies. In addition, persistent vomiting may force some patients to stop taking their chemotherapy and risk a recurrence of their cancer. It is therefore very important that these symptoms be adequately treated.

The nausea and vomiting that occurs with chemotherapy is often divided into three types: anticipatory, acute, and delayed. Anticipatory nausea and vomiting usually occurs before or during chemotherapy. These symptoms are thought to be caused by anxiety, and often occur in patients who have been previously treated with very toxic chemotherapy. Acute nausea and vomiting occurs within a few minutes to several hours after drug administration and usually stops within 24 hours. Delayed nausea and vomiting occurs several hours after chemotherapy, and can last several days.

Description

For the majority of patients, nausea and vomiting can be successfully treated with antiemetic medication. Metoclopramide is one of the most widely used and effective **antiemetics** for treating the delayed nausea and vomiting caused by chemotherapy. It has been used since the 1980s, and works in two ways. It affects a part of the brain known to trigger vomiting, and also affects the speed of intestinal motion. As a result, the stomach empties into the intestines more quickly, and the contents of the intestines move more quickly in the correct direction.

Metoclopramide is most often used in patients taking **cisplatin** (Platinol) chemotherapy. Cisplatin is used to treat a wide range of cancers including **bladder cancer**, **ovarian cancer** and non-small cell lung cancer. Compared with other cancer chemotherapy, cisplatin is often considered to cause the most severe nausea and vomiting. For 60% to 70% of patients taking cisplatin, however, metoclopramide provides adequate control of nausea and vomiting.

Recommended dosage

Although metoclopramide can be taken either orally or intravenously, cancer patients on chemotherapy usually receive the drug intravenously. Metoclopramide is usually given 30 minutes before chemotherapy, and then two more times after chemotherapy at two hour intervals.

The recommended dose varies from patient to patient, and depends on both the severity of nausea and vomiting, and on the toxicity of the drug. A higher dose will be given to patients with severe symptoms. Higher doses will also be given to patients receiving drugs such as cisplatin that are known to cause severe nausea and vomiting. Some patients receiving cisplatin may be given a combination of three different drugs to help combat their nausea: metoclopramide, **dexamethasone** (Dexone), and **lorazepam** (Ativan). The three work on different areas of the body and produce a greater effect together than they do when given separately.

Precautions

Metoclopramide can cause sleepiness and lack of concentration. Patients should avoid tasks that require mental alertness such as driving or operating machinery. Patients should also be aware that metoclopramide may enhance their response to alcohol and drugs that depress the central nervous system. Because metoclopramide can cause **depression**, patients with a history of serious clinical depression should take this drug only if absolutely necessary.

Metoclopramide can make the symptoms of Parkinson's disease worse, and patients with a history of seizures should not take metoclopramide, because the frequency and severity of the seizures may increase. The drug should also not be used in patients with intestinal problems such as bleeding, tears, or blockages. The safety of metoclopramide for pregnant women or children is unknown. The drug is found in the breast milk of lactating mothers.

Side effects

The most frequent side effects of metoclopramide are restlessness, drowsiness, and fatigue. These occur in about 10% of patients. Less common side effects include insomnia, headache, and dizziness. These occur in only 5% of patients. Feelings of anxiety or agitation may also occur, especially after a rapid intravenous injection of the drug. Some women may experience menstrual irregularities.

Metaclopramide therapy can cause some patients to make abnormal involuntary movements, a condition known as dyskinesia. These reactions are most common in young adults of 18–30 years of age, and often disappear about a day after the patient stops taking the drug. Among geriatric patients, particularly women, dyskinesia sometimes develops when patients stop taking metoclopramide after long term treatment.

Interactions

Patients who are also taking cabergoline (Dostinex), a drug used to treat hormonal problems and Parkinson's disease, should not take metoclopramide. Because metoclopramide affects the functioning of the intestines, it can interfere with the absorption of certain drugs. The effect of digoxin (Lanoxin), for example, may be reduced, whereas the effects of other drugs like aspirin, cyclosporine (Neoral, Sandimmune, SangCya) and tetracycline (Minocin, Vibramycin) may be enhanced.

KEY TERMS

Antiemetic—A drug that prevents nausea and vomiting.

Dyskinesia—A condition that causes a person to make abnormal, involuntary movements.

Palliative care—Care given to relieve pain and other symptoms of a disease but not to cure the disease.

Mistletoe

Description

Mistletoe is a parasitic evergreen plant that lives on trees such asoak, elm, fir, and apple. The parasitic plant has yellowish flowers, small yellowish green leaves, and waxy white berries. There are many species of this plant in the Viscacea and Loranthacea plant families. European mistletoe (*Viscum album*) and American mistletoe (*Phoradendron leucarpum*) are used as medical remedies. In addition to Europe and North America, mistletoe is also found in Australia and Korea.

Mistletoe berries are poisonous to cats and other small animals. There is, however, some debate about how toxic the berries are to humans, and there is controversy about whether it is safe to use mistletoe as a remedy. Mistletoe is also known as mystyldene, all-heal, bird lime, golden bough, and devil's fuge.

General use

Mistletoe is known popularly as the plant sprig that people kiss beneathduring the Christmas season. That custom dates back to pagan times when, according to legend, the plant was thought to inspire passion and increase fertility.

Over the centuries, mistletoe has acquired a reputation asan all-purpose herbal remedy. In the seventeenth century, French herbalistsprescribed mistletoe for nervous disorders, epilepsy, and the spasms known as the St. Vitus dance.

Mistletoe has also been used in folk medicine as a digestive aid, hearttonic, and sedative. It was used to treat arthritis, hysteria and other mentaldisturbances, **amenorrhea**, wounds, asthma, bed wetting, infection, and to stimulate glands.

For centuries, mistletoe also served as a folk medicine treatment for cancer, and as of early 2005, the plant is sometimes used in Europe to treat tumors. Iscador, an extract of the European mistletoe plant, is said to stimulate the immune system and kill cancer cells. It reportedly reducesthe size of tumors and improves the quality of life. Iscador is one brandname of the mistletoe extract in Europe, and other brand names include Helixorand Eurixor.

Although in alternative medicine mistletoe is viewed as a multipurpose remedy, there is disagreement among medical experts about the safety and effectiveness of this herb. The number of possible interactions with other medications described below indicates that mistletoe should be used with caution.

Preparations

In alternative medicine, the leaves, twigs, and sometimes the berries of mistletoe are used. In Europe, mistletoe remedies range from tea made from mistletoe leaves to injections of Iscador. However, the berries may be poisonous and the herb may cause liver damage.

Since as of 2005 mistletoe has not been tested by the United States Food and Drug Administration (FDA), many experts urge caution until more research is completed.

Home remedies

Mistletoe tea may be an alternative treatment for conditions that include high blood pressure, asthma, epilepsy, nervousness, **diarrhea**, andamenorrhea. The tea is prepared by adding 1 tsp (5 g) of finely cut mistletoe to 1 cup (250 ml) of cold water. The solution is steeped at room temperature for 12 hours and then strained.

Mistletoe wine is prepared by mixing 8 tsp (40 g) of the herb into 34oz (1 L) of wine. After three days, the wine can be consumed. Three to fourglasses of medicinal wine may be consumed each day.

Mistletoe must be stored away from light and kept above a drying agent.

Cancer treatment

Iscador, the European extract, may be injected before surgery for cancers of the cervix, ovary, breast, stomach, colon, and lung. Cancer treatments can take several months to several years. The treatment is given by subcutaneous injection, preferably near the tumor. Iscador may be injected into the tumor, especially tumors of the liver, cervix, or esophagus.

The dosage of Iscador varies according to the patient's age, sex, physical condition, and type of cancer. The treatment usually is given in the morning three to seven days per week. As treatment continues, the dosage may be increased or adjusted.

Advocates of Iscador believe it can stimulate the immune system, kill cancer cells, inhibit the formation of tumors, and extend the survival time of cancer patients. They maintain that mistletoe can help prevent cancer and be complementary to standard medical cancer treatments. They also think that mistletoe could possibly repair the DNA that is decreased by chemotherapy and radiation.

AIDS treatment

Mistletoe extract has been used to combat AIDS, but its efficacy has not been medically confirmed as of 2005.

Precautions

Opinions are sharply divided on how safe and effective the herb is as a home remedy and in the treatment of conditions such as cancer and AIDS. There is controversy about which parts of the plants are poisonous. Although the berries are classified as poisonous in the United States, some sources say that eating berries is only dangerous for babies, and only if handfuls are consumed. Pregnant or breast-feeding women, however, should not use the plant.

According to a report from the Hepatitis Foundation International, mistletoe is toxic to the liver. However, the *PDR for Herbal Medicines* advises that there are no health hazards when mistletoe is taken properly and in designated therapeutic dosages.

People considering mistletoe should consult with their doctors or practitioners. Until there is definitive proof otherwise, there is a risk that the herbal remedies will conflict with conventional treatment.

KEY TERMS

Amenorrhea—Abnormal absence or suppression of menstruation.

Orthostatic—Related to or caused by an upright position.

Pharmacognosist—A person involved in pharmacognosy, the scienceconcerned with the medical products of plants in their natural state.

Subcutaneous—Beneath the skin.

Vertiginous attacks—Attacks of vertigo or dizziness.

Side effects

Mistletoe may be toxic to the liver. For people diagnosed with hepatitis, use of an herb such as mistletoe may cause additional liver damage. However, advocates of mistletoe maintain it is safe, at least under certain circumstances.

Commercial mistletoe extracts may produce fewer side effects. The bodytemperature may rise and there may be flu-like symptoms. The patient may experience nausea, abdominal pain, and (if given the extract injection) inflammation around the injection sight. Allergy symptoms may result.

Interactions

Mistletoe should not be used by people who take monoamine oxidase (MAO) inhibitor antidepressants such as Nardil. Potential reactions include a dangerous rise in blood pressure and a lowering of blood potassium levels (hypokalemia). In addition, mistletoe may interfere with the action of antidiabetic medications, to increase the activity of diuretics, and to increase the risk of a toxic reaction to aspirin or NSAIDs. Cancer patients

considering mistletoe treatment should first consult with their doctors or practitioners.

Mithramycin *see* **Plicamycin**

Mitoguazone

Definition

Mitoguazone is an investigational (experimental) medicine used to stop growth of cancer and formation of new cancer cells.

Purpose

Mitoguazone may be effective in patients with **acute leukemia**, **chronic myelocytic leukemia**, **lymphoma**, **multiple myeloma**, **head and neck cancers**, **esophageal cancer**, and other types of malignancies.

Description

Mitoguazone, also known as MGBG, was discovered in 1898. The exact mechanism of MGBG action is not fully understood and a variety of mechanisms appear to be involved. Most likely, MGBG's anti-tumor activity comes from inhibition of spermine, a protein necessary for cell reproduction. This drug underwent numerous **clinical trials** in the early 1960s; however, the trials were discontinued due to severe toxicities noticed when MGBG was given on a daily basis. In these early research trials, MGBG was shown to have both anti-cancer and antiviral activity. Later, researchers discovered that MGBG has a long duration of action in the body and can be given less frequently. In 1976 MGBG enjoyed a rebirth when Southwest Oncology Group started using once weekly administration schedule of this agent in patients with lymphoma (Hodgkin's and non-Hodgkin's type), esophageal cancer, **prostate cancer** and other tumor types.

In addition to being effective as a single agent, MGBG was used in combination **chemotherapy** regimens containing **ifosfamide**, **methotrexate** and **etoposide** (also known as MIME regimen). The best results with MGBG have been obtained against Hodgkin's and non-Hodgkin's lymphoma using MIME regimen.

Mitoguazone appears particularly effective in patients who are malnourished and would be ideally suited for patients with AIDS-associated lymphomas. Another potential advantage of mitoguazone in patients with AIDS is its high penetration into the brain, since the brain is one area frequently involved by lymphoma in this patient population.

Recommended dosage

Adults

AIDS-ASSOCIATED NON-HODKIN'S LYMPHOMA Doses vary between different chemotherapy protocols. One of the schedules used was 600 mg per square meter of body surface area given intravenously on days 1, 8, and then every two weeks.

Children

There is no data available on dosing and use of mitoguazone in children.

Precautions

To maximize treatment effects, patients receiving mitoguazone should observe certain guidelines. In

KEY TERMS

AIDS—Also known as acquired immunodeficiency syndrome, caused by the progression of HIV, and is the leading cause of death from HIV. AIDS is characterized by opportunistic diseases, including fungal infections, pneumocystis carinii pneumonia, non-Hodgkin's lymphoma, and other malignant or infectious illnesses.

Non-Hodgkin's lymphoma—Lymphomas are some of the most treatable cancers with cure rates around 50% in 1990s. Non-Hodgkin's lymphoma mainly affects people over 50 years of age and has been more difficult to treat than the Hodgkin's type. There has been an increase in non-Hodgkin's lymphoma cases in the last two decades in patients with HIV.

addition to any modifications given by the oncologist, these guidelines should include regular visits with the oncologist and laboratory testing for white blood cell count, liver, and bone marrow function. Avoid any immunizations not approved or prescribed by the oncologist. When necessary wear a protective facemask. Use good oral hygiene to reduce incidence of mouth sores and avoid touching the eye and nasal areas unless hands have been properly washed immediately prior to contact. To reduce bleeding and bruising complications, patients should exercise extreme caution when handling sharp instruments and decline participation in contact sports. Prior to treatment, the patient's medical history should be thoroughly reviewed to avoid complications that might arise from previous conditions such as liver disease, chickenpox, shingles, peripheral **neuropathy** (tingling and weakness in hands or feet), suppressed immune system, stomach ulcers, mouth sores, or a history of allergic reactions to various drugs.

Contact a doctor immediately if any of these symptoms develop:

- signs of infection (**fever**, chills, sore throat)
- pain, numbness, and tingling in fingers or toes
- severe muscle weakness
- nausea, vomiting, and yellowing of the skin or eyes
- unresolved mouth sores
- mental status changes (euphoria, drowsiness, anxiety, emotional instability)
- unusual bleeding or bruising
- skin rash or itching

Side effects

The dose-limiting toxicity of MGBG is muscle weakness. The most common side effect of MGBG is flushing primarily on the face during infusion. Other toxicities associated with MGBG are usually mild, consisting of somnolence, tingling in the face or extremities, ringing in the ears, euphoria, mouth ulcers, nausea, vomiting, and **fatigue**. This drug also lacks significant **myelosuppression**, which makes it an ideal agent to consider for combination regimens.

Interactions

The drug and food interactions with MGBG have not been studied in research trials. There is a theoretical drug interaction between MGBG and pentamidine (a drug used to prevent and treat pneumocystis carinii **pneumonia** in AIDS patients). Pentamidine inhibits the same enzyme in the body as MGBG, which can enhance effects of MGBG. This interaction can either increase effectiveness of MGBG against cancer or put patients at higher risk of its side effects.

Olga Bessmertny, Pharm.D.

Mitomycin-C

Definition

Mitomycin-C is also known as mitomycin and MMC. It is an antineoplastic, or medicine that kills cancer cells. It is sold under the trade name Mutamycin.

Purpose

Mitomycin-C may be used to fight a number of different cancers, including cancer of the stomach, colon, rectum, pancreas, breast, lung, uterus, cervix, bladder, head, neck, eye, and esophagus.

It is impossible to provide a detailed description of how mitomycin-C may be combined with other medications in the treatment of each of these cancers, but some examples can be presented. In the treatment of non-small cell lung cancer (NSCLC), one therapeutic regimen that may be used is known as MT, which consists of mitomycin-C, **vindesine**, and **cisplatin**.

Mitomycin-C is sometimes used in patients with colorectal cancer metastatic to the liver. However, the side effects of mitomycin-C, especially those involving the bone marrow and **fatigue**, are so great that other medications may be tried first. In treating breast cancer

metastatic to the liver, mitomycin is regarded as salvage therapy as of the early 2000s.

For advanced stomach cancer, the FAM regimen may be used, which consists of **fluorouracil**, **doxorubicin** (adriamycin), and mitomycin-C. Mitomycin-C may also be used for colorectal cancer metastatic to the liver in combination with other medicines.

More recently, mitomycin has been found effective in treating malignant melanoma of the eye.

In addition to cancer treatment, mitomycin is sometimes used as a topical application in eye surgery to prevent visual haze after operations on the cornea (the transparent exterior coat that covers the front of the eye where light enters). It is also used topically by some doctors to keep incisions in the ear drum open in children with recurrent ear infections without the need to place ventilation tubes in the incisions. This use of mitomycin is considered experiental as of 2005.

Description

Mitomycin-C is an antitumor antibiotic. Mechanistically however, it belongs to DNA covalent binding (alkylating) agents. Mitomycin-C, upon bioactivation, kills cancer cells by disrupting the activity of DNA within the cells. DNA is an acid that contains genetic material.

Recommended dosage

Twenty milligrams per square meter should be given intravenously every six to eight weeks when this medication is used alone. Alternately, five to ten milligrams per square meter may be given every six weeks when the drug is used in combination with other drugs. Mitomycin-C, **leucovorin**, and fluorouracil may be used to treat metastatic **rectal cancer**; this regimen includes an injection of 10 milligrams per square meter of mitomycin-C. When mitomycin-C is combined with vindesine and cisplatin in the treatment of non-small cell lung cancer, eight milligrams per square inch are administered intravenously on days one and twenty-nine of a six-week cycle.

Precautions

Because of the side effects associated with mitomycin-C, some physicians perform blood tests and order chest x rays (of the lungs) for patients receiving this therapy. The likelihood that lung problems will appear in patients receiving mitomycin-C increases if oxygen therapy and/or x-ray therapy are administered.

Patients receiving less than 60 mg of mitomycin-C are at reduced risk of developing a complex medical condition called cancer-associated hemolytic uremia syndrome (HUS). HUS is characterized by **anemia**, other blood defects, and kidney problems. Doctors should carefully observe patients receiving mitomycin-C, as cancer-related HUS is best treated early. However, HUS is not likely to develop until four or more months after the patient received the final dose of mitomycin-C. To achieve early diagnosis of HUS, the doctor may carefully monitor kidney function and blood levels. In addition, transfusions may be avoided as may be certain other procedures involving the blood, as these may increase the risk HUS will develop.

KEY TERMS

Antineoplastic—A medicine given to kill cancer cells.

Salvage therapy—A term that refers to measures taken at a late point in the treatment process after other therapies have failed.

Topical—Referring to a medication or other preparation applied directly to the skin or other external body tissues.

Side effects

The ability of the bone marrow to produce blood cells may be affected. This side effect can be serious. If it occurs, the doctor may decide to reduce the dose of medicine administered. However, mitomycin-C may cause delayed, rather than immediate, bone marrow suppression. Once such suppression does occur it may last for as many as eight weeks.

Major lung problems may occur. Such lung deficits may start as no more than cough, fatigue, and breathing problems. Doctors may conduct lung function tests and obtain x rays to observe whether lung problems are developing. If these lung problems do occur, **corticosteroids** may provide effective therapy. Stopping mitomycin-C therapy may also be recommended.

Mitomycin-C may also cause cancer-associated HUS.

In addition, there may be **nausea and vomiting**, loss of appetite (anorexia), stomach problems, fatigue, **fever**, hair loss (alopecia), and lung problems. If bleeding does occur, there may be damage to the surrounding skin.

Mitotane

Definition

Mitotane (also known by the brand name Lysodren) is a medicine that has been proven to be effective in the treatment of adrenocortical carcinoma.

Purpose

Mitotane destroys cells of the adrenocortex. The adrenocortex, also called the adrenal cortex, is a section of adrenal gland that sits on top of the kidneys. Mitotane is usually used for patients whose cancer cannot be treated surgically and for patients whose cancer has metastasized.

KEY TERMS

Adrenocortex—The outer part of adrenal gland that sits on top of the kidneys.

Anorexia—A condition of uncontrolled lack or loss of desire for food.

Description

As a chemical, mitotane resembles the insecticides DDD and DDT, although mitotane does not harm people as these do. Scientists do not understand why, but the drug causes damage to the adrenocortex in such a way as to be helpful for some patients with adrenocortical tumors. In addition, mitotane restricts the ability of the gland to produce chemicals.

Recommended dosage

The dose of mitotane given to patients varies, although between four and eight grams (0.12–0.25 oz) per day is a typical dose. Patients vary in how much mitotane they tolerate, some patients tolerating two grams (0.1 oz) per day while others tolerate sixteen grams (0.5 oz) per day. The doses are given orally. At the beginning of the therapy, the patient may receive 500 milligrams of mitotane twice a day. At any one time a third or a quarter of an entire day's dose is taken. If the patient has difficulty tolerating a certain dose, the doctors may adjust this and use a somewhat smaller dose. Mitotane should be given for at least three months. If the medicine is effective, it may be continued indefinitely. However, most patients respond to the x-ray treatment of the pituitary gland and so do not need mitotane treatment to continue indefinitely.

Many doctors use mitotane in conjunction with **radiation therapy** directed to the pituitary gland, but other approaches to this medicine may also be taken.

Precautions

Many patients on mitotane should receive adrenocorticosteroids.

Side effects

Four out of five patients receiving mitotane experience **anorexia** and nausea. About one-third of patients

experience lethargy and sleepiness. Roughly one in five develop skin problems with the medicine. However, patients who experience these side effects do not have to stop taking the medication, although the doctor may lower the dose the person is receiving.

Interactions

Mitotane should not be given with spironolactone (a diuretic/water pill).

Bob Kirsch

Mitoxantrone

Definition

Mitoxantrone, also known by its trade name Novantrone, is an anticancer agent effective against certain kinds of leukemias. It is also used in Multiple Sclerosis (MS), and was approved by the Federal Drug Administration in 1987.

Purpose

Mitoxantrone is used with other drugs to treat acute non-lymphocytic leukemia (ANLL), a category that includes myelogenous, promyelocytic, monocytic and erythroid **acute leukemia**. In adults, ANLL accounts for up to 85% of all adult leukemia cases. Mitoxantrone may also be used in the treatment of acute lymphocytic leukemia, chronic myelocytic leukemia, **ovarian cancer**, advanced or recurrent **breast cancer**, **prostate cancer**, and MS.

Description

Mitoxantrone is classified as an anthracycline antitumor antibiotic, and closely resembles another drug in this category, **daunorubicin**. Although its precise mechanism is not clear, mitoxantrone is cell cycle non-specific, meaning that it is toxic to cells that are dividing, as well as those that are not.

Recommended dosage

Mitoxantrone is given intravenously over a thirty-minute time period. **Chemotherapy** dosages are based on a person's body surface area (BSA), which is calculated in square meters using height and weight measurements. Drug dosages are ordered in milligrams per square meter (mg/m^2).

In patients with cancer, the recommended dosage for induction therapy is 12mg/ mg/m^2 administered on the first three days of treatment. After that time, another chemotherapy drug is usually infused. This course of treatment is often adequate to induce remission, but may be repeated if it does not. In the second induction course, the dosage remains the same, but mitoxantrone is given for two days, rather than three, followed by other chemotherapy agents. Dosages may be altered, depending on the level of bone marrow toxicity the patient develops.

For patients with solid tumors, such as advanced hormone-refractory prostate cancer, a single dose of 12mg/ mg/m^2 is administered, and repeated every three to four weeks. Recent studies show that mitoxantrone used with glucocorticoids has resulted in improved pain control and quality of life in men with prostate cancer.

Precautions

Mitoxantrone's use in children has not been studied sufficiently to determine whether its use is safe and effective. It should not be used in individuals who have experienced a previous reaction to it.

Mitoxantrone is excreted by the liver and kidneys. It may alter the appearance of urine, causing it to be a blue-green color for approximately 24 hours. The sclera, or whites of the eyes, may temporarily be blue-tinged. Patients should not be alarmed by this change, but should alert their doctors if it is prolonged or is accompanied by other symptoms.

Mitoxantrone should not be administered to pregnant women, as damage to the fetus may occur. Throughout treatment, women should use methods to prevent pregnancy. It is excreted in breast-milk, so breast-feeding should be avoided during treatment.

Side effects

Mitoxantrone can cause severe and sometimes rapid **myelosuppression** leading to decreased white blood cell, red blood cell, and platelet counts. Blood counts should be monitored frequently throughout treatment. The white blood cells tend to nadir, or drop to their lowest point, within ten to fourteen days after mitoxantrone is administered. Patients should also be examined for symptoms of low white blood cell count, which typically resemble those of an infection: sore throat, burning with urination, increased temperature, or swelling. Patients should also be carefully monitored for indications that platelet count is low. Symptoms may include unexplained bruises, bleeding or increased bleeding with menstruation, and headache.

KEY TERMS

Body surface area (BSA)—A measurement, based on a patient's height and weight, that helps determine appropriate chemotherapy dosages.

Mucositis—A severe, painful inflammation of the mucous membranes.

Myelosuppression—A condition in which bone marrow activity is diminished, resulting in decreased platelet, red blood cell, and white blood cell counts.

Remission—The time period during which symptoms of a disease are absent.

Mitoxantrone can damage the heart, possibly causing changes that lead to congestive heart failure (CHF). Patients especially at risk are those previously treated with anthracyclines or radiation to the chest area, or those with an already existing heart condition. Symptoms to watch for include swelling of the hands and ankles, difficulty breathing, or heart palpitations.

Mitoxantrone can cause a severe, painful inflammation of the mucous membranes called **mucositis**. The condition may develop within a week of treatment. A patient may experience a burning sensation in his or her throat, as well as mouth pain. Mucositis typically resolves in a few weeks on its own, but there are measures one can take to hasten the process and provide comfort during healing. Hydration is very important to keep the mouth moist. Good oral hygiene is important—the teeth should be brushed with a very soft toothbrush, and flossed gently with unwaxed dental floss. (If bleeding occurs, using a toothbrush may not be safe. Patients should talk to their health care providers should this occur.) Your doctor or nurse may recommend a special mouthwash that helps relieve pain.

Patients undergoing treatment with mitoxantrone may be at risk for **tumor lysis syndrome**, a potentially life-threatening condition that develops when large numbers of cells rupture and release their contents into the blood stream. Preventative measures should be implemented to prevent adverse effects.

Interactions

Because mitoxantrone can alter normal blood counts, medications that contain aspirin should be avoided. Aspirin acts as a blood-thinner, and can predispose a person to bleeding. Patients should discuss all medications, whether they are prescribed or over-the-counter drugs, with their doctor to ensure there are no potential interactions. **Cytarabine**, another drug used to treat cancer, may increase the toxicity of mitixantrone if the drugs are used together.

Mohs' surgery

Definition

Mohs' surgery, also called Mohs' micrographic surgery, is a precise surgical technique that is used to remove all parts of cancerous skin tumors while preserving as much healthy tissue as possible. It is named for Frederic Edward Mohs, an American surgeon (1910–).

Purpose

Mohs' surgery is used to treat such skin cancers as **basal cell carcinoma**, **squamous cell carcinoma of the skin**, **melanoma**, Bowen's disease, extramammary Paget's disease, **leiomyosarcoma**, **laryngeal cancer**, **malignant fibrous histiocytoma**, microcystic adnexal carcinoma, mucoepidermoid carcinoma, and **Merkel cell carcinoma**.

Malignant skin tumors may appear as strange-looking asymmetrical shapes. The tumor may have long finger-like projections that extend across the skin (laterally) or down into the skin. Because these extensions may be composed of only a few cells, they cannot be seen or felt. Standard surgical removal (excision) may miss these cancerous cells leading to recurrence of the tumor. To assure removal of all cancerous tissue, a large piece of skin needs to be removed. This causes a cosmetically unacceptable result, especially if the cancer is located on the face. Mohs' surgery enables the surgeon to precisely excise the entire tumor without removing excessive amounts of the surrounding healthy tissue.

Precautions

To reduce the risk of bleeding, the use of nonsteroidal anti-inflammatory medications, alcohol, vitamin E, and fish oil tablets should be avoided prior to the procedure. Patients who use the anticoagulants aspirin, coumadin, or **heparin**, should consult with the prescribing physician before changing their use of these drugs.

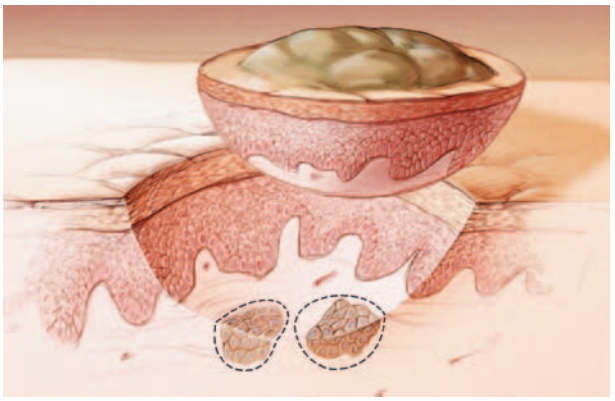
KEY TERMS

Debulking—The removal of the major portion of a tumor by surgery so that the remainder of the tumor can be treated more effectively, usually by chemotherapy or radiation therapy.

Fixative—A chemical that preserves tissue without destroying or altering the structure of the cells.

Fixed—A term used to describe chemically preserved tissue. Fixed tissue is dead so it does not bleed or sense pain.

Mohs' excision—Referring to the excision of one layer of tissue during Mohs' surgery. Also called stage.



Mohs' surgery is used to remove skin cancer tumors of many types, including melanoma. Here, the main portion of the tumor is excised (debulked) using a spoon-shaped tool (curette). Further layers of tissue will be removed as necessary. *(Custom Medical Stock Photo. Reproduced by permission.)*

Description

There are two types of Mohs' surgery: fresh-tissue technique and fixed-tissue technique. Seventy-two percent of surgeons who perform Mohs' surgery use only the fresh-tissue technique. The remaining surgeons use both techniques; however, the fixed-tissue technique is used in fewer than 5% of the patients. The main difference between the two techniques has to do with the preparation steps.

Fresh-tissue technique

Fresh-tissue Mohs' surgery is performed under local anesthesia for tumors of the skin. The area to be excised is cleaned with a disinfectant solution and a sterile drape is placed over the site. The surgeon may outline the tumor using a surgical marking pen or a dye. A local anesthetic (lidocaine plus epinephrine) is injected into the area. Once the local anesthetic has taken effect, the main portion of the tumor is excised (debulked) using a spoon-shaped tool (curette). To define the area to be excised and allow for accurate mapping of the tumor, the surgeon makes identifying marks around the wound. These marks may be made with stitches, staples, fine cuts with a scalpel, or temporary tattoos. One layer of tissue is carefully excised (first Mohs' excision), cut into smaller sections, and taken to the laboratory for analysis.

If cancerous cells are found in any of the tissue sections, a second layer of tissue is removed (second Mohs' excision). Because only the section(s) that have cancerous cells are removed, healthy tissue can be spared. The entire procedure, including surgical repair of the wound, is performed in one day. Surgical repair may be performed by the Mohs' surgeon, a plastic surgeon, or other specialist. In certain cases, wounds may be allowed to heal naturally.

Fixed-tissue technique

With fixed-tissue Mohs' surgery, the tumor is debulked as described above. Trichloracetic acid is applied to the wound (to control bleeding) followed by a preservative (fixative) called zinc chloride. The wound is dressed and the tissue is allowed to fix for 6 to 24 hours, depending on the depth of the tissue involved. This fixation period is painful. The first Mohs' excision is performed as above; however, anesthesia is not required because the tissue is dead. If cancerous cells are found, fixative is applied to the affected area for an additional 6 to 24 hours. Excisions are performed in this sequential process until all cancerous tissue is removed. Surgical repair of the wound may be performed once all fixed tissue has sloughed off, usually a few days after the last excision.

Preparation

Under certain conditions, such as the location of the skin tumor or health status of the patient, **antibiotics** may be taken prior to the procedure (prophylactic antibiotic treatment). Patients are encouraged to eat prior to surgery and bring along snacks in case of a lengthy procedure.

Aftercare

Patients should expect to receive specific wound care instructions from their physicians or surgeons, but

QUESTIONS TO ASK THE DOCTOR

- How long have you been performing Mohs' surgery?
- Will you use the fresh-tissue or fixed-tissue technique?
- Will I have to alter the use of my current medications for this procedure?
- What will you do if you don't find the border of the cancerous lesion?
- How will the wound be repaired?
- Will I need a plastic surgeon to repair the wound?
- What is the cure rate for this type of cancer when treated by Mohs' surgery?
- What is the chance that the tumor will recur?
- How often will I have follow-up appointments?

generally, wounds that have been repaired with absorbable stitches or skin grafts are kept covered with a bandage for one week. Wounds that were repaired using nonabsorbable stitches are covered with a bandage, which should be replaced daily until the stitches are removed one to two weeks later. Patients with nonabsorbable stitches may shower. Signs of infection (e.g., redness, pain, drainage) should be reported to the physician immediately.

Risks

Using the fresh-tissue technique on a large tumor requires large amounts of local anesthetic, which can be toxic. Complications of Mohs' surgery include infection, bleeding, scarring, and nerve damage.

Normal results

Mohs' surgery provides high cure rates for malignant skin tumors. For instance, the five-year cure rate for basal cell carcinoma treated by Mohs' surgery is greater than 99%. The frequency of recurrence is much lower with Mohs' surgery (less than 1%) than with conventional surgical excision.

Abnormal results

Tumors spread in unpredictable patterns. Sometimes a seemingly small tumor is found to be quite large and widespread, resulting in a much larger excision than was anticipated. Technical errors, such as those involving processing and interpretation of the tissue sections, may lead to local recurrence of cancer.

Monoclonal antibodies

Definition

Monoclonal antibodies are proteins produced in the laboratory from a single clone of a B cell, the type of cells of the immune system that make antibodies.

Description

Antibodies, also known as immunoglobulins (Igs), are proteins that help identify foreign substances to

the immune system, such as a bacteria or a virus. Antibodies work by binding to the foreign substance to mark it as foreign. The substance that the antibody binds to is called an antigen. All monoclonal antibodies of a particular type bind to the same antigen, which distinguishes them from polyclonal antibodies.

The structure of most antibodies can be divided into two parts: the section that binds the antigen and a section that identifies the type of antibody. This second region is called a constant region, because it is essentially the same within the same type of antibody. The most common type of antibody is IgG (immunoglobulin gamma), which is found in the blood and body fluids. For cancer treatments, monoclonal antibodies are often humanized. This involves using human sequences for the constant regions and using mouse or other animal-derived sequence for the binding region. Humanization reduces the immune reaction of the patient to the antibody itself.

When used as a treatment for cancer, there are three general strategies with monoclonal antibodies. One uses the ability of the antibodies to bind to the cancer cells having the tumor antigens on their surface. The immune system will see the cancer cells marked with bound antibodies as foreign and destroy them. A second strategy is to use the antibodies to block the binding of cytokines or other proteins that are needed by the cancerous cells to maintain their uncontrolled growth. Monoclonal antibodies designed to work like this bind to the receptors for the cytokine that are on the tumor cell surface. As doctors don't completely understand how monoclonal antibodies work as drugs, both strategies may help rid the body of the tumor cells.

A final strategy involves special antibodies that are linked (conjugated) to a substance that is deadly to the cancer cells. Both radioactive isotopes, like yttrium 90, and toxins produced by bacteria, like pseudomonas exotoxin, have been successfully conjugated to antibodies. The antibodies are then used to specifically destroy the tumor cells with the radioactivity or toxic substance. The use of monoclonal antibodies is a useful approach to cancer therapy and as scientists learn more about the function of the immune system and cancer, new antibodies and new strategies promise to become more and more effective.

Mucositis

Description

Mucositis involves the inflammation of the lining of the mouth and digestive tract, and frequently occurs in cancer patients after **chemotherapy** and radiation therapy. The cheek, gums, soft plate, oropharynx, top and sides of tongue, and floor of the mouth may be affected, as well as the esophagus and rectal areas. Along with redness and swelling, patients typically experience a strong, burning pain.

Although there are factors that increase the likelihood and severity of mucositis, there is no reliable manner to predict who will be affected. Not only is mucositis more common in elderly patients, the degree of breakdown is often more debilitating. The severity of mucositis tends to be increased if a patient exercises poor oral hygiene or has a compromised nutritional status. A pre-existing infection or irritation to the mucous membrane may also result in a more severe case of mucositis.

Causes

The precise mechanism by which cancer treatment induces mucositis is not clear, but it is believed to damage the rapidly dividing epithelial cells in the mucous membranes. This damage leads to inflammation and swelling, and then actual breakdown of the mucosa, the lining of the mouth and digestive tract. Another theory is that the body's natural defenses are weakened. For example, the immunoglobulin IgA is normally found in saliva. In patients who developed mucositis after undergoing cancer treatment with **methotrexate**, IgA levels in saliva were decreased.

The types of drug used to treat cancer and the schedule by which they are given influence the risk of developing mucositis. **Doxorubicin** and methotrexate, for example, frequently cause mucositis. The chemotherapy agent **fluorouracil** does not usually severely affect the mucous membranes when administered in small doses over continuous intravenous (IV) infusion. When the schedule is adjusted so that a higher dose is given over a shorter period of time (typically over five days), fluorouracil can cause very severe, painful, dose-limiting cases of mucositis. Patients undergoing treatment with high-dose chemotherapy and bone marrow rescue usually develop mucositis.

In addition, mucositis also tends to develop in **radiation therapy** administered to the oral cavity, or in dosages that exceed 180 cGy per day over a five-day period. Combination therapy, either multiple chemotherapy agents or chemotherapy and radiation therapy to the oral cavity, can increase the incidence of mucositis.

Treatments

Because there is no real cure for mucositis, treatment is aimed at prevention and management of symptoms. Mucositis typically resolves a few weeks after treatment as the cells regenerate, and treatment cessation is only occasionally required. In some cases, drug therapy will be altered so that a less toxic agent is given.

Patients at risk for mucositis should be meticulous about their oral hygiene, brushing frequently with a soft toothbrush and flossing carefully with unwaxed dental floss. If bleeding of the gums develops, patients should replace their toothbrushes with soft toothettes or gauze. Dentures should also be cleaned regularly. Patients should be well-hydrated, drinking fluids frequently and rinsing the mouth several times a day. Mouthwashes that contain alcohol or hydrogen peroxide should be avoided as they may dry out the mouth and increase pain. Lips should also be kept moist. Physical irritation to the mouth should be avoided. If time permits, dental problems, such as cavities or ill-fitting dentures, should be resolved with a dentist prior to beginning cancer treatment. Patients are generally more comfortable eating mild, medium-temperature foods. Spicy, acidic, very hot or very cold foods can irritate the mucosa. Tobacco and alcohol should also be avoided.

Hospital personnel and the patients themselves should inspect the mouth frequently to look for signs and symptoms of mucositis. Evidence of mucositis (inflammation, white or yellow shiny mucous membranes developing into red, raw, painful membranes) may be present as early as four days after chemotherapy administration.

Sodium bicarbonate mouth rinses are sometimes used to decrease the amount of oral flora and promote comfort, though there is no scientific evidence that this is beneficial. Typically, patients will rinse every few hours with a solution containing 1/2 teaspoon (tsp) salt and 1/2 tsp baking soda in one cup of water.

Pain relief is often required in patients with mucositis. In some cases, rinsing with a mixture of maalox, xylocaine, and **diphenhydramine** hydrochloride relieves pain. However, because of xylocaine's numbing effects, taste sensation may be altered. Worse, it may reduce the body's natural gag reflex, possibly causing problems with swallowing. Coating agents such as kaopectate and aluminum hydroxide gel may also help relieve symptoms. Rinsing with benzydamine has also shown promise, not only in managing pain, but also in preventing the development of mucositis. More severe pain may require liquid tylenol with codeine, or even intravenous opioid drugs. Patients with severe pain may not be able to eat, and may also require nutritional supplements through an I.V. (intravenous line).

KEY TERMS

Combination therapy—Treatment involving multiple drugs or treatment methods.

Mucosa—The lining of the mouth and digestive tract.

Alternative and complementary therapies

A treatment called **cryotherapy** has shown promise in patients being treated with fluorouracil administered in the aforementioned five-day, high-dose schedule. Patients continuously swish ice chips in their mouth during the thirty-minute infusion of the drug, causing the blood vessels to constrict, thereby reducing the drug's ability to affect the oral mucosa.

Chamomile and **allopurinol** mouthwashes have been tried in the past to manage mucositis, but studies have found them to be ineffective. Biologic response modifiers are being evaluated to determine their possible role in managing mucositis. Recent studies using topical antimicrobial lozenges have shown promise as well, but more research is needed.

Multiple endocrine neoplasia syndromes

Definition

The multiple endocrine neoplasia (MEN) syndromes are three related disorders in which two or more of the hormone-secreting (endocrine) glands of the body develop tumors. Commonly affected glands are the thyroid, parathyroids, pituitary, adrenals, and pancreas. Two common cancers are medullary **thyroid cancer** and gas-

trinomas. MEN is sometimes called familial multiple endocrine neoplasia (FMEN) and previously has been known as familial endocrine adenomatosis.

Description

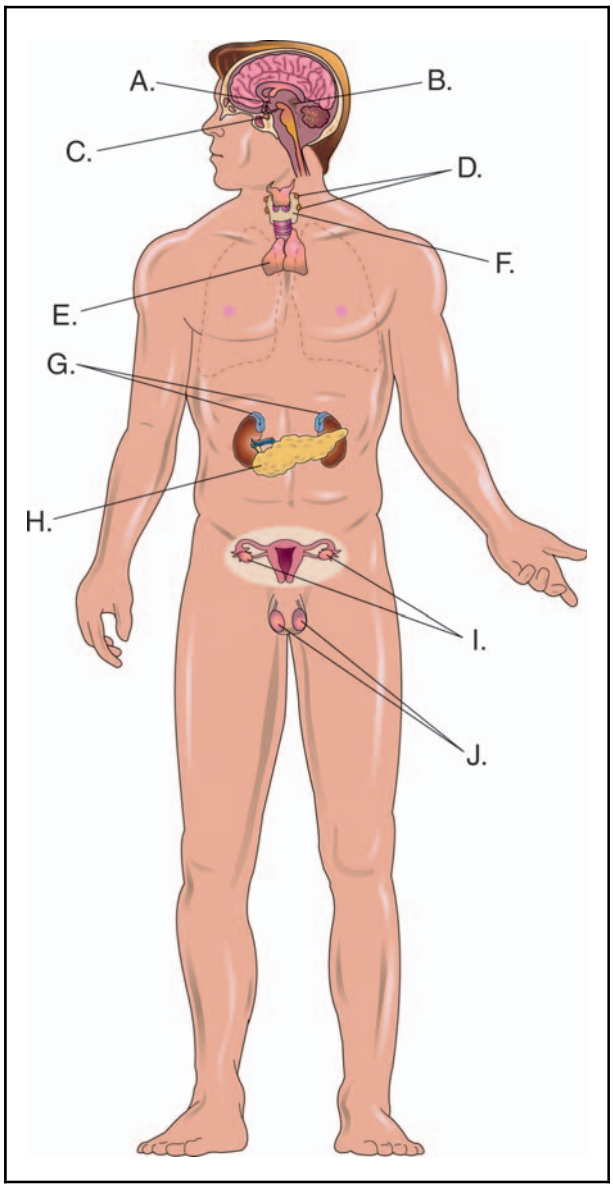
The three forms of MEN are MEN1 (Wermer's syndrome), MEN2A (Sipple syndrome), and MEN2B (previously known as MEN3). Each form leads to excessive growth of normal cells (hyperplasia) and overactivity of a number of endocrine glands. Excessive growth can result in the formation of tumors (neoplasia) that are either benign (noncancerous) or malignant (cancerous). Overactive endocrine glands increase the secretion of hormones into the bloodstream. Hormones are important chemicals that control and instruct the functions of different organs. Their levels in the body are carefully balanced to maintain normal functioning of many vital processes, including metabolism, growth, timing of reproduction, and the composition of blood and other body fluids.

All three forms are genetic disorders. They result when an abnormal form of a gene is inherited from one parent. The gene causing MEN1, named the MEN1 gene, was isolated in 1997. Both types of MEN2 are caused by mutations of the RET (REarranged during Transfection) gene. MEN1 and MEN2 are both autosomal dominant genetic conditions, meaning that an individual needs only one defective copy of the MEN1 gene or the RET gene to develop the associated disorder. In all forms, the children of an affected individual have a 50% chance of inheriting the defective gene.

The three forms of MEN are further distinguished by the endocrine glands affected. MEN1 is characterized by conditions of the parathyroid glands, pancreas, and pituitary gland. Patients with MEN2 commonly experience a form of thyroid cancer and **adrenal tumors**.

MEN1

Enlarged and overactive parathyroid glands, a condition called hyperparathyroidism, is present in 90% to 97% of MEN1 gene carriers and is usually the first condition to develop. The four parathyroid glands are located in the neck region, with a pair of the glands on either side of the thyroid. They produce parathyroid hormone, which regulates calcium and phosphorus levels. Hyperparathyroidism leads to elevated levels of the hormone, resulting in high blood calcium levels (**hypercalcemia**), which can cause kidney stones and weakened bones. All four parathyroid glands tend to develop tumors, but most tumors are benign and **parathyroid cancer** is rare. Hyperparathyroidism may be present during the teenage years, but most individuals are affected by age 40.



The human endocrine system: A. Hypothalamus. B. Pineal. C. Pituitary. D. Parathyroid. E. Thymus. F. Thyroid. G. Adrenals. H. Pancreas. I. Ovaries (female). J. Testes (male). *(Illustration by Electronic Illustrators Group.)*

Pancreatic tumors occur in 40% to 75% of individuals with the MEN1 gene. The pancreas, which sits behind the stomach, has two parts, an endocrine part and an exocrine part. Tumors in MEN1 occur only in the endocrine pancreas. Among the hormones secreted are ones that lower and raise blood sugar levels—insulin and glucagons—and the hormone gastrin, which is secreted into the stomach to aid in digestion. Thirty to 35% of pancreatic tumors are malignant, and they are the tumors most likely to cause cancer in MEN1 patients. Gastrin-produc-

Association of multiple endocrine neoplasias with other conditions

Form	Associated diseases/conditions
MEN 1 (Wermer's syndrome)	Parathyroid hyperplasia Pancreatic islet cell carcinomas, Pituitary hyperplasia Thymus, adrenal, carcinoid tumors (less common)
MEN 2A (Sipple syndrome)	Medullary thyroid carcinoma, Pheochromocytoma Parathyroid hyperplasia
MEN 2B	Medullary thyroid carcinoma, Pheochromocytoma Parathyroid hyperplasia Swollen lips Tumors of mucous membranes (eyes, mouth, tongue, nasal cavities) Enlarged colon Skeletal problems such as spinal curving
Familial medullary thyroid carcinoma	Medullary thyroid carcinoma

ing tumors (gastrinomas) are the most common tumors that form, representing about 50% of the MEN1 pancreatic tumors. Other tumors that form are insulin-producing tumors (insulinomas), representing 25% to 30%, and glucagon-producing tumors (glucagonomas), representing 5% to 10%.

Gastrinomas can cause recurring upper gastrointestinal ulcers, a condition called **Zollinger-Ellison syndrome**. About half of MEN1 patients with a pancreatic condition develop this syndrome. Insulinomas raise the insulin level in the blood and can lead to hypoglycemia, or low blood sugar (glucose), resulting in glucose levels that are too low to fuel the body's activity. Glucagonomas can cause high blood sugar levels, or hyperglycemia.

Pituitary tumors are the third most common condition in MEN1, occurring in about 50% of MEN1 patients. Fewer than 5% of these tumors are malignant. The pituitary gland, located at the base of the brain, secretes many hormones that regulate the function of other endocrine glands. The most common tumors forming in MEN1 patients are prolactin-producing tumors (prolactinomas) and growth hormone–secreting tumors, which lead to a condition known as acromegaly.

MEN2

Patients with MEN2A and MEN2B experience two main symptoms, medullary thyroid cancer (MTC) and a medullary adrenal tumor known as **pheochromocytoma**. Additional symptoms distinguish the two forms of MEN2. Twenty percent of MEN2A patients develop parathyroid tumors, which have not been reported for MEN2B. As in MEN1, parathyroid tumors in MEN2A affect all four glands and are usually benign. MEN2B is further characterized by the occurrence of benign tumors of the tongue, nasal cavities, and other facial surfaces (mucosal neuromas) and by a condition known as marfanoid habitus. Marfanoid habitus features a characteristic appearance resulting from severe wasting of the proximal muscles. A distinct facial appearance—an elongated face with a thick forehead, wide-eyed look, and broad nose—is often noted at birth. Gastrointestinal, skeletal, and pigmentation abnormalities may also occur. Mucosal neuromas occur in all MEN2B patients, and marfanoid habitus occurs in 65%. About 5% of MEN2 cases are MEN2B.

Ninety-five percent of MEN2A patients and 90% of MEN2B patients develop medullary thyroid **carcinoma** (MTC). Medullary thyroid carcinoma forms from the C-cells of the thyroid. C-cells make the hormone **calcitonin**, which is involved in regulating the calcium levels in the blood and calcium absorption by the bones. The thyroid, which is located in the front of the neck between the Adam's apple and the collarbone, also secretes hormones that are essential for the regulation of body temperature, heart rate, and metabolism.

Medullary thyroid carcinoma causes high blood levels of calcitonin. In MEN2B, MTC develops earlier and is more aggressive than in MEN2A. It has been described in MEN2B patients younger than one year, whereas in MEN2A patients it is likely to occur between the ages of 20 and 40.

Pheochromocytoma is found in 50% of MEN2A patients and 45% of MEN2B patients. A tumor of the medulla portion of the adrenal gland, it is usually a slow-growing and benign adrenal tumor. The two flat adrenal glands, one situated above each kidney, secrete the hormones epinephrine and norepinephrine to increase heart rate and blood pressure, along with other effects. Excessive secretion of these adrenal hormones can cause life-threatening hypertension and cardiac arrhythmia. Tumors form on both adrenal glands in 50% of MEN2 patients diagnosed with a pheochromocytoma. Tumor malignancy is very rare.

Demographics

MEN syndromes are rare. MEN1 occurs in about three to twenty persons out of 100,000, and MEN2 occurs in about three out of 100,000 people. Both MEN1 and MEN2 show no geographic, racial, or ethnic trend, and men and women have an equal chance of acquiring the MEN syndromes.

Ninety-eight percent of MEN1 gene carriers will develop varying combinations of tumors by age 30, but cancer has not been reported in patients younger than 18.

Seventy percent of MEN2A gene carriers will have symptoms by age 70, with most diagnoses occurring between the ages of 30 and 50. MEN2B can occur before one year of age, but most symptoms appear anytime between the ages of 20 and 70.

Causes and symptoms

MEN1

MEN1 is caused by mutations of the MEN1 gene. The MEN1 gene encodes for a previously unknown protein named menin. The role of menin in tumor formation in endocrine glands is not known. But the MEN1 gene is thought to be one of a group of genes known as a tumor suppressor gene. A patient who inherits one defective copy of a tumor suppressor gene from either parent has a strong predisposition to the disease because of the high probability of incurring a second mutation in at least one dividing cell. That cell no longer possesses even one normal copy of the gene. When both copies are defective, tumor suppression fails and tumors develop.

As of 2001, a number of different mutations have been discovered in the MEN1 gene, but people having the same mutation do not always develop the same endocrine conditions. Members within a single family can show different sets of conditions. The symptoms of MEN1 depend on the endocrine condition present:

- Hyperparathyroidism: weakness, **fatigue**, constipation, kidney stones, loss of appetite (anorexia), and bone and joint pain.
- Gastrinoma: peptic ulcers of the stomach and small intestine, **diarrhea**, and **weight loss**.
- Insulinoma: hypoglycemia characterized by weakness, shakiness, fast heartbeat, and difficulty concentrating.
- Glucagonoma: hyperglycemia characterized by inflammation of the tongue or stomach, **anemia**, weight loss, diarrhea, and blood clots.
- Prolactinoma: secretion of milk in women who are not nursing, headaches, sweating, fatigue, weight gain, fertility problems in men and women, and visual problems.
- Acromegaly: enlarged hands and feet, enlarged face, thickened oily skin, fatigue, sweating, bone and joint pain, weight gain, and high blood sugar.

MEN2

Both types of MEN2 are caused by mutations of the RET gene. The RET gene is a cancer-causing gene, or an oncogene. A number of different mutations lead to MEN2A, but only one specific genetic alteration leads to MEN2B.

Unlike for MEN1, the likelihood of developing different conditions in MEN2A is associated with specific mutations of the RET gene. Family history can indicate which conditions current family members are likely to develop. The symptoms of MEN2 are those that accompany hyperparathyroidism, MTC, and pheochromocytoma:

- Medullary thyroid cancer: enlargement of thyroid or neck swelling; lumps or nodules in the neck, pain in the neck region going to the ears, persistent cough unrelated to a cold, cough with bleeding, diarrhea or constipation, hoarseness, and difficulty swallowing or breathing.
- Pheochromocytoma: headaches, sweating, chest pains, feelings of anxiety.

The conditions of MEN2B patients show a variety of additional symptoms, including the occurrence of mucosal neuromas and marfanoid habitus, which is characterized by an elongated face, a thick forehead, and poor muscle development.

Diagnosis

The occurrence of one endocrine condition does not immediately lead to a suspicion of MEN syndromes. Diagnoses is based on the occurrence of one or more endocrine conditions and a family history of MEN1 or MEN2.

Since 1994, **genetic testing** using DNA technology has been available for both MEN1 and MEN2. The identification of the MEN1 gene in 1997 has made genetic screening for this gene more accurate.

A blood sample is usually analyzed for DNA testing, although other tissue can be used. The sample is sent to a laboratory that specializes in DNA diagnosis. There a geneticist will perform several tests on the DNA collected from the cells in blood sample. The exact tests performed will depend on whether MEN1 or MEN2 is suspected. Because different regions of the RET gene are associated with different endocrine conditions in MEN2A, several regions of the gene are examined. A positive result means the defective gene is present, and a negative result means the defective gene is not present.

The test results for the RET gene mutations are more reliable than for the MEN1 gene because detection techniques for identifying MEN1 are still being developed. A clinical diagnosis of MEN2 is confirmed with genetic testing 90–95% of the time. Even when a genetic test is negative, family medical records will be carefully reviewed to confirm the presence of MEN2, and periodic screening of related conditions will likely continue until age 30 or 40. The time required to obtain the test results for MEN2 is about 2–4 weeks, but MEN1 results will

likely take longer because there are fewer diagnostic labs set up for MEN1 analysis.

Those considered at risk for MEN1 or MEN2 based on genetic tests or family history are offered preventative surgery, regular screening for associated endocrine conditions, or a combination of these treatment options. Conditions are screened following the accepted procedure for each condition. Diagnosis is based on clinical features and on testing for elevated hormone levels.

MEN1

Hyperparathyroidism is diagnosed when high levels of calcium and intact parathyroid hormone are measured in a blood sample. Normal values of calcium for adults is 4.4–5.3 mg/dl (milligrams per deciliter), and normal values of parathyroid hormone are 10–55 pg/ml (picograms per milliliter). Prior to the parathyroid test, no food should be eaten for at least six hours. An **x ray** of bones may be taken and then examined by a radiologist for signs of low bone density. An x ray of the abdominal region can reveal kidney stones. Patients should be screened yearly.

Diagnosis of a gastrinoma follows established procedures and includes measuring the levels of gastrin in the blood and the level of stomach gastic acid production. Hypoglycemia associated with insulinomas is diagnosed by measuring blood glucose levels. This test may be administered while a patient is experiencing symptoms related to low insulin levels or during a supervised period of fasting. Depending on the type of test given, no food should be eaten from 6–12 hours prior to the test. Normal glucose levels range between 64–128 mg/dl. Blood glucagon levels above the normal range of 50–100 pg/ml can indicate hyperglycemia, which is associated with glucagonomas. Large pancreatic tumors are identified using **computed tomography** (CT scans) or radionuclide imaging, but **ultrasonography** conducted during surgery is the best method for detecting small tumors. There is no accepted system for staging the pancreatic tumors associated with MEN1.

Prolactinomas, the pituitary tumors most often associated with MEN1, are diagnosed when prolactin levels are greater than 20 ng/l (nanograms per liter). A tumor is identified using **magnetic resonance imaging** (MRI). Tumors secreting excess growth hormone are diagnosed when hormone levels are above the upper normal range of 3 ng/l and from observable changes in physical appearance.

MEN2

Medullary thyroid carcinoma is diagnosed by measuring calcitonin levels in blood and urine samples and from a **biopsy** of any thyroid nodules. Levels of calcitonin above 50 pg/ml can indicate the presence of MTC. Patients showing normal calcitonin levels may require a different test, in which calcitonin is measured at regular intervals after an injection of pentagastrin, a synthetic hormone.

Fine needle aspiration is the biopsy procedure used to diagnose MTC and other forms of thyroid cancer. A sample of cells is removed from a nodule, and the cells are then examined under a microscope by a pathologist to determine if cancer cells are present. MTC has four stages, based on the size of the tumor and where the cancer has spread. **Tumor staging** follows the system established for other forms of thyroid cancer.

A high level of epinephrine relative to norepinephrine indicates a pheochromocytoma on one or both adrenal glands. A CT scan, an MRI, or radionuclide imaging will be performed to locate the tumor.

Diagnosis of hyperparathyroidism in MEN2A patients is identical to its diagnosis for MEN1 patients, but with screening recommended every two to three years.

Treatment team

Conditions of MEN syndromes are first diagnosed by a pathologist who interprets blood and urine samples collected at a doctor's office or a clinic. Depending on the specific condition, a doctor specializing in conditions of the endocrine gland (an endocrinologist) may be consulted. When MEN syndromes are suspected, a genetic counselor will help prepare a patient for the genetic testing procedures and results. A geneticist will perform and interpret genetic tests. Since MEN syndromes often require surgery, the surgical team will likely consist of a surgeon experienced in operating on endocrine glands.

Clinical staging, treatments, and prognosis

No comprehensive treatment is available for genetic disorders such as MEN, but the symptoms of many conditions are treatable. Surgical removal of tumors is the recommended treatment for most conditions, and most MEN patients will require more than one endocrine gland surgery during a lifetime.

An important distinction between an endocrine condition in MEN patients and the same condition in patients not diagnosed with MEN is that endocrine tumors for MEN patients are likely to arise in many locations of a single gland or on multiple glands. Treatment options that work for patients with a single endocrine condition may not be effective in MEN patients. Surgery is often more extensive for MEN patients.

Genetic testing can exclude family members who do not have mutations of the RET or MEN1 gene. The advantage of testing is the early treatment and improved outcomes for those who carry the defective gene and relief from unnecessary anxiety and clinical testing for those not having the defective gene.

MEN1

A common approach to treating MEN1 is with regular screening. Surgical procedures may be delayed until a patient has developed clinical symptoms caused by excess hormone or an easily identifiable tumor.

There are two surgical options for MEN1 patients showing multiple symptoms of hyperparathyroidism or for patients having high blood calcium levels (hypercalcemia), even when no symptoms of the condition are present. All parathyroid tissue is identified and removed and parathyroid tissue is implanted in the forearm, or the surgeon removes three parathyroids and one half of the fourth. After surgery, blood calcium levels are regularly tested to ensure that the remaining parathyroid tissue has not enlarged and caused the condition to return. If hyperparathyroidism recurs, a portion of the remaining tissue is removed until calcium levels return to normal or all the remaining tissue is removed. For MEN1 patients, recurrence is likely within 15 years of the first surgery. Patients with no parathyroid tissue must take daily calcium and vitamin D supplements to prevent hypercalcemia.

There are two views on the best screening strategy for pancreatic tumors in MEN1 patients. One approach is yearly screening, particularly for gastrinomas. This strategy emphasizes the earliest possible detection and surgical removal of tumors. The other approach is screening every 2–3 years, with the reasoning that although tumors are detected at a later stage, they can be better managed with drugs and, if necessary, with surgery.

Surgical removal of insulinomas and glucagonomas, as well as of other less commonly occurring pancreatic tumors in MEN1 patients, is generally the recommended treatment because these tumors are difficult to treat with medication.

The best treatment option for gastrinomas is complex because in MEN1 patients there can be multiple gastrinomas of varying sizes on the pancreas and upper portion of the small intestine (duodenum), and they have a tendency to recur. Most doctors support the use of medication to control the condition and do not recommend surgical intervention. Common treatment of symptoms is the use of drugs that block acid production, called acid pump inhibitors. Others recommend surgery that includes removal of the duodenum and a section of the pancreas and cutting nerves to the section of the stomach involved in acid secretion. Surgery is supported as a way to reduce the risk for **metastasis**. In some cases, gastrin levels and gastric acid levels returned to normal, and MEN1 patients experienced no symptoms after the surgery. A treatment no longer recommended is removal of the entire stomach. Malignant gastrinomas cause death in 10% to 20% of MEN1 patients with this condition, and 30% to 50% will eventually spread to the liver.

Treatment of pituitary tumors in MEN1 patients rarely involves surgery. For prolactinomas, medications are effective in returning prolactin levels to normal and preventing tumor growth.

MEN2

Medullary thyroid carcinoma is the primary concern for those testing positive for the RET gene mutations. Since genetic testing became available for MEN2, two approaches have emerged to manage this cancer. Some recommend removing the entire thyroid gland (thyroidectomy) before any symptoms occur, although doctors disagree at what age to perform this surgery. This strategy emerged owing to a number of cases in which thyroids removed from identified MEN2 patients showing no clinical signs of MTC were found to be cancerous. Preventative thyroid surgery is offered to those with RET gene mutations beginning at age 5. Some recommend surgery after age 10, unless calcitonin tests are positive earlier. They contend that surgery before age 10 may increase the chance of damaging the larynx or the parathyroids.

The second approach is yearly blood calcitonin testing beginning in early childhood. A thyroidectomy is performed after the first abnormal calcitonin test. There is only a 10% chance of recurrence 15–20 years after surgery for those identified using this method. The advantage of this method is to delay surgery until it is necessary. The disadvantages are the cost and discomfort of yearly testing. Also, the first detection of elevated levels of calcitonin in the blood may occur after the cancer has already reached an advanced stage.

A thyroidectomy is the standard treatment for all stages of MTC. If MTC is diagnosed in an advanced stage, the spread of the cancer may have already occurred. Metastasis is very serious in MTC because **chemotherapy** and **radiation therapy** are not effective in controlling metastasis. Further tests are likely to include a CT scan and an MRI.

All MTC patients must take thyroid hormone medication for the rest of their lives in order to maintain normal body functions. Follow-up treatment to assure that the cancer has not recurred includes monitoring the lev-

els of calcitonin in the blood. The survival rate 10 years after the initial diagnosis is 46%. If the cancer is detected using genetic screening before the patient shows signs of having the disease, surgical removal of the thyroid gland can cure MTC.

Pheochromocytoma may occur after the MTC diagnosis by as much as 20 years. Pheochromocytoma in MEN2 can be cured by surgical removal of the affected adrenal gland. If a pheochromocytoma occurs on only one gland, there is some debate on whether to remove both adrenal glands or only the affected gland. Fifty percent of MEN2 patients who underwent removal of one adrenal gland developed a pheochromocytoma in the other gland within 10 years. Because malignancy is rare, most doctors recommend removing the affected glands first and then monitoring hormone levels to see if a second tumor occurs. If both glands are removed, hormone replacement therapy is required.

Alternative and complementary therapies

There are no alternative treatments specifically targeted for people with MEN syndromes, although cow and shark cartilage treatments are being investigated as a way to decrease tumor growth in some cancers. These treatments are administered orally, by injection, or as an enema, but studies of the effectiveness of this treatment for humans are inconclusive.

Coping with cancer treatment

The surgery that most MEN syndromes patients will face can cause anxiety and fear. Patients should discuss their concerns about an operation with their personal physician, the surgeon, nurses, and other medical personnel. Getting specific answers to questions can provide a clear idea of what to expect immediately after the surgery as well as any long-term changes in quality of life.

Clinical trials

Clinical studies of MEN syndromes focus on understanding the genes involved in the inheritance of MEN1 and MEN2 and on the unique treatment needs for the endocrine gland conditions occurring in MEN patients. One ongoing study investigates new imaging techniques for locating pheochromocytomas, particularly in MEN2 patients. Contact information:

National Institute of Child Health and Human Development (NICHD), 9000 Rockville Pike, Bethseda, MD 20892. (800) 411-1222

A second clinical trial is a genetic-analysis study of known and suspected individuals with MEN1. Participants are offered genetic counseling with an option for involvement in research designed to improve genetic counseling services. Contact information:

National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), 9000 Rockville Pike, Bethseda, MD 20892. (800) 411-1222

KEY TERMS

Endocrine—A term used to describe the glands that produce hormones in the body.

Exocrine—A term used to describe organs that secrete substances outward through a duct.

Hyperplasia—An overgrowth of normal cells within an organ or tissue.

Medullary thyroid cancer (MTC)—A slow-growing tumor of which about 20% are associated with MEN2.

Neoplasm—An abnormal formation of tissue; for example, a tumor.

Oncogene—A gene with a mutation that causes cell growth and division, leading to the formation of cancerous tumors.

Pheochromocytoma—A tumor of the medullary of the adrenal gland.

RET (REarranged during Transfection) gene—Located on chromosome 10q11.2, mutations in this gene are associated with two very different disorders, the multiple endocrine neoplasia (MEN) syndromes and Hirschsprung disease.

Tumor suppressor gene—A type of gene that instructs cells on the appropriate time to die. A mutation can turn off the gene, resulting in cell growth and tumor formation.

Prevention

There is no preventive measure to block the occurrence of the genetic mutations that cause MEN syndromes. Medullary thyroid carcinoma, one of the most serious conditions of MEN2, can be prevented by thyroidectomy.

Special concerns

It is important to seek professional genetic counseling before proceeding with genetic testing, particularly for children. Adults may have to make treatment decisions for children.

Genetic tests are often expensive. Whether or not **health insurance** will cover the costs of counseling and

QUESTIONS TO ASK THE DOCTOR

- Are the tumors associated with this condition cancerous?
- Can one endocrine tumor spread to other endocrine glands?
- What are the long-lasting effects of this disorder?
- What are the long-lasting effects of treatment?
- After treatment, what are the chances that a condition will recur?
- Are there alternative treatments to surgery?
- Will I need to take hormone supplements, if so, for how long?
- Will this disorder affect my ability to have children?
- What is the current status of predictive gene testing?
- Who in my family should be tested for this disorder?

testing will depend on individual policies. Some insurance companies cover the costs only when a patient shows symptoms of a condition. Genetic tests raise issues of privacy. Most states in the United States have legislation that restricts the use of genetic test results by insurance companies and employers.

Multiple myeloma

Definition

Multiple myeloma is a cancer in which antibody-producing plasma cells grow in an uncontrolled and invasive (malignant) manner.

Description

Multiple myeloma, also known as plasma cell myeloma, is the second-most common cancer of the blood. It is the most common type of plasma cell neoplasm. Multiple myeloma accounts for approximately 1% of all cancers and 2% of all deaths from cancer. Multiple myeloma is a disease in which malignant plasma cells spread through the bone marrow and hard outer portions of the large bones of the body. These myeloma cells may form tumors called plasmacytomas. Eventually, multiple soft spots or holes, called osteolytic lesions, form in the bones.

Bone marrow is the spongy tissue within the bones. The breastbone, spine, ribs, skull, pelvic bones, and the long bone of the thigh all are particularly rich in marrow. Bone marrow is a very active tissue that is responsible for producing the cells that circulate in the blood. These include the red blood cells that carry oxygen, the white blood cells that develop into immune system cells, and platelets, which cause blood to clot.

Plasma cells and immunoglobulins

Plasma cells develop from B lymphocytes or B cells, a type of white blood cell. B cells, like all blood cells, develop from unspecialized stem cells in the bone marrow. Each B cell carries a specific antibody that recognizes a specific foreign substance called an antigen. Antibodies are large proteins called immunoglobulins (Igs), which recognize and destroy foreign substances and organisms such as bacteria. When a B cell encounters its antigen, it begins to divide rapidly to form mature plasma cells. These plasma cells are all identical (monoclonal). They produce large amounts of identical antibody that are specific for the antigen.

Malignant plasma cells

Multiple myeloma begins when the genetic material (DNA) is damaged during the development of a stem cell into a B cell in the bone marrow. This causes the cell to develop into an abnormal or malignant plasmablast, a developmentally early form of plasma cell. Plasmablasts produce adhesive molecules that allow them to bond to the inside of the bone marrow. A growth factor, called interleukin-6, promotes uncontrolled growth of these myeloma cells in the bone marrow and prevents their natural death. Whereas normal bone marrow contains less than 5% plasma cells, bone marrow of an individual with multiple myeloma contains over 10% plasma cells.

In most cases of multiple myeloma, the malignant plasma cells all make an identical Ig. Igs are made up of four protein chains that are bonded together. Two of the chains are light and two are heavy. There are five classes of heavy chains, corresponding to five types of Igs with different immune system functions. The Igs from myeloma cells are nonfunctional and are called paraproteins. All of the paraproteins from any one individual are monoclonal (identical) because the myeloma cells are identical clones of a single plasma cell. Thus, the paraprotein is a monoclonal protein or M-protein. The M-proteins crowd out the functional Igs and other components of the immune system. They also cause functional antibodies, which are produced by normal plasma cells, to rapidly break down. Thus, multiple myeloma depresses the immune system.

In about 75% of multiple myeloma cases, the malignant plasma cells also produce monoclonal light chains, or incomplete Igs. These are called Bence-Jones proteins and are secreted in the urine. Approximately 1% of multiple myelomas are called nonsecretors because they do not produce any abnormal Ig.

Osteolytic lesions

About 70% of individuals with multiple myeloma have soft spots or lesions in their bones. These lesions can vary from quite small to grapefruit-size. In part, these lesions occur because the malignant plasma cells rapidly outgrow the normal bone-forming cells. In addition, malignant myeloma cells produce factors that affect cells called osteoclasts. These are the cells that normally destroy old bone, so that new bone can be produced by cells called osteoblasts. The myeloma cell factors increase both the activation and the growth of osteoclasts. As the osteoclasts multiply and migrate, they destroy healthy bone and create lesions. Osteoporosis, or widespread bone weakness, may develop.

Demographics

There are more than 40,000 multiple myeloma patients in the United States. The American Cancer Society predicts an additional 14,400 new cases in 2001. About 11,200 Americans will die of the disease in 2001. Multiple myeloma is one of the leading causes of cancer deaths among African-Americans.

In Western industrialized countries, approximately four people in 100,000 develop multiple myeloma. The incidence of multiple myeloma among African Americans is 9.5 per 100,000, about twice that of Caucasians. Asians have a much lower incidence of the disease. In China, for example, the incidence of multiple myeloma is only one in 100,000. The offspring and siblings of individuals with multiple myeloma are at a slightly increased risk for the disease.

At diagnosis, the average age of a multiple myeloma patient is 68 to 70. Although the average age at onset is decreasing, most multiple myelomas still occur in people over 40. This cancer is somewhat more prevalent in men than in women.

Causes and symptoms

Associations

The cause of multiple myeloma has not been determined. However, a number of possible associations have been identified:

- decreased immune system function; the immune systems of older individuals may be less efficient at detecting and destroying cancer cells
- genetic (hereditary) factors, suggested by the increased incidence in some ethnic groups and among family members
- occupational factors, suggested by the increased incidence among agricultural, petroleum, wood, and leather workers, and cosmetologists
- long-term exposure to herbicides, pesticides, petroleum products, heavy metals, plastics, and dusts such as asbestos
- radiation exposure, as among Japanese atomic bomb survivors, nuclear weapons workers, and medical personnel such as radiologists
- Kaposi's sarcoma-associated herpes virus (also called human herpes virus-8 or HHV-8), found in the blood and bone marrow cells of many multiple myeloma patients

Early symptoms

The accumulation of malignant plasma cells can result in tiny cracks or fractures in bones. Malignant

plasma cells in the bone marrow can suppress the formation of red and white blood cells and platelets. About 80% of individuals with multiple myeloma are anemic due to low red blood cell formation. Low white blood cell formation results in increased susceptibility to infection, since new, functional antibodies are not produced. In addition, normal circulating antibodies are rapidly destroyed. Low platelet formation can result in poor blood clotting. It is rare, however, that insufficient white blood cell and platelet formations are presenting signs of multiple myeloma.

These factors cause the early symptoms of multiple myeloma:

- pain in the lower back or ribs
- fatigue and paleness due to **anemia** (low red blood cell count)
- frequent and recurring infections, including bacterial **pneumonia**, urinary-tract and kidney infections, and shingles (herpes zoster)
- bleeding

Bone destruction

Bone pain, particularly in the backbone, hips, and skull, is often the first symptom of multiple myeloma. As malignant plasma cells increase in the bone marrow, replacing normal marrow, they exert pressure on the bone. As overly active osteoclasts (large cells responsible for the breakdown of bone) remove bone tissue, the bone becomes soft. Fracture and **spinal cord compression** may occur.

Plasmacytomas (malignant tumors of plasma cells) may weaken bones, causing fractures. Fractured bones or weak or collapsed spinal bones, in turn, may place unusual pressure on nearby nerves, resulting in nerve pain, burning, or numbness and muscle weakness. Proteins produced by myeloma cells also may damage nerves.

Calcium from the destroyed bone enters the blood and urine, causing **hypercalcemia**, a medical condition in which abnormally high concentrations of calcium compounds exist in the bloodstream. High calcium affects nerve cell and kidney function. The symptoms of hypercalcemia include:

- weakness and fatigue
- depression
- mental confusion
- constipation
- increased thirst
- increased urination
- nausea and vomiting
- kidney pain
- kidney failure

Hypercalcemia affects about one-third of multiple myeloma patients.

Serum proteins

The accumulation of M-proteins in the serum (the liquid portion of the blood) may cause additional complications, such as hyperviscosity syndrome, or thickening of the blood (though rare in multiple myeloma patients). Symptoms of hyperviscosity include:

- fatigue
- headaches
- shortness of breath
- mental confusion
- chest pain
- kidney damage and failure
- vision problems
- Raynaud's disease (Raynaud's phenomenon, can affect any part of the body, but particularly the fingers, toes, nose, and ears.)

Cryoglobulinemia occurs when the protein in the blood forms particles under cold conditions. These particles can block small blood vessels and cause pain and numbness in the toes, fingers, and other extremities during cold weather.

Amyloidosis is a rare complication of multiple myeloma. It usually occurs in individuals whose plasma cells produce only Ig light chains. These Bence-Jones proteins combine with other serum proteins to form amyloid protein. This starchy substance can invade tissues, organs, and blood vessels. In particular, amyloid proteins can accumulate in the kidneys, where they block the tiny tubules that are the kidney's filtering system. Indicators of amyloidosis include:

- carpal tunnel syndrome
- kidney failure
- liver failure
- heart failure

Diagnosis

Blood and urine tests

Often, the original diagnosis of multiple myeloma is made from routine blood tests that are performed for other reasons. Blood tests may indicate:

- anemia
- abnormal red blood cells
- high serum protein levels
- low levels of normal antibody
- high calcium levels
- high blood urea nitrogen (BUN) levels
- high creatinine levels

Urea and creatinine normally are excreted in the urine. High levels of urea and creatinine in the blood indicate that the kidneys are not functioning properly to eliminate these substances.

Protein electrophoresis is a laboratory technique that uses an electrical current to separate the different proteins in the blood and urine on the basis of size and charge. Since all of the multiple myeloma M-proteins in the blood and urine are identical, electrophoresis of blood and urine from a patient with multiple myeloma shows a large M-protein spike, corresponding to the high concentration of monoclonal Ig. Electrophoresis of the urine also can detect Bence-Jones proteins.

Bones

A bone marrow aspiration utilizes a very thin, long needle to remove a sample of marrow from the hip bone. Alternatively, a bone marrow **biopsy** with a larger needle removes solid marrow tissue. The marrow is examined under the microscope for plasma cells and tumors. If 10% to 30% of the cells are plasma cells, multiple myeloma is the usual diagnosis.

X rays are used to detect osteoporosis, osteolytic lesions, and fractures. Computed tomography (CAT or CT) scans can detect lesions in both bone and soft tissue. **Magnetic resonance imaging** (MRI) may give a more detailed image of a certain bone or a region of the body.

Treatment team

After the initial diagnosis, the treatment team for multiple myeloma may include a hematologist (a specialist in diseases of the blood) and an oncologist or cancer specialist. If radiation is used in treatment, a radiation oncologist may join the team. The treatment of multiple myeloma involves complex decisions, and obtaining second opinions from additional specialists may be important.

Clinical staging, treatments, and prognosis

Related disorders

Monoclonal gammopathy of undetermined significance (MGUS) is a common condition in which a monoclonal Ig is detectable. However, there are no tumors or other symptoms of multiple myeloma. MGUS occurs in about 1% of the general population and in about 3% of those over age 70. Over a period of years, about 16% to 20% of those with MGUS will develop multiple myeloma or a related cancer called malignant **lymphoma**.

Occasionally, only a single plasmacytoma develops, either in the bone marrow (isolated plasmacytoma of the bone) or other tissues or organs (extramedullary plasmacytoma). Some individuals with solitary plasmacytoma may develop multiple myeloma.

Clinical stages

The Durie-Salmon system is used to stage multiple myeloma. Stage I multiple myeloma requires all of the following (1 gram = approx. 0.02 pints, 1 deciliter = approx. 0.33 fluid ounces):

- hemoglobin (the oxygen-transporting molecule of red blood cells) above 10 grams/deciliter (g/dl)
- serum calcium below 12 mg/dl
- normal bone structure or only isolated plasmacytoma
- low M-protein, based on established guideline levels of Ig protein chains

Approximately 5% of multiple myeloma cases are not progressing at diagnosis, and may not progress for months or years. This is called smoldering myeloma. These patients have stage I blood chemistry but no symptoms.

Stage II multiple myeloma fits neither stage I nor stage III. Stage III multiple myeloma meets one or more the following criteria:

- hemoglobin below 8.5 g/dl
- serum calcium above 12 mg/dl
- advanced bone lesions
- high M-protein

Each stage is subclassified as A or B, based on serum creatinine indicators of normal or abnormal kidney function. Most patients have stage III multiple myeloma at diagnosis.

Prognostic indicators

Prognostic indicators for multiple myeloma may be used instead of, or in addition to, the staging system described above. Prognostic indicators are laboratory tests that help to define the stage of the disease at diagnosis, and its progression during treatment. These indicators are:

- plasmablastic multiple myeloma (presence of plasmablasts, the precursor malignant plasma cells)

- plasma cell labeling index (the percentage of plasma cells that are actively dividing)
- beta 2-microglobulin, a protein secreted by B cells that correlates with the myeloma cell mass (also indicates kidney damage)

Treatment

Since multiple myeloma often progresses slowly, and since the treatments can be toxic, the disease may not be treated until M-protein levels in the blood are quite high. In particular, MGUS and smoldering myeloma may be followed closely but not treated. Solitary plasmacytomas are treated with radiation and/or surgery and followed closely with examinations and laboratory tests.

CHEMOTHERAPY **Chemotherapy**, or treatment with anti-cancer drugs, is used for multiple myeloma. MP, a combination of the drugs **melphalan** and prednisone, is the standard treatment. Usually, the drugs are taken by mouth every 3 to 4 weeks for 6 to 9 months or longer, until the M-protein levels in the blood stop decreasing. MP usually results in a 50% reduction in M-protein.

Dexamethasone, a corticosteroid, sometimes is used to treat the elderly or those in poor health. It can drop the M-protein levels by 40% in untreated individuals and by 20% to 40% in patients who have not responded to previous treatment. Other chemotherapy drugs, including **cyclophosphamide**, **carmustine**, **doxorubicin**, **vincristine**, and **chlorambucil**, may be used as well.

Multiple myeloma usually recurs within a year after the end of chemotherapy. Although the chemotherapy can be repeated after each recurrence, it is progressively less responsive to treatment.

Side effects of chemotherapy may include:

- anemia
- hair loss (alopecia)
- nausea and vomiting
- diarrhea
- mood swings
- swelling
- acne

These side effects disappear after treatment is discontinued.

OTHER DRUG TREATMENTS **Bisphosphonates** are drugs that inhibit the activity of osteoclasts. These drugs can slow the progression of bone disease, reduce pain, and help prevent bone fractures. Different types of bisphosphonates inhibit osteoclasts in different ways. They also reduce the production of interleukin-6 by bone marrow cells. Laboratory studies suggest that bisphosphonates may kill or inhibit the growth of multiple myeloma cells. Pamidronate is the most common bisphosphonate for treating multiple myeloma.

Portion of spine from patient with multiple myeloma. In this disease, malignant plasma cells spread through the bone marrow and hard outer portions of the body's large bones. As malignant plasma cells increase in the bone marrow, replacing normal marrow, they exert pressure on the bone. Bones become soft and may fracture; spinal bones may collapse. *(Custom Medical Stock Photo. Reproduced by permission.)*

The drug **thalidomide** appears to have several anti-myeloma activities. Thalidomide affects the immune system in various ways and it appears to inhibit myeloma cells, both directly and indirectly. It also inhibits the growth of new blood vessels that are needed by tumors. However, if thalidomide is taken during pregnancy, it can cause severe birth defects or death of the fetus.

KEY TERMS

Amyloidosis—A complication of multiple myeloma in which amyloid protein accumulates in the kidneys and other organs, tissues, and blood vessels.

Anemia—Any condition in which the red blood cell count is below normal.

Antibody—Immunoglobulin produced by immune system cells that recognizes and binds to a specific foreign substance (antigen).

Antigen—Foreign substance that is recognized by a specific antibody.

B cell (B lymphocyte)—Type of white blood cell that produces antibodies.

Bence-Jones protein—Light chain of an immunoglobulin that is overproduced in multiple myeloma and is excreted in the urine.

Beta 2-microglobulin—Protein produced by B cells; high concentrations in the blood are indicative of multiple myeloma.

Cryoglobulinemia—Condition triggered by low temperatures in which protein in the blood forms particles, blocking blood vessels, leading to pain and numbness of the extremities.

Electrophoresis—Use of an electrical field to separate proteins in a mixture (such as blood or urine), on the basis of the size and electrical charge of the proteins.

Hemoglobin—Protein in red blood cells that carries oxygen.

Hypercalcemia—Abnormally high levels of calcium in the blood.

Hyperviscosity—Thick, viscous blood, caused by the accumulation of large proteins, such as immunoglobulins, in the serum.

Immunoglobulin (Ig)—Antibody; large protein produced by B cells that recognizes and binds to a specific antigen.

M-protein—Monoclonal or myeloma protein; paraprotein; abnormal antibody found in large amounts in the blood and urine of individuals with multiple myeloma.

Malignant—A characteristic of cancer cells that grow uncontrollably and invade other tissues.

Monoclonal—Identical cells or proteins; cells (clones) derived from a single, genetically distinct cell, or proteins produced by these cells.

Monoclonal gammopathy of undetermined significance (MGUS)—Common condition in which M-protein is present, but there are no tumors or other symptoms of disease.

Neoplasm—Tumor made up of cancer cells.

Osteoblast—Bone-forming cell.

Osteoclast—Cell that absorbs bone.

Osteolytic lesion—Soft spot or hole in bone caused by cancer cells.

Osteoporosis—Condition in which the bones become weak and porous, due to loss of calcium and destruction of cells.

Paraprotein—M-protein; abnormal immunoglobulin produced in multiple myeloma.

Plasma cell—Type of white blood cell that produces antibodies; derived from an antigen-specific B cell.

Platelet—Cell that is involved in blood clotting.

Stem cell—Undifferentiated cell that retains the ability to develop into any one of numerous cell types.

The drug **allopurinol** may be used to reduce high blood levels of uric acid that result from kidney dysfunction. Diuretics can improve kidney function. Infections require prompt treatment with **antibiotics**.

BONE AND PERIPHERAL BLOOD STEM CELL TRANSPLANTATION Bone marrow or peripheral blood stem cell transplantations (PBSCT) are used to replace the stem cells of the bone marrow following high-dosage chemotherapy. Chemotherapy destroys the bone marrow stem cells that are necessary to produce new blood cells. In an autologous transplant, the patient's bone marrow stem cells or peripheral blood stem cells (immature bone marrow cells found in the blood) are collected, treated with drugs to kill any myeloma cells, and frozen prior to chemotherapy. Growth factors are used to increase the number of peripheral stem cells prior to collection. A procedure called apheresis is used to collect the peripheral stem cells. Following high-dosage chemotherapy, the stem cells are reinjected into the individual. In an allogeneic transplant, the donor stem cells come from a genetically related individual such as a sibling.

OTHER TREATMENTS Blood transfusions may be required to treat severe anemia.

Plasmapheresis, or plasma exchange transfusion, may be used to thin the blood to treat hyperviscosity syndrome. In this treatment, blood is removed and passed through a machine that separates the plasma, containing the M-protein, from the red and white blood cells and platelets. The blood cells are transfused back into the patient, along with a plasma substitute or donated plasma.

Multiple myeloma may be treated with high-energy x rays directed at a specific region of the body. **Radiation therapy** is used for treating bone pain.

Alternative and complementary therapies

Interferon alpha, an immune-defense protein that is produced by some white blood cells and bone marrow cells, can slow the growth of myeloma cells. It usually is given to patients following chemotherapy, to prolong their remission. However, interferon may have toxic effects in older individuals with multiple myeloma.

Once multiple myeloma is in remission, calcium and vitamin D supplements can improve bone density. It is important not to take these supplements when the myeloma is active. Individuals with multiple myeloma must drink large amounts of fluid to counter the effects of hyperviscous blood.

Prognosis

The prognosis for individuals with MGUS or solitary plasmacytoma is very good. Most do not develop multiple myeloma. However, approximately 15% of all patients with multiple myeloma die within three months of diagnosis. About 60% respond to treatment and live for an average of two and a half to three years following diagnosis. Approximately 23% of patients die of other illnesses associated with advanced age.

The prognosis for a given individual may be based on the prognostic indicators described above. The median survival for those without plasmablasts, and with a low plasma cell labeling index (PCLI) and low beta 2-microglobulin, is 5.5 years. The median survival for patients with plasmablastic multiple myeloma, or with a high PCLI (1% or greater) and high beta 2-microglobulin (4 or higher), is 1.9 and 2.4 years, respectively. Many multiple myeloma patients are missing part or all of chromosome 13. The deletion of this chromosome, along with high beta 2-microglobulin, leads to a poor prognosis.

With treatment, multiple myeloma may go into complete remission. This is defined as:

- M-protein absent from the blood and urine
- myeloma cells not detectable in the bone marrow
- no clinical symptoms
- negative laboratory tests

However, with very sensitive testing, a few myeloma cells are usually detectable and eventually lead to a recurrence of the disease, in the bone or elsewhere in the body.

Coping with cancer treatment

Techniques such as biofeedback, guided imagery, and meditation may be helpful for reducing stress and relieving pain. Pain medication is usually prescribed for multiple myeloma. Back or neck braces may help relieve bone pain. Exercise, if possible, is important for retaining calcium in the bones.

Clinical trials

There are hundreds of ongoing **clinical trials** for the treatment of multiple myeloma. These take place throughout the United States and are sponsored by both government and industry. Clinical trials of treatments for multiple myeloma include:

- thalidomide
- thalidomide-like drugs that affect the immune system in various ways
- skeletal targeted radiotherapy (STP), in which a radioactive element is attached to a drug that binds to bone
- new anti-cancer drugs
- new combinations of drugs
- new chemotherapies in combination with PBSCT
- combinations of PBSCT, interleukin-2, and interferon alpha
- treatments for disease resulting from PBSCT (graft-versus-host disease)
- bone marrow transplantations
- immunotherapies, including **vaccines**, to destroy remaining myeloma cells after high-dosage chemotherapy and PBSCT
- treatments for MGUS

Prevention

There are no clearly established risk factors for multiple myeloma and it is possible that a combination of factors interact to cause the disease. Thus, there is no method for preventing multiple myeloma.

Special concerns

Since there is a high probability that multiple myeloma will recur after treatment, patients are followed

QUESTIONS TO ASK THE DOCTOR

- What stage of multiple myeloma do I have and what does it mean?
- What are my treatment options?
- What are the side effects of treatment?
- Are there clinical trials that may be appropriate for me?
- How long can I expect to survive?
- Is my cancer likely to recur?

carefully. Blood tests, x rays, and other **imaging studies** may be used to check for a recurrence.

Muromonab-CD3

Definition

Muromonab-CD3 is a mouse-derived (murine) monoclonal antibody that specifically binds to the CD3 (T3) protein found on the surface of T cells. It is a protein known to be necessary for activation (immune responses) of T cells. Muromonab-CD3 is marketed in the United States under the Orthoklone OKT3 brand name.

Purpose

Muromonab-CD3 is believed to have two effects when it binds to the CD3 protein on the surface of T cells. In the short term the T cells are activated and begin to excrete cytokines—small proteins that boost immune function. In the long term, function of the T cells is eliminated because access to the CD3 protein is blocked and binding by the antibody encourages removal of the cell from the bloodstream by the immune system.

When using muromonab-CD3 to treat cancer, doctors are seeking the short-term effect by boosting the activity of T cells against tumor antigens. In this setting muromonab-CD3 is not administered directly to the patient. Rather, it is used to stimulate white blood cells (lymphocytes) that have been removed from the patient, treated outside the body, then reinfused (infused back into the patient). In the test tube the binding of the antibody to the CD3 protein stimulates the T cells so they can begin the cell-mediated destruction of the tumor cells upon reentry into the patient's bloodstream. Often, the T cells used for this treatment are either preselected to be specific against the proteins found on the tumor surface (tumor antigens) or are genetically engineered

KEY TERMS

Antibody—A protective protein made by the immune system in response to an antigen; also called an immunoglobulin.

Cytokine—A protein produced by cells of the immune system that help boost immune function.

hOKT3—A humanized version of the muromonab-CD3 antibody.

Humanization—Fusing the constant and variable framework region of one or more human immunoglobulins with the binding region of an animal immunoglobulin; done to reduce human reaction against the fusion antibody.

Interleukin-2—A cytokine responsible for the activation of B and T cells of the immune system that induces growth and maturation of those cells.

Monoclonal antibody—Genetically engineered antibodies specific for one antigen.

before reinfusion to express the desired tumor-antigen specific receptors. This is often followed by stimulation of T-cell division using interleukin-2.

Clinical trials using this stimulated lymphocyte treatment are ongoing for **astrocytoma**, oligodendroglioma, nonmetastatic kidney cancer, metastatic **melanoma**, **Kaposi's sarcoma** (a twin study), and advanced epithelial **ovarian cancer**.

Description

In late 1986, Muromonab-CD3 was the first monoclonal antibody approved for use by the FDA as an immunosuppressive drug in kidney transplantation. The use of this drug in transplantation is based on the long-term effect of antibody binding, blocking cellular interaction with the CD3 protein known to be necessary to activate T cells involved in the rejection of transplanted tissue. As of mid-2001, it had not been approved for use as a cancer therapy. However, there were at least five active clinical trials to test its ability to activate lymphocytes outside the body in preparation for reinfusion.

A second use of the muromonab-CD3 antibody to treat cancer required the development of a humanized monoclonal antibody called hOKT3, using the same binding sites as muromonab-CD3. This treatment involves direct administration of the antibody to the patient. The humanized antibody retains the murine sequences at the antibody's two binding sites, but has human sequences in the other areas of the antibody molecule. This allows the monoclonal antibody to be directly administered to the patient without the immune reaction against the mouse antibodies seen when muromonab-CD3 is used. hOKT3 was used in a clinical trial of 24 patients against a wide variety of cancers. Although testing the antibody's function as a therapy was not the main goal of the study, three patients with cancers of the peritoneum cavity (lower abdomen) did see a clinical improvement.

Recommended dosage

To treat cancer, muromonab-CD3 is not administered directly to the patient. However, a similar humanized antibody, hOKT3, has been given to patients during a clinical trial. The most effective dosage in the trial was three doses of 800 micrograms every two weeks in a 10-minute infusion, but further study is necessary to confirm this finding.

Precautions

As the two uses of muromonab-CD3 are still in the clinical trial stage, the exact precautions for this drug (or the humanized version, hOKT3) are not yet known. However, for monoclonal antibody treatment in general, preexisting heart conditions and arrhythmias can make taking this drug more dangerous. Vaccination during the treatment session is also not recommended, given the T-cell depletion that occurs during treatment.

Side effects

During clinical trials the majority of side effects occurred during the first administration of activated T cells or humanized antibody. These side effects included flu-like symptoms, headache, dizziness, and shortness of breath. The humanized antibody also caused edema (collection of fluid) in all three patients who exhibited a clinical benefit from the treatment.

Interactions

Still in the early clinical trial stages in 2001, muromonab-CD3 had not been studied to determine interactions with other drugs.

Myasthenic syndrome of Lambert-Eaton

see **Eaton-Lambert syndrome**

Myasthenia gravis

Description

Myasthenia gravis (MG) is an autoimmune disease that causes muscle weakness. It affects the neuromuscular junction, interrupting the communication between nerve and muscle, and thereby causing weakness. People with MG may have difficulty moving their eyes, walking, speaking clearly, swallowing, and even breathing, depending on the severity and distribution of weakness. Increased weakness with exertion, and improvement with rest, is a characteristic feature of MG.

About 30,000 people in the United States are affected by MG. It can occur at any age, but is most common in women who are in their late teens and early twenties, and in men in their sixties and seventies.

MG has been associated with malignant **thymoma**, a disease in which cancer cells are found in the tissues of the thymus.

Causes

Myasthenia gravis is an autoimmune disease, meaning that it is caused by the body's own immune system. In MG, the immune system attacks a receptor on the surface of muscle cells. This prevents the muscle from receiving the nerve impulses that normally make it respond. MG affects "voluntary" muscles, which are those muscles under conscious control responsible for movement. It does not affect heart muscle or the "smooth" muscle found in the digestive system and other internal organs.

A muscle is stimulated to contract when the nerve cell controlling it releases acetylcholine molecules onto its surface. The acetylcholine lands on a muscle protein called the acetylcholine receptor. This leads to rapid chemical changes in the muscle which cause it to contract. Acetylcholine is then broken down by acetylcholinesterase enzyme, to prevent further stimulation.

In MG, immune cells create antibodies against the acetylcholine receptor. Antibodies are proteins normally involved in fighting infection. When these antibodies attach to the receptor, they prevent it from receiving acetylcholine, decreasing the ability of the muscle to respond to stimulation.

Why the immune system creates these self-reactive "autoantibodies" is unknown, although there are several hypotheses:

- During fetal development, the immune system generates many B cells that can make autoantibodies, but B cells that could harm the body's own tissues are screened out and destroyed before birth. It is possible that the stage is set for MG when some of these cells escape detection.
- Genes controlling other parts of the immune system, called MHC genes, appear to influence how susceptible a person is to developing autoimmune disease.
- Infection may trigger some cases of MG. When activated, the immune system may mistake portions of the acetylcholine receptor for portions of an invading virus, though no candidate virus has yet been identified conclusively.
- About 10% of those with MG also have thymomas, or tumors of the thymus gland. The thymus is a principal organ of the immune system, and researchers speculate that thymic irregularities are involved in the progression of MG. A definite relationship exists between MG and thymoma: of patients with MG, 15% also have thymoma, and of patients with thymoma, 50% have MG.

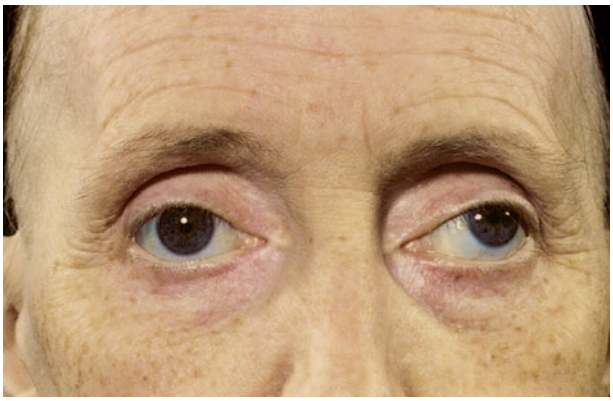
Treatment

While there is no cure for myasthenia gravis, there are a number of treatments that effectively control symptoms in most people. Even though no rigorously tested treatment trials have been reported and no clear consensus exists on treatment strategies, MG is one of the most treatable immune disorders. Several factors require consideration before initiating treatment, such as the severity, distribution, and rapidity of the MG progression.

Edrophonium (Tensilon) is a drug used to block the action of acetylcholinesterase, prolonging the effect of acetylcholine and increasing strength. An injection of edrophonium rapidly leads to a marked improvement in most people with MG. An alternate drug, neostigmine, may also be used.

Pyridostigmine (Mestinon) is usually the first drug tried. Like edrophonium, pyridostigmine blocks acetylcholinesterase. It is longer-acting, taken by mouth, and well-tolerated. Loss of responsiveness and disease progression combine to eventually make pyridostigmine ineffective in tolerable doses in many patients.

Thymectomy, or removal of the thymus gland, has increasingly become a standard form of treatment for MG. Up to 85% of people with MG improve after thymectomy, with complete remission eventually seen in about 30%. The improvement may take months or even several years to fully develop. Thymectomy is not usually recommended for children with MG, since the thymus continues to play an important immune role throughout childhood.



Face of a person afflicted with myasthenia gravis. Half of patients with thymoma (a cancer of the thymus) also have myasthenia gravis. *(Custom Medical Stock Photo. Reproduced by permission.)*

KEY TERMS

Antibody—An immune protein normally used by the body for combating infection and which is made by B cells.

Atropine—An alkaloid extract from belladonna.

Autoantibody—An antibody that reacts against part of the self.

Autoimmune disease—A disease caused by a reaction of the body's immune system.

Bulbar muscles—Muscles that control chewing, swallowing, and speaking.

Immunoglobulin—A protein substance produced by plasma cells which helps to fight infection.

Malignant thymoma—A disease in which cancer cells are found in the tissues of the thymus, a small organ that lies under the breastbone.

Neuromuscular junction—The site at which nerve impulses are transmitted to muscles.

Pyridostigmine bromide (Mestinon)—An anticholinesterase drug used in treating myasthenia gravis.

Tensilon test—A test for diagnosing myasthenia gravis. Tensilon is injected into a vein and, if the person has MG, muscle strength will improve for about five minutes.

Thymectomy —Removal of the thymus by surgery, radiation or chemical means

Thymus gland—A small gland located just above the heart, involved in immune system development.

Immune-suppressing drugs are used to treat MG if patient response to pyridostigmine and thymectomy is not adequate. These drugs include **corticosteroids** such as prednisone, and the non-steroids **azathioprine** (Imuran) and cyclosporine (Sandimmune).

Plasma exchange may also be performed to treat the condition or to strengthen very weak patients before thymectomy. In this procedure, blood plasma is removed and replaced with purified plasma free of autoantibodies. It can produce a temporary improvement in symptoms, but is too expensive for long-term treatment. Another blood treatment, intravenous immunoglobulin therapy, is also used. In this procedure, large quantities of purified immune proteins (immunoglobulins) are injected. For unknown reasons, this leads to symptomatic improvement in up to 85% of patients. It is also too expensive for long-term treatment. There are indications that IVIg is an effective immunoglobulin for some categories of MG patients.

People with weakness of the bulbar muscles may need to eat softer foods that are easier to chew and swallow. In more severe cases, it may be necessary to obtain nutrition through a feeding tube placed into the stomach (gastrostomy tube).

Alternative and complementary therapies

No alternative therapies have been shown to be effective for the treatment of MG. Reports claiming that herbal remedies or alternative treatments alleviate or cure MG have not been corroborated by properly controlled **clinical trials**, which are required to evaluate the benefit of such treatments.

Among complementary MG therapies, prescription of low dose atropine can help relieve the cramping and **diarrhea** often caused by the drug Mestinon. Propantheline bromide (ProBanthine) is a drug similar to atropine, and it may also be prescribed to treat gastrointestinal discomfort. Caution must be taken not to take too much atropine because it cancels the beneficial effects of the anticholinesterase drugs. Ephedrine is sometimes also used with anticholinesterase therapy to strengthen the muscle tissue of MG patients.

Mycophenolate mofetil

Definition

Mycophenolate mofetil (brand name CellCept) is a drug that has been shown to inhibit tumor growth in rodents, and that may prove useful in treating tumors in humans.

Purpose

The Food and Drug Administration (FDA) approved the use of mycophenolate mofetil in August 2000 for use in patients undergoing liver transplants, and the drug is used primarily to ease the acceptance of a transplanted organ by a recipient. The drug makes acceptance of the transplanted organ more likely because it prevents the recipient from mounting an **immune response** to the organ, or treating it like a foreign invader. The drug also seems to have the ability to inhibit tumor growth, and may prove effective in treating certain kinds of cancer.

In laboratory studies, mycophenolate mofetil has inhibited tumor growth in cancers of the pancreas, colon, lung, and blood. The value of the drug for anticancer therapy is still being evaluated.

In addition to its use in treating cancer, mycophenolate mofetil has been used by dermatologists to treat pyoderma gangrenosum, a rare skin disorder of unknown origin characterized by ulcerated areas on the legs. Pyoderma gangrenosum is associated with systemic diseases in about half the patients diagnosed with it, and mycophenolate mofetil has been found to be effective in treating these patients either alone or in combination with prednisone.

Mycophenolate mofetil is reported to be effective in relieving pain in patients with cluster headache; however, this use of the drug is considered investigational as of 2004.

Description

Mycophenolate mofetil suppresses, or prevents activity of, cells in the lymphatic system, both T cells and B cells. Under normal circumstances, T cells mount an immune response by reacting directly with foreign materials in the body and B cells release compounds that attack foreign materials. But during a transplant, T cells and B cells can cause a reaction that leads to the rejection of a donor organ.

Recommended dosage

The drug is given orally and by intravenous line. Dosages given for cancer therapy are experimental. To prevent immune response during organ transplants, the drug is dispensed in capsules of 250 mg, tablets of 500 mg, and by intravenous line in doses of 500 mg. Time intervals between dosages are determined according to the rate of the drug's breakdown in the patient's body.

Precautions

Mycophenolate mofetil is known to cause or may cause lymphomas and skin cancer. The benefit of taking the drug must be weighed against the increased risk of the cancers it causes.

It is critical for the patient's doctor to monitor blood levels carefully when using this drug, as patients vary widely in their rate of clearance of mycophenolate mofetil, particularly when it is given in combination with other immunosuppressants.

Side effects

In addition to increasing the risk of lymphomas and skin cancer, mycophenolate mofetil may cause a number of other unwanted reactions. They include dizziness, headache, trembling, as well as pain in the chest, swelling (edema), and high blood pressure (hypertension). Many digestive tract upsets from constipation to **diarrhea** to vomiting are also possible side effects. There is also a chance of hemorrhage, or uncontrolled bleeding in the digestive tract.

Interactions

Taking the drug is likely to make oral contraceptives ineffective and another form of birth control should be used. Stomach medications that contain magnesium and aluminum hydroxides, such as antacids, can block the uptake of mycophenolate mofetil across the gut. They should be avoided. As always, the physician in charge of the care plan should be told of every drug a patient is taking so that the potential for interactions can be avoided. The drug is considered superior to some others used as a suppressant of the immune response in transplants because it does not show as many drug interactions as other drugs do. But the short list of interactions might be

KEY TERMS

B cell—A type of cell in the lymphatic system that contributes to immunity by releasing compounds that attack foreign bodies, such as bacteria and viruses.

Clearance—A measure of the rate at which a drug or other substance is removed from the blood.

Intravenous line—A tube that is inserted directly into a vein to carry medicine directly to the blood stream, bypassing the stomach and other digestive organs that might alter the medicine.

Kilogram—Metric measure that equals 2.2 pounds.

Lymphatic system—The system that collects and returns fluid in tissues to the blood vessels and produces defensive agents for fighting infection and invasion by foreign bodies.

Milligram—One-thousandth of a gram, and there are one thousand grams in a kilogram. A gram is the metric measure that equals about 0.035 ounces.

Mutant—Altered, not normal.

T cell—A cell in the lymphatic system that contributes to immunity by attacking foreign bodies, such as bacteria and viruses, directly.

in part related to its limited time on the market, and interactions that are yet unidentified.

Mycosis fungoides

Definition

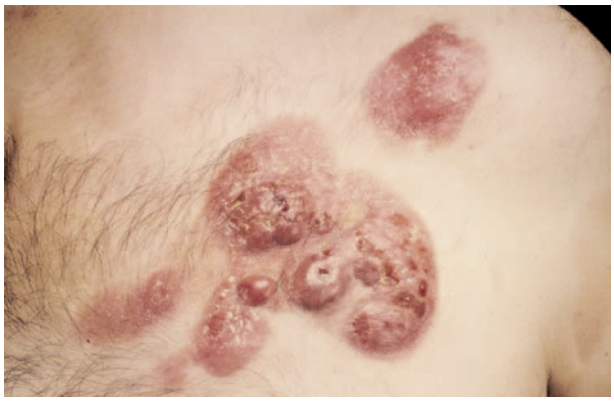
Mycosis fungoides is a skin cancer characterized by patches, plaques, and tumors where cancerous T lymphocytes have invaded the skin.

Description

Mycosis fungoides, the most common type of **cutaneous T-cell lymphoma**, originates from a type of white blood cell called a T lymphocyte or T cell. In mycosis fungoides, cancerous T cells accumulate in the skin. These cells and the skin irritation they create become visible as growths or changes in the skin's color or texture.

Mycosis fungoides usually develops and progresses slowly. It often begins as an unexplained rash that can wax and wane for years. Whether this stage represents early mycosis fungoides or a precancerous stage is controversial. The classic symptoms of mycosis fungoides are red, scaly skin patches that develop into raised plaques, then into large, mushroom-shaped tumors. The patches often originate on parts of the body that are covered by clothing and sometimes improve when they are exposed to sunlight. **Itching** can be intense.

As the cancer progresses, the cancer cells lose their affinity for the skin and spread to nearby lymph nodes and other internal organs. The normal T cells also start to disappear. Because T cells are very important in immunity, this leaves the patient susceptible to infections. Treatment at an earlier stage of the disease can often stop or slow this progression.



Red, scaly plaque on skin of patient with mycosis fungoides. *(Custom Medical Stock Photo. Reproduced by permission.)*

Sézary syndrome is a variant of mycosis fungoides. Sézary syndrome is characterized by red, thickened skin and large numbers of cancer cells in the blood.

Demographics

Mycosis fungoides is usually diagnosed after the age of 50, but has been seen as early as childhood. Mycosis fungoides develops twice as often in men as in women and is more common in people of African than of European origin.

Causes and symptoms

Environmental chemicals, virus infections, allergies, and genes have all been suggested as possible causes of this cancer. As of 2001, there is little concrete evidence to favor any of these possibilities.

The symptoms of mycosis fungoides include:

- Patches: patches are red or brown, sometimes scaly, flat areas. There may be one patch or many. Patches may itch and can resemble psoriasis, eczema, allergies, or other skin diseases. Some patients do not have a patch stage.
- Plaques: plaques are red or brown, sometimes scaly, raised areas. Itching is usually more intense than during the patch stage. The hair sometimes falls out in the affected skin. If the face is involved, the facial features can change.
- Tumors: tumors can originate from plaques, red skin, or normal skin. They are usually reddish brown or purple. The itching can diminish, but the tumors may develop painful open sores or become infected. Some tumors can become very large. Patches, plaques, and tumors can co-exist.
- Erythrodermic form: in the erythrodermic form, the skin becomes red, thickened, and sometimes peels and flakes. The palms and soles thicken and may crack. Itching is usually intense. More than 90% of the time, the erythrodermic form is associated with Sézary syndrome.
- Other, more rare symptoms are also seen, including itching alone.

Diagnosis

A physical examination, history of the symptoms, blood tests, and skin **biopsy** are usually the key to diagnosing this cancer. The blood tests examine the health of the internal organs and look for cancer cells in the blood. The skin biopsy checks for the typical microscopic changes seen in this disease. This biopsy is a brief, simple procedure often done in the doctor's office. After numbing the skin with an injection of local anesthetic, the doctor snips out one or more tiny pieces of abnormal skin. The skin samples are sent to a trained pathologist for examination, and results may take up to a week to come back.

During its early stages, mycosis fungoides can be very difficult to diagnose. The symptoms resemble other skin diseases and numerous biopsies may be needed before the typical features are found. Special stains and DNA tests on the skin sample may find the cancer a little earlier.

To stage this cancer, the lymph nodes are checked for abnormal size or texture and, if necessary, biopsied. The doctor may also recommend x-ray studies of the chest, **computed tomography**, or biopsies of the internal organs to look for cancer cells.

Treatment team

Patients diagnosed with mycosis fungoides are often referred to an oncologist. A dermatologist may also become involved. Depending on the treatment chosen, the team may include other specialists, such as a radiation oncologist, specially trained nurses, a dietitian, or a social worker.

Clinical staging, treatments, and prognosis

Staging

In stage I, the lymph nodes look normal and cancer cells cannot be found in the internal organs. In stage IA, patches or plaques cover less than 10% of the skin. In stage IB, they are present on more than 10%.

In stage IIA, some of the lymph nodes look swollen or abnormal. Patches or plaques may cover any amount of skin. In stage IIB, the lymph nodes may or may not look abnormal, but there is at least one tumor on the

skin. Neither the lymph nodes nor the internal organs contain detectable cancer cells in stage IIA or IIB.

In stage III, the skin looks thickened, red and sometimes scaly. The lymph nodes sometimes look abnormal, but no cancer cells can be detected in them or within internal organs.

In stage IVA and IVB, the skin may have patches, plaques, tumors, or widespread reddening. In stage IVA, cancer cells have been found in the lymph nodes but not in other internal organs. In stage IVB, cancer cells have been found in internal organs and sometimes the lymph nodes.

Treatment

Mycosis fungoides is rarely cured. Instead, most treatments are aimed at controlling the symptoms, improving the quality of life, and preventing the disease from progressing into later stages. This cancer responds well to a variety of therapies and frequently goes into remission, particularly if it is caught early. Even in stage IV, treatment can significantly improve the symptoms in the skin.

In stages III and IV, treatments directed against the cancer cells in the skin may be combined with **chemotherapy** or other therapies against metastatic cells. Experimental treatments are sometimes offered, especially in stage III or stage IV. If the cancer relapses, retreatment may be possible or other therapies can be tried.

One treatment option for early cancers is ultraviolet B (UVB) light. UVB light can treat mycosis fungoides patches, but not plaques or tumors. About 70% of patients go into complete remission and 15% into partial remission. The side effects can include itching, sunburn, aging of the skin, and a risk of developing other skin cancers. The eyes must be protected from UVB light.

Psoralen and ultraviolet A (PUVA) photochemotherapy is an option for all stages, although earlier stages usually have a better response. In PUVA, the drug methoxypsoralen is taken before exposure to ultraviolet A (UVA) light. The drug sensitizes the cancer cells to the light. The complete remission rate with this treatment is 62–90%. The side effects may include itching, dry skin, sunburn, nausea, nail discoloration, and a risk of developing other skin cancers. The eyes must be protected to prevent damage to the retina and possibly cataracts.

Total skin electron-beam irradiation (TSEB) is also effective for all stages. TSEB is a type of radiation treatment that uses beams of electrons to irradiate the skin. The electrons stop at the skin and do not penetrate deeper tissues. Up to 80% of patients in stages II and III will respond. The side effects can include flaking of the skin, alopecia or hair loss (usually temporary), loss of sweat glands, skin irritation, blisters, dryness, temporary loss of the nails, and a risk of developing other skin cancers. These side effects limit the number of times this treatment can be given. TSEB is not available everywhere.

Other types of radiation—for instance, focused electron beam irradiation or x rays—can shrink or destroy some tumors or plaques.

Mechlorethamine (nitrogen mustard) is a drug that can be painted onto the skin to suppress the cancer. A thin layer is applied to the whole skin at bedtime, then washed off in the morning. The side effects can include dryness, skin irritation, darkening of the skin, allergies to the ingredients, and possibly a risk of other skin cancers. Half to 80% of mycosis fungoides patients in stage IA and 25–75% of patients in stage IB or IIA go into complete remission. In stage IIB, the complete remission rate is up to 50%. In stage III, it is 20–40% and, in stage IV, up to 35%. In stages III and IV, this treatment is used to decrease the skin symptoms and is often combined with other treatments.

Carmustine (BCNU) is an alternative drug. Its effectiveness is similar to mechlorethamine. In addition to side effects in the skin, this drug may cause **myelosuppression**.

Bexarotene is a drug used for cases that do not respond to other treatments. About 40% of patients have a complete or partial remission. The side effects may include dryness of the mucous membranes, aching joints or muscles, headaches, **fatigue**, and increased fragility of the skin. One of the most serious side effects is an increase in the fats in the blood, which can lead to pancreatitis.

Aldesleukin fusion toxin contains a poison that damages cells, attached to a molecule that directs that poison to T cells. About 10% of patients have complete remissions and 40% respond to some extent. The side effects can include chills, nausea, fluid retention, and allergic reactions to the drug.

Chemotherapy is sometimes combined with other therapies for stages III and IV. In stage IV, chemotherapy is directed against the metastatic cells in the lymph nodes or internal organs. Approximately 60% of mycosis fungoides patients in stage IV respond to single drugs, but the remission usually lasts less than six months. No cures have been reported, and it is not certain whether chemotherapy lengthens survival.

Corticosteroids are sometimes added to other treatments. These drugs decrease skin irritation and can destroy T cells. Fifty percent of patients have complete

KEY TERMS

Acyclovir—A drug used to kill viruses.

Antibody—A protein made by the immune system. Antibodies attach to target molecules and can be useful as drugs.

Biopsy—A sample of an organ taken to look for abnormalities. Also, the technique used to take such samples.

Computed tomography (CT)—A special x-ray technique that produces a cross-sectional image of the body.

Cutaneous T-cell lymphoma—A type of skin cancer originating from T lymphocytes.

Electron beam—A type of radiation composed of electrons. Electrons are tiny, negatively charged particles found in atoms.

Hypericin—A chemical derived from plants that kills cells after being activated by visible light.

Interferon alpha—A chemical made naturally by the immune system and also manufactured as a drug.

Local anesthetic—A liquid used to numb a small area of the skin.

Lymph node—A small organ full of immune cells that are found in clusters throughout the body. Lymph nodes are where reactions to infections usually begin.

Myelosuppression—A decrease in blood cell production from the bone marrow. This can result in anemia, an increased risk of infections, or bleeding tendencies.

Oncologist—A doctor who specializes in the treatment of cancer.

Pancreatitis—Inflammation of the pancreas. This disease is potentially serious and life-threatening.

Pathologist—A doctor who specializes in examining cells and other parts of the body for abnormalities.

Precancerous—Abnormal and with a high probability of turning into cancer, but not yet a cancer.

Remission—A decrease in the symptoms of the cancer. In a complete remission, there is no longer any evidence of the cancer, although it may still be there.

Retinoids—Drugs related to vitamin A.

T lymphocyte or T cell—A type of white blood cell. Some T cells, known as helper T cells, aid other cells of the immune system. Other T cells, called cytotoxic T cells, fight viruses and cancer.

Ultraviolet light—Light waves that have a shorter wavelength than visble light, but longer wavelength than x rays. UVA light is closer to visible light than UVB.

White blood cells—The cells in the blood that fight infections. There are several types of white blood cells. Also called immune cells.

remissions on corticosteroids and 40% have partial remissions.

Supportive therapies can also help. Antihistamines or other drugs can decrease the itching. Mild moisturizing soaps and moisturizers can also combat the dryness and itching. If infection sets in, **antibiotics** may be necessary.

Prognosis

If mycosis fungoides is caught early, the prognosis is very good. If treatment begins during stage IA, most patients can expect to live as long as someone of the same age and gender who does not have this cancer. Median survival in stage IA is at least 20 years and most people die of diseases unrelated to the cancer. The overall 5-year survival in stage I is 80–90%. In stage II, five-year survival is 60–70%. As tumors develop and the cancer cells spread internally, the prognosis becomes worse. Five-year survival drops to 30% in stage IIB, 40–50% in stage III, and 25–35% in stage IV. Cancer cells can spread into almost any organ in the later stages of mycosis fungoides. Once this happens, many patients die of cancer complications, particularly skin infections that spread into the blood. Overall, half of mycosis fungoides patients live for at least 10 years after their cancer is diagnosed.

Alternative and complementary therapies

Complementary treatments can decrease stress, reduce the side effects of cancer treatment, and help patients feel more in control. For instance, some people find activities such as biofeedback, hypnosis, pet therapy, yoga, massage, pleasant distractions, meditation and prayer, mild physical exercise, or visualization helpful. Patients should check with their doctors before starting any complementary or

QUESTIONS TO ASK THE DOCTOR

- What stage is my cancer?
- If it is treated, is my cancer likely to progress?
- Which treatment(s) do you recommend?
- What are the side effects of these treatments?
- Can you recommend anything to help with those side effects?
- How should I prepare for the treatment?
- Are there any other treatments which might work as well?
- Do you expect me to go into remission and, if so, how long can I expect it to last?
- How often should I return for check-ups?

alternative treatment. This is particularly important for alternative treatments that attempt to cure the cancer, boost the immune system, or reduce the side effects of conventional treatments. Some alternative treatments may interfere with the standard medical treatments or be dangerous when they are combined.

Coping with cancer treatment

Many of the treatments used for mycosis fungoides can dry and irritate the skin. Some ways to help are:

- Wear soft, loose clothing over the affected areas.
- Protect the skin from the sun.
- Don't scratch or rub the affected areas.
- Check with a doctor or nurse before using lotions, moisturizers, sunscreens, or cosmetics on the area.
- If allowed, use moisturizer and a moisturizing soap.

Clinical trials

Because mycosis fungoides is unlikely to be cured with the standard treatments, all patients with this disease are candidates for **clinical trials**. Patients should check with their medical insurers before enrolling in a clinical trial. Insurers may not pay for some treatments; however, this varies with the insurer and each individual case.

Some clinical trials are testing new drugs, including some retinoids, acyclovir, and hypericin.

In extracorporeal photochemotherapy, the white blood cells are exposed to a chemical called a psoralen, temporarily separated from the rest of the blood and treated with UVA light, then returned to the body. This treatment may stimulate the immune system to destroy the cancer cells.

Interferon alpha is a drug that is injected into plaques and tumors. About 55% of patients have some response and 17% go into complete remission. The side effects may include fevers, fatigue, loss of appetite (anorexia), decreases in the number of white blood cells, or irregular heartbeats.

Antibodies can block important molecules on the cancer cells or carry poisons or radioactive molecules to the cancer.

Some clinical trials are testing whether **bone marrow transplantation** can produce lasting remissions.

Prevention

The risk factors for mycosis fungoides are unknown and there is no known means of prevention.

Special concerns

Because mycosis fungoides is rarely cured, patients must usually return periodically for check-ups or treatments to maintain the remission. Between visits, patients should also be alert for skin infections. These infections can spread into the blood and become serious if they are not controlled. Because mycosis fungoides can affect the appearance, patients may wish to discuss cosmetic concerns with a doctor, other professional, or support group. Mycosis fungoides increases the risk of developing other types of lymphocyte cancers.

Myelodysplastic syndrome

Definition

Myelodysplastic syndrome (MDS) is a disease that is associated with decreased production of blood cells. Blood cells are produced in the bone marrow, and the blood cells of people with MDS do not mature normally. There are three major types of blood cells—red blood cells, white blood cells and platelets. Patients with MDS can have decreased production of one, two, or all three types of blood cells.

Description

Overview

Blood cells are used in the body for many different and important functions, such as carrying oxygen (red blood cells), fighting infection (white blood cells), and controlling bleeding (platelets). Blood cells are formed and stored in the bone marrow, which is the spongy tissue inside large bones. Stem cells, or immature blood cells, are stored in the bone marrow and have the ability to develop into all three types of mature blood cells. When the body needs a specific type of blood cell, the bone marrow uses its stockpile of stem cells to produce the kind of mature cells needed for that particular situation.

In patients who have MDS, blood cells fail to mature normally. In other words, the bone marrow is unable to develop a normal amount of mature blood cells, and is also not able to increase blood cell production when mature cells are needed. Sometimes, even the cells that are produced do not function normally. The marrow eventually becomes filled with the immature cells (blasts) and there is not room for the normal cells to grow and develop. MDS therefore causes a shortage of functional blood cells.

Subtypes of MDS

MDS is divided into five different subtypes that are classified according to the number and appearance of blast cells in the bone marrow. It is important for doctors to know the type of MDS a patient has, because each subtype affects patients differently and requires specific treatment. The International Prognostic Scoring System (IPSS) can help the doctor to determine the best treatment for an individual patient. The subtypes are as follows:

- Refractory **anemia** (RA). Bone marrow with less than 5% blast cells and abnormal red blood cell blasts.
- Refractory anemia with ring sideroblasts (RARS). Bone marrow with less than 5% blasts and characteristic abnormalities in red blood cells.
- Refractory anemia with excess blasts (RAEB). Bone marrow with 5-20% blast cells, and higher risk of changing into **acute leukemia** over time.
- Refractory anemia with excess blasts in transformation (RAEBT). Bone marrow with 21-30% blast cells. This form is most likely to change into acute leukemia.
- Chronic myelomonocytic leukemia (CMMoL). Marrow with 5-20% blasts and excess monocytes (a specific type of white blood cell).

Demographics

Approximately 15,000 new cases are diagnosed annually in the United States. The average age at diagnosis is 70. The most common types are RA and RARS. It is rare to have MDS before age 50. MDS is slightly more common in males than in females.

Causes and symptoms

Causes

There is no clear cause for the majority of MDS cases, which is referred to as primary or *de novo* myelodysplastic syndrome. In some cases, however, MDS results from earlier cancer treatments such as radiation and/or **chemotherapy**. This type of MDS is called secondary or treatment related MDS, is often seen three to seven years after the exposure, and usually occurs in younger people.

Other possible causative agents for MDS include exposure to radiation, cigarette smoke or toxic chemicals such as benzene. Children with pre-existing chromosomal abnormalities such as Down syndrome have a higher risk of developing MDS. MDS does not appear to run in families, nor can it be spread to other individuals.

Symptoms

MDS symptoms are related to the type of blood cells that the body is lacking. The earliest symptoms are usually due to anemia, which results from a shortage of mature red blood cells. Anemia causes patients to feel tired and out of breath because there is a lack of cells transporting oxygen throughout the body. MDS may also lead to a shortage of white blood cells resulting in an increased likelihood of infections. Another symptom of MDS is increased bleeding (e.g. blood in stool, nose bleeds, increased bruises or bleeding gums) which is due to low level of platelets. These symptoms can occur in any combination, depending on a given patient's specific subtype of MDS.

Diagnosis

Blood tests

People who have MDS usually visit their primary care doctor first, with symptoms of **fatigue**, and are then referred to a hematologist (a physician who specializes in diseases of the blood). The diagnosis of MDS requires a complete analysis of the patient's blood and bone marrow, which is done by the hematologist. A complete blood count (CBC) is done to determine the number of each blood cell type within the sample. Low numbers of red blood cells, white blood cells, and or platelets are signs that a patient has MDS. Numerous other medical problems such as bleeding, nutritional deficiencies, or adverse reaction to a medication can also cause low blood counts. The hematologist will investigate other causes for low blood counts before assigning a diagnosis of MDS. Blood cells in patients with MDS can also be abnormal when viewed under the microscope.

Bone marrow aspiration and biopsy

A bone marrow **biopsy** is required to confirm the diagnosis of MDS and determine the correct MDS subtype. This procedure involves a needle used to take a sample of marrow from inside the bone. The area of the skin where the needle is inserted is numbed and sometimes the patient is also sedated. Patients may experience some discomfort but the procedure is safe and is over fairly quickly. Marrow samples are usually taken from the back of the hip bone (iliac crest). A sample of the marrow, known as an aspirate, and a small piece of bone are both removed with the needle.

A hematologist or a pathologist (a specialist in diagnosing diseases through cell examination) will carefully examine the bone marrow sample through a microscope. Microscopic examination allows the doctor to determine the number and type of blast cells within the marrow in order to identify the MDS subtype. Cells from the bone marrow are also sent for cytogenetic testing, which analyzes the cells' chromosomes. Forty to seventy percent of MDS patients have abnormal bone marrow chromosomes as a result of the disease. The pattern of these abnormalities can be used to predict how a patient will respond to a particular treatment. Thus, the full set of information provided by a bone marrow biopsy and CBC will ultimately allow the doctor to recommend the most effective treatment plan.

Clinical staging, treatments, and prognosis

International Prognostic Scoring System (IPSS) for MDS

Once a diagnosis of MDS is established, the doctor will calculate the IPSS score for each individual patient. The bone marrow blast percentage, chromosomal abnormalities and number of different blood types that are reduced determine the score. A score of 0 to 3.5 is assigned to each patient. Patients with lower score have a better prognosis and usually should not undertake treatment upon initial diagnosis. Patients with a higher score have more aggressive disease and should consider more aggressive treatment.

Treatments

SUPPORTIVE CARE Treatment for MDS is tailored to the patient's age, general health, specific MDS subtype, and IPSS score. Treatment varies for each patient, but most treatment strategies are designed to control the symptoms of MDS. This approach is called supportive care and aims to improve the patient's quality of life.

Supportive care for the MDS patients commonly includes red blood cell transfusions to relieve symptoms related to anemia. Red cell transfusions are relatively

safe and the physician will review risks and benefits with this approach. Transfusions of any type only last a certain amount of time and therefore need to be repeated at certain intervals. Platelet transfusions can also be a way to control excessive bleeding. The doctor will decide with each individual patient when it is appropriate to give a transfusion. **Antibiotics** are used when needed to combat infections that can occur more frequently in patients with low white blood cell counts.

BONE MARROW TRANSPLANTATION **Bone marrow transplantation** (BMT) is a type of treatment that attempts to provide MDS patients with a cure. This strategy requires the patients to be in fairly good health and are therefore more likely to be used in younger patients. Bone marrow transplantation (BMT) has been found to be a successful treatment for MDS patients under the age of 50 (and some over 50 in good health). Following BMT, many patients are able to achieve long-term, disease-free survival. Unfortunately, most MDS patients cannot receive a traditional bone marrow transplant because of older age or because they do not have a suitable donor. Bone marrow donors are usually siblings or are obtained from the national bone marrow registry. "Mini"-bone marrow transplants use less intense chemotherapy, and are currently being tested in older patients who would otherwise not be candidates for traditional bone marrow transplants.

CHEMOTHERAPY Chemotherapy has been used to treat some MDS patients; however, the disease often recurs after a period of time. This type of therapy uses cell-killing drugs that may also damage healthy cells in the body. Most chemotherapy drugs are associated with some side effects. For these reasons, chemotherapy is generally not used until the MDS becomes more aggressive or the patient has a high IPSS score.

GROWTH FACTORS Growth factors are natural proteins that the body normally uses to control blood production. These substances stimulate the patient's bone marrow to produce healthy blood cells. Growth factors that stimulate white cell production are G-CSF (also called neupogen or **filgrastim**) and GMCSF (Leukine, **sargramostim**). In order to increase red cell production another growth factor, **erythropoietin** (Procrit) is used. These growth factors are safe with few side effects and are available only in the injectable form. The physician will decide if this treatment is appropriate for an individual patient.

Prognosis

The prognosis for MDS patients depends on the subtype of their disease and the IPSS score. Patients with RA, RARS or low IPSS score rarely develop leukemia and may live with disease for some years. The higher-risk patients including those with RAEB, RAEBt, CMMoL or high IPSS scores progress more rapidly, and require intensive therapy to control the disease.

Managing MDS requires frequent doctor appointments to monitor disease progression and to evaluate the response to treatment. Fortunately for many patients, recent advances in therapy have significantly enhanced their ability to cope with MDS. Experimental drugs and a better understanding of the disease are likely to improve the overall prognosis in the future.

Alternative and complementary therapies

There are no alternative therapies that have been proven to successfully treat MDS. Some of the available alternative drugs can have adverse side effects and therefore a physician should be informed if they are being used.

Clinical trials

Many **clinical trials** are available for MDS patients. These trials are testing new drugs or procedures in this condition. These treatments have not yet been proven to have success in this condition, but the principal investigators are hopeful that patients will benefit. The physician can discuss appropriate clinical trials with interested patients. Trials can involve new chemotherapy drugs, low-dose bone marrow transplantation and novel non-chemotherapy drugs. It is important for a patient to thoroughly understand the risks (listed in the consent form) before signing up for such treatments.

Prevention

MDS is usually impossible to prevent. Being careful about daily activities and avoiding the use of aspirin-like products that thin the blood may prevent secondary complications of MDS such as bruising and bleeding. Practicing good hygiene and avoiding crowds or people with infections can sometimes prevent infections. A well-balanced diet is recommended to increase overall energy.

Special concerns

MDS is the subject of extensive research, and new treatments are under development. In addition to treatment by their local hematologist or oncologist, motivated patients can pursue experimental treatments at major medical centers.

Myelofibrosis

Definition

Myelofibrosis is a rare disease of the bone marrow in which collagen builds up fibrous scar tissue inside the marrow cavity. This is caused by the uncontrolled growth of a blood cell precursor, which results in the accumulation of scar tissue in bone marrow. Myelofibrosis goes by many names including idiopathic myelofibrosis, agnogenic myeloid metaplasia, chronic myelosclerosis, aleukemic megakaryocytic myelosis, and leukoerythroblastosis.

Description

Myelofibrosis can be associated with many other conditions including **breast cancer**, **prostate cancer**, **Hodgkin's disease**, **non-Hodgkin's lymphomas**, acute myelocytic leukemia, **acute lymphocytic leukemia**, **hairy cell leukemia**, **multiple myeloma**, **myeloproliferative diseases**, tuberculosis, Gaucher's disease, and Paget's disease of bone. Myelofibrosis typically becomes progressively worse and can cause death.

In myelofibrosis, abnormal cells (hematopoietic stem cells) grow out of control and begin to produce both immature blood cells and excess scar (fibrous) tissue. The fibrous tissue builds up (fibrosis) primarily in the bone marrow, the place where blood cells are produced. The fibrous tissue interferes with the production of normal blood cells. The outcome of this is that the blood made by the bone marrow is of poor quality. To compensate for this, blood cell production occurs in other parts of the body (extramedullary hematopoiesis), but most notably in the spleen and liver. This causes enlargement of the spleen (splenomegaly) and the liver (hepatomegaly). Extramedullary hematopoiesis is not effective and, combined with the reduced production of blood cells by the bone marrow, a condition called **anemia** results.

The abnormal stem cells can spread throughout the body, settle in other organs, and form tumors that produce more abnormal blood cells and fibrous tissue. These tumors are most commonly found in the adrenals, kidneys, lymph nodes, breast, lungs, skin, bowel, thymus, thyroid, prostate, and urinary tract.

Demographics

Most patients with myelofibrosis are over 50 years old; the average age at diagnosis is 65 years. However, myelofibrosis can occur at any age. Myelofibrosis occurs with equal frequency in women and men, but in children it affects girls twice as often as it does boys.

Causes and symptoms

Myelofibrosis is caused by an abnormality in a single stem cell, which causes it to grow out of control. Myelofibrosis tumors that have originated from a single cell are called monoclonal. The cause of the stem cell abnormality is unknown. Persons who were exposed to benzene or high doses of radiation have developed myelofibrosis. There may be an association between myelofibrosis and autoimmune diseases, such as systemic lupus erythematosus and scleroderma, in which the immune system treats certain molecules of the body as foreign invaders.

Symptoms usually appear slowly over a long period of time. About one quarter of all patients with myelofibrosis have no symptoms (asymptomatic). An enlarged spleen discovered at an annual medical examination may be the first clue. Symptoms of myelofibrosis include:

- fatigue
- weight loss
- paleness
- fever
- sweating
- weakness
- heart palpitations
- shortness of breath
- itching
- feeling full after eating a small amount of food
- stomach pain or discomfort
- pain in the left shoulder or upper left portion of the body

- unexpected bleeding
- **bone pain**, especially in the legs

Diagnosis

Because symptoms are similar to other diseases (mostly leukemias), myelofibrosis is not easy to diagnose. The doctor would use his or her hands to feel (palpate) for enlargement of the spleen and liver. Blood tests and urine tests would be performed. **Bone marrow aspiration and biopsy** can help make a diagnosis, but they often fail because of the fibrosis. X-ray imaging and **magnetic resonance imaging** (MRI) may be performed.

Treatment

Many asymptomatic patients, if stable, do not require treatment. There is no cure for myelofibrosis, although **bone marrow transplantation** is curative in some cases. Treatment is aimed at reducing symptoms and improving quality of life.

Medications

Male hormones (androgens) can be used to treat anemia but, in women, these drugs can cause the development of male characteristics (e.g., hair growth on the face and body). Glucocorticoid therapy is also an effective treatment of anemia and can improve myelofibrosis in children. Nutrients that stimulate blood formation (hematinics), such as iron, **folic acid**, and vitamin B_{12}, may reduce anemia. Cancer **chemotherapy** (usually **hydroxyurea**) can decrease splenomegaly and hepatomegaly, reduce symptoms of myelofibrosis, lessen anemia, and sometimes reduce bone marrow fibrosis. The bone marrow of myelofibrosis patients is often not strong enough to withstand the harsh chemotherapy drugs, so this treatment is not always an option. Interferon-alpha has been shown to reduce spleen size, reduce bone pain, and, in some cases, increase the number of blood platelets (structures involved in blood clotting).

Other treatments

In certain cases, the enlarged spleen may be removed (**splenectomy**). Conditions that warrant splenectomy include spleen pain, the need for frequent blood transfusion, very low levels of platelets (**thrombocytopenia**), and extreme pressure in the blood vessels of the liver (portal hypertension).

Radiation therapy is used to treat splenomegaly, spleen pain, bone pain, tumors in certain places such as next to the spinal cord, and fluid accumulation inside the abdomen (**ascites**). Patients who are not strong enough to undergo splenectomy are often treated with radiation therapy.

Bone marrow transplantation may be used to treat some patients with myelofibrosis. This procedure may

KEY TERMS

Anemia—Low numbers of red blood cells in the blood.

Benzene—A colorless volatile flammable toxic liquid hydrocarbon used as a solvent and as a motor fuel.

Biopsy—Surgical removal of tissue for microscopic examination.

Fibrosis—Buildup of scar tissue.

Glucocorticoid therapy—Treatment using corticoids that are anti-inflammatory and immunosuppressive.

Leukemia—Cancer of white blood cells.

Portal hypertension—Extreme pressure on the blood vessels of the liver.

Stem cell—A cell that has the ability to become many different specialized cells.

be performed on patients who are less than 50 years old, have a poor life expectancy, and have a brother or sister with blood-type similarities.

Patients with severe anemia may require blood transfusions.

Prognosis

Similar to leukemias, myelofibrosis is progressive and often requires therapy to control the disease. Myelofibrosis can progress to acute lymphocytic leukemia or lymphoma. Although a number of factors to predict the survival time have been proposed, advanced age or severe anemia are consistently associated with a poor prognosis. The average survival rate of patients diagnosed with myelofibrosis is five years. Death is usually caused by infection, bleeding, complications of splenectomy, heart failure, or progression to leukemia. Spontaneous remission is rare.

Prevention

Persons who have been exposed to radiation, benzene, or radioactive thorium dioxide (a chemical used during certain diagnostic radiological procedures) are at risk for myelofibrosis.

Myeloma

Definition

Cancer that arises in the bone marrow and involves plasma cells, a type of white blood cell that produces proteins called immunoglobulins.

Myeloproliferative diseases

Definition

The myeloproliferative diseases are four conditions—essential thrombocythemia, polycythemia vera, **chronic myelocytic leukemia**, and agnogenic myeloid metaplasia—characterized by overproduction of normal-looking blood cells.

Because chronic myelocytic leukemia has its own individual entry, it is not covered in depth in this entry.

Description

The prefix "myelo—" refers to marrow. Bone marrow, a reddish substance in the middle of some bones, produces blood cells. In the myeloproliferative diseases, the body makes too many blood cells. Blood contains red blood cells to carry oxygen, white blood cells to fight infections, and platelets to begin blood clotting. Myeloproliferative diseases develop when a myeloid progenitor cell—a cell that makes red blood cells, platelets, and certain types of white blood cells—becomes overactive. The abnormal progenitor cell continues to make normal blood cells, but it makes too many of them. This excess of blood cells results in varying symptoms, depending on the progenitor cell involved.

Other problems develop when some of the abnormal myeloid progenitor cells travel to the spleen, liver, or

lymph nodes and begin making blood cells there. Most often, they migrate to the spleen. An enlarged spleen can crowd other organs in the abdomen and cause discomfort or digestive troubles. It is also susceptible to painful damage from blocked arteries. Massively swollen spleens can use large amounts of energy and cause muscle wasting and **weight loss**.

In the later stages of myeloproliferative diseases, the bone marrow can become scarred. This may leave no space for progenitor cells. As a result, blood cell production can drop to dangerously low levels. The abnormal progenitor cells may also mutate and develop into leukemia. These two serious complications are rare in some myeloproliferative diseases but very common in others.

Types of myeloproliferative disease

The four myeloproliferative diseases include essential thrombocythemia, polycythemia vera, chronic myelocytic leukemia, and agnogenic myeloid metaplasia.

In essential thrombocythemia (primary thrombocythemia), the myeloid progenitor cell makes too many platelets. Blood containing too many platelets may either clot too easily or too slowly. Blood that clots too easily can lead to a variety of health problems, including strokes or heart attacks. Blood that clots too slowly can cause symptoms such as easy bruising, frequent nosebleeds, bleeding from the gums, or life-threatening hemorrhages. Excessive numbers of platelets can also cause headaches or erythromelalgia, an unusual condition characterized by warmth, redness and pain in the hands or feet. Typically, patients with this disease have long periods without symptoms, interspersed with clotting or bleeding episodes. Some patients may have no symptoms at all. Rarely, this disease ends in scarring of the bone marrow or leukemia. Patients with bone marrow scarring have symptoms identical to agnogenic myeloid metaplasia.

In polycythemia vera (primary polycythemia, Vaquez disease), the bone marrow makes too many red blood cells. Large numbers of red blood cells can make the blood too thick. Viscous blood flows sluggishly, pools in the veins, and delivers oxygen poorly. Patients may experience headaches, dizziness, **fatigue**, chest pains, or weakness and cramping in the calves while walking. The abnormal blood flow can also result in bleeding tendencies or blood clotting inside the veins. Many patients also have increased numbers of white blood cells or platelets, but most symptoms are caused by the sluggish blood flow. The spleen often enlarges. Polycythemia rarely leads to leukemia, but occasionally ends in bone marrow scarring.

In chronic myelocytic leukemia (chronic myelogenous leukemia), the myeloid progenitor cell makes a type of white blood cell called a granulocyte. With this condition, platelets can also increase. In the early stages of this disease, the white blood cells look outwardly normal. However, in 90–95% of patients, two chromosomes—number 9 and number 22— inside the progenitor cell have broken and exchanged parts. This chromosome rearrangement is known as the Philadelphia chromosome, and this genetic abnormality destabilizes these cells and inevitably they become cancerous.

Agnogenic myeloid metaplasia (idiopathic **myelofibrosis**, myelofibrosis with myeloid metaplasia) begins like other myeloproliferative diseases, with overproduction of blood cells. However, bone marrow scarring develops very quickly and causes most of the symptoms. Blood cell numbers drop, causing fatigue and weakness from **anemia**. Many of the cells found in the blood are also immature or oddly shaped. Although myeloid progenitor cells in the spleen and liver can partly compensate, the enlargement of these organs creates additional problems. Occasionally, this disease also ends in leukemia.

Demographics

Essential **thrombocytopenia**, polycythemia vera, and agnogenic myeloid metaplasia are usually diagnosed late in life, at an average (median) age of 60.

Essential thrombocythemia may be slightly more common in women and agnogenic myeloid metaplasia and polycythemia vera slightly more common in men; however, estimates vary. At one time, polycythemia vera was thought to develop more often in Jews. More recent statistics do not confirm this.

Causes and symptoms

No consistent chromosomal abnormalities have been discovered in essential thrombocythemia, polycythemia vera, or agnogenic myeloid metaplasia. The causes of these diseases are unknown.

Myeloproliferative diseases share many features, such as enlargement of the spleen and abnormalities in blood clotting. Symptoms that can be seen in any of these diseases include:

- fatigue
- poor appetite (anorexia)
- weight loss
- **night sweats**
- fullness in the stomach after eating only a small amount
- abdominal pain or discomfort, especially in the upper left side

- nosebleeds, bleeding from the gums, easy bruising, or intestinal bleeding
- symptoms of blood clots including strokes, heart attacks, pain and swelling in the legs, or difficulty breathing
- disturbances in vision

Other symptoms of essential thrombocythemia can include:

- weakness
- dizziness
- headaches
- prickling or tingling in the skin
- erythromelalgia (warmth, redness, and pain in the extremities)

Other symptoms of polycythemia vera can include:

- headaches
- dizziness
- ringing in the ears
- pain in the chest (angina)
- weakness or cramping pains in the legs that disappear during rest
- redness of the face
- a blue tinge to the skin and other body surfaces (cyanosis)
- high blood pressure
- **itching**, especially after a warm bath or shower
- tingling or prickling of the skin
- erythromelalgia
- ulcers
- kidney stones
- gout

Other symptoms of agnogenic myeloid metaplasia can include:

- **fever**
- gout
- bone pain

Diagnosis

The diagnosis of a myeloproliferative disease relies mainly on a physical examination, examination of a blood sample, and sometimes a bone marrow **biopsy**. In the blood samples, the doctor will find excessive numbers of the cells characteristic of each disease. Chromosome studies on the blood can often distinguish chronic myelocytic leukemia from the other three diseases. Bone marrow samples reveal increased cell production and sometimes scarring. An enlarged spleen can often be detected during a physical examination, but occasionally ultrasound or **computed tomography** scans may be necessary.

Myeloproliferative diseases can resemble normal reactions to infections and other diseases. Various tests may be done to rule out such diseases.

Clinical staging, treatments, and prognosis

Staging

There is no staging system for essential thrombocythemia, polycythemia vera, or agnogenic myeloid metaplasia.

Treatments

ESSENTIAL THROMBOCYTHEMIA Treatments for essential thrombocythemia lower the risk of bleeding or blood clots. One option is **hydroxyurea** (Hydrea), a drug that suppresses platelet production. Hydroxyurea has few side effects but can occasionally cause a rash, intestinal upsets, sores on the skin, or a fever. This drug may also slightly increase the risk of leukemia. **Anagrelide** (Agrylin), an alternative, is effective in more than 90% of patients. It does not promote leukemia but can cause dizziness, headaches, fluid retention, rapid heartbeats, **diarrhea**, and rare cases of heart failure. Hydroxyurea and anagrelide both increase the risk of miscarriages during the first trimester in pregnant women.

A patient under 60 who has never had a blood clot has a 3% chance of developing one in the future. Some doctors recommend treatment for these patients only during high-risk situations such as surgery. Low doses of aspirin are sometimes used to control symptoms such as erythromelalgia.

POLYCYTHEMIA VERA Periodically removing small amounts of blood, called phlebotomy, is a safe and very effective way to treat polycythemia vera. In some studies, phlebotomy has increased the risk of blood clotting. However, this may not occur when the hematocrit (the percentage of red blood cells in the blood) is kept below 45% in men and 43% in women. Phlebotomy can result in symptoms of iron deficiency such as abnormal food cravings (particularly a craving for ice).

Patients who are unlikely to develop blood clots may not need any other treatments. Patients with a higher risk of clotting are sometimes given hydroxyurea. This drug has relatively few side effects, but it may increase the chance of developing leukemia. In some studies, 3–5% of patients taking hydroxyurea eventually developed leu-

kemia, compared to 1.5–2% treated with phlebotomy alone. Alternatives to hydroxyurea include interferon alpha and anagrelide. These drugs do not increase the risk of leukemia, but they tend to have more side effects. Interferon alpha may be particularly difficult to tolerate. Its side effects include flu-like symptoms (fever, chills, postnasal drip and poor appetite), fatigue, weight loss, **depression**, insomnia, memory loss, and nausea.

Radioactive phosphorus is used mainly in elderly patients who do not expect to need many years of treatment. In 80–90% of patients, this treatment can suppress the disease symptoms for six months to several years. However, up to 17% of patients develop leukemia within 15 years.

Other symptoms of polycythemia vera are treated with a variety of drugs. Itching is sometimes suppressed by phlebotomy, but antihistamines are often needed as well. Other options include extracorporeal photochemotherapy, hydroxyurea, or interferon alpha. **Allopurinol** (Zyloprim) prevents kidney stones and gout. Aspirin can suppress the symptoms of erythromelalgia.

One of the most difficult complications to treat is enlargement of the spleen. In the early stages of the disease, this enlargement can often be controlled by phlebotomy. Later, interferon alpha, hydroxyurea, or surgical removal may be necessary. Surgery to remove a very large spleen is difficult and can be fatal in up to 10% of patients. Complications can include infections, bleeding, serious blood clotting, or increased numbers of white blood cells and platelets. Radiation treatments directed at the spleen may be another option, but they can suppress the bone marrow.

AGNOGENIC MYELOID METAPLASIA Agnogenic myeloid metaplasia can be cured by a bone marrow transplant from a healthy donor. In patients eligible for this treatment, it is successful in about a third. **Bone marrow transplantation** may not be feasible for many patients, particularly those who are older or in poor health. This procedure can have serious or fatal complications including infections, organ damage, and bleeding. In addition, compatible donors are not available for all patients.

Other treatments for this disease are not curative and are mainly intended to improve the quality of life. Anemia is often treated with regular transfusions of red blood cells. Adverse effects can include heart failure or damage to the liver from excess iron. Drugs can sometimes make red blood cells last longer. **Corticosteroids** combined with an androgen (**fluoxymesterone**) are effective in about a third of all patients. **Danazol**, another androgen, works in about 20%. These drugs may damage the liver and can produce masculine traits in women. Injections of **erythropoietin**, a hormone that stimulates red blood cell production, also work in a few patients.

About half of all patients with anemia improve after surgical removal of the spleen (splenectomy). This surgery can also help patients who have abdominal discomfort, weight loss, muscle wasting, or high blood pressure in the liver. However, it can be dangerous and sometimes fatal. Removal of the spleen may make the disease progress more quickly, but this is not certain.

A painfully enlarged spleen can also be treated with hydroxyurea, interferon alpha, or radiation treatments. Hydroxyurea has few side effects, but it may increase the risk of leukemia. Interferon alpha shrinks the spleen in 30–50% of patients, but has many side effects. Radiation treatments can decrease the symptoms for three to six months, but sometimes fatally suppress the blood-producing cells.

Prognosis

Patients with essential thrombocythemia can expect a near normal life-span. Average (median) survival is 12 to 15 years. The chance of developing either leukemia or serious scarring of the bone marrow is less than 5%.

Without treatment, patients with polycythemia vera usually die from bleeding or blood clotting within months. With treatment, average (median) survival is about 10 years in older patients and more than 15 years in younger patients. Many patients can reach their normal life expectancy if they do not develop bone marrow scarring or leukemia. The risk of bone marrow scarring after 10 years is approximately 15–20%. If polycythemia vera is treated with phlebotomy alone, the risk of developing leukemia is 2%.

Unless they receive a successful bone marrow transplant, most patients with agnogenic myeloid metaplasia become progressively worse. The anemia becomes more severe and the liver and spleen continue to swell. Average (median) survival in this disease is 3.5 to 5.5 years, but survival is often unpredictable and may be much longer or much shorter. Leukemia develops in about 5–20% of patients. In other patients, death occurs from heart failure, infections, bleeding or blood clots.

Alternative and complementary therapies

In traditional Chinese and Japanese medicine, herbal preparations are used to treat symptoms of chronic illnesses such as fatigue, loss of appetite, and night sweats, or to decrease red blood cell formation in polycythemia vera. Patients who are interested in non-traditional complementary remedies should discuss them with their doctors. Some may have dangerous side effects or be harmful when combined with traditional therapies.

KEY TERMS

Androgen—A drug related to the male sex hormones.

Autoimmune disease—A disease that develops when white blood cells attack normal cells or organs.

Biopsy—A sample of an organ taken to look for abnormalities. Also, the technique used to take such samples.

Bone marrow—A group of cells and molecules found in the centers of some bones. It makes all of the cells found in the blood.

Computed tomography (CT)—A special x-ray technique that produces a cross-sectional image of the organs inside the body.

Corticosteroids—A class of drugs, related to hormones naturally found in the body, that suppresses the immune system. One example is prednisone, sold under many brand names including Deltasone.

Erythromelalgia—A condition characterized by warmth, redness and pain in the hands and especially the feet.

Erythropoietin—A drug that stimulates the bone marrow to make more red blood cells. It is also known as epoetin alfa.

Extracorporeal photochemotherapy—A technique in which the white blood cells are exposed to a chemical called a psoralen, temporarily separated from the rest of the blood and treated with UVA light, then returned to the body.

Gout—A painful swelling of the joints that results from an accumulation of uric acid. This disease often affects the big toe.

Granulocyte—One of three types of white blood cells (neutrophils, eosinophils, and basophils) that contain visible granules.

Lymph node—A small organ full of white blood cells, found in clusters throughout the body. Lymph nodes are where reactions to infections usually begin.

Median—A type of average. The median is the number in the middle of a sequence of numbers.

Myeloid progenitor cell—A cell normally found in the bone marrow that makes red blood cells, platelets, and some white blood cells (granulocytes and monocytes).

Phlebotomy—The removal of blood.

Platelets—Tiny fragments of cells that begin the blood clotting process. They are found in the blood.

Red blood cells—The cells in the blood that carry oxygen.

Spleen—An organ in the abdomen near the stomach. The spleen makes white blood cells, stores red blood cells, and removes old blood cells from the circulation.

Transfusion—A transfer of blood or blood products from one person to another.

Ultrasound—A technique that uses sound waves to form an image of organs inside the body.

White blood cells—The cells in the blood that fight infections. There are several types of white blood cells. Also known as immune cells.

Coping with cancer treatment

Acetaminophen and antidepressant drugs can help reduce some of the side effects of interferon alpha. Taking this drug at night may also make it easier to tolerate.

Clinical trials

The following therapies are being tested in **clinical trials**. Patients should check with their medical insurers before enrolling in a clinical trial. Insurers may not pay for some treatments but this varies with the insurer and each individual case.

Interferon alpha injections are being tested in essential thrombocythemia. This drug can lower platelet numbers and decrease the size of the spleen in about 80% of patients.

Several new drugs are in clinical trials. **Thalidomide** and SU5416 are being tested in patients with agnogenic myeloid metaplasia. R115777 and 12-O-tetradecanoylphorbol-13-acetate (TPA) are in clinical trials open to patients with various myeloproliferative diseases.

Another possible treatment for agnogenic myeloid metaplasia is to purify the normal progenitor cells and return them to the body after destroying the abnormal progenitor cells with **chemotherapy**.

Prevention

The following environmental factors have been linked to myeloproliferative diseases:

- working as an electrician or in a petroleum manufacturing plant

QUESTIONS TO ASK THE DOCTOR

- Does my condition require treatment?
- What treatment would you recommend I try?
- What risks and side effects should I expect?
- How will it affect my quality of life?
- Are there any alternative treatments that might work equally well?
- Are there any activities I should avoid? For how long?

- prolonged use of dark hair dyes
- exposure to nuclear bomb blasts or thorium dioxide

Special concerns

Whether polycythemia vera, essential thrombocythemia, and agnogenic myeloid metaplasia progress to leukemia is influenced by the specific treatment strategies. Patients should be aware that some treatments, particularly radioactive phosphorus, can substantially increase the risk of developing cancer.

Myelosuppression

Description

Myelosuppression is a decrease in the production of blood cells. Normal blood contains large numbers of cells, including red blood cells to carry oxygen and white blood cells to fight infections. The blood also contains platelets, tiny cell fragments that initiate blood clotting. These cells and fragments are made in the bone marrow, a reddish substance found in the centers of some bones. Healthy bone marrow makes large numbers of red blood cells, white blood cells, and platelets each day to replace those that wear out. In myelosuppression, the bone marrow makes too few of these cells.

A decrease in the number of red blood cells, called **anemia**, is very common in cancer patients. A drop in white blood cell numbers is often a problem during **chemotherapy**. One type of white blood cell, called a neu-

KEY TERMS

Anemia—Too few red blood cells in the blood.

Blood cells—The red blood cells and white blood cells found in the blood.

Bone marrow—A group of cells and molecules found in the centers of some bones. It makes all of the cells found in the blood.

Erythropoietin—A growth factor that stimulates the bone marrow to make more red blood cells. It is also known as epoetin alfa.

Granulocyte colony-stimulating factor (G-CSF)—A growth factor that stimulates the bone marrow to make neutrophils and some other types of white blood cells. It is also known as filgrastim.

Granulocyte-macrophage colony-stimulating factor (GM-CSF)—A growth factor that stimulates the bone marrow to make neutrophils and some other types of white blood cells. It is also known as sargramostim or molgramostim.

Growth factor—A chemical that stimulates body cells to grow or make more cells. Growth factors are found naturally in the body, but can also be manufactured and used as drugs.

Interleukin 11 (IL-11)—A growth factor that stimulates the bone marrow to make platelets. It is also known as oprelvekin.

Neutropenia—Too few neutrophils in the blood.

Neutrophil—A type of white blood cell that destroys bacteria.

Packed red blood cells—Blood that has had the fluid portion (plasma) removed.

Platelets—Tiny fragments of cells that begin the blood clotting process. They are found in the blood.

Red blood cells—The cells in the blood that carry oxygen.

Thrombocytopenia—Too few platelets in the blood.

Transfusion—A transfer of blood or blood products from one person to another.

Transfusion reaction—An allergic reaction to some of the cells or proteins in another person's blood.

White blood cells—The cells in the blood that fight infections. There are several types of white blood cells.

trophil, is usually affected most severely. A decrease in these cells is called **neutropenia**. Because neutrophils are responsible for defending the body against bacteria, neutropenia increases the chance of an infection. **Thrombocytopenia**, a drop in the number of platelets in the blood, is more rare; platelet numbers become low enough to cause problems in less than 10% of cancer patients.

Myelosuppression is a painless condition, but the decreases in important blood cells can result in **fatigue**, an increased risk of infections, or excessive bleeding. The consequences vary from mild to life-threatening, depending on how low the blood cell numbers fall.

Causes

The most common cause of myelosuppression is cancer treatment. Many of the drugs used in chemotherapy temporarily suppress the bone marrow. Therapeutic x rays that reach the bone marrow are also destructive. Cancer cells can also cause myelosuppression. Some cancers invade the bone marrow and crowd out the cells normally found there. Others can suppress the bone marrow without invasion. Nutritional deficiencies, common in cancer patients, also slow blood cell production as do viruses and some non chemo drugs.

Myelosuppression usually starts seven to ten days after an injury to the bone marrow. However, the bone marrow generally returns to normal within the next few weeks. Less often, cumulative damage can be caused. Occasionally, irreversible damage causes permanent myelosuppression. Very intensive chemotherapy or radiation can destroy all of the cells in the bone marrow.

Treatments

Myelosuppression is not always treated, especially if it is mild.

If the myelosuppression is a result of chemotherapy or radiation therapy, the cancer treatments may be stopped, delayed, or reduced to give the bone marrow a chance to recover. This may mean that the full dose of the treatment is not received.

Careful monitoring of possible neutropenia in cancer patients is important. If a cancer patient has a fever

and other signs of possible infection, the physician may treat the patient with injected antibiotics, possibly for several days.

Red blood cells or platelets can be replaced by transfusions, packed red blood cells, or platelets. These treatments can be very effective in the short term; however, the transfused cells are short-lived and the treatment may need to be repeated. There is a small chance of a transfusion reaction and a slight risk of infection by a virus carried in the blood. Transfusions of white blood cells are ineffective and rarely given.

Injections of growth factors may also be effective. Growth factors are chemicals, found naturally in the body, that stimulate the bone marrow to make blood cells. Each type of growth factor affects specific blood cells. Several are being manufactured as drugs. They include **erythropoietin**, granulocyte colony-stimulating factor (G-CSF, or filgrastim), granulocyte-macrophage colony-stimulating factor (GM-CSF, or sargramostim), and interleukin 11 (**oprelvekin**). Erythropoietin injections stimulate red blood cell production. They can decrease the need for a transfusion and improve the quality of life. This drug has few side effects if the kidneys are healthy, but it may not be effective if the body is already making enough natural erythropoietin. G-CSF and GM-CSF can speed the return of neutrophils. Their side effects include **bone pain**, fevers, rashes, muscle pains, and nausea. Interleukin 11 can increase platelet numbers. Its side effects may include fluid retention, a rapid heartbeat, red eyes, and difficulty breathing. Growth factors are expensive and several injections are usually needed.

Complete destruction of the bone marrow is incompatible with life. If the bone marrow is severely damaged, a bone marrow transplant may be necessary.

Alternative and complementary therapies

Supportive therapy can help to minimize the effects of myelosuppression. If nutrition is a contributing factor, iron or vitamin supplements may be beneficial. **Antibiotics** can aid in preventing infections. Some patients find that mild exercise and enjoyable distractions help with fatigue.

Nasal cancer

Definition

Nasal cancer is any cancer that occurs within the nose, either in the nasal vestibule (the immediate interior of the nose, just beyond the nostrils), or the nasal cavity (the deep interior of the nose). Many different types of cancer can occur within the nose, and the type of treatment and the chance of cure will vary according the type of cancer that occurs.

Description

Nasal cancers are very rare, making up less than 2% of all tumors of the respiratory tract in the United States. Less than 50 cases a year are diagnosed in the United States. Although squamous cell **carcinoma** is the most common type of cancer that occurs within the nose, many other types can also occur, including adenocarcinoma, **melanoma**, different kinds of **sarcomas**, inverted papilloma, **lymphoma**, and esthesioneuroblastoma.

Squamous cell carcinomas arise from skin tissue. They are the most common type and are often the result of either cigarette smoking or occupational exposure to dusts or chemical fumes. Adenocarcinomas are malignancies that resemble glandular tissue. Nasal adenocarcinomas are also often associated with occupational exposure to dusts or chemical fumes. T-cell lymphomas (Non-Hodgkins) in the nasal area are strongly associated with a virus (**Epstein-Barr virus**, EBV). Although nasal T-cell lymphomas are fairly common in some parts of the world, they are very rare in the United States.

Inverted papillomas are associated with another virus (**human papilloma virus**, HPV) and arise from benign but locally invasive nasal polyps. They are rare, comprising only about 0.5% of all nasal tumors. Although a definite association with HPV has been shown, a tumor may require interaction of the virus with chemicals or other factors, which appear to cause transformation of the inverted papilloma into squamous cell carcinoma in the nose. Esthesioneuroblastoma is a very rare nasal tumor, with less than 200 cases reported in the last 25 years. They are tumors that arise in the nerves in the nose, and have occurred most commonly in teenagers and senior citizens.

Demographics

Although the overall risk of nasal cancer is quite low (since this type of cancer is very rare), relative risks for some specific groups are fairly high. For example, nasal T-cell lymphomas are virus-associated and occur in high incidence in Asia and South America. Nasal squamous cell carcinomas occur much more frequently in cigarette smokers and individuals who have occupational exposures to dusts or chemical fumes, especially in Europe. Consumption of salted and pickled foods creates an increased relative risk of nasal cancer in Asia. Nasal cancers are also more frequent in some African populations that use mahogany wood in cooking fires.

In the United States, nasal cancers are rare. There are no significant racial differences in incidence. Males experience all types of nasal cancer in significantly greater numbers than women, probably due to more occupational exposure to agents that can cause these types of cancer. Most nasal cancers occur in people over 40, although the rare esthesioneuroblastoma has occurred in relatively high percentages in adolescents.

Causes and symptoms

All cancers are caused when a genetic mutation is made in a gene that is involved in the control of cell division. This mistake can arise naturally, can be inherited, or it can be caused by a virus, by sunlight or other radiation, or by some chemical that a person is exposed to, usually through eating, drinking or breathing. For nasal cancers, all of these factors have been shown to play a part.

The use of tobacco products has been strongly associated with the occurrence of nasal adenocarcinomas and squamous cell carcinomas. Chronic occupational

exposures to leather, wool, or wood dust or chemical mixtures, particularly nickel, dioxane, nitrosamine, chromium used in dye manufacturing, mustard gas, rubbing alcohol, or formaldehyde, have a demonstrated association with nasal adenocarcinomas and squamous cell carcinomas as well. Some rare nasal T-cell lymphomas have been shown to be very strongly associated with a virus (Epstein-Barr Virus, EBV). Some nasal malignancies (about 5%) begin as inverted papillomas, a locally aggressive tumor which does not usually metastasize but which may turn malignant. These are also thought to be caused by a virus, although a different one: Human papilloma virus (HPV). Some nasal cancers have a strong hereditary component: people with genetic alterations that cause hereditary **retinoblastoma** have a much higher incidence of nasal cancers than average, which indicates that the genetic change that caused their original disease may also contribute to nasal cancer.

People with nasal cancer may think that they have a cold or chronic sinus infections. They may experience a feeling of stuffiness or blockage in the nose, persistent nasal drainage, or frequent nose bleeds. Other symptoms can occur if the tumor has invaded other tissues around the nose, particularly the orbit of the eye or the base of the skull. Other symptoms which may occur include:

- double vision
- bulging of the eye
- a lump on the face or around the eye
- loose teeth
- frequent headaches

In advanced stages, patients with nasal cancers may suffer from **fatigue**, **weight loss**, lack of appetite (anorexia), and **fever**.

Diagnosis

When otherwise unexplainable symptoms lead a doctor to suspect that a patient may have nasal cancer, often he or she will arrange for endoscopic examination of the nasal cavity (and possibly the sinuses) in order to see if there is a tumor. Definite diagnosis requires a **biopsy**, in which a small piece of the tumor is cut out and examined to see what types of cells it contains. After a nasal cancer is diagnosed (depending on the type of cancer), many doctors will ask the patient to have an **x ray**, **computed tomography** scanning (CT scans), or **magnetic resonance imaging** (MRI). These techniques visualize the tumor and show the doctor how much the tumor has invaded surrounding tissues. Because treatment for nasal cancer, as well as **paranasal sinus cancer**, involves surgery in a small, complex space which requires the surgeon to set very precise surgical boundaries, and because most nasal cancers are advanced by the time a patient sees a doctor, it is very important that the doctor evaluate the tumor thoroughly before planning treatment. If the tumor appears to have invaded other tissues, often a doctor will schedule a surgical exploration of the tumor in order to better evaluate the cancer, with the goal of constructing the best possible treatment plan. Sometimes, in addition, surgical exploration is necessary to determine whether the position and invasion of the tumor into surrounding tissue makes surgical removal of the tumor impossible.

Treatment team

As the understanding of cancer grows and new treatment approaches are developed, the complexity of cancer treatment also increases. Today, a multidisciplinary approach to cancer treatment is considered necessary for effective patient care. People involved in the treatment of a nasal cancer will typically include the referring physician, an otolaryngologist, a medical oncologist, a pathologist, and a nurse. If **radiation therapy** is pursued, a radiation oncologist, radiation therapist, radiation nurse, radiation physicist, and a dosimetrist will also be involved. Treatment will also probably include a psychologist, nutritionist, social worker and chaplain. For nasal cancers, a reconstructive or plastic surgeon may be necessary for optimum cosmetic results after removal of a nasal tumor. If surgical removal of the eye is necessary, specialists in prosthetic eye replacement will be necessary as well.

Clinical staging, treatments, and prognosis

When a cancer develops, the original tumor can spread, usually through the blood or lymph system, to other parts of the body. Since the cancer spreads through the lymph system, often the lymph nodes in the area of the original tumor are the first other sites where cancerous cells can be found. Common other places that metastatic disease may appear are the lungs, the liver, and the bones.

One of the foremost goals of a doctor's assessment of a cancer patient is to determine how far the cancer has already spread and how likely it is to spread further, both of which are key factors in the likelihood that the patient will be cured. The assessment of the tumor's spread is termed staging, and the assessment of how aggressive the cancer cells are is termed grading.

Staging of nasal cancers is performed by visual inspection of tumors (maybe through endoscopy) or visualization of tumors by imaging techniques like x rays, MRIs, or CT scans. The doctor may also attempt to feel for tumors manually. This information will be

used to create an official stage for the tumor that is a standardized expression of how much the tumor has already spread.

Because tumors of the nasal vestibule and cavity are rare, and because they are comprised of so many different types, no one staging system has been defined for use with these cancers. Cancers of the paranasal sinuses have a defined staging system based on the TNM system, and this system is often used for describing nasal cancers. The T in the TNM system represents the growth of the local tumor, N describes the spread of the tumor to the lymph nodes, and M describes the spread, or **metastasis**, of the cancer to distant body sites. The cancer is given various numbered ratings in each letter category, and these are used to create a standardized stage. Generally, tumors with no invasion of local tissues are described as Stage I, while tumors with minimal invasion of local tissues are identified as Stage II. Tumors that have extensive local invasion or that have spread to the lymph nodes but which have not metastasized are described as Stage III or early Stage IV (A and B). Stage IVC tumors are any tumors which have metastasized.

Most nasal cancers (up to 80%) have already spread to other body sites by the time the symptoms prompt a patient to see their doctor. This fact, combined with the fact that the area is anatomically complex and tightly constructed, makes it very important that the first attempt at treatment is well-planned, with input from a multidisciplinary team and thorough evaluation of the cancer before treatment is begun.

Since cancers of the nasal cavity and vestibule include many different types of cancers, treatment will vary depending on the type of cancer involved, where it is located, and the extent to which it has already spread. Because of this, and because of the complexity of the anatomy in the area and the multitude of other important structures that may be involved in later stages, treatment of nasal cancers is highly individualized, with no firm standard practice guidelines.

For most nasal cancers, treatment will involve surgical removal of the tumor followed by four to five weeks of radiation therapy. In advanced cancers, preoperative radiation therapy may also be employed. However, since radiation therapy has proven very effective for nasal cancers and because radiation has better cosmetic results than surgical removal of a tumor, for many nasal cancers (especially T-cell lymphomas and esthesioneuroblastomas), radiation will be the initial treatment option. If the doctor decides to remove as much of the tumor as possible surgically, radiation therapy (external) will usually be used for four to five weeks after surgery in order to destroy any remaining cancerous tissue. One exception is the case of inverted papillomas, for which surgical excision alone is usually employed. Surgery, because of the tight anatomical area in which a surgeon must work, may also involve more recent techniques like cryosurgery (freezing tissue) or laser surgery.

Tumors initially treated by either radiation or surgery alone may, if they come back, be treated by the untried option or by employing both. External radiation may be supplemented, especially in advanced nasal vestibule cancer, by internal radioactive implants. In addition, advanced stage or recurrent nasal cancer may be treated by **chemotherapy**, usually involving a combination of drugs. Drugs are used in combination in most chemotherapy because combinations of different drugs (with different side effects) deliver the highest cancer-destroying effect, while minimizing the chance for a serious adverse reaction to the therapy. The drug combinations used in nasal cancer vary on the type of cancer, and may include one or all of the drugs **cisplatin**, **fluorouracil**, **bleomycin**, or **methotrexate**. In addition, nasal cancers described as Stage III or IV will probably be treated with preventative radiation therapy of the neck area, in order to destroy cancerous cells which may have traveled to the lymph nodes.

Although nasal cancers are made up of many different types of cancer, all types of nasal cancers are considered aggressive. The majority of nasal cancers, because symptoms mimic upper respiratory illnesses and because symptoms often do not occur until the cancer has already filled up the nasal cavity and has invaded surrounding tissues, are already in advanced stages when a patient seeks medical help. For this reason, and because treatment is difficult because of the complexity of the anatomical area, fewer than half of nasal cancer patients survive. If the first treatment attempt is successful, and a patient is cancer-free at two years, however, chances improve greatly.

Nasal cancer is unusual in that, although many patients have metastasis to the lymph nodes or beyond (usually to the lungs), metastasis is not usually the reason for a patient's death. Most nasal cancer patients who succumb to the disease die from invasion of the tumor into vital areas of the brain.

Alternative and complementary therapies

Alternative and complementary therapies are treatments that are not traditional, first-line therapies like surgery, chemotherapy, and radiation. Complementary therapies are those that are meant to supplement traditional therapies and usually have the objective of relieving symptoms or helping cancer patients cope with the disease or traditional treatments. Alternative therapies

Cancerous tumor in nose. *(Custom Medical Stock Photo. Reproduced by permission.)*

are nontraditional treatments that are chosen instead of traditional treatments in an attempt to cure the disease. Alternative therapies have typically not been proven to be effective in the same way that traditional drugs are evaluated, in **clinical trials**.

Common complementary therapies that may be employed by patients with nasal cancer are art therapy, massage, meditation, visualization, music therapy, prayer, t'ai chi, and yoga or other forms of exercise, which reduce anxiety and can increase a patient's feeling of well-being.

Numerous alternative therapies exist in cancer treatment, but none has been proven in clinical trials to be effective. Laetril, a product of apricot seeds, is probably one of the most well known. Laetril contains a form of cyanide that may be released by tumor enzymes and may then act to kill cancerous cells. Laetril is not approved for use in the United States, although it is available in Mexico. The National Cancer Institute (NCI) sponsored two trials of Laetril in the late 1970s and early 1980s, but found Laetril to be ineffective and concluded that no further study of the substance was necessary. **Vitamins** and other nutritional elements like vitamins A, C, and E, and selenium are thought to act as **antioxidants**. Vitamin E, melatonin, aloe vera, and a compound called beta-1, 3-glucan are reported to stimulate the immune system. Natural substances like garlic, ginger, and shark cartilage are also commonly held to shrink tumors, with less defined modes of action.

Antineoplastons are believed by some to be another alternative approach to a cancer cure. Antineoplastons are small proteins which may act as molecular messengers and which may be absent from the urine and blood of many cancer patients. Proponents believe that replacing these proteins may have beneficial effects. The NCI has been unable to draw definitive conclusions about the usefulness of antineoplastons as a therapy because no large-scale clinical trials of the therapy have been completed.

Coping with cancer treatment

Treatment of nasal cancers commonly includes surgery, radiation therapy and chemotherapy. Although the use of chemotherapy and radiation therapy in addition to surgery has improved the chance of survival for nasal cancer patients, both of these treatments unavoidably result in damage to some healthy tissues and other undesirable side effects.

Fatigue is a very common side effect of both radiation therapy and chemotherapy. Side effects of the actual treatments combine with the natural depletion of the body's resources as it fights off the disease and normal psychological consequences of the disease such as **depression** to make coping with fatigue a very significant aspect of dealing with cancer treatment. The best way to deal with these symptoms is to cut back on stressful activities and take plenty of time to allow the body to heal. It is also important to try to maintain a well-balanced, nutritious diet, and to exercise. Patients should avoid as much extra stress as possible and should limit visitors, if needed, to avoid being overtired. At the same time, it is also important for psychological health for the patient to pursue their interests as much as possible and to avoid becoming isolated.

The biggest problem for those undergoing radiation therapy is the development of dry, sore, "burned" skin in the area being treated. (Radiation does not hurt during treatment and does not make the person radioactive.) Skin in the treatment area will become red, get itchy and sore, and may blister and peel, becoming painful. Patients with fair skin or those who have undergone previous chemotherapy have a greater risk of more serious

reactions. Dry, itchy or sore skin is temporary, but affected skin may be more sensitive to sun exposure for the rest of the patient's lifetime, so a good sunscreen and a hat should be used whenever affected skin is exposed to sunlight.

Other effects, specific to the nasal area, may also occur. Sometimes very thick mucus is produced that may be difficult to cough up. Some patients become hoarse and find it difficult to eat. It is important for patients to keep well-hydrated by drinking plenty of fluids and to eat as much protein as possible. If patients cannot eat enough to maintain a high-protein diet, liquid high-protein drinks should be consumed. Patients may be more susceptible to upper respiratory infections after treatment, so some physicians will prescribe preventative **antibiotics**. If eating is extremely painful, tylenol can be consumed in milk about thirty minutes before a meal for pain relief. Patients should be prepared for the fact that symptoms of radiation treatment can persist for up to a month after the last treatment.

Some of the more common side effects of chemotherapy include hair loss, and **nausea and vomiting**. Hair loss (**alopecia**) is a difficult part of dealing with cancer treatment for most patients, especially women. Hair may thin out gradually, or it may fall out in big clumps. To slow down the rate of hair loss, avoid any unnecessary sources of damage to the hair, like curling, blow-drying, or chemical treatments.

Different patients choose different ways of coping with the loss of their hair. Some patients may find they are more comfortable hiding hair loss with a wig; it is a good idea to cut off a lock of hair before hair loss begins in case a wig is later desired. Some patients may choose to remain bald, or may want to choose hats or scarves instead of wigs. In any case, it is important to remember that the loss of hair is a sign that the medication is doing its job, and that hair loss is temporary. Hair usually begins regrowth within a few months of the end of intensive chemotherapy, although it may come in a different color or texture than the original hair.

Nausea and vomiting are other fairly common side effects of many chemotherapy drugs. (Radiation to the brain or the GI tract can also cause nausea and vomiting.) After a few courses of chemotherapy drugs, some patients will become nauseated just from thinking about an upcoming treatment or from smelling certain odors. Drugs that combat nausea and vomiting can be prescribed, but are often not effective for anticipatory nausea. If nausea and vomiting are a problem, heavy, regular meals should be avoided in favor of small, frequent snacks made up of light but nourishing foods like soup. Avoiding food smells and other strong odors may help.

KEY TERMS

Carcinoma—Any malignant tumor

Endoscopy—A diagnostic procedure in which a miniature videocamera on the end of a flexible tube is inserted into internal body cavities so that the physician can view the internal structures.

Lymphoma—A type of cancer that arises in the lymph nodes

Nasal polyp—A non-cancerous mass that grows out from the inner lining of the nasal cavity

Sarcoma—A tumor that arises from bone or connective tissue

Squamous cell carcinoma—A malignancy that arises from outer skin cells

Desensitization, hypnosis, guided imagery, and relaxation techniques may be used if nausea and vomiting are severe. These techniques help to identify the triggers for the nausea and vomiting, decrease patient anxiety, and distract the patient from thinking about getting sick. Acupressure bands, commonly used for seasickness, and acupuncture, may also provide some relief for some patients.

Both radiation therapy and chemotherapy treatments require a substantial level of commitment from the patient in terms of time and emotional energy. Fear and anxiety are major factors in coping with cancer in general and these cancer treatments. The feelings are completely normal. Some patients find that concentrating on restful, pleasurable activities like hobbies, prayer, or meditation is helpful in decreasing negative emotions. It is also very important that patients have people to whom they can express their fears and other negative emotions. Support groups may help to provide an environment where fears can be freely expressed and understood.

Clinical trials

Clinical trials are studies in which new treatments for disease are evaluated in human patients. Current clinical trials for nasal cancer patients are concentrating on the addition of chemotherapy to the more common treatments of surgery and radiation therapy, either before or after those treatments, in order to improve cure rates or to lessen the side effects of radiation.

Nasal cancer patients are also being recruited for a clinical trial evaluating an alternative therapy known as antineoplaston therapy.

Prevention

Although mutations in genetic material happen frequently, most of these do not result in cancer. This is because a healthy body repairs most mistakes before a cancer develops and because, if a cancer does develop, the immune system of a healthy body will usually destroy it. In general, therefore, a healthy lifestyle that includes exercise, plenty of sleep, a diet rich in fruits and vegetables, regular health screenings and the avoidance of stress, excessive sun exposure, tobacco use, or excessive **alcohol consumption** will help to prevent most cancers.

Since nasal cancers, in particular, are often caused by chemical exposures, many of these cancers are preventable by avoiding excessive inhalation of wood dust or chemical mixtures and by avoiding use of all tobacco products. (Nasal cancers resulting from wood dust appear to require high-dose, long-term exposure, especially to hardwoods.)

One type of nasal cancer appears to be virus-associated and is more prevalent in people with a history of nasal polyps. People who are diagnosed with nasal polyps should discuss their removal with their physicians and have existing polyps checked regularly in order to detect a malignant polyp as quickly as possible.

Patients with nasal cancer can increase their chances of a cure by making sure that they see their doctors for all scheduled follow-up appointments. This is especially important for the first two years (when most recurrences of nasal cancer occur), but it is also important to maintain follow-up beyond that. Many nasal cancer patients experience a second tumor somewhere else in the upper respiratory tract.

Special concerns

One of the unique aspects of dealing with nasal cancer is the fact that surgical removal of a nasal tumor can result in substantial facial disfigurement. Patients who are dealing with this aspect of nasal cancer are forced to cope with the substantial emotional burden of disfigurement in addition to the other emotional ramifications of the disease.

People with facial disfigurement may be forced to cope with negative reactions from other people in public places, including staring, whispering, rude remarks or averted eyes, and other avoidance of interpersonal interaction.

In addition, the loss of the accustomed appearance will be experienced much like a bereavement. Patients will probably initially feel numb, then experience intense, overwhelming feelings of sadness, fear, and anger. The period characterized by intense, almost unbearable emotions is usually followed by a period of time when the patient feels completely empty, fatigued, and apathetic. Given time, most patients will come to an acceptance of their new reality and begin to enjoy old friends and activities again. It is important not to expect patients in such circumstances to immediately accept their situation or to suppress the natural emotions that accompany the change in their appearance. Patients can ease the process by trying to focus on one day at a time and by finding people who can help them work through the process by listening and accepting their emotions. It is very important that a patient dealing with these changes have friends or family members to whom they can express their feelings of grief and anger. A support group might also be helpful.

QUESTIONS TO ASK THE DOCTOR

- Can you explain what kind of cancer I have?
- Can you explain the grade and stage of my cancer? What are the chances that it will come back?
- How was this cancer diagnosed?
- What is my prognosis?
- How much will the surgery alter my facial appearance?
- What treatments are we going to pursue? What happens if these don't work?
- Do you have experience in treating this type of cancer?
- Is there anything I can do to optimize treatment? Are there any particular side effects I should expect?
- Are there complementary therapies that you would recommend? Any other things that would help me cope with the diagnosis or treatment?
- How often will I need further check-ups? Is there anything I can do to keep this cancer from coming back?

Nasopharyngeal cancer

Definition

Nasopharyngeal cancer is an uncontrolled growth of cells that begins in the nasopharynx, the passageway at the back of the nose.

Description

The nasopharynx connects the nose (hence, naso) to the pharynx, the shared passageway for air and food at the back of the nose and mouth. Air moves through the pharynx on its way into and out of the trachea, the tube that carries air to the lungs. Food passes through the pharynx on its way to the esophagus, the muscular tube that carries food to the stomach.

Although it is possible for people to breathe through the mouth, breathing through the nose is better. The nose warms and moistens air, and the interior of the nose has hairs to filter particles from the air. Thus, any blockage, such as a tumor or cancer in the nasopharynx, interferes with normal breathing.

Not all tumors that grow in the nasopharynx are malignant. Many are benign, but the tumors still cause problems because they often grow into the vessels that supply blood to the nose. Malignant cancers in the nasopharynx grow from squamous, or flat, epithelial cells. Epithelial cells form body coverings, such as skin. Cancers that originate in epithelial cells are known as carcinomas.

Demographics

Nasopharyngeal cancer is rare in most parts of the world. The exception is in Southeast Asia, where there are as many as 40 new cases each year for every 100,000 people. In other parts of the world, there are as few as one new case per year for every 100,000 people. Men are at a greater risk than women. Although all age groups can be affected by this cancer, like many other cancers, people over the age of 40 tend to be more susceptible.

Causes and symptoms

Several factors put people at risk for nasopharyngeal cancer. One is an infection with a type of herpes virus called **Epstein-Barr virus** (EBV). Another factor is genetic make-up, or inherited DNA. Finally, anything that introduces radioactive elements into the diet or respiratory pathway increases the risk of developing this cancer.

In certain parts of China, the soil has a high concentration of uranium and thorium, which break down into radioactive elements such as radium and radon. The elements are taken up by trees, which are burned for wood and become airborne. They also dissolve in water, and fish and plants draw them up. The fish are eaten. Some of the plants are used for tea. The scenario seems to increase the risk of nasopharyngeal cancer, but the exact way in which it does is not known.

In all parts of the world, people who work in sawmills or with wood products have a higher likelihood of acquiring nasopharyngeal cancer. Sawdust or chemicals in the wood may contribute to its development.

Recently, E. Lopez-Lizarraga demonstrated that human papilloma virus (HPV) is often present in people who contract nasopharyngeal cancer. Neither this link nor the others cited show a precise cause and effect, however. Some of the links may mask true causes. For example, in the HPV study, subjects who had HPV infection also tended to have poor oral hygiene. And in the case of EBV, infection with the virus is so common that some researchers are now investigating whether there is a unique strain of the EBV that puts individuals at greater risk for nasopharyngeal cancer.

Symptoms of nasopharyngeal cancer include:

- lump in the nose or neck
- headaches
- ear pain
- numbness on the side of the face
- difficulty breathing
- difficulty speaking

Diagnosis

A physician examines the nasopharynx in various ways, usually starting with an instrument such as a

nasoscope. The nasoscope allows a look at the inside of the nasal cavity. Palpating, or touching, lymph nodes in the neck to check for enlarged ones is also part of the examination.

If suspicious growths are found, a **biopsy** is done to take a tissue sample. Different types of biopsy can be used. An incision may be made to obtain tissue, or a needle with a small diameter may be inserted into a suspicious mass to obtain cells, especially if there is a lump in the neck.

Computed tomography (CT) and **magnetic resonance imaging** (MRI) scans are also used. They help determine whether the cancer has spread from the walls of the nasopharynx. MRI offers a good way to examine the tonsils and the back of the tongue, which are soft tissues. CT is used as a way of studying the jaw, which is bone.

Treatment team

Generally, physicians with special training in the organs of the nose and throat take initial responsibility for the care of a patient with nasopharyngeal cancer. They are called otolaryngologists, or occasionally, otorhinolaryngologists. Otolaryngologists are usually labeled ENT (for ear, nose, and throat) specialists. An ENT specializing in cancer will probably lead the team, accompanied by radiation therapists and oncologists.

Clinical staging, treatments, and prognosis

Stage I describes a cancer that has not spread. It is not in the lymph nodes and is localized in the nasopharynx. Stage II describes a larger cancer, one that affects more than half the area of the nasopharynx, that is not in the lymph nodes. Stage III nasopharyngeal cancer has spread beyond the nasopharynx; it might affect the oropharynx, the cavity at the back of the mouth, or part of the throat. Or, it might have spread to the lymph nodes. Stage IV involves one or more of the following indications:

- spread of cancer to a site near the original site, such as the bones and nerves of the head
- more than one lymph node with cancer
- spread to other parts of the body, such as the larynx, the trachea, the bronchi, the esophagus, or more distant points, such as the lungs

The outlook for recovery from nasopharyngeal cancer is better the earlier the stage in which the cancer is diagnosed. For stage I and stage II, radiation or **chemotherapy** treatment of the affected area is sometimes all that is required to halt the cell growth. Decisions about which method to use depend on many factors, but the tolerance a patient has for radiation or chemotherapy and the size of the tumor are important.

Often, the most promising treatment option for a person with nasopharyngeal cancer is a clinical trial. The outlook for early stage diagnoses of nasopharyngeal cancer is good. The five-year survival rate is over 80% for small cancers, which are typically in Stage I. Cancers that are larger, but have not spread to the lymph nodes, usually have survival rate of 50% or more. Unfortunately, about half of all people diagnosed with nasopharyngeal cancer are not diagnosed until the cancer is advanced, which leads to a poorer prognosis.

Coping with cancer treatment

The patient should be an active member of the treatment team, listening to information and making decisions about which course of treatment to take. Premier cancer centers encourage such a role.

Appetite might be affected before, during, and after treatment. Before treatment, the presence of a tumor can interfere with chewing and swallowing food, and food might not seem as appealing as it once did. During treatment, particularly radiation treatment, the treated nasopharynx will be sore, and eating and breathing may be difficult.

Patients should also seek out a support network to help them cope with the psychological implications of cancer. In addition to family and friends, local support organizations can offer guidance, answer questions, and link newly diagnosed patients with others who have survived a similar experience.

KEY TERMS

Biopsy—A diagnostic procedure in which a tissue sample is removed from the body for examination.

Computed tomography (CT)—A radiographic technique in which multiple x-ray images assembled by a computer to give a three-dimensional image of a structure.

Endoscope—Instrument designed to allow direct visual inspection of body cavities, a sort of microscope in a long access tube.

Magnetic resonance imaging (MRI)—Magnetic fields and radio frequency waves are used to image internal structures of the body.

Nasoscope—A type of endoscope designed specifically to be inserted through the nose and used for examination of the nasal cavity.

QUESTIONS TO ASK THE DOCTOR

- In what stage is this cancer?
- What is the outlook for a patient with my profile?
- What are the side effects of the treatments that are recommended? Which treatment gives the best combination of survival and quality of life?
- Is there a clinical trial for which I am eligible?

Alternative and complementary therapies

Any technique, such as yoga, meditation, or biofeedback, that helps a patient cope with anxiety over the condition and discomfort from treatment is useful and should be explored as an option. Many herbal remedies are available to ease the symptoms of nausea that accompany treatment; the physician, however, should be notified of any remedies, herbal or otherwise, that are taken.

Clinical trials

There are a number of **clinical trials** currently in progress, especially with biological response modifiers (BMR), or substances that take advantage of the capabilities of the body's own immune system. **Aldesleukin** is one BMR that has been used to fight nasopharyngeal cancer, with inconclusive results. The Cancer Information Service at the National Institutes of Health offers information about clinical trials that are looking for volunteers. The service offers a toll-free number at (800) 422-6237.

Prevention

The link between HPV and nasopharyngeal cancer suggests that any precaution taken to avoid contracting sexually transmitted diseases, such as the use of condoms, affords protection. Radon gas levels should be checked in homes, and measures taken to reduce them if they are high. Individuals working with wood, especially those exposed to sawdust and chemicals, should wear protective respiratory covers, such as a breathing mask.

Special concerns

Additional cancers that begin in the nasopharynx can start in the lymph cells found there. Because of their origin, these cancers are called lymphomas.

Nausea and vomiting

Description

Nausea and vomiting are recognized as two separate and distinct conditions. Nausea is the subjective, unpleasant feeling or urge to vomit, which may or may not result in vomiting. Vomiting is the forceful expelling of the contents of the stomach and intestines through the mouth. To some, nausea is a more distressing symptom than vomiting. Nausea and vomiting are major problems for patients being treated with cancer, with approximately 50% of patients experiencing nausea and vomiting as a result of cancer treatments even though **antiemetics** (anti-nausea and vomiting medications) were used. In addition, more than 50% of cancer patients experience nausea and vomiting as a result of progression of the disease, or as a result of exposure to other therapies used to treat the cancer.

Not all patients diagnosed with cancer will experience nausea and vomiting. However, nausea and vomiting remain two of the side effects associated with cancer and cancer treatment that patients and their families fear the most. The negative aspects of nausea and vomiting can influence all facets of a patient's life. If nausea and vomiting are not controlled in the patient with cancer, the result can be serious metabolic problems such as disturbances in fluid and electrolyte balance and nutritional status. Psychological problems associated with nausea and vomiting include anxiety and **depression**. Uncontrolled nausea and vomiting can also lead to the decision by the patient to stop potentially curative cancer therapy.

Causes

The most common causes of nausea and vomiting in cancer patients include treatment with **chemotherapy** and **radiation therapy**; tumor spread to the gastrointestinal tract, liver, and brain; constipation; infection; and use of some **opioids**, which are drugs used to treat cancer pain. The mechanisms that control nausea and vomiting are not fully understood, but both are controlled by the central nervous system. Nausea is thought to arise from stimulation of the autonomic nervous system. It is theorized that chemotherapy causes vomiting by stimulating areas in the gastrointestinal tract and the brain. The areas in the brain that are stimulated are the chemoreceptor trigger zone (CTZ) and the emetic or vomiting center (VC). When the VC is stimulated, muscular contractions of the abdomen, chest wall, and diaphragm occur, which result in the expulsion of stomach and intestinal contents.

Chemotherapy-induced nausea and vomiting

Not all chemotherapeutic agents cause nausea and vomiting. Chemotherapy drugs vary in their ability or potential to cause nausea and vomiting. This variation is known as the emetogenic potential of the drug, or the potential of the drug to cause emesis. Chemotherapy drugs are classified as having severe (greater than 90% of patients exposed to this drug will experience nausea and vomiting), high (60–90% of patients will experience nausea and vomiting), moderate (30–60% will experience nausea and vomiting), low (10–30% will experience nausea and vomiting), and very low (less than 10% experience nausea and vomiting) emetogenic potential.

The incidence and severity of chemotherapy-induced nausea and vomiting varies and is related to the following factors: the emetogenic potential of the drug, the drug dosage, the schedule of administration of the drug, and the route of the drug. For example, even a drug with a low emetogenic potential may cause nausea and vomiting if given at higher doses. Factors that are associated with increased nausea and vomiting after chemotherapy include female gender, age greater than six in children, age less than 50 in adults, history of motion sickness, and history of vomiting in pregnancy.

When nausea and vomiting result from chemotherapy administration, the nausea and vomiting can be classified as anticipatory, acute, or delayed. Anticipatory nausea and vomiting occur prior to the actual chemotherapy treatment and are a response primarily to an environmental stimulus, such as a specific odor, which is then associated with the chemotherapy treatment in the future. That is, the smell of the odor alone can be enough to induce or trigger nausea and vomiting in the sensitized patient. Acute nausea and vomiting occur within 24 hours of administration of the chemotherapeutic agent. Delayed nausea and vomiting occur after the acute phase and may last 48 or more hours after chemotherapy administration.

Radiation therapy induced nausea and vomiting

Although not all patients receiving radiation therapy will experience nausea and vomiting, patients receiving radiation therapy to the gastrointestinal tract and brain are most likely to experience those side effects. Radiation therapy to the brain is believed to stimulate the CTZ, the VC, or both. The higher the radiation therapy dose and the greater the body surface area irradiated, the higher the potential for nausea and vomiting. Also, the larger the amount of gastrointestinal tract tissue exposed to radiation the more likely nausea and vomiting will occur. Nausea and vomiting associated with radiation therapy usually occurs one-half hour to several hours after treatment and usually does not occur on the days when the patient is not undergoing treatment.

Treatments

Pharmacologic management

The most commonly used intervention to manage nausea and vomiting in cancer patients is the use of antiemetic drugs. Many of these drugs work by inhibiting stimulation of the CTZ and perhaps the VC. Most of the drugs used today to clinically treat nausea and vomiting are classified into one of the following groups: dopaminergic antagonists, neurokinin receptor antagonists, **corticosteroids**, cannabinoids, and serotonin receptor antagonists. Antiemetics can be utilized as single agents or several drugs can be prescribed together as combination therapy.

Examples of dopaminergic antagonists include phenothiazines such as prochlorperazine (Compazine), substituted benzamides such as metaclopramide (Reglan), and butyrophenones such as droperidol (Inapsine) and haloperidol (Haldol). Side effects of the dopaminergic antagonists include extrapyramidal reactions (e.g., tremors, slurred speech, anxiety, distress, paranoia) and sedation. In 2004, the FDA approved a new drug called aprepitant (Emend) for use in cancer patients. It is used in combination with other antiemetics for relief of acute and delayed nausea and vomiting caused by high-dose chemotherapy, most often caused by the chemotherapy drug cisplatin. Side effects of aprepitant include fatigue, dizziness, stomach pain, nausea, hiccups, diarrhea, constipation, and loss of appetite.

Steroids may be used to treat mild to moderately emetogenic chemotherapy. However, long-term corticosteroid use is considered inappropriate due to the multiple adverse effects associated with long-term use.

Cannabinoids (substances similar to, or derived from, **marijuana**) may be effective in selected patients but are usually not prescribed as first line therapy due to generally low rates of effectiveness. Controversy continues to exist related to the use of cannabinoids, which may not be accepted cultural or societal practice for some patients. Side effects of cannabinoids include physical and psychogenic effects such as acute withdrawal syndrome, dizziness, dry mouth, sedation, depression, anxiety, paranoia, and panic.

The newest class of antiemetics is the serotonin or 5-HT_3 antagonists. In 2001, three serotonin receptor antagonists were available in the United States: granisetron (Kytril), ondansetron (Zofran), and dolasetron (Anzemet). Serotonin receptor antagonists are better tolerated, are generally more effective, and result in fewer side effects than previously available antiemetics. A common adverse effect of the serotonin antagonists is asthenia, a state of unusual fatigue and weakness. Asthenia usually occurs two to three days after treatment with serotonin antagonists and may last one to four days. Serotonin receptor antagonists may not be offered or made available to all patients due to the relatively high cost of the drugs. Controversy exists related to the optimal role of serotonin receptor antagonists. Some clinicians argue there is the potential for overuse of the serotonin receptor antagonists when used to treat patients who are not receiving chemotherapeutic agents with moderate to severe emetogenic potential and when less expensive agents would be as effective.

Another class of drugs, the benzodiazepines including **lorazepam** (Ativan), midazolam (Versed), and alprazolam (Xanax), may be used in conjunction with antiemetics in the prevention and treatment of anxiety and expected chemotherapy-induced nausea and vomiting. These agents appear to be especially effective in highly emetogenic regimens administered to children. The benzodiazepines have only modest antiemetic properties. Therefore, they are usually used as adjuncts to antiemetic agents. Adverse effects of the benzodiazepines include sedation, confusion, hypotension (unusually low blood pressure), and visual disturbances.

Alternative and complementary therapies

The use of antiemetics is considered the cornerstone of therapy to treat chemotherapy-induced vomiting. Nonpharmacologic therapies may be used in conjunction with pharmacologic agents to enhance the effects of the drugs. Nonpharmacologic strategies include behavioral interventions such as guided imagery, hypnosis, systematic desensitization, and attentional distraction. Dietary interventions such as eating cold or room temperature foods and foods with minimal odors while avoiding spicy, salty, sweet, or high-fat foods may be beneficial to some patients while undergoing chemotherapy treatments. Another dietary recommendation is the use of ginger or ginger capsules to decrease episodes of nausea and vomiting. Acupressure, specifically stimulation of the Nei-Guan point (P6) of the dominant arm or stimulation of the Inner Gate and ST36 or Three Miles point (below the knee and lateral—outside area—to the tibia) has proven helpful to some patients. Music therapy interventions have also been effective as diversional interventions to reduce incidence and severity of chemotherapy-induced nausea and vomiting.

KEY TERMS

Antiemetics—Medications used to treat nausea and vomiting.

Emesis—An act or episode of vomiting.

Retching—Dry heaves that sometimes accompany nausea and vomiting.

Vomiting center—The location in the medulla of the brain that when stimulated leads to emesis.

Nephrostomy

Definition

Nephrostomy is a procedure in which a catheter (plastic tube) is inserted through the skin and into the kidney to drain it of urine. Urine drains into a bag outside the body.

Purpose

The ureter is the tube that carries urine from the kidney to the bladder. When this tube is blocked, urine backs up into the kidney. Serious, irreversible kidney damage can occur because of this backflow of urine. Infection is also a common implication in this stagnant urine.

Nephrostomy is performed in several different circumstances:

- when the ureter is blocked by a kidney stone
- when the ureter is blocked by a tumor
- when there is a hole in the ureter or bladder and urine is leaking into the body
- as a diagnostic procedure to assess kidney anatomy
- as a diagnostic procedure to assess kidney function

Precautions

People preparing for a nephrostomy should review with their doctors all the medications they are taking. People taking anticoagulants (blood thinners such as Coumadin) may need to stop medication. People taking metformin (Glucophage) may need to stop taking the medication for several days before and after nephrostomy. Diabetics should discuss modifying their insulin doses because fasting is required before the procedure.

Description

Nephrostomy is done by an interventional radiologist or urologist with special training in the procedure. It can be done either as an inpatient or an outpatient procedure, depending on why it is needed. For most cancer patients, nephrostomy is an inpatient procedure that is covered by insurance.

First, the patient is given an anesthetic to numb the area where the catheter will be inserted. The doctor then inserts a needle into the kidney. There are several imaging technologies such as ultrasound and **computed tomography** that are used to help the doctor guide the needle into the correct place.

QUESTIONS TO ASK THE DOCTOR

- Why am I having a nephrostomy?
- How long do you think I will have to stay in the hospital?
- How long do you expect the catheter to stay in?
- How much help will I need in caring for the catheter?

Next, a fine guide wire follows the needle. The catheter, which is about the same diameter as IV tubing, follows the guide wire to its proper location. The catheter is then connected to a bag outside the body that collects the urine. The catheter and bag are secured so that the catheter will not pull out. The procedure usually takes one to two hours.

Preparation

Either the day before or on the day of the nephrostomy, blood samples will be taken. Other diagnostic tests done before the procedure vary depending on why the nephrostomy is being done, but the patient may have a computed tomography (CT) scan or ultrasound to help the doctor locate the blockage.

Patients should not eat for eight hours before a nephrostomy. On the day of the procedure, the patient will have an intravenous (IV) line placed in a vein in the arm. Through this the patient will receive **antibiotics** to prevent infection, medication for pain, and fluids. The IV line will remain in place after the procedure for at least several hours, and often longer.

Aftercare

Outpatients will be expected to stay about 8–12 hours after the procedure to make sure the catheter is functioning properly. They should plan to have someone drive them home and stay with them at least the first 24 hours after the procedure. Inpatients may stay in the hospital several days. Generally people feel sore where the catheter is inserted for about a week to ten days.

Care of the catheter is important. The catheter will be located on the patient's back, so it may be necessary to have someone help with catheter care. The catheter should be kept dry and protected from water when taking showers. The skin around it should be kept clean, and the dressing over the area changed frequently. Special care is needed in handling the urine collection bag so that it does not dislodge the catheter.

Risks

Nephrostomy is an established and generally safe procedure. As with all operations, there is always a risk of allergic reaction to anesthesia, bleeding, and infection.

Normal results

In a successful nephrostomy, the catheter is inserted, and urine drains into the collection bag. How long the catheter stays in place depends on the reason for its insertion. In people with pelvic cancer or **bladder cancer** where the ureter is blocked by a tumor, the catheter will stay in place until the tumor is surgically removed. If the cancer is inoperable, the catheter may have to stay in place for the rest of the patient's life.

Abnormal results

Bruising at the catheter insertion site occurs in about half of people who have a nephrostomy. This is a minor complication. Major complications are infrequent, but include the tube becoming blocked or dislodged requiring tube replacement, bleeding and blood in the urine, and perforation of other organs.

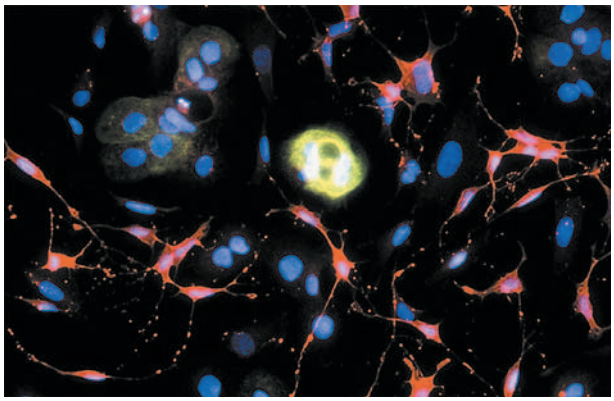
Neuroblastoma

Definition

Neuroblastoma is a type of cancer that usually originates either in the tissues of the adrenal gland or in the ganglia of the abdomen or in the ganglia of the nervous system. (Ganglia are masses of nerve tissue or groups of nerve cells.) Tumors develop in the nerve tissue in the neck, chest, abdomen, or pelvis.



Immunofluorescent light micrograph of human neuroblastoma cancer cells. The normal epithelial cells appear green, the cytoplasm of neuroblastoma is red, and the nuclei are blue. *(Photograph by Nancy Kedersha. Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Description

Neuroblastoma is one of the few cancer types known to secrete hormones. It occurs most often in children, and it is the third most common cancer that occurs in children. Approximately 7.5% of the **childhood cancers** diagnosed in 2001 were neuroblastomas, affecting one in 80,000 to 100,000 children in the United States. Close to 50% of cases of neuroblastoma occur in children younger than two years old. The disease is sometimes present at birth, but is usually not noticed until later. By the time the disease is diagnosed, it has often spread to the lymph nodes, liver, lungs, bones, or bone marrow. Approximately one-third of neuroblastomas start in the adrenal glands.

Demographics

According to some reports, African-American children develop the disease at a slightly higher rate than Caucasian children (8.7 per million compared to 8.0 per million cases diagnosed).

Causes and symptoms

The causes of neuroblastoma are not precisely known. Current research holds that neuroblastomas develop when cells produced by the fetus (neuroblast cells) fail to mature into normal nerve or adrenal cells and keep growing and proliferating. The first symptom of a neuroblastoma is usually an unusual growth or lump, found in most cases in the abdomen of the child,

causing discomfort or a sensation of fullness and pain. Other symptoms such as numbness and **fatigue**, arise because of pressure caused by the tumor. **Bone pain** also occurs if the cancer has spread to the bone. If it has spread to the area behind the eye, the cancer may cause protruding eyes and dark circles around the eyes; in a few cases, blindness may be the presenting symptom. Or paralysis may result from compression of the spinal cord. **Fever** is also reported in one case out of four. High blood pressure, persistent **diarrhea**, rapid heartbeat, reddening of the skin, and sweating occur occasionally. Some children may also have uncoordinated or jerky muscle movements, or uncontrollable eye movements, but these symptoms are rare. If the disease spreads to the skin, blue or purple patches are observed.

Diagnosis

A diagnosis of neuroblastoma usually requires blood and urine tests to investigate the nature and quantity of chemicals (neurotransmitters) released by the nerve cells. These are broken down by the body and released in urine. Additionally, scanning techniques are used to confirm the diagnosis of neuroblastoma. These techniques produce images or pictures of the inside of the body and they include **computed tomography** scan (CT scan) and **magnetic resonance imaging** (MRI). To confirm the diagnosis, the physician will surgically remove some of the tissue from the tumor or bone marrow (**biopsy**), and examine the cells under the microscope.

Treatment team

The treatment team usually consists of an oncologist specialized in the treatment of neuroblastoma, a surgeon to perform biopsies and possibly attempt surgical removal of the tumor, a **radiation therapy** team and, if indicated, a **bone marrow transplantation** team.

Clinical staging, treatments, and prognosis

Staging

Once neuroblastoma has been diagnosed, the physician will perform more tests to determine if the cancer has spread to other tissues in the body. This process, called staging, is important for the physician to determine how to treat the cancer and check liver and kidney function. The staging system for neuroblastoma is based on how far the disease has spread from its original site to other tissues in the body.

Localized resectable (able to be cut out) neuroblastoma is confined to the site of origin, with no evidence that it has spread to other tissues, and the cancer can be surgically removed. Localized unresectable

KEY TERMS

Adjuvant chemotherapy—Treatment of the tumor with drugs after surgery to kill as many of the remaining cancer cells as possible.

Adrenal gland—Gland located above each kidney consisting of an outer wall (cortex) that produces steroid hormones and an inner section (medulla) that produces other important hormones, such as adrenaline and noradrenaline.

Alternative therapy—A therapy is generally called alternative when it is used instead of conventional cancer treatments.

Biopsy—A small sample of tissue removed from the site of the tumor to be examined under a microscope.

Complementary therapy—A therapy is called complementary when it is used in addition to conventional cancer treatments.

Conventional therapy—Treatments that are widely accepted and practiced by the mainstream medical community.

Disseminated—Spread to other tissues.

Hormone—A substance produced by specialized cells that affects the way the body carries out the biochemical and energy-producing processes required to maintain health (metabolism).

Localized—Confined to a small area.

Monoclonal antibody—A protein substance which is produced in the laboratory by a single population of cells. They are being tested as a possible form of cancer treatment.

Neoadjuvant chemotherapy—Treatment of the tumor with drugs before surgery to reduce the size of the tumor.

Neuroblast cells—Cells produced by the fetus which mature into nerve cells and adrenal medulla cells.

Resectable cancer—A tumor that can be surgically removed.

Salvage therapy—Treatment measures taken late in the course of a disease after other therapies have failed. It is also known as rescue therapy.

Staging system—A system based on how far the cancer has spread from its original site, developed to help the physician determine how best to treat the disease.

Unresectable cancer—A tumor that cannot be completely removed by surgery.

neuroblastoma is confined to the site of origin, but the cancer cannot be completely removed surgically. Regional neuroblastoma has extended beyond its original site, to regional lymph nodes, and/or surrounding organs or tissues, but has not spread to distant sites in the body. Disseminated neuroblastoma has spread to distant lymph nodes, bone, liver, skin, bone marrow, and/or other organs. Stage 4S (or IVS, or "special") neuroblastoma has spread only to liver, skin, and/or, to a very limited extent, bone marrow. Recurrent neuroblastoma means that the cancer has come back, or continued to spread after it has been treated. It may come back in the original site or in another part of the body.

Treatments

Treatments are available for children with all stages of neuroblastoma. More than one of these treatments may be used, depending on the stage of the disease. The four types of treatment used are:

- Surgery (removing the tumor in an operation)
- Radiation therapy (using high-energy x rays to kill cancer cells)
- **Chemotherapy** (using drugs to kill cancer cells)
- Bone marrow transplantation (replacing the patient's bone marrow cells with those from a healthy person).

Surgery is used whenever possible, to remove as much of the cancer as possible, and can generally cure the disease if the cancer has not spread to other areas of the body. Before surgery, chemotherapy may be used to shrink the tumor so that it can be more easily removed during surgery; this is called neoadjuvant chemotherapy. Radiation therapy is often used after surgery; high-energy rays (radiation) are used to kill as many of the remaining cancer cells as possible. Chemotherapy (called adjuvant chemotherapy) may also be used after surgery to kill remaining cells. Bone marrow transplantation is used to replace bone marrow cells killed by radiation or chemotherapy. In some cases the patient's own bone marrow is removed prior to treatment and saved for transplantation later. Other times the bone marrow comes from a matched donor, such as a sibling.

One novel approach to treatment of neuroblastomas is therapy with desferoxamine (DFO), which is ordinarily used to treat iron poisoning. DFO has been shown to have antitumor activity in neuroblastomas and other cancers of the central nervous system. It is thought that the drug works by lowering the increased iron levels in the body associated with cancer.

As of 2004, there are significant differences in treatment protocols for neuroblastoma between the major North American study group (Children's Oncology Group) and its European counterpart, the Société Internationale d'Oncologie Pédiatrique (SIOP). These differences include biopsy techniques, the timing and extent of surgery, chemotherapy dosages, and the types of salvage therapy employed.

Prognosis

The chances of recovery from neuroblastoma depend on the stage of the cancer, the age of the child at diagnosis, the location of the tumor, and the state and nature of the tumor cells evaluated under the microscope. Infants have a higher rate of cure than do children over one year of age, even when the disease has spread. In general, the prognosis for a young child with neuroblastoma is good: the predicted five-year survival rate is approximately 85% for children who had the onset of the disease in infancy, and 35% for those whose disease developed later.

Alternative and complementary therapies

No alternative therapy has yet been reported to substitute for conventional neuroblastoma treatment. Complementary therapies—such as retinoic acid therapy—have been shown to be beneficial to patients when administered after a conventional course of chemotherapy or transplantation.

Coping with cancer treatment

Neuroblastoma is a childhood cancer and it must be recognized that children, adolescents and their families have very special needs. These are best met at cancer centers for children working in close contact with the

QUESTIONS TO ASK THE DOCTOR

- What treatment choices do we have?
- Has the neuroblastoma spread to other parts of the body?
- What is the stage of the cancer?
- Based on your experience in treating neuroblastoma, how long do you think my child will survive if there is no response to treatment or the cancer comes back?
- How long will it take to recover from treatment?
- Will my child develop any long-term risks or complications from the cancer or its treatment?
- Can you recommend a support group in my town for people who are coping with neuroblastoma?

treatment team and the primary care physician. These centers have experience in recognizing the unique needs of children having to cope with cancer and they are staffed by pediatric support professionals other than the oncology treatment team while being associated with a children's hospital.

Clinical trials

As of 2004, the National Cancer Institute supported over 55 neuroblastoma **clinical trials** to evaluate a variety of anticancer drugs either combined to other drugs or to other treatments. No fewer than 14 of these studies involve stem cell transplantation, alone or in combination with other forms of treatment. Other clinical trials are concerned with anticancer drugs that are still considered investigational.

Prevention

Neuroblastoma may be a genetic disease passed down from the parents. In 2004, a group of German researchers reported that a series of neuroblastomas demonstrated a consistent pattern of deletions and overrepresentations on chromosomes 3, 10, 17q, and 20. There is currently no known method for its prevention.

Special concerns

After completion of a course of treatment for neuroblastoma, physicians sometimes recommend that the child undergo an investigative operation. This procedure allows the treatment team to evaluate how effective treatment has been, and may offer an opportunity to remove more of the tumor if it is still present.

Neuroendocrine tumors

Definition

Neuroendocrine tumors are tumors that develop from the cells of the diffuse neuroendocrine system, such as the enterochromaffin (EC) cells. These tumors are characterized by the presence of cells that possess secretory granules and have the ability to secrete neurohormones.

Description

The endocrine system is a network of glands consisting of endocrine cells that produce hormones in the body. The neuroendocrine system cells are specialized endocrine cells of the nervous system and produce neurohormones. Neuroendocrine cells do not form a specific gland; instead, they are found distributed in a wide variety of body organs where they help regulate body function.

Neuroendocrine tumors therefore represent a large class of cancers that can occur wherever neuroendocrine cells are found throughout the body. They are sometimes called carcinoid tumors, but it would be more accurate to consider these tumors as a sub-category of the larger family of neuroendocrine tumors. Neuroendocrine tumors are most often found in the digestive system and the lung. Statistically, 38% occur in the appendix, 23% in the ileum, 13% in the rectum, and 11.5% in the bronchi. Neuroendocrine pancreatic tumors are rather rare cancers with an incidence of 1-2 cases per 100,000 people. They occur with the same frequency in men and women and the average age at diagnosis is 53 years. Neuroendocrine tumors are also known as apudomas, or tumors that contain apud cells. These cells release excessive amounts of a variety of neurohormones in the bloodstream with chemical composition that varies with location, as does their effect on the body. Neuroendocrine tumors therefore have symptoms that vary with location. Unlike other cancers that are located in a specific organ, the hormone-releasing action of these tumors causes other symptoms to appear in many other organs of the body as well. The majority of neuroendocrine tumors can give rise to metastases with time if they are left untreated.

The total incidence of neuroendocrine tumors is thought to be between five and nine million people in the United States. It is possible that these tumors are underreported because they grow slowly and do not always produce dramatic symptoms.

Types of cancers

Because they can occur wherever neuroendocrine cells are found, neuroendocrine tumors come in a wide variety of types and have been classified according to their site of origin, usually either as digestive system, pancreatic or lung neuroendocrine tumors.

Neuroendocrine tumors of the digestive system

The types of neuroendocrine tumors found in the digestive system are also indicative of their general location:

- Foregut neuroendocrine tumors. Foregut tumors arise in the stomach or duodenum (first part of the small intestine) and represent approximately 15% to 25% of neuroendocrine tumors.
- Midgut neuroendocrine tumors. Midgut tumors are the most common variety and they include small and large intestine tumors.
- Hindgut neuroendocrine tumors. Hindgut tumors occur less frequently and are found in parts of the colon and in the rectum.

Pancreatic neuroendocrine tumors

Most neuroendocrine pancreatic tumors produce multiple hormones but usually there is excessive production of only one hormone. This is why neuroendocrine pancreatic tumors are often classified according to the predominant hormone secreted or resulting symptoms observed. For example, insulinomas produce excessive amounts of insulin, and gastrinomas produce excessive amounts of the peptide gastrin. Glucagonomas are associated with skin lesions and irritation around the eyes,

and somatostatinomas are associated with gallstones, slight diabetes and **diarrhea** or constipation.

Lung neuroendocrine tumors

There are four main types of neuroendocrine lung tumors:

- Small-cell lung cancer (SCLC). SCLC represents one of the most rapidly growing types of cancer.
- Large-cell neuroendocrine **carcinoma**. A rare form of cancer, similar to SCLC in prognosis and treatment, except that the cancer cells are unusually large.
- Typical carcinoid tumors. These types of neuroendocrine lung tumors grow slowly and do not often spread beyond the lungs.
- Atypical carcinoid tumors. Atypical lung carcinoids tumors grow faster than the typical tumors and are more likely to metastasize to other organs.

Other classifications for neuroendocrine tumors

Additionally, neuroendocrine tumors are subclassified into "functionally active" and "functionally inactive" tumors. Functionally active neuroendocrine tumors display specific symptoms, such as the excessive release of specific neurohormones from the tumor cell, as described above for pancreatic neuroendocrine tumors.

A recent classification groups neuroendocrine tumors into two types, depending on the kind of cells they develop from:

- Group I (epithelial). This group includes neuroendocrine carcinomas, graded 1, 2, and 3. Grade 1 neuroendocrine carcinomas are also known as carcinoid tumors. Grade 2 include tumors such as atypical carcinoid tumors, medullary thyroid carcinomas, and some pancreatic endocrine tumors. Grade 3 includes small-cell as well as large-cell neuroendocrine carcinomas.
- Group II (neural). Group II neuroendocrine tumors include paragangliomas, neuroblastomas, primitive neuroectodermal tumors, medulloblastomas, retinoblastomas, pineoblastomas and peripheral neuroepitheliomas.

Diagnosis

The diagnosis of carcinoid syndrome is made by the measurement of 5–hydroxy indole acetic acid (5–HIAA) in the urine. 5–HIAA is a breakdown (waste) product of serotonin. If the syndrome is diagnosed, the presence of carcinoid tumor is a given. When the syndrome is not present, diagnosis may be delayed, due to the vague symptoms present. Diagnosis can sometimes take up to two years. It is made by performing a number of tests, and the specific test used depends on the tumor's suspected location. The tests that may be performed include gastrointestinal endoscopy, **chest x ray**, computed tomography scan (CT scan), **magnetic resonance imaging**, or ultrasound. A biopsy of the tumor is performed for diagnosis. A variety of hormones can be measured in the blood as well to indicate the presence of a carcinoid.

Treatment

The only effective treatment for carcinoid tumor is surgical removal of the tumor. Although **chemotherapy** is sometimes used when metastasis has occurred, it is rarely effective. The treatment for carcinoid syndrome is typically meant to decrease the severity of symptoms. Patients should avoid **stress** as well as foods that bring on the syndrome. Some medications can be given for symptomatic relief; for example, tumors of the gastrointestinal tract may be treated with octreotide (Sandostatin) or lanreotide (Somatuline) to relieve such symptoms as diarrhea and flushing. These drugs are known as somatostatin analogs.

Liver transplantation is a treatment option for patients with neuroendocrine tumors that have metastasized only to the liver. As of 2004, this approach is reported to offer patients long disease-free periods and relief of symptoms.

Prognosis

The prognosis of carcinoid tumors is related to the specific growth patterns of that tumor, as well as its location. For example, a group of researchers at the University of Wisconsin reported in 2004 that patients with gastrointestinal tumors in the hindgut had longer periods of disease-free survival than those with foregut or midgut cancers. For localized disease the five-year survival rate can be 94%, whereas for patients where metastasis has occurred, the average five-year survival rate is 18%. It is not unusual for patients with carcinoid tumors to live ten or fifteen years after the initial diagnosis.

Prevention

Neuroendocrine tumors such as carcinoid tumors are rare, and no information consequently is yet available on cause or prevention.

See also Adenoma; Carcinoid tumors, gastrointestinal; Carcinoid tumors, lung; Cushing's syndrome; Endocrine system tumors; Lung cancer, small cell; Merkel cell carcinoma; Pancreatic cancer, endocrine; Parathyroid cancer; Pituitary tumors; Zollinger-Ellison syndrome.

KEY TERMS

Apudoma—A tumor capable of Amine Precursor Uptake and Decarboxylation (APUD).

Bronchi—Air passages to the lungs.

Diffuse neuroendocrine system—Concept developed by Feyrter, a German pathologist, more than 60 years ago, to unify tumors that occur in various parts of the body and possess secretory activity as well as similar properties when examined under a microscope.

Epithelial cells—Cells that cover the surface of the body and line its cavities.

Gastrointestinal tract—The GI tract, also called the digestive tract, starts from the oral cavity (mouth) and proceeds to the esophagus, the stomach, the duodenum, the small intestine, the large intestine (colon), the rectum and the anus. It processes all the food we eat. Along its way, food is digested, nutrients are extracted and waste is eliminated from the body in the form of stool and urine.

Gland—An organ that produces and releases substances for use in the body, such as fluids or hormones.

Hormone—Chemical substances produced by endocrine glands and transported by the bloodstream to the organs which require them to regulate their function.

Ileum—The last portion of the small intestine.

Metastasis—The transfer of cancer from one location or organ to another one not directly related to it.

Nervous system—The network of nerve tissue of the body. It includes the brain, the spinal cord and the ganglia (group of nerve cells).

Neurohormone—A hormone produced by specialized neurons or neuroendocrine cells.

Neuron—Specialized cell of the nervous system, that transmits nervous system signals. It consists of a cell body linked to a long branch (axon) and to several short ones (dendrites).

Syndrome—A series of symptoms or medical events occurring together and pointing to a single disease as the cause.

Neuropathy

Description

Neuropathy, also known as peripheral neuropathy, is an inflammation, injury, or degeneration of any nerve outside of the central nervous system. These nerves, known as the peripheral nerves, help the muscles to contract (motor nerves) and allow a range of sensations to be felt (sensory nerves). Peripheral nerves also help control some of the involuntary functions of the autonomic nerves, which regulate the sweat glands, blood pressure, and internal organs. Unfortunately, peripheral nerves are fragile and easily damaged. The symptoms of neuropathy depend upon the cause and on which nerve, or nerves, are involved.

In cancer patients, neuropathy may be a consequence of certain **chemotherapy** drugs, the cancers themselves, or other diseases and medications. If the sensory nerves are involved, the symptoms may include pain, numbness and tingling, burning, or a loss of feeling. If the motor nerves are affected, there may be weakness or paralysis of the muscles that control those nerves. These symptoms may begin gradually. Depending upon the specific nerves involved, symptoms can range from mild tingling or numbness in the fingers or toes to severe pain in the hands or feet. Patients may also describe these symptoms as burning, prickling, or pinching. Some patients report that the skin is so sensitive that the slightest touch is agonizing. They may also experience heaviness or weakness in the arms and legs. As neuropathy increases in severity, patients might have an unsteady gait and can have difficulty feeling the floor beneath them. Those with autonomic neuropathy might experience dizziness, constipation, difficulty urinating, impotence, vision changes, and hearing loss.

Causes

Neuropathy occurs in cancer patients for a number of reasons. The cancer itself may be infiltrating the nerves. Patients may have other diseases such as diabetes, nutritional imbalances, alcoholism, and kidney failure, which may also cause neuropathy. It is important for the physician to distinguish which factor is responsible, so the appropriate treatment can be initiated. The most common cause in cancer patients, however, is chemotherapy drugs. Neuropathy occurs in approximately 10–20% of cancer patients receiving chemotherapy. The most common chemotherapy drugs that cause neuropathy include:

- platinum compounds (e.g., **cisplatin**, carboplatin)
- taxanes (e.g., **docetaxel** and paclitaxel)
- vincristine

The following chemotherapy agents can also cause neuropathy, but the incidence is relatively small compared to the prior ones listed. These include:

- procarbazine
- cytosine Arabinoside (Ara C or cytarabine)
- metronidazole

Treatments

Not long ago, few options were available to prevent or stop the progress of peripheral neuropathy. Treatments are now available that can halt the development of chemotherapy-caused neuropathy or at least diminish its effects.

The only effective preventive therapy is the use of **amifostine** (Ethyol). Some of the side effects of this medication include temporary low blood pressure, and **nausea and vomiting**. Patients should have adequate fluid intake before and during the 15-minute intravenous administration of amifostine. Blood pressure readings should be taken every five minutes during the infusion. Chemotherapy is administered shortly after giving the amifostine so that the maximum amount of the drug is in the cells before the chemotherapy is started.

If neuropathy does develop, it may be necessary to discontinue the suspected chemotherapy drug causing it. Administration of amifostine may reverse the neuropathy or lessen its symptoms.

A variety of medications are available that can ease symptoms for those suffering from neuropathy. These medications include:

- Pain relievers. Pain medicines available over-the-counter, such as acetaminophen (Tylenol), and nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen (Advil, Motrin IB, Nuprin), can help to alleviate mild symptoms. For more severe symptoms, the physician may recommend a prescription NSAID.
- Tricyclic antidepressants. Certain antidepressant medications, including **amitriptyline** (Elavil), nortriptyline (Pamelor), desipramine (Norpramin) and imipramine (Tofranil), can help with mild to moderate symptoms.
- Antiseizure medications. Certain drugs intended to treat epilepsy, such as **carbamazepine** (Tegretol) and **phenytoin** (Dilantin), can be effective in treating jabbing, shooting pain.
- Other drugs. Mexiletine (Mexitil), a drug normally used to treat irregular heart rhythms, may help to relieve burning pain.

KEY TERMS

Autonomic nervous system—The part of the nervous system that controls involuntary bodily functions.

Peripheral nervous system—The portion of the nervous system outside of the central nervous system.

The physician or pharmacist should be consulted regarding potential side effects or interactions with other medications.

Alternative and complementary therapies

Several other drug-free techniques can be helpful in providing pain relief. These are frequently used in conjunction with medication. These include:

- Biofeedback. This therapy uses a special machine to teach the patient how to control certain responses that can reduce pain.
- Transcutaneous electronic nerve stimulation (TENS). The physician may prescribe this treatment that may prevent pain signals from reaching the brain. It is generally more effective for acute pain than chronic pain.
- Acupuncture. This may be effective for chronic pain, including the pain of neuropathy.
- Hypnosis. The patient under hypnosis typically receives suggestions intended to decrease the perception of pain.
- Relaxation techniques. These techniques can help decrease the muscle tension that aggravates pain. They may include deep-breathing exercises, visualization, and meditation.

Neutropenia

Description

Neutropenia is an abnormally low level of neutrophils in the blood. Neutrophils are white blood cells (WBCs) produced in the bone marrow and comprise approximately 60% of the blood. These cells are critically important to an **immune response** and migrate from the blood to tissues during an infection. They ingest and destroy particles and germs. Germs are microorganisms such as bacteria, protozoa, viruses, and fungus that cause disease. Neutropenia is an especially serious disorder for cancer patients who may have reduced immune functions because it makes the body vulnerable to bacterial and fungal infections. White blood cells are especially sensitive to **chemotherapy**. The number of cells killed during **radiation therapy** depends upon the dose and frequency of radiation, and how much of the body is irradiated.

Neutrophils can be segmented (segs, polys, or PMNs) or banded (bands) which are newly developed, immature neutrophils. If there is an increase in new neutrophils (bands) this may indicate that an infection is present and the body is attempting a defense. Neutropenia is sometimes called agranulocytosis or granulocytopenia because neutrophils display characteristic multi-lobed structures and granules in stained blood smears.

The normal level of neutrophils in human blood varies slightly by age and race. Infants have lower counts than older children and adults. African Americans have lower counts than Caucasians or Asians. The average adult level is 1,500 cells/mm^3 of blood. Neutrophil counts (in cells/mm^3) are interpreted as follows:

- Greater than 1,000. Normal protection against infection.
- 500-1,000. Some increased risk of infection.
- 200-500. Great risk of severe infection.
- Lower than 200. Risk of overwhelming infection; requires hospital treatment with **antibiotics**.

Neutropenia has no specific symptoms except the severity of the patient's current infection. In severe neutropenia, the patient is likely to develop periodontal disease, oral and rectal ulcers, **fever**, and bacterial **pneumonia**. Fever recurring every 19–30 days suggests cyclical neutropenia.

Diagnosis is made on the basis of a white blood cell count and differential. The cause of neutropenia can be difficult to establish and depends on a combination of the patient's history, genetic evaluation, bone marrow **biopsy**, and repeated measurements of the WBC. However, in cancer patients it is usually an expected side effect of chemotherapy or radiation. The overall risk of infection is dependent upon the type of cancer an individual has as well as the treatment received. Patients at greater risk include those with hematologic malignancies, leukemia/lymphoma (cancers) and those who receive bone marrow transplants.

It is important to detect infections early. Some signs that indicate infection include:

- coughing and difficulty breathing, congestion
- an oral temperature greater than 105° with typical fever symptoms of chills and sweating
- problems in the mouth such as white patches, sore and swollen gums
- changes in urination or in stools
- drainage and pain from any cuts or tubes used in the cancer treatments such as catheters and feeding tubes
- an overall feeling of illness

Causes

Neutropenia may result from three processes:

Decreased WBC production

Lowered production of white blood cells is the most common cause of neutropenia. It can result from:

- Cancer, including certain types of leukemia.
- Radiation therapy.
- Medications that affect the bone marrow, including cancer drugs (chemotherapy), chloramphenicol (Chloromycetin), anticonvulsant medications, and antipsychotic drugs (Thorazine, Prolixin, and other phenothiazines). In hematopoietic stem cell transplantation (HSCT), high levels of total body irradiation (TBI) or chemotherapy are used to kill cancer cells, or these treatments may be combined. Two types of HSCT treatments are **bone marrow transplantation** (BMT) and peripheral blood stem cell transplantation (PBSCT). During the treatment process, the patient's normal bone marrow stem cells are killed along with the cancer cells. The stem cells are not able to mature into immune cells such as neutrophils, causing neutropenia. To reduce neutropenia, the normal stem cells

KEY TERMS

Cyclical neutropenia—A rare genetic blood disorder in which the patient's neutrophil level drops below 500/mm^3 for six to eight days every three weeks.

Cytokine—A type of protein produced by immune cells that affects the actions of other cells.

Differential—A blood cell count in which the percentages of cell types are calculated as well as the total number of cells.

Filigrastim—G-CSF cytokine normally produced in the body at low levels. G-CSF helps the body produce more neutrophils to fight infection.

Granulocyte—Any of several types of white blood cells that have granules in their cell substance. Neutrophils are the most common type of granulocyte.

Neutrophil—A granular white blood cell that ingests bacteria, dead tissue cells, and foreign matter.

Opportunistic infection— A type of infection caused by an organism that would not normally cause disease in a healthy person, but can do so when the immune system of the host is weakened.

Sargramostim—A medication made from yeast that stimulates WBC production. It is sold under the trade names Leukine and Prokine.

Sequestration and margination—The removal of neutrophils from circulating blood by cell changes that trap them in the lungs and spleen.

from the patient may be removed prior to treatment and given back at a later time. Cells can also be supplied from another donor.

- Hereditary and congenital disorders that affect the bone marrow, including familial neutropenia, cyclic neutropenia, and infantile agranulocytosis.
- Exposure to pesticides.
- Vitamin B_{12} and folate (**folic acid**) deficiency.

Destruction of White Blood Cells

WBCs are used and die at a faster rate by:

- Acute bacterial infections in adults.
- Infections in newborns.
- Certain autoimmune disorders, including systemic lupus erythematosus (SLE).
- Penicillin, **phenytoin** (Dilantin), and sulfonamide medications (Benemid, Bactrim, Gantanol).

Sequestration and margination of WBCs

Sequestration and margination are processes in which neutrophils are removed from the general blood circulation and redistributed within the body. These processes can occur because of:

- Hemodialysis
- Felty's syndrome, or malaria. The neutrophils accumulate in the spleen.
- Bacterial infections. The neutrophils remain in the infected tissues without returning to the bloodstream.

Special concerns

Often the infections that develop in a cancer patient are opportunistic infections. That is, the organisms responsible for the infection normally would not cause disease in a healthy person, but do so in a cancer patient because the immune system is weak. Several steps can be taken on a daily basis to reduce the risk of developing an infection.

Steps to Prevent Infection

- Care should be taken to keep the body clean. Hands should be washed after using the bathroom and before eating.
- Avoid stagnant or still water in the environment that might contain bacteria such as flower vases and birdbaths, or containers that may hold items such as dentures.
- Use antiseptic mouthwashes to cleanse the mouth. Use those that do not contain alcohol.
- Use deodorant. Antiperspirants will not allow the body to sweat, trapping bacteria within the body that may increase the risk of infection.
- Women with neutropenia should consider using sanitary napkins instead of tampons during their menstruation to help prevent possible infection such as toxic shock syndrome.
- Avoid others who are ill and large crowded areas where one might encounter illness.
- Avoid activities that may increase the chance of physical injury. Take care to protect the body by wearing gloves, shoes, and other items. Tend to all injuries as soon as possible.
- Neutropenic patients should consult their doctors before receiving any vaccinations.

QUESTIONS TO ASK THE DOCTOR

- What symptoms lead to this diagnosis?
- What can be expected with this condition and how long it last?
- What is the plan for treatment? Will it be covered by my insurance? Can it be done at home?
- What support and monitoring for home health care might be available? Would supervision be required? Would this be appropriate and what are the risks of complications? What are the costs?
- What are the side effects of treatment? Are there any drugs, foods, etc. that should not be taken during treatment? Should daily activities be modified?
- What complementary and alternative treatment methods have been shown to be helpful in addition to conventional medical treatments? Have any of these treatments been helpful to reduce symptoms and side effects from medication?
- Are complementary treatments easy to access and what is the cost of such treatments? Are these covered by my insurance as well?
- Where can a person get more information about this condition?
- What avenues for emotional and spiritual support might be available to help cope with this diagnosis?

Treatments

Treatment of neutropenia depends on the underlying cause.

Medications

Patients with fever and other signs of infection are treated with antibiotics. Some antibiotics used in the treatment of cancer patients include imipenem, meropenem, aminoglycoside, antipesudomonal penicillin, rifampin, and vancomycin. Combination therapy can be used that uses several types of antibiotics to stop the infection, but some of the drugs may be toxic or costly.

Patients receiving chemotherapy for cancer may be given drugs even in health to help restore the WBC to normal. A blood growth factor called **sargramostim** (Leukine, Prokine) stimulates WBC production. Another commonly used medication to reduce neutropenia in cancer patients is the cytokine G-CSF (granulocyte colony-stimulating factor, or filgrastim by Amgen-Roche). This substance is normally produced in the body at low levels. G-CSF helps the body produce more neutrophils to fight infection. This is especially useful in that many bacteria can not be killed by antibiotics due to antibiotic resistance.

Throughout the course of treatment it is important that the patient be monitored closely. This requires hospitalization for some patients, while others may be adequately treated at home.

Alternative and complementary therapies

A healthy lifestyle should be adopted that includes good nutrition, plenty of sleep, and appropriate levels of exercise. Avoid uncooked foods that may contain harmful bacteria. A nutritionist should be consulted to determine an appropriate, healthy diet.

Psychological stress can also weaken the immune system, making a person more susceptible to illness. It is important to find emotional support through family, friends, support groups, or through spiritual means.

See also Immunologic therapies; Infection and sepsis; Chronic myelocytic leukemia.

Night sweats

Description

Night sweats can be a side effect of cancer treatment or a symptom of certain cancers. Night sweats are part of a variety of symptoms referred to as vasomotor. Vasomotor symptoms stem from the body's thermoregulatory center, which is affected by circulating hormones.

Women may undergo **oophorectomy** (the surgical removal of one or both ovaries), either for **ovarian cancer** or when accompanied by hysterectomy for **endometrial cancer** or uterine sarcoma, as part of their cancer treatment. Pelvic radiation may also damage the ovaries. Removal or permanent damage to the ovaries results in immediate menopause. Many women with ovarian cancer have already gone through menopause, as a function of their age. However, when ovarian or reproductive tract cancer strikes a pre-menopausal woman, the immediate, versus gradual, loss of circulating hormones is dramatic, and is a concern in the immediate post-operative period. In an *American Cancer Society News Today* of January 29, 2001, the ACS reported on a study that found women undergoing systemic treatment for **breast cancer**, especially those on **tamoxifen**, reported

a higher frequency and intensity of menopausal symptoms such as night sweats, hot flashes, and **fatigue**. Men may also experience vasomotor symptoms with metastatic adenocarcinoma of the prostate, or following removal of the prostate for **prostate cancer**.

Vasomotor symptoms such as night sweats add to the existing stress for individuals undergoing cancer treatment, as they can reduce the quality of sleep, make daily life very uncomfortable, and decrease the quality of life.

Night sweats can be a sign of infection in the immuno-compromised cancer patient, as well as being a symptom of undiagnosed cancer and early AIDS. Drenching night sweats may be a sign of Hodgkin's or non-Hodgkin's **lymphoma**, both in children as well as in adults. Night sweats may also be present with liver hemangioma tumors. Generalized symptoms such as night sweats, **fever**, chills, and sweating are sometimes referred to as B symptoms. Night sweats have also been associated with malignant **melanoma** and with metastatic compression of the optic nerve. Children who are ultimately diagnosed with a malignancy may present to a rheumatologist with a variety of symptoms, including night sweats. Night sweats in the absence of explained fever or perimenopause should be brought to the attention of one's health care provider for evaluation.

Causes

The ovary produces the hormone estrogen. When the ovary is removed, there is a dramatic termination of circulating estrogen, with symptoms such as night sweats, hot flashes, and vaginal dryness. Estrogen replacement therapy (ERT) can relieve these symptoms. However, the use of ERT is controversial with some cancers, because of the association with estrogen-receptor positive cancers. Women who are approaching menopause at the time of **chemotherapy** may lose ovarian function as a result of treatment, thus undergoing significant menopausal symptoms. The use of tamoxifen in postmenopausal women has been associated with an increase in vasomotor symptoms.

Hodgkin's and non-Hodgkin's lymphomas are cancers of the lymphatic system. Symptoms include night sweats, painless swelling in the lymph nodes, especially in the neck, underarm or groin, unexplained **weight loss**, recurrent fevers, and itchy skin. The night sweats in Hodgkin's disease appears to be related to an instability in the thermoregulatory center of the hypothalamus. Risk factors for Hodgkin's and non-Hodgkin's lymphomas include reduced immune function, transplant surgery, occupational exposure to herbicides and other toxic chemicals, Sjögren's syndrome, and **Epstein-Barr virus**.

KEY TERMS

Hirsutism—The development of male-pattern hair growth as a result of the use of male hormones.

Lymphatic system—The lymphatic system is a complex network of vessels, ducts, nodes, and organs that produce, filter, and carry lymph throughout the body. It is part of the body's immune system.

Oophorectomy—Surgical removal of the ovaries.

Perimenopause—The time period prior to menopause that may last 10 to 15 years, even beginning in one's 30s. It is associated with decreased ovarian function and decreasing estrogen levels.

Vasomotor symptoms—Vasomotor symptoms include night sweats, hot flashes, and sweating.

Treatments

Some research has been conducted using estrogen-androgen replacement therapy. The concerns about ERT and estrogen-sensitive cancers remains the same. The androgen component assists in the healing process, as well as in a sense of well-being, sexual desire and arousal, and increased energy level. The use of androgens can result in hirsutism (growth of male-pattern hair), which may be dose-dependent.

Successful diagnosis of the cause of the night sweats can lead to proper treatment for the condition. Successful treatment of Hodgkin's or non-Hodgkin's lymphoma resolves the night sweats.

Alternative and complementary therapies

Acupuncture has been effective for both men and women. Individuals considering herbal remedies or supplements for reproductive-related night sweats associated with cancer treatment should seek the counsel of a knowledgeable practitioner. Substances that function through mimicking estrogenic properties could have an adverse effect in estrogen-sensitive tumors.

Non-Hodgkin's lymphoma

Definition

One of two general types of lymphomas (cancers that begin in lymphatic tissues and can invade other organs) differing from **Hodgkin's disease** (HD) by a lack of Hodgkin's-specific Reed-Sternberg cells.

Description

Non-Hodgkin's lymphoma (NHL) is a cancer of lymphocytes, a type of white blood cell that moves around the body as part of its role in the immune system. NHL is much less predictable than HD and is more likely to spread to areas beyond the lymph nodes.

NHL is comprised of approximately 10 subtypes and 20 different disease entities. Division is based on whether the lymphoma is low grade (progressing slowly) or high grade (progressing rapidly). NHL is also grouped according to cell type—B cells or T cells. Physicians can diagnose the type of lymphoma by performing a **biopsy**, in which a lymph node is removed and examined in the laboratory. Some of the Non-Hodgkin's lymphoma types include: **Burkitt's lymphoma**, diffuse large B-cell lymphoma, follicular center lymphoma, and **mantle cell lymphoma**.

Nonsteroidal anti-inflammatory drugs

Definition

Nonsteroidal antiinflammatory drugs (NSAIDs) are a type of drug that reduce pain and inflammation.

Purpose

NSAIDs often are used to relieve mild to moderate pain for all types of cancer, as well as the pain of arthritis, menstrual cramps, sore muscles following exercise, and tension headaches. Most NSAIDs are available in over-the-counter formulations.

Ibuprofen and naproxen are two NSAIDs that are also used to bring down fever and treat the side effects of radiation therapy.

Description

This class of drugs eases discomfort by blocking the pathway of an enzyme that forms prostaglandins (hormones that cause pain and swelling). By doing so, the drugs lessen the pain in different parts of the body.

Some of the NSAIDs used in cancer treatment include: ibuprofen (Motrin, Advil, Rufen, Nuprin), naproxen (Naprosyn, Naprelan, Anaprox, Aleve), nabumetone (Relafen), ketorolac, sulindac and diclofenac (Cataflam, Voltaren). The class of drugs known as Cyclooxygenase-2 inhibitors that emerged in the late 1990s for dealing with arthritis pain, such as the brand names Celebrex and Vioxx, is also considered part of the group of NSAIDS.

If NSAIDs are not strong enough to keep a cancer patient comfortable, physicians often will combine them with such opioids (narcotics) as codeine. In later stages, doctors also may combine NSAIDs with stronger opioids like morphine, to treat very severe pain.

NSAIDs also may be used to prevent **colon cancer** and other types of cancer, although scientists are still studying this experimental approach (see entry on **chemoprevention**).

Recommended dosage

Patients typically take NSAIDs on an as-needed basis. Doses vary depending on the type of NSAID being used. For example, the most common type, ibuprofen, is available over the counter in 200mg caplets, which can be taken at regular intervals throughout the day. The maximum daily dose for ibuprofen is 1,200 mgs.

Precautions

Most doctors recommend taking NSAIDs with a full glass of water. Avoid taking these drugs on an empty stomach. Smoking **cigarettes** and drinking alcohol while taking NSAIDs may irritate the stomach.

People who take NSAIDs should notify their doctors before having surgery or dental work, since these drugs can prevent wounds from healing properly.

Women who are pregnant or breastfeeding should check with their doctor before taking NSAIDs, because they may be harmful to a developing fetus or a newborn.

Diabetics, people who take aspirin, blood thinners, blood pressure medications, or steroids also should check with their doctors before taking NSAIDs.

Side effects

Many NSAID users experience mild side effects, such as an upset stomach. In 4 to 7% of cases, more serious complications develop, such as stomach ulcers. Typically, elderly people experience the most serious complications.

Common side effects include stomach upset, constipation, dizziness and headaches.

More severe side effects include stomach ulcers and bleeding ulcers. If a person has black, tarry stools or starts vomiting blood, it may be caused by a bleeding ulcer.

Kidney dysfunction is another severe complication of long-term NSAID use. Signs of kidney problems include dark yellow, brown or bloody urine. NSAID use also may cause liver function problems over longer periods of time.

To guard against ulcers, physicians may ask patients to take NSAIDs with such anti-ulcer medications as omeprazole or misoprostol. Another option is to take the NSAID in a different, non-oral form. Often topical creams or suppositories are available. Finally, doctors may decide to switch to a different type of pain killer, such as a cyclooxygenase-2 (COX-2) inhibitor like Celebrex, which may be easier on the stomach. Some studies indicate that the use of COX-2 inhibitors may postpone the need to prescribe narcotic medications for severe pain.

Some patients who have had problems with side effects from NSAIDs may benefit from acupuncture as an adjunctive treatment in pain management. A recent study done in New York found that older patients with lower back pain related to cancer reported that their pain was relieved by acupuncture with fewer side effects than those caused by NSAIDs.

KEY TERMS

Cyclooxygenase-2 inhibitor—A type of drug, such as Celebrex, that reduces pain and inflammation. Also called a COX-2 inhibitor.

Enzyme—A type of protein that speeds up the chemical reactions in the body.

NSAIDs—A category of drugs that reduce pain, fever and swelling.

Opioids—A class of pain-killing drugs either derived directly from the opium poppy or from synthetic compounds resembling morphine. Opioids are also known as narcotics.

Prostaglandins—Hormones that cause pain and swelling in the body.

Interactions

NSAIDs can be taken with most other prescription and over-the-counter drugs without any harmful interactions. Certain drug combinations, however, should be avoided. For instance, when ibuprofen is combined with **methotrexate** (used for **chemotherapy** and arthritis treatment) or certain diabetic medicines and anti-depressants, it can amplify negative side effects. Patients should check with a pharmacist before taking NSAIDs with other drugs.

NSAIDs may also interact with certain herbal preparations sold as dietary supplements. Among the herbs known to interact with NSAIDs are bearberry (*Arctostaphylos uva-ursi*), feverfew (*Tanacetum parthenium*), evening primrose (*Oenothera biennis*), and gossypol, a pigment obtained from cottonseed oil and used as a male contraceptive. In most cases, the herb increases the tendency of NSAIDs to irritate the digestive tract. It is just as important for patients to inform their doctors of herbal remedies that they take on a regular basis as it is to give the doctors lists of their other prescription medications.

False-color bone scintigram (nuclear bone scan) of a person suffering from a secondary (metastatic) bone cancer (white area) affecting the dorsal spine. *(Copyright CNRI, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Nuclear medicine scans

Definition

A nuclear medicine scan is a test in which radioactive material is taken into the body and is used to create an image of a specific organ or bone.

Purpose

The purpose of a nuclear medicine scan is to locate areas of impaired function in the organ or bone being scanned. Nuclear medicine scans are widely used for diagnosis and monitoring of many different conditions. In the diagnosis and treatment of cancer, nuclear medicine scans are used to identify cancerous sites, for tumor localization and staging, and to judge response to therapy.

Precautions

Women who are pregnant or breast feeding should not undergo this test. A patient who is unable to remain still for an extended period of time may require sedation for a nuclear medicine scan.

Description

A nuclear medicine scan is an extremely sensitive test that can provide information about the structure and function of specific parts of the body. Types of nuclear scans include bone scans, heart scans, lung scans, kidney and bladder scans, thyroid scans, liver and spleen scans, and gallbladder scans. Brain scans are done to detect malignancy.

In a nuclear medicine scan, a small amount of radioactive material, or tracer, is injected or taken orally by the patient. After a period of time during which the radioactive material accumulates in one area of the body, a scan is taken by a special radiation detector, called a

KEY TERMS

Tracer—A radioactive, or radiation-emitting, substance used in a nuclear medicine scan.

radionuclide scanner. This machine produces an image of the area for analysis by the medical team.

This test is performed in a radiology facility, either in a hospital department or an outpatient x-ray center. During the scan, the patient lies on his or her back on a table, but may be repositioned to the stomach or side during the study. The radionuclide scanner is positioned against the body part to be examined. Either the camera, the table, or both, may change position during the study. Depending on the type of scan, the procedure may take anywhere from 15 to 60 minutes. It is important for the patient not to move except when directed to do so by the technologist.

Preparation

The required preparation for nuclear medicine scans ranges from slight to none. The doctor may advise that certain prescription medications be discontinued before the test or that the patient not eat for three to four hours before the test. Depending on the type of test, a reference scan or specialized blood studies may be done before the scan is taken. Jewelry or metallic objects should be removed.

The patient should advise the doctor of any previously administered nuclear medicine scans, recent surgeries, sensitivities to drugs, allergies, prescription medications, and if there is a chance that she is pregnant.

Aftercare

No special care is required after the test. Fluids are encouraged after the scan to aid in the excretion of the radioactive material. It should be almost completely eliminated from the body within 24 hours.

Risks

The risks of nuclear medicine scans are very low. Most scans use the same or less amount of radiation as a conventional **x ray** and the radioactive material is quickly passed through the body. Side effects or negative reactions to the test are very rare.

Normal results

A normal result is a scan that shows the expected distribution of the tracer and no unusual shape, size, or function of the scanned organ.

QUESTIONS TO ASK THE DOCTOR

- How long will my scan take?
- How long will the tracer stay in my body?
- Will repeat scans be necessary?

Abnormal results

Depending on the tracer and technique used, the scan can identify and image particular types of tumors or certain cancers. Too much tracer in the spleen and bones, compared to the liver, can indicate potential hypertension or cirrhosis. Liver diseases such as hepatitis may also cause an abnormal scan, but are rarely diagnosed from the information revealed by this study alone.

In a bone scan, a high concentration of tracer occurs in areas of increased bone activity. These regions appear brighter and may be referred to as "hot spots." They may indicate healing fractures, tumors, infections, or other processes that trigger new bone formation. Lower concentrations of tracer may be called "cold spots." Poor blood flow to an area of bone, or bone destruction from a tumor, may produce a cold spot.

Nutritional support

Description

Achieving adequate nutritional support is difficult during cancer therapy or treatment. However, preservation of body composition and proper nutrition will help

to maintain strength and may improve daily function and ability to cope with cancer therapies. Adequate nutrition may contribute to a patient feeling better and stronger and may help to fight off infection.

Malnutrition is a primary concern and is an important cause of illness in cancer patients due to difficulty consuming enough calories and nutrients. Protein-energy malnutrition (or protein-calorie malnutrition) is particularly problematic, which is the most common secondary illness in cancer patients. It occurs when a lack of protein and energy (calories) are consumed to sustain the body composition, instigating **weight loss**. When body stores are severely compromised, the body's functionality declines, which may lead to illness and perhaps death. Exhaustion, weakness, decreased resistance to infection, progress wasting, and difficulties tolerating cancer therapies may result from inadequate nutrition.

People with cancer commonly experience **anorexia**, which is characterized by a loss of appetite. Anorexia is the most predominate cause of malnutrition and deterioration in patients with cancer. Another common problem in cancer is weight loss and cachexia. Cachexia is a condition where the bodyweight wastes away, characterized by a constant loss of weight, muscle, and fat. It is known as a wasting syndrome and can occur in individuals who consume enough food, but due to disease complications, cannot absorb enough nutrients. Malnutrition, anorexia, and cachexia are serious in cancer patients and can lead to death.

Causes

There are many reasons for malnutrition in cancer patients, including the effect of the tumor, effect of treatment, or psychological issues such as **depression**. The growth of tumors in the digestive system may induce blockage, lead to **nausea and vomiting**, or cause poor digestion or absorption of nutrients.

Cancer therapies and their side effects may also lead to nutrition difficulties. For example, following surgery, malabsorption of protein and fat may occur. In addition, there may be an increased requirement for energy due to infection or **fever**.

Special concerns

Cancer patients should maintain an adequate intake of fluids, energy, and protein. The patient's nutrient requirements can be calculated by a dietitian or doctor because requirements vary considerably from patient to patient.

Enteral nutrition may be administered through a nose tube (or surgically placed tubes) for patients with eating difficulties due to upper gastrointestinal blockage such as difficulty swallowing, esophageal narrowing, tumor, stomach weakness, paralysis, or other conditions that preclude normal food intake. If the gastrointestinal tract is working and will not be affected by the cancer treatments, then enteral support is preferable. Parenteral nutrition (most often an infusion into a vein) can be used if the gut is not functioning properly or due to other reasons that prevent enteral feeding.

KEY TERMS

Anorexia—A condition where weight loss is due to a loss of appetite or lack of desire to eat.

Cachexia—A condition in which the bodyweight "wastes" away, characterized by a constant loss of weight, muscle, and fat.

Cancer—A term for diseases in which abnormal cells divide without control. Cancer cells can invade nearby tissues and can spread through the bloodstream and lymphatic system to other parts of the body.

Enteral nutrition—Feedings administered through a nose tube (or surgically placed tubes) for patients with eating difficulties.

Nutraceutical—Also called a functional food. These food products have other health promoting or disease preventing properties over and above their use as a food product. Specifically, a nutraceutical or functional food is a food for which a health claim has been authorized.

Parenteral nutrition—Feeding administered most often by an infusion into a vein. It can be used if the gut is not functioning properly or due to other reasons that prevent normal or enteral feeding.

Protein-energy (or protein-calorie) malnutrition—Not enough protein and energy are consumed to sustain the body composition, resulting in weight loss and possibly death.

Treatments

Nutritional problems related to side effects should be addressed to ensure adequate nutrition and prevent weight loss. The following suggestions will provide some helpful hints on dealing with side effects such as loss of appetite, nausea, vomiting, **fatigue**, and taste alteration. To deal with appetite loss and weight loss:

- Eat more when feeling the hungriest.
- Eat foods that are enjoyed the most.

- Eat several small meals and snacks instead of three large meals.
- Have ready-to-eat snacks on hand such as cheese and crackers, granola bars, muffins, nuts and seeds, canned puddings, ice cream, yogurt, and hard boiled eggs.
- Eat high-calorie foods and high-protein foods.
- Begin with small portions during a meal to enjoy the satisfaction of finishing a meal. Have additional servings if still hungry.
- Eat in a pleasant atmosphere with family and friends if desired.
- Make sure to consume at least 8–10 glasses of water per day to maintain fluid balance.
- Consider commercial liquid meal replacements such as Ensure.
- Discuss with a physician the possibility of using appetite-increasing medications such Megace or Marinol.

Nausea is a common side effect of several cancer treatments including surgery, **chemotherapy**, biological therapy, and radiation. If nausea is problematic, the following methods may provide relief:

- Avoid fatty, fried, spicy, greasy, or hot foods with a strong odor.
- Eat small meals frequently but slowly.
- If nausea is particularly worse in the morning, consume dry toast or crackers before getting up.
- Try consuming such foods as clear liquids, toast, crackers, yogurt, sherbet, pretzels, oatmeal, skinned chicken (baked or broiled), angel food cake, and fruits and vegetables that are soft or bland.
- Drink beverages cool or chilled.
- Hot foods may add to nausea, so consume foods at room temperature or cooler.
- Drink or sip liquids (a straw may help) throughout the day, but not during meals. Try sucking on ice chips.
- Discuss with a physician the possibility of using anti-nausea medications (also called **antiemetics**) such Zofran or Kytril.

Vomiting may occur for several reasons due to the cancer itself, treatment, or emotional upset. If vomiting occurs, the following guidelines may help:

- Do not drink or eat until vomiting has subsided, then consume small amounts of clear liquids.
- When able to tolerate clear liquids, try to consume a full liquid diet (including dairy products unless they are difficult to digest). Begin with small quantities and gradually return to a regular diet if nausea and vomiting have dissipated.

QUESTIONS TO ASK THE DOCTOR

- What effect will the treatment or disease have on my body nutritionally (i.e., on the ability to eat, digest food, absorb nutrients, energy requirements)?
- How long will the negative side effects last?
- Is there a risk of malnutrition or weight loss with this type of cancer or treatment?
- What nutrients are most important to obtain during treatment?
- Are there any nutritional supplements that may be required?

If fatigue is preventing receiving adequate nutrition, the following strategies may help:

- Try using frozen, canned, or ready-to-use foods.
- Eat high-calorie foods.
- Have ready-to-eat snacks on hand such as cheese and crackers, granola bars, muffins, nuts and seeds, canned puddings, ice cream, yogurt, and hard-boiled eggs.
- Consider using a service such as Meals on Wheels, a delivery or home care service.
- Invite friends or family over to assist with meal preparation.
- Consider commercial liquid meal replacements such as Ensure.

Taste changes can give foods a metallic or off flavor. Consider the following strategies to alleviate taste changes.

- If meats have a metallic taste, try other sources of protein such as dairy products, poultry, fish, seafood, peanut butter, eggs, seeds, nuts, tofu, and legumes.
- Use plastic utensils to decrease metallic flavor.
- Choose tart foods such as citrus juices, lemonade, cranberry juice, and pickles to help alleviate a metallic taste. If sore mouth and throat symptoms are also present, do not consume these foods.
- Consume a variety of foods.
- Try different seasonings, herbs, and sauces.

- Choose foods that look and smell good.
- Dilute drinks that are too strong or sweet with water.
- Rinse mouth often with baking soda and water.

Alternative and complementary therapies

There is no alternative or complementary nutritional therapy that has proven effective for **cancer prevention** or cancer treatment. However, the are several foods and nutraceuticals such as garlic, plant sterols, green and black tea polyphenols, and soybean products (soy isoflavones) that have shown promise in previous research for anticarcinogenic properties. Many of these products are actively being tested in **clinical trials** to elucidate anticarcinogenic properties. As for prevention, past research has clearly demonstrated that intake of fruits and vegetables are correlated to a lower incidence rate for certain types of cancer. It is important to check with a dietitian or doctor before taking nutritional supplements or alternative therapies because they may interfere with cancer medications or treatments.

O

Occupational exposures and cancer

Definition

Occupational exposure to cancer occurs at the workplace. Some individuals develop cancer from exposure to certain substances at an indoor workplace such as a factory or a restaurant. Others may be exposed to carcinogenic substances while working primarily outdoors, such as construction or lawn maintenance workers.

Description

About 5% of cancer in men and 1% of cancer in women result from exposure to carcinogenic substances in their work environment. The most common cancers associated with occupational exposure are:

- lung and pleura
- bladder
- skin
- laryngeal
- nasal cavity
- leukemia
- throat
- **lymphoma**
- soft-tissue sarcomas
- liver

Causes

Tobacco smoking is considered the greatest risk factor for lung cancer. Individuals who do not smoke can still develop lung cancer. Employees in smoke-filled environments such as bars, restaurants, casinos, bingo halls, and bowling alleys are at greatest risk from second-hand smoke. Second-hand smoke is highly toxic. For instance, non-smokers who live with a smoker are at 30% greater risk of developing lung cancer than if they lived with a non-smoker. However, many states, and now other countries, have worked on laws to ban smoking in some work environments.

Asbestos is a known carcinogen. Individuals whose work exposes them to asbestos are seven times more likely to die from lung cancer. Asbestos workers who smoke are 50–90 times more likely to develop lung cancer than the average individual. Asbestos affects the lining of the lungs, causing malignant **mesothelioma**. Mesothelioma is considered incurable and fatal, and may not be detected until as long as 45 years after exposure. Asbestos still exists in schools, offices, factory buildings, and homes in the form of insulation. Workers who remove asbestos from buildings need to take special precautionary measures to avoid inhalation of asbestos fibers, and wear special clothing so that they do not bring home the dust on their clothes. Asbestos can affect railroad workers, ship builders, gas mask manufacturers, and workers in insulation factories. Because of the way in which asbestos in inhaled and processed in the body, it can also lead to cancers of the larynx, esophagus, pancreas, kidney, and colon.

Radon is another substance that can cause lung cancer. Houses or commercial properties that are built on soil containing radon may contain radon in gas form. Many inhaled chemicals put workers at risk. This includes uranium and talc miners and workers who are exposed to the chemicals arsenic, vinyl chloride, nickel chromates, coal products, mustard gas, and chloromethyl ethers. While these industries need to provide safety gear to protect workers from these substances, it is always best if the worker makes sure she or he is properly protected.

Workers who are exposed to diesel fumes, such as railroad crews and truck drivers, may have a 40% greater risk of lung cancer. Diesel fumes contain benzene, formaldehyde, and dioxins. Formaldehyde alone can cause respiratory cancers. It also is used as a sterilizing agent

in dialysis units, disinfectant in operating rooms, carpet and furniture glues, as well as for embalming.

Painters, printers, and chemists are also at increased risk for lung cancer because of their occupational exposure to certain chemicals. Employees exposed to fine silica particles also have an increased risk for lung cancer. Silica appears in sand, rock, and mineral ores, and is used in sandblasting, masonry work, tunnel construction, ceramics, laying railroad track, soap manufacturing, glass manufacturing, shipbuilding, and agriculture.

Bladder cancer from occupational exposure is most common in individuals working with radiation or dyes that involve the aromatic amine chemicals such as benzidine and beta naphthylamine. Factory workers involved in the production of these dyes, as well as those who use these dyes, such as hair colorists, and possibly even people who apply their own permanent hair dye at least once a month may be at increased risk for bladder cancer.

Chemicals used in the rubber, leather, textile, and paint industries can also be carcinogenic. The risk of bladder cancer rises with age, and smoking increases significantly the risk of developing bladder cancer. Individuals who have taken the herb *Aristocholia fangchi* as part of an herbal **weight loss** product may also be at higher risk for bladder cancer. Drinking at least 11 cups of fluid a day can decrease the risk of bladder cancer, as it increases urination and decreases the concentration and the amount of time that carcinogenic substances come into contact with the bladder lining.

There are several types of skin cancer, varying in aggressiveness. Basal and squamous cell cancers are considered very curable. **Melanoma** is the most serious type, and the most likely to metastasize. Exposure to ultraviolet rays, coal tar, pitch, creosote, arsenic, and radium can lead to skin cancer. Individuals whose work is primarily outdoors, such as employees of road and building construction, landscaping, outdoor painting, and beach and boating work are at greater risk. A 2004 study in Germany found a dose-dependent relationship with exposure. In other words, the more UV rays workers were exposed to, the higher their risk proportionately rose. Using sunscreen and protective clothing such as a long-sleeved shirt, long pants, and a wide-brimmed hat can decrease exposure.

Laryngeal cancer. Individuals whose work includes heavy exposure to wood dust, paint fumes, and asbestos, and workers exposed to certain chemicals in the metal-working, petroleum, plastic, and textile industries are at increased risk for laryngeal and hypopharyngeal cancers. Tobacco and heavy alcohol use can increase the risk for these cancers by as much as 100 times.

KEY TERMS

Carcinogen—A substance, method, or process that has been scientifically shown to be a causative factor in the development of a certain cancer.

Metastasize—The ability of a cancer to spread from its site of origin to other sites in the body. The more a cancer has metastasized, the worse is the individual's prognosis for cure.

Pleura—The pleura is a membrane that covers the lungs, and lines the chest cavity.

Farmers and others who have long-term exposure to herbicides and pesticides are at increased risk for leukemia. Children whose parent has **chronic lymphocytic leukemia** (CLL) have two to four times greater risk of getting CLL themselves. Long-term exposure to benzene places the employee at greater risk of developing **acute leukemia**. Herbicides and pesticides are both associated with the development of lymphomas, so workers involved in their production as well as their application are at increased risk. Children exposed to pesticides on a regular basis are significantly more likely to develop non-Hodgkin's lymphoma than children not exposed.

Farmers appear to have an increased incidence of **prostate cancer**. The reason is not yet clear. While some have suggested it may be due to a diet high in red meat and fatty foods, studies are investigating the link between prostate cancer and pesticides, fertilizers, chemical solvents, and farm equipment fumes. Salivary gland cancer may be linked to working with nickel alloy and silica dust, and exposure to radioactive substances.

Pancreatic cancer appears to be associated with significant exposure to pesticides, certain dyes, and chemicals found in gasoline. Occupational exposure to asbestos, cadmium, and organic solvents (especially trichloroethylene) seems to increase the risk of getting kidney cancer. Dioxin is a known carcinogen, and may be a causative factor in a variety of cancers. It is a byproduct in industrial processing that deals with chlorine and hydrocarbons, such as found in incinerators and paper and pulp factories.

Other chemicals linked with cancer are DDT and PCBs (polychlorinated biphenols). Health care professionals, both human and veterinary, may be exposed to carcinogenic substances in caring for their patients. Body fluid exposure can increase the risk of hepatitis B and hepatitis C, cause liver failure, and increase the risk of liver cancer. HIV can cause AIDS and increase the risk of a variety of malignant tumors. Chemicals in paint and paint solvents are also used in ceramic factories.

QUESTIONS TO ASK THE DOCTOR

- What type and stage is my cancer?
- What do you think is the cause of my cancer?
- Will I be able to work during my cancer treatment?
- Will I be able to go back to my same job after treatment is finished?
- If not, what kind of limitations will there be on my activity level?
- What kind of work will I be able to do when my treatment is over?
- Is anyone at home at risk for cancer or illness because of my work?

Electric and magnetic fields surround electric tools and machinery. Studies have been done to investigate whether these fields are harmful to humans. Research findings continue to be controversial, some showing an increased incidence of cancers, others not finding an association. However, federally funded research studies continue.

Special concerns

Cancers that originate in the workplace do not require different treatment than if the same cancer had developed from another source. However, workers who develop cancer through occupational exposure may not be able to return to the same job, perhaps not even the same company. This means that even if the individual has survived the cancer, and gone though all that treatment entails, they cannot pick up their life where they left it at the time of the cancer diagnosis. They may be disabled, and not be able to work at all, or they may have to retrain for work, either a different job within the same company, or a whole new job and environment.

If the person is older, he or she may be less employable after illness because of age. Depending on the type of cancer, it may be difficult to prove that the work environment was a causal factor in the development of the disease. This can make it harder to obtain work-related benefits. Consequently, financial concerns may be a great burden. Also, certain cancers may have developed from the inhalation of substances that were also brought home on the employee's clothing. Others in the family may have gotten ill as well. Fine dust particles can come home on workers' clothing, shoes, skin, hair, facial hair, tools or lunch boxes, and on the inside or outside of their car.

Workers in any occupation need to be fully informed of the substances with which they come in contact. Federal regulations are in place to improve employee safety, but the regulations are ineffective if the employees do not utilize the protective clothing, masks, and other safety measures at their disposal. Individuals who learned their trade prior to the installation of many safety measures may find it difficult to *retrain* themselves with the new equipment. But not doing so may raise their risk of cancer.

While many cancers have an unknown source, cancers due to occupational exposures have known sources. This means that they are preventable, if proper safety equipment is used all of the time, and always used correctly.

Treatments

Treatments for cancers due to occupational exposure should be the same as for the same cancer developed from a different source. Treatment will depend on the type and stage of the cancer diagnosed, as well as the age and fertility needs of the patient. Access to treatment may vary, however, depending on the type of insurance the individual holds. Access to experimental treatments, or treatment that a **health insurance** deems experimental can vary.

Alternative and complementary therapies

Alternative therapy options for cancer due to occupational exposure should be the same as if the cancer developed from another source. Complementary treatments that improve the functioning of the body's immune system, or that decrease treatment side effects such as nausea, can be helpful. There may be different stresses in the life of the person with a work-related cancer. So therapies such as meditation, guided imagery, therapeutic touch, yoga, and t'ai chi can help deal with the stress of having cancer, going through treatment, and having to find alternative work options.

Oligodendroglioma

Definition

Oligodendrogliomas are a rare form of brain tumors. The brain is made up of many supporting cells that are called glial cells. Any tumor of these glial cells is called a glioma. Oligodendrogliomas are tumors that arise from a type of glial cell called oligodendrocytes. These cells are the specialized cells of the brain that produce the fatty covering of nerve cells (myelin).

Description

Oligodendrogliomas can grow in different parts of the brain, but they are most commonly found in the frontal or temporal lobes of the cerebrum. The frontal lobes are responsible for cognitive thought processes (knowing, thinking, learning, and judging). The temporal lobes are responsible for coordination, speech, hearing, memory, and awareness of time.

There are two types of oligodendroglioma: the well-differentiated tumor, which grows relatively slowly and in a defined shape; and the anaplastic oligodendroglioma, which grows much more rapidly and does not have a well-defined shape. Anaplastic oligodendrogliomas are much less common than well-differentiated oligodendrogliomas.

More common than either form of pure oligodendroglioma is the mixed glioma, or oligoastrocytoma. These mixed gliomas are a mixture of oligodendroglioma and **astrocytoma**. An astrocytoma is a tumor that arises from the astrocytes, specialized cells in the brain that regulate the chemical environment of the brain and help to form the blood–brain barrier.

Oligodendrogliomas and mixed gliomas account for approximately 4–5% of all primary brain tumors and 10% of all gliomas. A primary brain tumor is a tumor that begins in the brain, as opposed to a secondary (or metastatic) brain tumor, which originates in another organ and spreads (metastasizes) to the brain.

Demographics

Oligodendromas occur in approximately nine in every one million people. Oligodendrogliomas can occur in people of any age, but most occur in middle-aged adults.

Oligodendrogliomas occur with equal frequency in members of all races and ethnic groups. There does not appear to be any relation of oligodendrogliomas to any geographic region. For unknown reasons, men are affected by oligodendrogliomas in higher numbers than women.

Causes and symptoms

The cause, or causes, of oligodendrogliomas are not known; however, most people with these types of tumors have some type of genetic mutation on chromosome 1, chromosome 19, or on both chromosomes 1 and 19. In early 2001, investigations were ongoing in an attempt to determine if these genetic factors, or other factors, cause oligodendrogliomas. Oligodendrogliomas are not contagious.

The symptoms of oligodenrogliomas are the result of increased pressure in the fluid within the skull (intracranial hypertension). These symptoms include:

- nausea
- vomiting
- irritability
- headache
- vision disturbances
- enlargement of the head
- seizures

Oligodendrogliomas may also be accompanied by a weakness or paralysis on the side of the body opposite to the side of the brain where the tumor is located. When the tumor is located in a frontal lobe, the patient may experience gradual changes in mood and personality. When it is located in a temporal lobe, the patient may

experience difficulty with speech, hearing, coordination, and memory.

Diagnosis

The diagnosis of oligodendrogliomas begins in the doctor's office with a basic neurological examination. This examination involves:

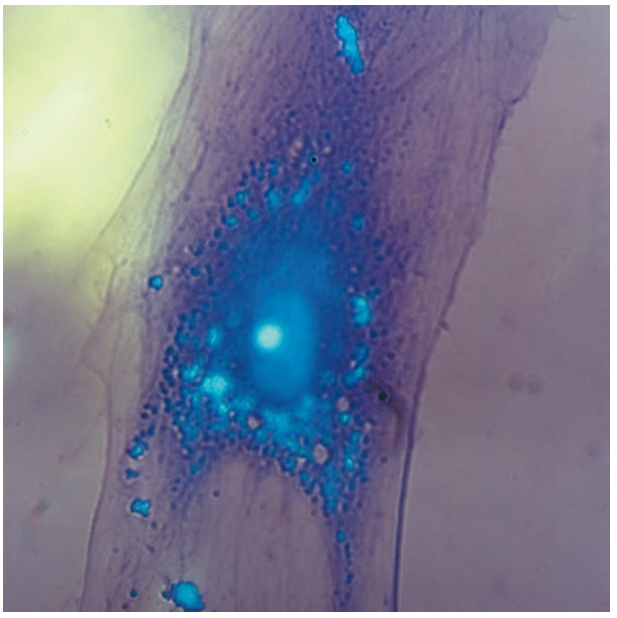
- testing eye reflexes, eye movement, and pupil reactions
- testing hearing with a tuning fork or ticking watch
- reflex tests with a rubber hammer
- balance and coordination tests
- pin-prick and cotton ball tests for sense of touch
- sense of smell tests with various odors
- facial muscle tests (e.g., smiling, frowning, etc.)
- tongue movement and gag reflex tests
- head movement tests
- mental status tests (e.g., asking what year it is, who the President is, etc.)
- abstract thinking tests (e.g., asking for the meaning of a common saying, such as "every cloud has a silver lining.")
- memory tests (e.g., asking to have a list of objects repeated, asking for details of what a patient ate for dinner last night, etc.)

If the doctor suspects a brain tumor may be present, further diagnostic tests will be ordered. These tests are performed by a neurological specialist. Imaging tests that may be ordered include computed tomography (CT) and **magnetic resonance imaging** (MRI). Other tests may include a spinal tap, to examine the cerebrospinal fluid, and an electroencephalogram (EEG), which measures the electrical activity of the brain.

Treatment team

Treatment of any primary brain tumor, including oligodendrogliomas, is different from treating tumors in other parts of the body. Brain surgery requires much more precision than most other surgeries. Also, many medicinal drugs cannot cross the blood–brain barrier. Therefore, the therapies that are used to treat oligodendrogliomas, and the side effects of these therapies, are quite complex.

The most up-to-date treatment opportunities are available from experienced, multi-disciplinary medical professional teams made up of doctors, nurses, and technologists who specialize in cancer (oncology), neurology, medical imaging, drug or **radiation therapy**, and anesthesiology.



Malignant oligodendroglioma cells from the human brain. *(Copyright Cecil Fox, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Clinical staging, treatments, and prognosis

Oligodendrogliomas and other primary brain tumors are diagnosed, or staged, in grades of severity from I to IV. Grade I tumors have cells that are not malignant and are nearly normal in appearance. Grade II tumors have cells that appear to be slightly abnormal. Grade III tumors have cells that are malignant and clearly abnormal. Grade IV, the most severe type of brain tumors, contain fast-spreading and abnormal cells. Well-defined oligodendrogliomas are generally stage I or stage II tumors. Anaplastic oligodenrogliomas are generally stage III or stage IV tumors.

The standard treatment for all grades of oligodendrogliomas is surgery to remove the tumor completely. This surgery is generally aided by an image guidance system that allows the surgeon to determine the most efficient route to location of the tumor. Approximately half of oligodendroglioma patients gain relief of the increased intracranial pressure after complete removal of their tumors. The other half require a spinal fluid shunt to allow drainage of the excess fluid.

In some instances of oligodendroglioma, the tumor is inoperable or cannot be completely removed. Patients

KEY TERMS

Anaplastic oligodendroglioma—A form of oligodendroglioma that does not have a well-defined shape and grows very rapidly and aggressively.

Astrocytoma—A type of brain tumor that arises from the astrocytes, specialized brain cells that regulate the chemical environment of the brain and form the blood-brain barrier. These types of tumors are often mixed with oligodendrogliomas to form oligoastrocytomas.

Frontal lobes—The two lobes of the cerebrum of the brain that are responsible for cognitive thought processes (knowing, thinking, learning, and judging).

Glioma—Any tumor that arises from the supporting cells in the brain called glial cells.

Intracranial hypertension—A higher-than-normal pressure of the fluid in the skull.

Oligoastrocytoma—A type of brain tumor that is a mixture of oligodendroglioma and astrocytoma. This is also called a mixed glioma.

Spinal fluid shunt—A small tube that is surgically implanted to allow excess spinal fluid to drain directly into the abdominal cavity.

Temporal lobes—The two lobes of the cerebrum of the brain that are responsible for coordination, speech, hearing, memory, and awareness of time.

Well-differentiated tumor—A tumor that grows relatively slowly and in a well-defined shape.

with inoperable oligodendrogliomas are generally treated with radiation therapies. Oligodendrogliomas are among the only brain tumors that can be successfully treated with a type of **chemotherapy** called PCV (**Procarbazine**, CCNU or **lomustine**, and **Vincristine**). Chemotherapy is usually used only in cases of recurrent anaplastic oligodendrogliomas.

For patients with well-defined oligodendrogliomas, median survival exceeds 10 years. For patients with anaplastic dendrogliomas, median survival ranges from two to five years.

Alternative and complementary therapies

For oligodendrogliomas, there are no effective alternative treatments—treatments used instead of conventional treatments like surgery or chemotherapy.

QUESTIONS TO ASK THE DOCTOR

- Which type of oligodendroglioma do I have?
- Is my tumor operable?
- What is the likelihood of my type of oligodendroglioma coming back?
- How often should I seek follow-up examinations?

Coping with cancer treatment

Most patients who undergo brain surgery to remove their tumors can resume their normal activities within a few days of the operation.

Clinical trials

There were 47 **clinical trials** underway by 2005, aimed at the treatment of oligodendrogliomas. More information on these trials, including contact information, may be found by conducting a clinical trial search at the web site of the National Cancer Institute, CancerNet <http://cancernet.nci.nih.gov/trialsrch.shtml>.

Prevention

Because the cause or causes of oligodenrogliomas are not known, there are no known preventions.

Special concerns

Repeat surgery may be necessary for oligodendrogliomas because these tumors sometimes redevelop. Careful monitoring by the medical team will be required. Also, if the tumor is located in the dominant hemisphere of the patient's brain, any treatment, especially surgery, requires special consideration and care not to disrupt the personality or other higher brain functions of the patient.

Omega-3 fatty acids

Definition

Essential to human health, omega-3 fatty acids are a form of polyunsaturated fats that are not made by the body and must be obtained from a person's food.

Purpose

Eating foods rich in omega-3 fatty acids is part of a healthy diet and helps people maintain their health.

Description

In recent years, a great deal of attention has been placed on the value of eating a low fat diet. In some cases, people have taken this advice to the extreme by adopting a diet that is far too low in fat or, worse yet, a diet that has no fat at all. But the truth is that not all fat is bad. Although it is true that trans and saturated fats, which are found in high amounts in red meat, butter, whole milk, and some prepackaged foods, have been shown to raise a person's total cholesterol, polyunsaturated fats can actually play a part in keeping cholesterol low. Two especially good fats are the omega-3 fatty acids and the omega-6 fatty acids, which are polyunsaturated.

Two types of omega-3 fatty acids are eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA), which are found mainly in oily cold-water fish, such as tuna, salmon, trout, herring, sardines, bass, swordfish, and mackerel. With the exception of seaweed, most plants do not contain EPA or DHA. However, alpha-linolenic acid (ALA), which is another kind of omega-3 fatty acid, is found in dark green leafy vegetables, flaxseed oil, fish oil, and canola oil, as well as nuts and beans, such as walnuts and soybeans. Enzymes in a person's body can convert ALA to EPA and DHA, which are the two kinds of omega-3 fatty acids easily utilized by the body.

Many experts agree that it is important to maintain a healthy balance between omega-3 fatty acids and omega-6 fatty acids. As Dr. Penny Kris-Etherton and her colleagues reported in their article published in the *American Journal of Nutrition* an over consumption of omega-6 fatty acids has resulted in an unhealthy dietary shift in the Americandiet. The authors point out that what used to be a 1:1 ratio between omega-3 and omega-6 fatty acids is now estimated to be a 10:1 ratio. This poses a problem, researchers say, because consuming some of the beneficial effects gained from omega-3 fatty acidsare negated by an over consumption of omega-6 fatty acids. For example, omega-3 fatty acids have anti-inflammatory properties, whereas omega-6 fatty acids tend to promote inflammation. Cereals, whole grain bread, margarine, and vegetable oils, such as corn, peanut, and sunflower oil, are examples of omega-6 fatty acids. In addition, people consume a lot of omega-6 fatty acid simply by eating the meat of animals that were fed grain rich in omega-6. Some experts suggest that eating one to four times more omega-6 fatty acids than omega-3 fatty acids is a reasonable ratio. In other words, as dietitians often say, the key to a healthy diet is moderation and balance.

The health benefits of omega-3 fatty acids

There is strong evidence that omega-3 fatty acids protect a person against atherosclerosis andtherefore against heart disease and stroke, as well as abnormal heart rhythms that cause sudden cardiac death, and possibly autoimmune disorders, such as lupus and rheumatoid arthritis. In fact, Drs. Dean Ornish and Mehmet Oz, renowned heart physicians, said in a 2002 article published in *O Magazine* that the benefits derived from consuming the proper daily dose of omega-3 fatty acids may help to reduce sudden cardiac death by as much as 50%. In fact, in an article published by *American Family Physician*, Dr. Maggie Covington, a clinical assistant professor at the University of Maryland, also emphasized the value of omega-3 fatty acids with regard tocardiovascular health and referred to one of the largest **clinical trials** to date, the GISSI-Prevenzione Trial, to illustrate her point. In the study, 11,324 patients with coronary heart disease were divided into four groups: one group received 300 mg of vitamin E, one group received 850 mg of omega-3 fatty acids, one group received the vitamin E and fatty acids, and one group served as the control group. After a little more than three years, "The group given omega-3 fatty acids only had a 45% reduction in sudden death and a 20% reduction in all-cause mortality," as stated by Dr. Covington.

According to the American Heart Association (AHA), the ways in which omega-3 fatty acids may reduce cardiovascular disease are still being studied. However, the AHA indicates that research as shown that omega-3 fatty acids:

- decrease the risk of arrthythmias, which can lead to sudden cardiac death
- decrease triglyceride levels
- decrease the growth rate of atherosclerotic plaque
- lower blood pressure slightly

In fact, numerous studies show that a diet rich in omega-3 fatty acids not only lowers bad cholesterol, known as LDL, but also lowers triglycerides, the fatty material that circulates in the blood. Interestingly, researchers have found that the cholesterol levels of Inuit Eskimos tend to be quite good, despite the fact that they have a high fat diet. The reason for this, research has found, is that their diet is high in fatty fish, which is loaded with omega-3 fatty acids.The same has often been said about the typical Mediterranean-style diet.

Said to reduce joint inflammation, omega-3 fatty acid supplements have been the focus of many studies attempting to validate its effectiveness in treating rheumatoid arthritis. According to a large body of research in the area, omega-3 fatty acid supplements are clearly effective in reducing the symptoms associated with rheumatoid arthritis, such as joint tenderness and stiffness. In some cases, a reduction in the amount of medication needed by rheumatoid arthritis patients has been noted.

More research needs to be done to substantiate the effectiveness of omega-3 fatty acids in treating eating disorders, attention deficit disorder, and **depression**. Some studies have indicated, for example, that children with behavioral problems and attention deficit disorder have lower than normal amounts of omega-3 fatty acids in their bodies. However, until there is more data inthese very important areas of research, a conservative approach should be taken, specially when making changes to a child's diet. Parents should to talk to their child's pediatrician to ascertain if adding more omega-3 fatty acids to their child's diet is appropriate. In addition, parents should take special care to avoid feeding their children fish high in mercury. A food list containing items rich in omega-3 fatty acids can be obtained from a licensed dietitian.

Mercury levels and concerns about safety

A great deal of media attention has been focused on the high mercury levels found in some types of fish. People concerned about fish consumption and mercury levels can review public releases on the subject issued by the U. S. Food and Drug Administration and the Environmental Protection Agency. Special precautions exist for children and pregnant or breastfeeding women. They are advised to avoid shark, mackerel, swordfish, and tilefish. However, both the U.S. Food and Drug Administration and the Environmental Protection Agency emphasis the importance of dietary fish. Fish, they caution, should not be eliminated from the diet. In fact, Robert Oh, M.D., stated in his 2005 article, which was published in *The Journal of the American Board of Family Practice* "With the potential health benefits of fish, women of childbearing age should be encouraged to eat 1 to 2 low-mercury fish meals per week."

Other concerns regarding fish safety have also been reported. In 2004, Hites and colleagues assessed organic contaminants n salmon in an article published in *Science*. Their conclusion that farmed salmon had higher concentrations of polychlorinated biphenyls than wild salmon prompted public concerns and a response from the American Cancer Society. Farmed fish in Europe was found to have higher levels of mercury than farmed salmon in North and South America; however, the American Cancer Society reminded the public that the "levels of toxins Hites and his colleagues found in the farmed salmon were still below what the U. S. Food and Drug Administration, which regulates food, considers hazardous." The American Cancer Society still continues to promote a healthy, varied diet, which includes fish as a food source.

Recommended dosage

The AHA recommends that people eat two servings of fish, such as tuna or salmon, at least twice a week. A person with coronary heart disease, according to the AHA, should consume 1 gram of omega-3 fatty acids daily through food intake, most preferably through the consumption of fatty fish. The AHA also states that "people with elevated triglycerides may need 2 to 4 grams of EPA and DHA per day provided as a supplement," which is available in liquid orcapsule form. Ground or cracked flaxseed can easily be incorporated into a person's diet by sprinkling it over salads, soup, and cereal.

Sources differ, but here are some general examples:

- 3 ounces of pickled herring = 1.2 grams of omega-3 fatty acids
- 3 ounces of salmon = 1.3 grams of omega-3 fatty acids
- 3 ounces of halibut = 1.0 grams of omega-3 fatty acids
- 3 ounces of mackerel = 1.6 grams of omega-3 fatty acids
- 1 1/2 teaspoons of flaxseeds = 3 grams of omega-3 fatty acids

Precautions

In early 2004, the U.S. Food and Drug Administration, along with the the Environmental Protection Agency, issued a statement that women who are or may be pregnant, as well as breastfeeding mothers and children, should avoid eating some types of fish thought to contain high levels of mercury. Fish that typically contain high levels of mercury are shark, swordfish, and mackerel, whereas shrimp, canned light tuna, salmon, and catfish are generally thought to have low levels of mercury. Because many people engage in fishing as a hobby, women should be sure before they eat any fish caught by friends and family that the local stream or lake is considered low in mercury.

Conflicting information exists whether it is safe for patients with macular degeneration to take omega-3 fatty acids in supplement form. Until more data becomes available, it is better for people with macular degeneration to receive their omega-3 fatty acids from the food they eat.

Side effects

Fish oil supplements can cause **diarrhea** and gas. Also, the fish oil capsules tend to have a fishy aftertaste.

Interactions

Although there are no significant drug interactions associated with eating foods containing omega-3 fatty acids, patients who are being treated with blood-thinning medications shouldn't take omega-3 fatty acid supplements without seeking the advice of their physicians. Excessive bleeding could result. For the same reason, some patients who plan to take more than 3 grams of omega-3 fatty acids in supplement form should first seek the approval of their physicians.

Ommaya reservoir

Definition

The Ommaya reservoir is a plastic, dome–shaped device, with a catheter (thin tubing) attached to the

underside used to deliver **chemotherapy** (anticancer drugs) to the central nervous system (CNS or brain and spinal cord).

Purpose

Chemotherapy may be administered to patients by various methods, depending on the type of cancer being treated. Some cancer types respond well to chemotherapy given by intravenous (IV) injection, and some cancer types may be treated with oral medication. In both cases, the chemotherapy reaches its target site systemically (carried by the blood). Cancers that affect the CNS pose a special challenge. Systemically delivered drugs seldom reach the CNS because of a network of blood vessels that surround the brain. This protective shield is called the blood–brain barrier. It acts as a filtering device for the brain by blocking the passage of foreign substances from the blood to the CNS. To avoid the obstacle created by the blood–brain barrier, alternative delivery treatments must be used. These treatments are collectively called intrathecal chemotherapy treatments. These treatments require injecting the chemotherapy directly into the cerebrospinal fluid (CSF). The CSF is the clear fluid surrounding the CNS. An oncologist (a physician specializing in cancer study and treatment) will determine the frequency of the treatment schedule and will decide if it is better for the patient to receive intrathecal chemotherapy injections directly into the spinal column or through an Ommaya reservoir implanted in the brain. The Ommaya reservoir may be used in several ways. Its primary function is to facilitate the uniform delivery of the intrathecal chemotherapy. By implanting the Ommaya reservoir, multiple rounds of chemotherapy may be given through a single access site, thereby increasing patient comfort and reducing the stress and pain associated with repeated spinal injections. The Ommaya reservoir also serves as a sampling site for removal of CSF. Samples are withdrawn an analyzed for the presence of abnormal cells. Some physicians utilize the reservoir to deliver pain medication, and more recently, trials have been conducted to test the efficacy of using the Ommaya reservoir to deliver gene therapy (treating a disease caused by a malfuncting gene, by introducing a normal gene back into the diseased individual) to cancer patients.

Precautions

High-dose chemotherapy drugs such as **methotrexate** may produce toxic effects if the reservoir or catheter becomes compromised. For infants and children being considered as candidates for an Ommaya reservoir implant, the age of the patient should be considered. Some studies have suggested that infants may be at a higher risk for post–treatment neurologic and endocrinologic problems, cognitive (learning) disabilities, and higher infant mortality when high–dose chemotherapy agents are administered via the Ommaya reservoir. These conditions are significantly reduced in adult patients. Any patient compromised by a pre–existing suppressed immune system should make the physician aware of this condition so the choice of chemotherapy and specific protocols for administering the drugs are employed.

KEY TERMS

Blood–brain barrier—The blood vessel network surrounding the brain that blocks the passage of foreign substances into the brain.

Central nervous system (CNS)—The body system composed of the brain and spinal cord.

Cerebrospinal fluid (CSF)—The fluid surrounding the brain and spinal cord.

Chemotherapy—Anticancer drugs

Intrathecal chemotherapy—Chemotherapy that must be given directly into the CSF.

Description

Placement of the Ommaya reservoir requires a minor surgical procedure with the patient placed under general anesthesia. The procedure is performed in the hospital by a neurosurgeon (a physician specially trained to perform surgery on the brain or spinal cord). The reservoir is placed under the scalp with the catheter positioned into the cavity of the brain where the CSF is formed. Once in place, chemotherapy treatments using the Ommaya reservoir may be conducted as outpatient visits either in the hospital, the home, or a satellite clinic staffed by specially trained healthcare professionals. To perform an Ommaya reservoir tap (CSF sampling and chemotherapy delivery) requires 15–20 minutes with little or no pain to the patient. Basic guidelines for the tap include:

- Remove hair from over the reservoir area.
- Gently pump the reservoir to allow the reservoir to fill with CSF.
- Clean the area with alcohol and iodine solution, maintaining a sterile field.
- The healthcare professional will insert a small needle into the reservoir and slowly withdraw a sample of CSF.

- The chemotherapy will be delivered by slowly injecting the prescribed medication into the reservoir.
- The needle is removed and the site covered with sterile gauze.
- Light pressure is applied, and the reservoir is gently pumped to enhance uniform distribution of the chemotherapy into the CSF.
- The site is covered with a Band–Aid.

Preparation

Placement of the Ommaya reservoir will require a minimal stay in the hospital. The surgeon will provide detailed pre–operative instructions for the patient prior to the hospital visit. Post–operative recovery will monitor vital signs and watch for possible side effects from the anesthesia. Before the patient is discharged, an initial round of chemotherapy administered via the Ommaya reservoir will be performed to assure the device is working properly. No special preparations are required for routine scheduled chemotherapy treatments.

Aftercare

Following an Ommaya tap, the patient may participate in all normal activities. Hair may be washed. There are no special requirements for care of the reservoir site; however, a physician should be notified if symptoms appear such as a spike in **fever**, headaches with or without vomiting, neck stiffness, tenderness, redness, or drainage at the access site of the reservoir.

Risks

The most common risks associated with the use of the Ommaya reservoir primarily deal with complications due to malposition or malfunction of the device. Either condition may result in blockage or leakage of the catheter, leading to improper drug delivery. Lesions may develop along the catheter, infection may develop, and chemotherapy may reach toxic levels. In cancer patients scheduled for surgical intervention, who have previously received chemotherapy via an Ommaya reservoir, there is some evidence of increased perioperative morbidity (a diseased condition existing at the time of surgery).

Normal results

Patients may expect successful delivery of the intrathecal chemotherapy during each treatment session with minimal discomfort. It should be noted, however, that the chemotherapy delivered by the Ommaya reservoir works on cells that are actively growing and dividing. This means both cancer cells and certain normal cell types may be affected and may result in side effects. Depressed blood cell counts may lower resistance to infection and increase susceptibility to bruising and bleeding. There may be an overall decrease in energy levels. Hair loss (alopecia) may occur, and cells of the digestive tract may be damaged resulting in bouts of nausea, vomiting, and mouth sores. For female patients, symptoms of menopause may develop, and in males, sperm production may stop.

QUESTIONS TO ASK THE DOCTOR

- What makes me a good candidate for the Ommaya reservoir?
- What types of chemotherapy will I receive?
- How often will the treatments be scheduled, and will there be side effects after each one?
- How will I know if the Ommaya reservoir is working properly?
- Is this device and procedure covered by insurance?

Abnormal results

Severe complications associated with drug delivery could occur. Due to improper function of the reservoir, toxic levels of chemotherapy could induce behavioral abnormalities, confusion, dementia, irritability, convulsions, sensory impairment, damage to pulmonary and renal function, and patient death.

Oophorectomy

Definition

Oophorectomy is the surgical removal of one or both ovaries. It is also called ovariectomy or ovarian ablation. If one ovary is removed, a woman may continue to menstruate and have children. If both ovaries are removed, menstruation stops and a woman loses the ability to have children.

Purpose

Oophorectomy is performed to:

- remove cancerous ovaries
- remove the source of estrogen that stimulates some cancers
- remove a large ovarian cyst
- excise an abscess
- treat endometriosis
- lower the risk of an ectopic pregnancy
- lower the risk of cancer in a woman with a family history of ovarian or breast cancer

In an oophorectomy, one, or a portion of one, ovary may be removed or both ovaries may be removed. When oophorectomy is done to treat **ovarian cancer** or other spreading cancers, both ovaries are always removed. This is called a bilateral oophorectomy. Oophorectomies are sometimes performed on pre-menopausal women who have estrogen-sensitive **breast cancer** in an effort to remove the main source of estrogen from their bodies. This procedure has become less common than it was in the 1990s. Today, **chemotherapy** drugs are available that alter the production of estrogen and **tamoxifen** blocks any of the effects any remaining estrogen may have on cancer cells.

Until the 1980s, women over age 40 having hysterectomies (surgical removal of the uterus) routinely had healthy ovaries and fallopian tubes removed at the same time. This operation is called a bilateral salpingo-oophorectomy. Many physicians reasoned that a woman over 40 was approaching menopause and soon her ovaries would stop secreting estrogen and releasing eggs. Removing the ovaries would eliminate the risk of ovarian cancer and only accelerate menopause by a few years.

In the 1990s, the thinking about routine oophorectomy began to change. The risk of ovarian cancer in women who have no family history of the disease is less than 1%. Meanwhile, removing the ovaries increases the risk of cardiovascular disease and accelerates osteoporosis unless a woman takes prescribed hormone replacements.

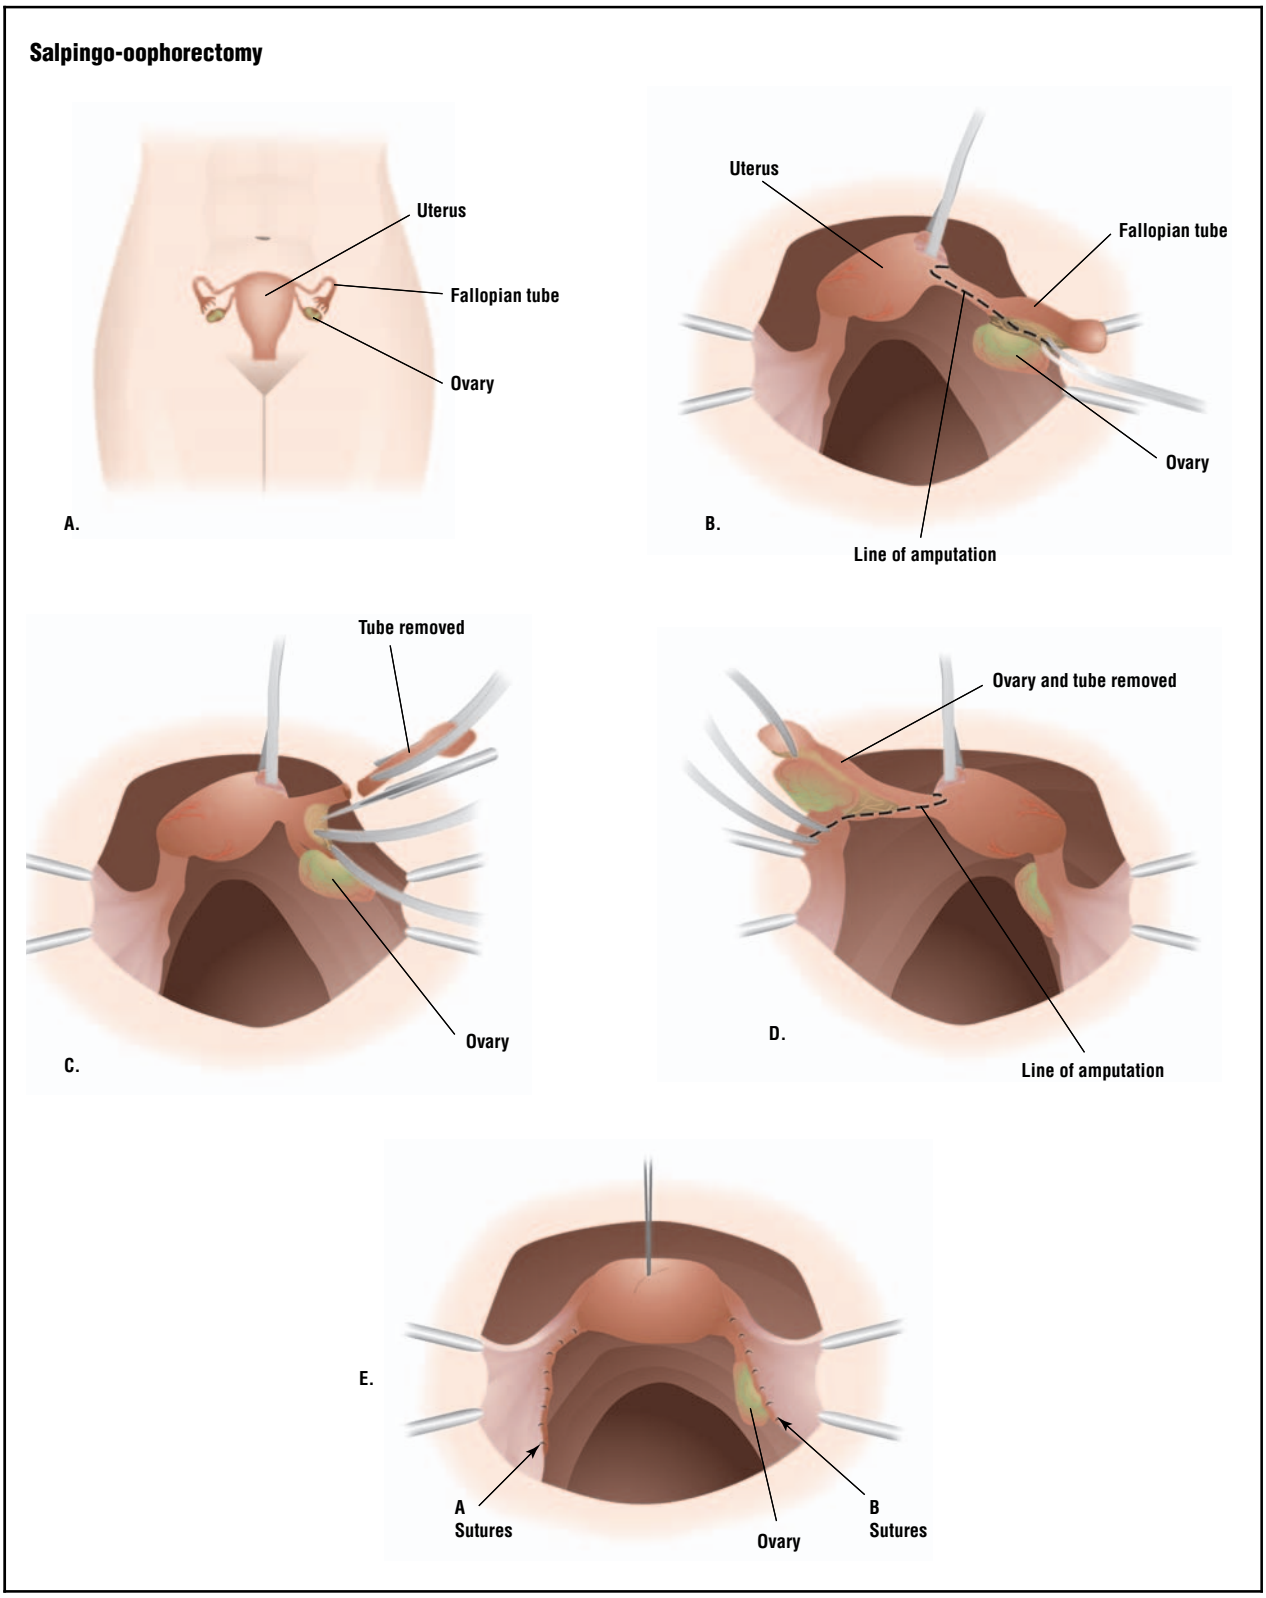
Under certain circumstances, oophorectomy may still be the treatment of choice to prevent breast and ovarian cancer in certain high-risk women. A study done at the University of Pennsylvania and released in 2000 showed that healthy women who carried the BRCA1 or BRCA2 genetic mutations that pre-disposed them to breast cancer had their risk of breast cancer drop from 80% to 19% when their ovaries were removed before age 40. Women between the ages of 40 and 50 showed less risk reduction, and there was no significant reduction of breast cancer risk in women over age 50.

Overall, ovarian cancer still ranks low on a woman's list of health concerns: It accounts for only 4% of all cancers in women. But the lifetime risk for developing ovarian cancer in women who have mutations in BRCA1 is significantly increased over the general population and may cause an ovarian cancer risk of 30% by age 60. For women at increased risk, oophorectomy may be considered after the age of 35 if childbearing is complete.

The value of ovary removal in preventing both breast and ovarian cancer has been documented. However, there are disagreements within the medical community about when and at what age this treatment should be offered. Preventative oophorectomy, called preventative bilateral oophorectomy (PBO), is not always covered by insurance. One study conducted in 2000 at the University of California at San Francisco found that only 20% of insurers paid for PBO. Another 25% had a policy against paying for the operation, and the remaining 55% said that they would decide about payment on an individual basis.

Precautions

There are situations in which oophorectomy is a medically wise choice for women who have a family



(Illustration by Argosy Publishing. Reproduced by permission of The Gale Group.)

history of breast or ovarian cancer. However, women with healthy ovaries who are undergoing hysterectomy for reasons other than cancer should discuss with their doctors the benefits and disadvantages of having their ovaries removed at the time of the hysterectomy.

Description

Oophorectomy is done under general anesthesia. It is performed through the same type of incision, either vertical or horizontal, as an abdominal hysterectomy. Horizontal incisions leave a less noticeable scar, but vertical incisions give the surgeon a better view of the abdominal cavity.

After the incision is made, the abdominal muscles are pulled apart, not cut, so that the surgeon can see the ovaries. Then the ovaries, and often the fallopian tubes, are removed.

Oophorectomy can sometimes be done with a laparoscopic procedure. With this surgery, a tube containing a tiny lens and light source is inserted through a small incision in the navel. A camera can be attached that allows the surgeon to see the abdominal cavity on a video monitor. When the ovaries are detached, they are removed though a small incision at the top of the vagina. The ovaries can also be cut into smaller sections and removed.

The advantages of abdominal incision are that the ovaries can be removed even if a woman has many adhesions from previous surgery. The surgeon gets a good view of the abdominal cavity and can check the surrounding tissue for disease. A vertical abdominal incision is mandatory if cancer is suspected. The disadvantages are that bleeding is more likely to be a complication of this type of operation. The operation is more painful than a laparoscopic operation and the recovery period is longer. A woman can expect to be in the hospital two to five days and will need three to six weeks to return to normal activities.

Preparation

Before surgery, the doctor will order blood and urine tests, and any additional tests such as ultrasound or x rays to help the surgeon visualize the woman's condition. The woman may also meet with the anesthesiologist to evaluate any special conditions that might affect the administration of anesthesia. A colon preparation may be done, if extensive surgery is anticipated.

On the evening before the operation, the woman should eat a light dinner, then take nothing by mouth, including water or other liquids, after midnight.

Aftercare

After surgery a woman will feel discomfort. The degree of discomfort varies and is generally greatest with abdominal incisions, because the abdominal muscles must be stretched out of the way so that the surgeon can reach the ovaries.

When both ovaries are removed, women who do not have cancer are started on hormone replacement therapy to ease the symptoms of menopause that occur because estrogen produced by the ovaries is no longer present. If even part of one ovary remains, it will produce enough estrogen that a woman will continue to menstruate, unless her uterus was removed in a hysterectomy. **Antibiotics** are given to reduce the risk of post-surgery infection.

Return to normal activities takes anywhere from two to six weeks, depending on the type of surgery. When women have cancer, chemotherapy or radiation are often given in addition to surgery. Some women have emotional trauma following an oophorectomy, and can benefit from counseling and support groups.

Risks

Oophorectomy is a relatively safe operation, although like all major surgery, it does carry some risks. These include unanticipated reaction to anesthesia, internal bleeding, blood clots, accidental damage to other organs, and post-surgery infection.

Complications after an oophorectomy include changes in sex drive, hot flashes, and other symptoms of menopause if both ovaries are removed. Women who have both ovaries removed and who do not take estrogen replacement therapy run an increased risk for cardiovascular disease and osteoporosis. Women with a history of psychological and emotional problems before an oophorectomy are more likely to experience psychological difficulties after the operation.

Normal results

If the surgery is successful, the ovaries will be removed without complication, and the underlying problem resolved. In the case of cancer, all the cancer will be removed.

Abnormal results

Complications may arise if the surgeon finds that cancer has spread to other places in the abdomen. If the cancer cannot be removed by surgery, it must be treated with chemotherapy and radiation.

KEY TERMS

Cyst—An abnormal sac containing fluid or semi-solid material.

Ectopic pregnancy—A pregnancy that develops when a fertilized egg implants outside the uterus, usually in the Fallopian tubes, but sometimes in the ovary itself.

Endometriosis—A benign condition that occurs when cells from the lining of the uterus begin growing outside the uterus.

Fallopian tubes—Slender tubes that carry ova from the ovaries to the uterus.

Hysterectomy—Surgical removal of the uterus.

Osteoporosis—The excessive loss of calcium from the bones, causing the bones to become fragile and break easily.

Opioids

Definition

Opioids are narcotic drugs that are generally prescribed to manage pain. The most commonly prescribed opioids are: buprenorphine, butorphanol, codeine, fentanyl, hydrocodone, hydromorphone, levorphanol, **meperidine**, methadone, morphine, nalbuphine, oxycodone, oxymorphone, pentazocine, and propoxyphene. These opioids are prescribed alone or in combination with aspirin or acetaminophen (Tylenol).

The most common brand names for these drugs are:

- Actiq
- Astramorph PF
- Buprenex
- Cotanal-65
- Darvon
- Demerol
- Dilaudid
- Dolophine
- Duragesic
- Duramorph
- Hydrostat IR
- Kadian
- Levo-Dromoran
- Methadose
- M S Contin
- MSIR
- MS/L
- MS/S
- Nubain
- Numorphan
- OMS
- Oramorph SR
- OxyContin
- PP-Cap

- Rescudose
- RMS Uniserts
- Roxanol
- Roxicodone
- Stadol
- Talwin

When combined with aspirin or acetaminophen, the most common brand names are:

- Allay
- Anexsia
- Anolor
- Bancap-HC
- Capital with Codeine
- Co-Gesic
- Damason-P
- Darvocet
- Darvon
- DHCplus
- Dolacet
- Dolagesic
- Duocet
- E-Lor
- Empirin with codeine
- Endocet
- Endodan
- EZ III
- Hycomed
- Hyco-Pap
- Hydrocet
- Hydrogesic
- HY-PHEN
- Lorcet
- Lortab
- Margesic
- Oncet
- Panacet
- Panasal
- Panlor
- Percocet
- Percodan
- Phenaphen with codeine
- Polygesic
- Propacet
- Propoxyphene Compound-65
- Pyregesic-C
- Roxicet
- Roxilox
- Roxiprin
- Stagesic
- Synalgos-DC
- Talacen
- Talwin compound
- T-Gesic
- Tylenol with codeine
- Tylox
- Ugesic
- Vanacet
- Vendone
- Vicodin
- Vicoprofen
- Wygesic
- Zydone

Purpose

Opioids are primarily used to manage pain. Some narcotics are also used just prior to, or during, surgery to increase the effectiveness of certain anesthetics. Codeine and hydrocodone are used to relieve coughing. Methadone is used to help people control their dependence on heroine or other narcotics.

Description

Opioids act on the central nervous system (CNS) to relieve pain. Many of these drugs are habit-forming and physical dependence may lead to withdrawal side effects when the medication is stopped. Because of the potential habit-forming nature of these drugs, most prescriptions cannot be refilled and a new prescription must be obtained after each preceding prescription runs out.

Recommended dosage

Opioids may be taken either orally (in pill or liquid form), by injection (or as part of an intravenous [IV]. line), as an anal suppository, or as a patch attached to the

skin. The dosage prescribed may vary widely depending on the patient, the cancer being treated, and whether or not other medications are also being taken.

A typical adult dosage for buprenorphine is 0.3 mg injected into a muscle or vein every six hours as necessary. For children between the ages of two and twelve years, the dosage is typically 0.002 to 0.006 mg per kilogram (2.2 pounds) of body weight.

A typical adult dosage for butorphanol is 1-4 mg injected into a muscle or 0.5-2 mg injected into a vein every four hours as necessary. For children between the ages of two and twelve years, the dosage is typically based on the body weight of the child.

A typical adult dosage for codeine is 15-60 mg taken orally or injected into a muscle or vein every four to six hours as necessary for pain. This dosage is decreased to 10 to 20 mg when codeine is used to control coughing.

Fentanyl is most often used to manage pain in cancer patients who are already receiving and are tolerant to other opioids. This drug is available as a lozenge and as a skin patch. It is not used for the treatment of pain caused by injury or surgery. The dosage of fentanyl is determined on an individual patient basis by that patient's oncologist.

A typical adult dosage for hydrocodone is 5-10 mg taken orally every four to six hours as necessary for pain, 5 mg to control coughing.

A typical adult dosage for hydromorphone is 1-2 mg injected into a muscle, 2-2.5 mg taken orally, or 3 mg taken as a suppository every three to six hours as necessary.

A typical adult dosage for levorphanol is 2-4 mg taken orally or injected into a vein every four hours as necessary.

A typical adult dosage for meperidine is 100 mg taken orally or injected into a muscle or vein every four hours as necessary.

A typical adult dosage for methadone is 5-20 mg as an oral solution, 2.5-10 mg as an oral tablet or injection, every four to eight hours as necessary for pain. When used for detoxification, methadone is initially given in a dose of 15-40 mg per day as an oral solution. This dose is then decreased until the patient no longer requires the medication. The injection form of methadone is only used for detoxification in patients who are unable to take the medication by mouth.

Morphine is most often used to manage severe, chronic pain in patients who have already been receiving other narcotic pain relievers. The starting dose of morphine is generally determined based on the dosages of prior narcotic pain relievers the patient had been receiving. A typical starting dose is 5-30 mg every four hours.

100mg Demerol tablet. *(Copyright 2002 Thomson Micromedex. Reproduced by permission.)*

A typical adult dosage for nalbuphine is 10 mg injected into a muscle or vein every three to six hours as necessary.

A typical adult dosage for oxycodone is 5 mg taken orally every three to six hours, or 10-40 mg taken as a suppository three to four times per day as necessary.

A typical adult dosage for oxymorphone is 1-1.5 mg injected into a muscle every three to six hours, or 5 mg taken as a suppository every four to six hours as necessary.

A typical adult dosage for pentazocine is 50 mg taken orally, or 30 mg injected into a muscle or vein every three to four hours as necessary.

Propoxyphene comes in two salt forms: propoxyphene hydrochloride and propoxyphene napsylate. The typical adult dosage for propoxyphene hydrochloride is 65 mg taken orally every four hours with a maximum daily dosage of 390 mg. The typical adult dosage for propoxyphene napsylate is 100 mg taken orally every four hours with a maximum daily dosage of 600 mg.

Precautions

Opioids magnify the effects of alcohol and other central nervous system depressants, such as antihistamines, cold medicines, sedatives, tranquilizers, other prescription and over-the-counter pain medications, barbiturates, seizure medications, muscle relaxants, and certain anesthetics including some dental anesthetics. Alcohol and other central nervous system depressants should not be taken or consumed while opioids are being taken.

Opioids are powerful narcotics. These drugs can cause some people to feel drowsy, dizzy, or lightheaded. People taking opioids should not drive a car or operate machinery.

Opioids can be habit-forming. Patients who have been taking these types of medication for a period of several weeks should not stop taking this type of medication all at once. The dosage should be slowly tapered off to avoid potential withdrawal side effects.

Intentional or accidental overdose of any of the opioids can lead to unconsciousness, coma, or death. The signs of opioid overdose include confusion, difficulty speaking, seizures, severe nervousness or restlessness, severe dizziness, severe drowsiness, and/or slow or troubled breathing. These symptoms are increased by alcohol or other central nervous system depressants. Anyone who feels that he or she, or someone else, may have overdosed on opioids, or a combination of opioids and other central nervous system depressants, should seek emergency medical attention for that person at once.

Opioids can interfere with or exacerbate certain medical conditions. For these reasons, it is important that the prescribing physician is aware of any current case, or history of:

- alcohol abuse
- brain disease or head injury
- colitis
- drug dependency, particularly of narcotics
- emotional problems
- emphysema, asthma, or other chronic lung disease
- enlarged prostate
- gallstones or gallbladder disease
- heart disease
- kidney disease
- liver disease
- problems with urination
- seizures
- underactive thyroid

KEY TERMS

Central nervous system depressant—Any drug that tends to reduce the activity of the central nervous system. The major drug categories included in this classification are alcohol, anesthetics, antianxiety medications, antihistamines, antipsychotics, hypnotics, narcotics, sedatives, and tranquilizers.

Narcotic—Any drug that produces insensibility or stupor and/or generally causes effects similar to those caused by morphine.

Side effects

The most common side effects of opioids include:

- constipation
- dizziness
- drowsiness
- itching
- nausea
- urine retention
- vomiting

Less common side effects of opioids include:

- abnormally fast or slow heartbeat
- blurred or double vision
- cold, clammy skin
- depression or other mood changes
- dry mouth
- fainting
- hallucinations
- hives
- loss of appetite
- nightmares or unusual dreams
- pinpoint pupils of the eyes
- redness or flushing of the face
- restlessness
- rigid muscles
- ringing or buzzing in the ears

- seizure
- severe drowsiness
- skin reaction at the site of injection
- stomach cramps or pain
- sweating
- trouble sleeping (insomnia)
- yellowing of the skin or whites of the eyes

Interactions

Opioids should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician. It is particularly important that the prescribing physician be aware of the use of any of the following drugs:

- carbamazepine (Tegretol; antiepileptic)
- central nervous system depressants
- monoamine oxidase (MAO) inhibitors (a class of antidepressants) such as furazolidone, isocarboxazid, pargyline, phenelzine, **procarbazine**, or tranylcypromine
- Naltrexone (opioid antagonist)
- Rifampin (antituberculosis drug)
- tricyclic antidepressants such as **amitriptyline**, amoxapine, clomipramine, desipramine, doxepin, imipramine, nortiptyline, protriptyline, or trimipramine
- Zidovudine (antiviral against aids virus)
- any **radiation therapy** or **chemotherapy** medicines

Paul A. Johnson, Ed.M.

Opium tincture *see* **Antidiarrheal agents**

Oprelvekin

Definition

Oprelvekin, also known as Neumega, is a hematopoietic stimulant used as supportive care after myelosuppressive **chemotherapy** to combat thrombopenia.

Purpose

Oprelvekin is a prescription medication used following the administration of myelosuppressive chemotherapy drugs such as **azathioprine** and mercaptopurine. Myelosuppressive chemotherapy acts on bone marrow and causes a decrease in the amount of white blood cells (leukopenia) and platelets (thrombopenia). Oprelvekin acts as a growth factor stimulating stem cells to proliferate. The result is an increase in the amount of platelets (or thrombocytes).

Description

Oprelvekin is a recombinant human interleukin. Further it is a synthetic version of the naturally occurring interleukin-11, which is produced by the cells of the bone marrow. It is a growth factor that stimulates the formation of platelets, which are necessary in the process of blood clot formation. Oprelvekin is therefore important in increasing platelet formation after treatment with cancer medications that cause **thrombocytopenia**.

The Food and Drug Administration approve oprelvekin for prevention of severe thrombocytopenia, which is observed after chemotherapy. Oprelvekin is in **clinical trials** for treatment support and therapy for acute myelocytic leukemia.

Recommended dosage

This drug is available by injection. The dose is different from person to person and is dependent on the patient's body weight. Generally, 50 mcg/kg is given once daily in either the abdomen, thigh or hip. This medication should be taken at the same time every day for best results. If a dosage of oprelvekin is missed, the patient should skip the missed dose and take the next dose at the scheduled time.

Precautions

Although oprelvekin is effective at increasing the number of platelets in patients following chemotherapy, patients should understand that there are a number of precautions that should be taken when their physician is prescribing oprelvekin.

If the patient has any existing medical problems, he or she should tell the doctor prior to beginning treatment with oprelvekin. Congestive heart failure may be worsened when taking oprelvekin as it causes increased water retention. Oprelvekin can also cause atrial arrhythmias that result in heart rhythm problems. It should also be used with caution in patients with preexisting papilledema or with tumors that involve the central nervous system.

Oprelvekin has not been studied in pregnant women, women who are nursing or children. However, animal testing has shown that oprelvekin can have negative effects on the fetus and can cause joint and tendon problems in children. It is eliminated primarily by the kidneys and should be used carefully in patients with renal impairment.

KEY TERMS

Growth factor—A body-produced substance that regulates cell division and cell survival. It can also be produced in a laboratory for use in biological therapy.

Hematopoietic—Related to the formation of blood cells.

Thrombopenia—Decreased number of platelets.

Papilledema—Swelling around the optic disk.

Side effects

Although oprelvekin is a synthetic version of a naturally occurring growth factor, there are side effects associated with taking it. The side effects should be weighed against the needed effects of this medication. Some side effects do not require medical attention and others do.

The following are side effects that do not require medical attention and could gradually go away as treatment progresses:

- red eyes
- weakness
- numb extremities such as the hands and feet
- skin reactions such as rash and discoloration

If patients encounter any of the following side effects, they should contact their physicians immediately:

- rapid heartbeat
- irregular heartbeat
- short breath
- white spots in the mouth or on the tongue
- swelling feet and legs
- bloody eye
- blurred vision
- heart rhythm problems

If the patient notices any other side effects not listed, a physician should be contacted immediately.

Interactions

There are no known interactions with oprelvekin.

Sally C. McFarlane-Parrott

Oral cancers

Definition

Cancer of the mouth or the oral cavity and the oropharynx is referred to as oral cancer.

Description

Oral cavity describes a broad array of parts within the mouth including the lips, lining on the lips and cheeks referred to as buccal mucosa, teeth, tongue, floor of the mouth under the tongue, hard palate (which is the firm bony top of the mouth), and the gums. The oropharynx includes the back of the tongue, the soft palate, and the tonsils (fleshy part on either side of the mouth). There are glands through out the oral cavity that produce saliva that keep the mouth moist, known as salivary glands. The secretions from these glands called saliva aid in digesting the food.

Under normal circumstances, the oral cavity and oropharynx are comprised of several types of tissues and cells, and tumors can develop from any of these cells. These tumors may either be benign (they do not spread to the adjoining tissues), or the tumor may invade other tissues of the body. Any potential growth of a benign tumor into a cancerous (malignant) tumor is referred to as a precancerous condition. Leukoplakia or erythroplakia, which are abnormal areas in the oral cavity, may develop in many of the oral cancers as the first stage. Leukoplakia is a white area that is a benign condition, but approximately 5% of leukoplakias develop into cancer. Erythroplakia is a red bumpy area that bleeds when scraped, and has the potential to develop into cancer within 10 years if not treated.

Benign tumors are those that are not invasive and thus incapable of spreading. Examples of benign tumors of the oral cavity include keratocanthoma, leiomyoma, osteochondroma, neurofibroma, papilloma, schwannoma, and odontogenic tumors. These tumors are generally harmless and can be surgically removed. Recurrence of these tumors after surgical removal is very rare.

More than 90% of malignant tumors of the oral cavity and oropharynx are squamous cell carcinoma also referred to as squamous cell cancer. Squamous cells form the lining of the oral cavity and oropharynx and morphologically, they appear flat and scale-like. When the cancer cells appear just in the lining of the oral cavity, it marks the initial stages of the squamous cell cancer and is referred to as carcinoma in situ. Appearance of cancer cells on deeper layers of the oral cavity or oropharynx refers to invasive squamous cell cancer which is a more serious condition.

Verrucous carcinomas are a type of squamous cell carcinoma that seldom metastasize but can spread to the adjoining tissues. Thus a surgeon might suggest removal of a wide area of surrounding tissues in addition to removing the cancerous tissue. The chances of developing a second cancer in the oral region (oral cavity or pharynx) at a later time during the life period is about 10-40%, thus necessitating thorough follow-up examinations. In addition, refraining from smoking and drinking will help to prevent the disease recurrence. Among other types of malignant tumors of the oral cavity are salivary gland cancers and Hodgkin's disease. The former affects the salivary glands present throughout the mucosal lining of the oral cavity and oropharynx. The latter is the cancer that develops in the lymphoid tissue of the tonsils and base of the tongue.

Demographics

The statistical survey on oral cancers reveals that more men are affected by the disease than women. The American Cancer Society has estimated that about 28, 260 new cases of oral cavity and pharyngeal cancers will be diagnosed in the United States in the year 2004. Of these, predictions are that 18,550 cases will occur in men and 9,710 in women. The estimates also suggest that about 7,230 Americans will die of cancer of the oral cavity or oropharynx in 2004. The incidence and the mortality rate have been directed toward a decreasing trend in the last 20 years. Studies on patient survival show that about 82% of patients diagnosed with oral cancer survive for more than a year, about 51% survive for five years and about 48% for 10 years.

Certain geographic differences affect the incidence of oral cavity cancers. Hungary and France show higher incidence of the disease as compared to the United States. However, the disease is much less common in Japan and Mexico suggesting that environmental factors do play a key role in the outcome of the disease.

About 15% of patients diagnosed with either oral or oropharynx cancer are more often known to develop cancer of the adjoining organs (or tissues) including larynx, oesophagus or lung. The chances of developing a second cancer in the oral region (oral cavity or pharynx) for survivors, at a later time during the life period is about 10% to 40%. Thus, a person once diagnosed with cancer of oral cavity has to undergo through follow up examinations for the rest of his or her life, even if cured completely. In addition, restraining from smoking tobacco and drinking alcohol will greatly facilitate in preventing the disease occurrence as tobacco use has been shown to be responsible for 90% of tumors of oral cavity in men and 60% among women.

Causes and symptoms

The major risk factors for oral and oropharyngeal cancers are smoking and **alcohol consumption**. These two factors account for 75% of all the oral cavity cancers reported in the United States. Smokeless tobacco (chew or spit tobacco) is yet another important cause for oral cancers. Each dip or chew of tobacco has been shown to contain 5 times more nicotine than one cigarette and 28 potential carcinogens. For lip cancer, exposure to sun may be one of the risk factors. Geographical factors and sexual differences also attribute to the risk factors of oral cancers. Men are twice as susceptible to oral cancers than women. While oral cancer is ranked sixth leading cancer among men in the United States, it is the fourth leading cancer in African American men. Age also seems to be a factor in the susceptibility of oral cancer. About 95% of oral cancer cases are diagnosed in people older than 45 years and the median age for diagnosis is 64 years. In addition to these factors, genetic predisposition may be one of the factors that should not be ignored in any type of cancer.

Many of the symptoms listed below may be of a less serious nature or related to other cancers. Common symptoms include:

- mouth sores that do not heal
- persistent pain in the mouth
- thickening in the mouth
- white or red patch on tongue, gums, tonsils or lining of the mouth
- sore throat
- difficulty in chewing or swallowing
- difficulty moving the jaw or tongue
- numbness of gums, tongue or any other area of the mouth
- swelling of the jaw
- loosening of the teeth
- voice changes
- **weight loss**
- feeling of lumpy mass in the neck

Any of the above symptoms that persists for more than a few weeks needs prompt medical attention.

Diagnosis

Routine screening or examination of oral cavity by a physician or a dentist is the key for early detection of oral and oropharyngeal cancers. Thorough self-examination is also highly recommended by physicians that may lead to an early diagnosis of abnormal growth in the oral cavity

or neck. If any of the signs outlined above suggests the presence of oral cancer, the physician may recommend additional tests or procedures to confirm the diagnosis. These may be one or more of the following factors.

Head and neck examination

In addition to thorough physical examinations, physicians attach special attention to the neck and head area. Highly sophisticated fiberoptic scopes are used to view the oropharynx after inserting a tube through the mouth or nose. Because of the risk of additional cancers in patients with oral cancers, other parts of the head and neck including nose, larynx, lymph nodes are carefully examined. Depending on the parts examined, the procedures are termed as pharyngoscopy, **laryngoscopy** or nasopharyngoscopy.

Panendoscopy

Depending on the risk factors, the surgeon may suggest further examination of oral cavity, oropharynx, larynx, esophagus, trachea and the bronchi. This overall examination called panendoscopy is done under general anesthesia to avoid discomfort to the patient and allow a thorough check-up of the neck and head regions. During this process, a **biopsy** of the suspected tissue is done to determine the severity of the cancer. The specimens used could be a scraping from the suspected area and smeared into a slide which is stained and viewed under the microscope. This technique is easy, inexpensive and offers information on the abnormal lesions. Incisional biopsy is the removal of a piece of small tissue from an area of the tumor. This is a relatively simple procedure and is performed either in the doctor's office or in the operating room depending upon the area of the tumor to be removed. The biopsy tissue samples are treated through various steps before the cells can be viewed under the microscope. Fine-needle aspiration (FNA) biopsy is the aspiration of fluid from a mass, lump or cyst in the neck. This would also include excisional biopsy. Depending upon the type of cells recognized in the aspiration, the pathologists can determine whether the cancer is related to neck or oral region or it has metastasized from a distant organ. FNA may also determine whether the neck mass is benign that resulted from any infection related to mouth or oropharynx.

Computed tomography (or Computer Axial tomography)

A sophisticated x-ray test that scans parts of body in cross-section. This procedure is carried out after administering a dye that can aid in locating abnormalities. This helps in judging the extent of cancer spread to lymph nodes, lower mandible and neck.

Magnetic resonance imaging (MRI)

This is used for evaluting soft tissue details such as the cancers of the tonsil and base of tongue and the procedure is governed by magnets and radio waves.

Panorex

This is a rotating **x ray** of upper and lower jawbones that determines changes that occur due to cancers in the oral cavity.

In addition to the imaging tests already noted, chest x rays help in checking for lung cancers in oral cancer patients with smoking habits. Barium swallow is a commonly performed series of x rays to assess the cancers of the digestive tract in patients with oral cancer. A radionulide bone scan may be suggested if there is concern that the cancer may have spread to the bones.

Other tests may include blood tests given to provide a complete blood analysis, including a determination of **anemia**, liver disease, kidney disease and RBC and WBC counts.

Treatment team

Cancer care team typically involves physician specialists to include, surgeon (oral or neck and head surgeon), a dentist (in cases of oral cancers), a medical oncologist and a radiation therapist.

Clinical staging, treatments, and prognosis

Clinical staging

TNM system of the American Joint Committee on Cancer has been followed in staging the cancer in which the size (T), spread to regional lymph nodes (N) and **Metastasis** to other organs (M) are classified.

T CLASSIFICATION

- Tx: Information not known and thus tumor cannot be assessed.
- T0: No evidence of primary tumor.
- Tis: Carcinoma in situ which means the cancer has affected the epithelial cells lining the oral cavity or the oropharynx and the tumor is not deep.
- T1: Tumor 2 cm (1 cm equals 0.39 inches) or smaller.
- T2: Tumor larger than 2 cm but smaller than 4 cm.
- T3:Tumor larger than 4 cm.
- T4: Tumor of any size that invades adjacent structures like larynx, bone, connective tissues or muscles.

N CLASSIFICATION

- Nx: Information not known, cannot be assessed.
- N0: No metastasis in the regional lymph node.
- N1: Metastasis in one lymph node on the same side of the primary tumor and smaller than 3cm.
- N2: Divided into 3 subgroups. N2a is metastasis in one lymph node larger than 3cm and smaller than 6cm. N2b is metastasis in multiple lymph nodes on the same side of tumor, none larger than 6cm. N2c denotes one or more lymph nodes, may or may not be on the side of primary tumor, none larger than 6 cm.
- N3: Metastasis in lymph node larger than 6cm.

M CLASSIFICATION

- Mx: Distant metastasis cannot be assessed, information not known.
- M0: No distant metastasis.
- M1: Distant metastasis present.

STAGE GROUPING

- Stage 0 (carcinoma in situ): Tis,N0,M0
- StageI: T1,N0,M0
- Stage II: T2,N0,M0
- Stage III: T3,N0,M0 or T1,N1,M0 or T2,N1,M0 or T3,N1,M0
- Stage IVA: T4,N0,M0 or T4,N1,M0 or Any T,N2,M0
- Stage IVB: Any T,N3,M0
- Stage IVC: Any T, any N,M1

Treatments

After the cancer is diagnosed and staged, the medical team dealing with the case will discuss the choice of treatment. This may be **chemotherapy** alone or in combination with **radiation therapy** or surgery. The treatment option is made depending upon the stage of the disease, the physical health of the patient, and after discussing the possible impact of the treatment on speech, swallowing, chewing, or general appearance.

SURGERY Primary tumor resection involves removal of the entire tumor with some normal adjacent tissue surrounding the tumor to ensure that all of the residual cancerous mass is removed. Partial mandible resection is carried out in cases where the jaw bone is suspected to have been invaded but with no evidence from x ray results. Full mandible resection is performed when the x rays indicate jaw bone destruction.

Maxillectomy is the removal of the hard palate if that is affected. A special denture called a prosthesis can alter the defect caused in the hard palate resulting from the surgery. Moh's surgery involves removal of thin sections of lip tumors. Immediate examination of the sections for potential cancer cells allows the surgeons to decide whether or not the cancer is completely removed.

Laryngectomy is the surgical removal of larynx (voice box). This is done when there is risk of food entering the trachea and infecting the lungs, as a result of removal of tumors of tongue or oropharynx. By removing the larynx, the trachea is attached to the skin of the neck thus eliminating the risk of infecting the lung and potential **pneumonia**.

Neck dissection is a surgical procedure involving removal of lymph nodes in the neck that are known to contain cancer cells. The side effects of this surgery include numbness of the ear, difficulty in raising the arm above the head, discomfort to the lower lip—all of which are caused by different nerves involved in the surgery.

Tracheostomy is an incision made in the trachea to facilitate breathing for oral cancer patients who may develop considerable swelling following surgical removal of the tumor in oral cavity. This prevents any obstruction in the throat and allows easy breathing.

In addition to the those surgical procedures, dental extractions and removal of large tumors in oral cancer patients may need reconstructive surgeries which may vary from one patient to the other depending upon the site and size of the tumors.

RADIATION THERAPY Use of high-energy rays to kill the cancer cells or reduce their growth is radiation therapy. It may be given as the only treatment of small tumors or given in combination with surgery to destroy deposits of cancer cells. Radiation is also suggested for relieving symptoms of cancer including difficulty in

KEY TERMS

Biopsy—Removal of a portion of tissue or cells for microscopic examination. Incisional biopsy is removal of only a sample tissue. Excisional biopsy is removal of entire tumor or lesion. Sample of tissue or fluid removed with a needle is fine-needle biopsy.

Lymph node—Bean-shaped mass of lymphatic tissue surrounded by connective tissue. These contain lymphocytes which are cells that helps in maintaining the immune system.

Close-up of large cancerous tumor on the tongue. *(Copyright Biophoto Associates, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

swallowing and bleeding. Radiation may be externally or internally administered. External radiation (also called external beam radiation therapy) delivers radiation to oral or oropharyngeal cancers from outside the body. Brachytherapy or internal radiation involves the surgical implant of metal rods that deliver radioactive materials in or near the cancer.

CHEMOTHERAPY Chemotherapy involves administering of anticancer drugs parenterally or orally. Chemotherapy may be suggested in combination with radiation therapy to avoid surgery in some large tumors of head and neck region. Some studies reveal that chemotherapy is ideal for shrinking the size of the tumor before surgery or radiation therapy is initiated. This is termed neoadjuvant chemotherapy.

Treatment choices by stage and prognosis

Depending on the stage of cancer spread, different treatment options are recommended for oral cancer.

Stage 0: Surgical stripping or thin resection is suggested at this stage where the cancer has not become invasive. If there is repeated recurrence, radiation therapy is an option. More than 95% of the patients at this stage survive for long-term without the requirement of any surgery of their oral cavity.

Stages I and II: Surgery or radiation therapy is the choice of treatment depending on the location of the tumor in the oral cavity and oropharynx.

Stages III and IV: A combination therapy of either surgery and radiation or radiation and chemotherapy or all the three types of treatment may be required for these advanced stages of cancer. About 20% to 50% of patients undergoing a combination of surgery and radiation for stages III and IV oral cavity and oropharyngeal cancers have the chances of five-year disease-free survival.

Alternative and complementary therapies

Various alternative medications are being tried periodically. While choosing any alternative therapy, a thorough discussion of the advantages and disadvantages of the suggested therapy with the medical team is highly recommended.

As of 2000, researchers had demonstrated that Bowman-Birk inhibitor, a protein found in soybeans shrinks leukoplakia or the precancerous growth in the mouth. The study has pointed to a reduction in the size of the leukoplakia to a third or half of the original size when the protein is orally administered for a month. The studies also suggest that a combination of soybean intake and termination of smoking tobacco will have a cumulative effect in the shrinking of leukoplakia. However, a thorough investigations in a larger patient population is necessary to confirm the therapeutic utility of the soybean protein in oral cancer.

Coping with cancer treatment

Cancer of any type is a psychologically distressful journey from the time of diagnosis, treatment and recovery. Coping with the side effects of treatment both physically and emotionally is a challenge to the patient, the family and the medical team. Oral cancers are further complicated by the fact that surgery most often leads to disfigurement which may be devastating in a society where importance is attached to physical appearance. Reconstruction surgeries or facial prostheses may be psychologically helpful and the cancer care team may advise on this issue. Laryngectomy or removal of the voice box leaves the person without speech, and breathing through stoma (in the neck). A stoma cover helps in hiding the mucus that the stoma secretes and also serves as a filter in the absence of nose's natural filter. The odors from the stoma can be prevented by use of cologne, and by avoiding strongly scented foods such as garlic. Studies reveal that lack of normal speech has a serious impact on sexual activity in couples. In addition to laryngectomy, surgery on the jaw, plate or tongue can also disrupt speech. These problems need to be discussed with the cancer care team or contact organizations such as the American Cancer Society who could provide relevant information on coping with specific issues on oral cancers.

Side effects of chemotherapy such as **fatigue** and hair loss (alopecia) may affect the quality of life in a

patient. A wig may be used for cosmetic purposes that can hide the hair loss. Studies have shown that patients may gradually regain their health after chemotherapy if they abstain from smoking and drinking.

Clinical trials

Evaluation of a potential treatment method for a disease on aselected patient population is called a clinical trial. Some of the ongoing **clinical trials** include:

- Paclitaxel and cisplatin for Stage III and IV of squamous cell carcinoma of the oral cavity following radiotherapy.
- Phase I study of intratumoral EGFR antisense DNA and DC chol liposomes in patients with advanced squamous cell carcinoma of oral cavity.
- Phase I immunotoxin therapy (PE38 immunotoxin) in treating patients with advanced lip and oral cavity cancer.
- Phase III megestrol acetate administration to patients undergoing cancer treatment for lip, oral cavity, and oropharyngeal cancers. This drug improves appetite and thus may prevent weight loss in cancer patients.
- Phase I combination of chemotherapy and radiation therapy in treating Stage III/IV lip, oral cavity, and **oropharyngeal cancer**. The drug tested is docetaxel.

Resources regarding these clinical trials, as well as many others regarding oral cancers, including any recruiting of patients for the trial are available at <Clinical Trials.gov.> which is a service of the National Cancer Institute, National Institutes of Health.

Prevention

Oral cavity and oropharyngeal cancer patients are at risk for recurrences, or for developing secondary cancers in the head and neck area. Thus a close follow-up is mandatory in the first couple of years following the indicence. A thorough examination every month in the first year, and at least every three months during the following year, and each year thereafter is the recommended schedule to facilitate early detection, if any. Various chemopreventive drugs are being tested to prevent the occurrence of secondary tumors in the neck and head region. Vitamin A analog is one such chemopreventive drug under investigation that may help in suppressing the tumor formation.

Tobacco (smoking, chewing, spitting) and alcohol consumption are the major causes of oral and oropharyngeal cancers. Public knowledge regarding the risk factors of the oral cancers and the signs of early detection is limited. Only 25% of U.S. adults can detect early signs of abnormal oral cavity; and only13% understand the implications of regular alcohol consumption in developing oral cancer. **Cancer prevention** and control programs are growing rapidly with screening services for high risk opulation, health promotion, education and intervention strategies. National Spit Tobacco Education Program (NSTEP), an initiative of Oral Health America, has been educating the public about dangers of spit tobacco and oral cancer.

Exposure to sun may cause **lip cancers**. Use of a lip balm will protect the lip from the sun rays. In addition, pipe smokers are more at risk for lip cancers.

QUESTIONS TO ASK THE DOCTOR

- What is oral cavity or oropharyngeal cancer?
- What is the extent of cancer spread beyond the primary site?
- What is the stage, and the severity of the stage?
- What are the treatment options available?
- What are the chances of survival,and the time frame of survival?
- What are the side of effects of treatment?
- What are the potential risks of specific treatments?
- How long will it take to recover from treatment?
- What are the chances of recurrence?
- What is the benefit of one treatment over the other in terms of recurrence?
- How to get ready for the treatment?
- Discuss the possibility of getting a second opinion.

Special concerns

Surgery for oral cancer treatment may affect normal speech and swallowing. A speech pathologist will educate, and suggest remedies for restoring speech and swallowing problems. In addition, a dietitian may be consulted for choosing the more palatable food in the advent of chewing and swallowing problems. In case of dryness, a saliva supplement can be recommended by a physician.

Advances in reconstructive surgery of the mouth and lower face in the early 2000s have significantly improved patients' appearance and quality of life after treatment for oral cancer.

The side effects of cancer treatment will make the patient fatiqued. Giving ample time to recover will help improve energy for the long-term. **Smoking cessation** and elimination of alcohol, and maintaining a balanced diet with fruits, vegetables, and whole grain are key to returning to a normal life for patients suffering from oral cancers.

Orchiectomy

Definition

Orchiectomy is a surgical procedure to remove one or both testes in men with prostate or **testicular cancer**. The procedure is sometimes called orchidectomy.

Purpose

In men who have **prostate cancer**, an orchiectomy, up until the 1990s, was considered the standard treatment. By removal of the testes, the influence of **testosterone**, the male hormone produced by the testes, is removed. Testosterone stimulates prostate cancer growth and progression of the disease.

Orchiectomy is done in men with testicular cancer to remove one or both testes that have cancer. By removing the cancerous testes, there will then be zero chance that the cancer can recur in the testes.

In children or in younger men, the surgeon may perform what is known as testis-sparing or testicular-sparing surgery, in which only the tumor is removed while the healthy testicular tissue is allowed to remain. According to one Canadian study of 51 boys between infancy and 16 years of age, testicular-sparing surgery is highly successful with regard to cancer control as well as tissue preservation.

Precautions

The orchiectomy operation is generally a very basic and safe operation. As in any surgery, some bleeding will be expected, so men should not be taking any medications like aspirin or ibuprofen that could decrease their blood's ability to clot.

Description

An orchiectomy usually takes place in a hospital setting, either in an outpatient surgery clinic or in the hospital itself. General presurgery procedures, such as

blood work, are done a few days to a week before the procedure.

To ensure that a patient having an orchiectomy does not suffer any pain, anesthetic will be used during the procedure. Generally, two types of anesthetic are used during an orchiectomy: general anesthesia and epidural anesthesia. General anesthesia causes the patient to go into a sleeplike state. With epidural anesthesia, the patient is awake but is totally numb from the waist down and therefore cannot feel the operation.

Once the patient is adequately anesthetized, the surgeon will make a four-inch incision through the lower abdomen. After the incision in the lower abdomen is made, the surgeon will gently push the testicles up through the inguinal canal and out through the incision.

The orchiectomy operation generally takes only 45 minutes to an hour. Patients either stay overnight in the hospital or are discharged from the hospital the same day if there appear to be no complications. Pain from the surgery is usually mild to moderate; narcotic pain medications can control the pain for most patients.

Preparation

There are no specific preparations for having an orchiectomy versus any other type of surgery. Blood will be taken before the surgery to check for infections or other contraindications to surgery. Patients are also advised not to take any medications such as aspirin or ibuprofen that may interfere with the blood's clotting ability.

Aftercare

For approximately two to four weeks or even longer, patients are advised not to participate in any strenuous physical activity. Pain in the scrotum and abdominal area may persist for days to weeks. The surgical wound site should be kept clean and dry. It should also be watched for any signs of infection, such as an increase in pain, unusual redness or swelling, or a foul-smelling discharge.

Risks

The risks of orchiectomy include such general surgical risks as pain, bleeding, and infection. In rare cases more serious complications could develop, including abscess formation and bladder damage.

Normal results

The goal of an orchiectomy is to remove the testicles without undue damage to any other organs or structures. For testicular cancer, the end result is to remove the cancerous testicle and cure the cancer. For prostate cancer,

KEY TERMS

Inguinal canal— A pair of internal openings that connect the abdominal cavity with the scrotum in the male fetus, allowing for the developing testes to descend into the scrotal sac.

Testes— The male sex organs that produce sperm and male sex hormones.

the end result is to remove the testicles to shut down the synthesis of testosterone, which is known to promote prostate cancer growth.

Abnormal results

Abnormal results of an orchiectomy can include incomplete removal of the testicles. In the case of both testicular cancer and prostate cancer, this could result in the progression of the cancer.

Oropharyngeal cancer

Definition

Oropharyngeal cancer is an uncontrolled growth of cells that begins in the oropharynx, the area at the back of the mouth.

Description

The oropharynx is the passageway at the back of the mouth. It connects the mouth to the esophagus (tube through which food passes) and to the pharynx (the channel for the flow of air into and out of the lungs). It takes its name from the way it ties the oral cavity (hence the oro) to the rest of the pharynx, one part of which extends toward the back of the nose (nasopharynx). The base of the tongue, the soft palate (the soft roof of the mouth, above the base of the tongue) and the tonsils are part of the oropharynx.

If the oropharynx is blocked or injured in any way, the condition presents a threat to life because it interferes with both eating and breathing. Thus, an obstruction caused by oropharyngeal cancer is in itself a problem. Oropharyngeal cancer also contributes to problems with chewing and talking because of the importance of the oropharynx in these activities. If the oropharyngeal cancer spreads to the bone, muscle, and soft tissue in the neck, there is a severe effect on the ability of the neck to support the head. In individuals with oropharyngeal cancer that has spread, surgical options might be limited.

Oropharyngeal cancer usually begins in the squamous cells of the epithelial tissue. The squamous cells are flat, and often layered. The epithelial tissue forms coverings for the surfaces of the body. Skin, for example, has an outer layer of epithelial tissue. Throughout the oropharynx there are some very small salivary glands and one of more of them sometimes becomes the site of tumor growth.

Many times cancer that begins in the oropharynx spreads to the base of the tongue. Oropharyngeal cancer can spread to the muscle and bone in the neck, and also to the soft tissue that fills the space around the muscle and bone.

Demographics

In the United States, about 4,000 cases of oropharyngeal cancer are diagnosed each year. Most of the cancer is found in people who are more than 50 years old. A history of tobacco or alcohol use, especially heavy use, is typically linked to the diagnosis. Men are three to five times more likely to be diagnosed than women.

Some benign tumors arise in the oropharynx. Although they are benign, many studies suggest the growths indicate the person is at greater risk for a malignant tumor growth in the future.

Causes and symptoms

The cause of oropharyngeal cancer is not known, but the risk factors for oropharyngeal cancer are understood. Three important lifestyle choices increase the chance a person will be diagnosed with cancer of the oropharynx. They are tobacco use, alcohol consumption, and certain sexual practices.

Anything that passes into the lungs or stomach through the nose and mouth must move through the oropharynx. (Air moves through the nasopharynx to reach the oropharynx.) Long periods of exposure to substances such as tobacco byproducts and alcohol somehow trigger cells to begin uncontrolled growth, cancer. About 90 percent of all cancer of the oropharynx starts in a squamous cell.

Since tobacco and alcohol come into direct contact with the squamous cells of the oropharynx as they move through the cavity, they might change the genetic material (DNA) of cells. If a cell cannot repair damage to DNA, a cancerous growth can begin.

A serious interaction occurs between tobacco and alcohol. Individuals who smoke and drink alcoholic beverages are at much greater risk for oropharyngeal cancer. They have as much as 30 times or 40 times the normal risk. The estimate is difficult to make because not all individuals diagnosed are accurate in the statements they make to physicians about their use of these substances. Patients often say they used less tobacco or less alcohol than they actually did.

Viral infection increases the risk of oropharyngeal cancer. So does reduced immunity, which is a condition that may be caused by viral infection. Individuals with human papilloma viruses, which are sexually transmitted, are known, as of 2004, to be at greater risk, particularly those infected by HPV-16. The virus increases a person's risk of cancer because it inactivates the TP53 gene, which regulates the cycle of cell division by keeping cells from dividing in an uncontrolled fashion. The specific sexual practices associated with an increased risk of oropharyngeal cancer include a high lifetime number of sexual partners, oral-gential sex, and oral-anal sex.

Marijuana seems to be linked with oropharyngeal cancer too. Vitamin A deficiency, or specifically, the absence of the carotene (from fruits and vegetables) that the body uses to make vitamin A, might also be a contributing factor.

Symptoms of oropharyngeal cancer include:

- difficulty swallowing
- difficulty chewing
- change in voice
- loss of weight
- lump in the throat
- lump in the neck

Diagnosis

Cells grow old and flake off regularly from epithelial tissues. The first step in diagnosing oropharyngeal cancer often makes use of the natural process. It is given the name exfoliative **cytology**. A physician scrapes cells from the part of the oropharynx where a cancer is suspected and smears them on a slide. The cells are then treated with chemicals so they can be studied with a microscope. If they do not appear normal, a **biopsy**, or a tissue sample from a deeper layer of cells, is taken for examination.

Different sorts of biopsies are used. An incision, or cut, is be made to obtain tissue. Or, a needle with a small diameter is inserted into the neck to obtain cells, especially if there is a lump in the neck.

Computed tomography (CT) and **magnetic resonance imaging** (MRI) scans are also used. They help determine whether the cancer has spread from the walls of the oropharynx. MRI offers a good way to examine the tonsils and the back of the tongue, which are soft tissues. CT is used as a way of studying the jaw, which is bone.

Many extremely specialized means of determining the condition of the oropharynx have been developed. One of them relies on the same sort of light wave technology that now powers much of the communications world, fiberoptics. A fiber (a bundle of glass fibers, actually) with a very small diameter is inserted in the oropharynx and the area is probed with light that is reflected on mirrors for interpretation. Lighting up the oropharynx with the high intensity, very low heat illumination of fiberoptics, a physician can get a good look at the cavity.

Another special way of getting a good look at the oropharynx involves studying it from within by inserting an endoscope into the oropharynx and then, weaving it through adjacent connecting structures. The structures include the trachea, the bronchi, the larynx and the esophagus. The patient is given an anesthetic, local or general, for this procedure. When several organs are examined at the same time, the procedure is called a

panendoscopy. The tool used is generally named for the organ for which it is most closely designed. For example, there is a laryngoscope.

Because oropharyngeal cancer often spreads, bones near the oropharynx must be examined carefully. Some special types of equipment are used. A rotating **x ray** called panorex provides for close inspection of the jaw.

Oropharyngeal cancer also spreads to the esophagus, so physicians usually examine the esophagus when they diagnose oropharyngeal cancer. To do so, they ask the patient to drink a liquid containing barium, a chemical that can be seen on x rays. Then, they can x ray the esophagus and look for bulges or lumps that indicate cancer there.

Treatment team

Generally, physicians with special training in the organs of the throat take responsibility for the care of a patient with oropharyngeal cancer. They are called otolaryngologists or occasionally by a longer name, otorhinolaryngologists.

In abbreviation, otolaryngologists are usually labeled ENT (for Ear, Nose and Throat) specialists. An ENT specializing in cancer will probably lead the team. Some ENTs have a specialty in surgery. Some have a specialty in oncology. Some have a specialty in both.

Nurses, as well as a nutritionist, speech therapist and social worker will also be part of the team. Depending on the extent of the cancer when diagnosed, some surgery and treatments result in extensive changes in the throat, neck and jaw. The social worker, speech therapist and nutritionist are important in helping the patient cope with the changes caused by surgery and radiation treatment. If there is great alteration to the neck because of surgery, rehabilitation will also be part of the recovery process and a rehabilitation therapist will be added to the team.

The treatment team may also include a psychiatrist, as patients with oropharyngeal cancer have extremely high rates of depression compared with other cancer patients. A study carried out at Memorial Sloan-Kettering Cancer Center in New York reported in 2004 that as many as 57% of patients with oropharyngeal cancer suffer an episode of major depression, compared to 50% of pancreatic cancer patients, 46% of breast cancer patients, and 44% of lung cancer patients.

Clinical staging, treatments, and prognosis

Stage 0 indicates some cells with the potential to grow erratically are discovered. But the cells have not multiplied beyond the surface layer of the epithelial tissue of the oropharynx. Stage I describes a cancer less than approximately 2.5 cm (about one inch in diameter) that has not spread. Stage II describes a bigger cancer, up to about 5 cm. (about two inches), that has not spread.

Stage III oropharyngeal cancer is either larger than two inches or has spread to one lymph node. The lymph node is enlarged but not much larger than an inch.

In Stage IV, one or more of several things happens. There is either a spread of cancer to a site near the original site. Or, there is more than one lymph node with cancer. Or, the cancer has spread to other parts of the body, such as the larynx, the trachea, the bronchi, the esophagus, or even more distant points, such as the lungs.

The outlook for recovery from oropharyngeal cancer is better the earlier the stage in which the cancer is diagnosed. For stage I and stage II, surgical removal or radiation therapy of the affected area is sometimes all that is required to halt the cell growth. Decisions about which method to use depend on many factors. The tolerance a patient has for radiation or **chemotherapy**, and the size of the tumor are crucial to the decision process.

Surgical removal can interfere with speech, eating and breathing. So, if nonsurgical treatment is an option, it is a good one to try. The larger the tumor, the more urgent is its removal. Smaller tumors can be treated with radiation or chemotherapy to shrink them before surgery. Some smaller tumors can be removed completely with a carbon dioxide laser. In some cases, surgery might be avoided. For stage III cancer with lymph node involvement, the lymph nodes with the cancer are also removed.

Chemotherapy might be used at any stage, but it is particularly important for stage IV cancer. In some cases, chemotherapy is used before surgery, just as radiation is, to try to eliminate the cancer without cutting, or at least to make it smaller before it is cut out (excised). After surgery, **radiation therapy** and chemotherapy are both used to treat patients with stage IV oropharyngeal cancer, sometimes in combination. Treatments vary in Stage IV patients depending on the extent of the spread.

Some tumors are so large they cannot be completely removed by surgery. Often, the most promising treatment option for a person with such a tumor is a clinical trial. One technique that has had some success with recurrent or advanced oropharyngeal tumors is radiofrequency ablation. In radiofrequency ablation, the tumor is heated by the application of 90–150 watts of energy to an internal temperature of 60–110°C (140–230°F) for a period of 5–15 minutes.

Besides categories, or stages, that indicate how far the disease has progressed, there are many categories that are used to describe the kind, or grade, of tumor. The

grades take into account such factors as the density of a tumor. Eventually, physicians hope information about tumor grade will make it possible to match treatment and condition very precisely.

Coping with cancer treatment

The patient should be an active member of the treatment team, listening to information and making decisions about which course of treatment to take. Premier cancer centers encourage such a role.

Prior to surgery, discuss the need for a way to communicate if speech is impaired after surgery. A pad and pencil might be all that are needed for a short interval. If there will be a long period of difficulty, the patient should be ready with other means, including special phone service.

A change in appearance after the removal of part of the oropharynx, whether part of the tongue or soft palate or some other portion, can lead to concerns about **body image**. Social interaction might suffer. A support group can help. Discussions with a social worker also can be beneficial.

If any part of the oropharynx is removed, speech therapy might be necessary to relearn how to make certain sounds. If the surgery requires the removal of some or all of the tongue, a person's speech will be greatly impaired.

Appetite might be affected before, during and after treatment. Before treatment, the presence of a tumor can interfere with chewing and swallowing food, and food might not seem as appealing as it once did. During treatment, particularly radiation treatment, the treated oropharynx will be sore and eating and breathing will be difficult, or impossible.

In some cases, a patient requires a feeding tube (inserted at the opening of the esophagus, through the mouth), a stomach tube (inserted directly in the stomach, if there is no access to the opening of the esophagus) or a breathing tube (inserted directly in the trachea) for some interval of time. The tubes bypass the normal entryways to the stomach and lungs. Liquid food is put directly into the esophagus or stomach. Air is taken directly into the trachea during breathing. The incision or cut in the trachea is called a tracheotomy and the opening in the neck around the trachea is a tracheostomy. Air that enters the trachea directly is not warmed or moistened, and the dry, cold air in the lungs can lead to respiratory complications. Attachments are now available that are positioned at the opening in the neck and filter and add moisture to the air entering the tracheal tube. Learning how to care for the tracheotomy and tracheostomy, how to keep the openings clean and what to do if the tube pops out, relieves anxiety and improves ease of breathing.

After treatment, a loss of sensation in the part of the oropharynx affected, or a loss of part of the tongue or the jaw, can reduce appetite. A nutritionist can help with supplements for people who experience significant **weight loss** and who do not have an appetite (anorexia).

Patients who are dependent on tobacco or alcohol products and want to reduce or eliminate their intake, will have to deal with the psychological effects of substance withdrawal in addition to the side-effects from treatment. A support group for tobacco or alcohol dependence might be considered, and joined before treatment begins.

Clinical trials

There are a number of **clinical trials** in progress. For example, the better researchers understand the nature of cancer cells, the better they are able to design drugs that attack only cancer cells. Or, in some cases, drugs that make it easier to kill cancer cells have also been designed.

The Cancer Information Service at the National Institutes of Health, Bethesda, Md., offers information about clinical trials that are looking for volunteers. The Service offers a toll-free number at 1-800-422-6237.

Prevention

Avoiding smoking, drinking alcohol, and having oral sex with a large number of partners are important in the prevention of oropharyngeal cancer. Including lots of fruits and vegetables in the diet is also an important step to preventing cancer. (Even though the importance of fruits and vegetables is not proven to prevent oropharyngeal cancer, overall fruits and vegetables are demonstrated cancer fighters.) Carotene, which the body uses to make vitamin A, seems to be important in the diet of people who are less likely to be diagnosed with oropharyngeal cancer. Any precaution that is taken to avoid contracting sexually transmitted diseases, such as the use of condoms, also offers protection from oropharyngeal cancer.

Special concerns

Growths sometimes develop in the oropharynx that are not cancerous. The benign tumors can be removed by surgery. They usually do not recur. The surgeon should be able to give a patient an accurate appraisal identifying the noncancerous growth, and whether it is likely to indicate future problems.

KEY TERMS

Biopsy—Tissue sample is taken from body for examination.

Bronchi—Branches of the trachea that distribute air to the air sacs (alveoli) of the lungs.

Computed tomography (CT)—X rays are aimed at slices of the body (by rotating equipment) and results are assembled with a computer to give a three-dimensional picture of a structure.

Endoscope—Instrument designed to allow direct visual inspection of body cavities, a sort of microscope in a long access tube.

Fiberoptics—Cool, refracted (bounced) light passes (bounces) along extremely small diameter glass tubes. (Used to illuminate body cavities, such as the oropharynx, with high intensity, and almost heatless light.)

Larynx—Commonly known as the voice box, the place between the pharynx and the trachea where the vocal cords are located.

Magnetic resonance imaging (MRI)—Magnetic fields and radio frequency waves are used to take pictures of the inside of the body.

Salivary glands—Structures in the mouth that make and release (secrete) saliva that helps with digestion.

Tonsils—Lymph nodes in the throat that are partly encapsulated (enclosed). They are components of the lymphatic system that functions in immunity and removes the excess fluid around cells and returns it to cells.

Trachea—Tube ringed with cartilage that connects the larynx with the bronchi.

Oropharyngeal cancer frequently recurs in patients who have been treated for the condition. Thus, after treatment, patients must be examined monthly for one year. They also must be committed to telling their physician if they notice any changes. By the second year, examinations can be at two-month intervals; and then, three-month intervals by the third year and six-month intervals beyond that.

Mouthwash has been suspected as a cancer-causing agent for oropharyngeal cancer. Studies are not conclusive. One line of reasoning suggests alcohol-based mouthwashes add to the effects of alcohol consumed by heavy drinkers. Alcohol-based mouthwashes can be avoided.

QUESTIONS TO ASK THE DOCTOR

- In which stage is the cancer?
- What is the outlook for a patient with my profile?
- What are the side effects of the treatments that are recommended? Which treatment gives the best combination of survival and quality of life?
- Is there a clinical trial for which I am eligible?

Osteosarcoma

Definition

Osteosarcoma, also called osteogenic **sarcoma**, is a type of cancer that develops from bone. Osteosarcoma is destructive at its original area and is likely to spread to other parts of the body.

Description

Osteosarcoma is a malignant (cancerous) tumor that arises from bone itself, and is thus called a primary bone cancer. Primary bone cancers are relatively rare overall. Approximately 2,400 new cases of osteosarcoma occur in the United States every year.

Osteosarcoma occurs most frequently during childhood or adolescence. About 60% of cases of this disease develop during the second decade of life. The incidence of osteosarcoma rises again among people in their 40s and 50s.

Osteosarcoma may occur in any bone, but develops most commonly in long bones, particularly near the knee or in the upper arm. The cancer starts growing within a bone and forms an expanding, ball-like mass. The tumor eventually breaks through the surface of the bone and begins to invade adjoining structures such as muscles. If untreated, the disease usually appears elsewhere in the same limb and metastasizes to distant parts of the body, such as the lungs.

Causes and symptoms

There are numerous theories regarding the causes of osteosarcoma. Many cases occur during a time of rapid bone growth, as in teenagers or people with Paget's disease. This suggests that the cancer may develop when the body loses its ability to control the multiplication of certain bone cells. Some cases of osteosarcoma are likely to have a genetic basis, and numerous genetic abnormalities have been found in patients with osteosarcoma. Osteosarcoma is also the most common second cancer to develop in survivors of **retinoblastoma**, a cancer of the eye that often has a genetic cause. Other cases arise in people who have been exposed to radiation, either accidentally or as part of a medical treatment.

The most common early symptoms of osteosarcoma are often vague. There may be pain or swelling at the site of the tumor, but these symptoms initially may not seem serious in a young, active person. Thus, the patient or medical personnel may attribute the symptoms to growing pains, or an injury from sports, for example, and the diagnosis may be delayed. Eventually, it is usually possible to feel a firm lump on the bone, and this lump will be uncomfortable to the touch.

Diagnosis

The complete diagnosis of osteosarcoma is a complicated process, requiring a variety of tests and the help of several types of medical specialists. Physicians must determine the stage of the cancer (the extent to which it has spread), and the grade of the cancer (the degree of cancerous qualities shown by its cells in a **biopsy** specimen). A higher grade or stage indicates a more serious disease than does a lower grade or stage.

Initial diagnosis begins with x-ray images of the affected area. These pictures will show a destructive growth within the bone, which is often described as having a "moth-eaten appearance". The patient then requires further imaging tests such as **computed tomography** (CT, CAT) or magnetic resonance (MR, MRI) scans of the tumor, a chest x-ray series or chest CT, and a nuclear medicine scan of the entire skeleton (bone scan). Blood tests, such as measurements of alkaline phosphatase (alk phos) provide additional information. These tests all help determine the stage of the cancer.

Finally, physicians require a biopsy sample of the diseased bone, obtained with a needle or by a surgical procedure, to be sure that the disease is truly cancer and to identify its grade. There are numerous tests, mostly involving examinations under the microscope, to perform on this biopsy specimen.

Treatment and prognosis

Before the 1980s, limb **amputation** was the standard treatment for osteosarcoma. Usually, however, the tumor had already spread elsewhere in the body and the patient eventually died of the disease. Overall results were dismal.

KEY TERMS

Alkaline phosphatase (Alk phos)—A body protein, measurable in the blood, that often appears in high amounts in patients with osteosarcoma. However, many other conditions also elevate the level of alkaline phosphatase.

Chemotherapy—A type of treatment for cancer that attempts to kill tumor cells with doses of powerful, often toxic, chemicals.

Grade—As a noun: a classification of the cancerous qualities of an individual tumor. A higher grade indicates a more serious disease than does a lower grade. As a verb: to classify the cancerous qualities of an individual tumor.

Malignant—Cancerous.

Metastasize—To spread to another part of the body.

Monoclonal antibody—A protein, produced in large quantities in a laboratory, designed to attack a specific target in the body.

Osteogenic—Creating bone.

Osteogenic sarcoma—Osteosarcoma.

Paget's disease—A non-cancerous disease marked by excessive growth of abnormal bone material.

Retinoblastoma—A cancerous tumor of the eye.

Stage—As a noun - the extent to which an individual cancer has spread. A higher stage indicates a more serious disease than does a lower stage. As a verb - to determine the extent to which an individual cancer has spread.

Tumor—An abnormal growth of cells in the body. Tumors may be benign (non-cancerous) or malignant.

Newer medical developments make it possible to avoid amputation and yet treat many patients with osteosarcoma successfully. Patients almost always receive **chemotherapy** with more than one drug (multi-drug therapy) before surgery to shrink the original cancer and reduce the likelihood of spread to other areas. Techniques known as limb-sparing surgery often allow removal of the tumor while saving the rest of the extremity. Afterward, patients usually continue to receive chemotherapy, and may require bone grafts or prosthetic devices to replace parts of bones or joints that have been removed.

Future treatments under investigation include **monoclonal antibodies** that destroy specific cancer cells, techniques to slow cancer growth by controlling certain cellular genes, and bone-seeking substances that directly target areas of active bone growth.

Alternative and complementary therapies

Current treatments with chemotherapy and surgery offer a substantial improvement over past therapies. Radiation treatment has not been effective. Complementary and alternative medicine techniques may improve a patient's sense of well-being but will not cure this destructive type of cancer.

Prognosis

Prognosis for an individual patient reflects a complex balance among the extent to which the cancer has already spread at the time of diagnosis, the aggressiveness of the cells within the cancer, and the response to chemotherapy. Early detection is extremely important. The best chance of cure occurs when a tumor shows no sign of **metastasis** at the time of original surgery, is well-confined within a single bone and is completely removed, and responds well to chemotherapy. The five-year survival rate for osteosarcoma in a long bone of a limb is about 70%. All patients must be followed closely by a physician to watch for cancer recurrence.

Prevention

Prevention of osteosarcoma is difficult since doctors do not know the cause of most cases. Perhaps research eventually will make prevention possible. Early detection of the disease remains vital. Anyone with persistent pain in a bone or limb should report this to a physician. People with special risk factors including Paget's disease, exposure to significant amounts of radiation, or a family history of certain types of cancer must be especially vigilant.

Ovarian cancer

Definition

Ovarian cancer is cancer of the ovaries, the egg-releasing and hormone-producing organs of the female reproductive tract. Cancerous, or malignant, cells divide and multiply in an abnormal fashion.

Description

The ovaries are small, almond-shaped organs, located in the pelvic region, one on either side of the uterus. When a woman is in her childbearing years, the ovaries alternate to produce and release an egg each month during the menstrual cycle. The released egg is picked up by the adjacent fallopian tube, and continues down towards the uterus. The ovaries also produce and secrete the female hormones estrogen and progesterone, which regulate the menstrual cycle and pregnancy, as well as support the development of the secondary female sexual characteristics (breasts, body shape, and body hair). During pregnancy and when women take certain medications, such as oral contraceptives, the ovaries are given a rest from their usual monthly duties.

Types of ovarian cancers

Ninety percent of all ovarian cancers develop in the cells lining the surface, or epithelium, of the ovaries and so are called epithelial cell tumors. About 15% of epithelial cancers are considered low malignant potential or LMP tumors. These tumors occur more often in younger women, and are more likely to be caught early, so prognosis is good.

Germ cell tumors develop in the egg-producing cells of the ovary, and comprise about five percent of ovarian tumors. These tumors are usually found in teenage girls or young women. The prognosis is good if found early, but as with other ovarian cancers, early detection is difficult.

Primary peritoneal **carcinoma** (PPC) is a cancer of the peritoneum, the lining of the abdominal cavity where the internal organs are located. Although it is a distinct disease, it is linked with ovarian cancer. This is because the ovarian and peritoneal cells have the same embryonic origin. This means that the very early cells of the embryo that will ultimately develop into the ovaries and the peritoneum share a common origin. The term *primary* means that the cancer started first in the peritoneum, as opposed to the cancer starting in the ovary and then moving, or metastasizing, into the peritoneum.

Demographics

Ovarian cancer can develop at any age, but is most likely to occur in women who are 50 years or older. More than half the cases are among women who are aged 65 years and older. Industrialized countries have the highest incidence of ovarian cancer. Caucasian women, especially of Ashkenazi Jewish descent, are at somewhat higher risk; African-American and Asian women are at a slightly lower risk. The risk of developing the disease increases with age. Ovarian cancer is the fourth most common cancer among women in the United States, and the second most common gynecologic cancer. It accounts for 4% of all cancers in women. However, because of poor early detection, the death rate for ovarian cancer is higher than for that of any other cancer among women. About 1 in 70 American women will develop ovarian cancer during her lifetime, and 1 in 100 will die from it. The American Cancer Society estimates about 26,000 new cases of ovarian cancer in 2004 in the United States, and about 16,000 deaths.

Only 50% of the women who are diagnosed with ovarian cancer will survive five years after initial diagnosis. This is due to the cancer being at an advanced stage at the time of diagnosis. With early detection, however, survival at five years post diagnosis may be 95%.

Causes and symptoms

Causes

The actual cause of ovarian cancer remains unknown, but several factors are known to increase one's chances of developing the disease. These are called risk factors. Women at a higher risk than average of developing ovarian cancer include women who:

- have never been pregnant or had children
- are Caucasian, especially of Northern European or Askenazi Jewish descent
- are over 50. Half of all diagnosed cases are in women over 65.
- have a family history of breast, ovarian, endometrial (uterine), prostate or colon cancer
- have had **breast cancer**
- have a first-degree relative (mother, daughter, sister) who has had ovarian cancer. (The risk is greater if two or more first-degree relatives had the disease. Having a grandmother, aunt or cousin with ovarian cancer also puts a woman at higher-than-average risk.)
- have the genetic mutation BRCA1 or BRCA2. (Not all women with these genetic breast cancer mutations will develop ovarian cancer. By age 70, a woman who has

the BRCA1 mutation carries about a 40–60% risk of developing ovarian cancer. Women with the genetic mutation BRCA2 have a 15% increased risk of developing ovarian cancer. However, heredity only plays a role in about 5–10% of cases of ovarian cancer.)Women who have a strong familial history may benefit from genetic counseling to better understand their risk factors.

In addition to the above risk factors, the following factors appear to play a role in affecting a women's chances of developing ovarian cancer.

REPRODUCTION AND HORMONES. Early menstruation (before age 12) and late menopause seem to put women at a higher risk for ovarian cancer. This appears to be because the longer, or more often, a woman ovulates, the higher her risk for ovarian cancer. As mentioned above, women who were never pregnant have a higher risk of developing the disease than women with one or more pregnancies. It is not yet clear from research studies whether a pregnancy that ends in miscarriage or stillbirth lowers the risk factor to the same degree as the number of term pregnancies. The use of post-menopausal estrogen supplementation for 10 years or more may double a woman's risk of ovarian cancer. Short-term use does not seem to alter one's risk factor.

INFERTILITY DRUG-STIMULATED OVULATION. Research studies have reported mixed findings on this issue. It appears that women who take medications to stimulate ovulation, yet do not become pregnant, are at higher risk of developing ovarian cancer. Women who do become pregnant after taking fertility drugs do not appear to be at higher risk. One study reported that the use of the fertility drug clomiphene citrate for more than a year increased the risk of developing LMP tumors. LMP tumors respond better to treatment than other ovarian tumors.

TALC. The use of talcum powder in the genital area has been implicated in ovarian cancer in many studies. It may be because talc contains particles of asbestos, a known carcinogen. Female workers exposed to asbestos had a higher-than-normal risk of developing ovarian cancer. Genital deodorant sprays may also present an increased risk. Not all studies have brought consistent results.

FAT. A high-fat diet has been reported in some studies to increase the risk of developing ovarian cancer. In one study the risk level increased with every 10 grams of saturated fat added to the diet. This may be because of its effect on estrogen production.

Symptoms

Most of the literature on ovarian cancer states that there are usually no early warning symptoms for the disease. Ovarian cancer is often referred to as a silent killer, because women either are unaware of having it, or have symptoms that are not accurately diagnosed until the disease is in an advanced state. However, a November 2000 study reported in the medical journal *Cancer* analyzed more than 1,700 questionnaires completed by women with stage III and stage IV ovarian cancer. The researchers found that 95% of the women reported having had early symptoms that they brought to their doctors. Most symptoms were somewhat vague and either abdominal or gastrointestinal in nature, and consequently were either not properly diagnosed or were recognized as being ovarian in nature only after a significant length of time had passed.

The following symptoms are warning signs of ovarian cancer, but could also be due to other causes. Symptoms that persist for two to three weeks, or symptoms that are unusual for the particular woman should be evaluated by a doctor right away.

- digestive symptoms, such as gas, indigestion, constipation, or a feeling of fullness after a light meal
- bloating, distention or cramping
- abdominal or low-back discomfort
- pelvic pressure or frequent urination
- unexplained changes in bowel habits
- nausea or vomiting
- pain or swelling in the abdomen
- loss of appetite (anorexia)
- **fatigue**
- unexplained weight gain or loss
- pain during intercourse
- vaginal bleeding in post-menopausal women

Diagnosis

In the best-case scenario a woman is diagnosed with ovarian cancer while it is still contained in just one ovary. Early detection can bring five-year survival to near 95%. Unfortunately, about 75% of women (3 out of 4) have advanced ovarian cancer at the time of diagnosis. (Advanced cancer is at stage III or stage IV when it has already spread to other organs.) Five-year survival for women with stage IV ovarian cancer may be less than 5%.

Diagnostic tests and techniques

If ovarian cancer is suspected, several of the following tests and examinations will be necessary to make a diagnosis.

- a complete medical history to assess all the risk factors
- a thorough bi-manual pelvic examination
- CA-125 assay
- one or more various imaging procedures
- a lower GI series, or **barium enema**
- diagnostic laparoscopy

BI-MANUAL PELVIC EXAMINATION The exam should include feeling the following organs for any abnormalities in shape or size: the ovaries, fallopian tubes, uterus, vagina, bladder, and rectum. Because the ovaries are located deep within the pelvic area, it is unlikely that a manual exam will pick up an abnormality while the cancer is still localized. However, a full examination provides the practitioner with a more complete picture. An enlarged ovary does not confirm cancer, as the ovary may be large because of a cyst or endometriosis. While women should have an annual **Pap test**, this test screens for **cervical cancer**. Cancerous ovarian cells, however, might be detected on the slide. Effectiveness of using Pap smears for ovarian cancer detection is about 10-30%.

CA-125 ASSAY This is a blood test to determine the level of CA-125, a biomarker or tumor marker. A tumor marker is a measurable protein-based substance given off by the tumor. A series of CA-125 tests may be done to see if the amount of the marker in the blood is staying stable, increasing or decreasing. A rising CA-125 level usually indicates cancer, while a stable or declining value is more characteristic of a cyst. The CA-125 level should never be used alone to diagnose ovarian cancer. It is elevated in about 80% of women with ovarian cancer, but in 20% of cases is not. In addition, it could be elevated because of a non-ovarian cancer, or it can be elevated with non-malignant gynecologic conditions, such as endometriosis or ectopic pregnancy. During menstruation the CA-125 level may be elevated, so the test is best done when the woman is not having her menstrual period.

IMAGING There are several different imaging techniques used in ovarian cancer evaluation. A fluid-filled structure such as a cyst creates a different image than does a solid structure, such as a tumor. An ultrasound uses high-frequency sound waves that create a visual pattern of echoes of the structures at which they are aimed. It is painless, and is the same technique used to check the developing fetus in the womb. Ultrasound may be done externally through the abdomen and lower pelvic area, or with a transvaginal probe.

Other painless imaging techniques are **computed tomography** (CT) and **magnetic resonance imaging** (MRI). Color Doppler analysis provides additional contrast and accuracy in distinguishing masses. It remains unclear whether Doppler is effective in reducing the high number of false-positives with transvaginal **ultrasonography**. These imaging techniques allow better visualization of the internal organs and can detect abnormalities without having to perform surgery.

LOWER GI SERIES A lower GI series, or barium enema, uses a series of x rays to highlight the colon and rectum. To provide contrast, the patient drinks a chalky liquid containing barium. This test might be done to see if the cancer had spread to these areas.

DIAGNOSTIC LAPAROSCOPY This technique uses a thin hollow lighted instrument inserted through a small incision in the skin near the belly button to visualize the organs inside of the abdominal cavity. If the ovary is believed to be malignant, the entire ovary is removed (**oophorectomy**) and its tissue sent for evaluation to the pathologist, even though only a small piece of the tissue is needed for evaluation. If cancer is present, great care must be taken not to cause the rupture of the malignant tumor, as this would cause spreading of the cancer to adjacent organs. If the cancer is completely contained in the ovary, its removal functions also as the treatment. If the cancer has spread or is suspected to have spread, then a saline solution may be instilled into the cavity and then drawn out again. This technique is called peritoneal lavage. The aspirated fluid will be evaluated for the presence of cancer cells. If peritoneal fluid is present, called **ascites**, a sample of this will also be drawn and examined for malignant cells. If cancer cells are present in the peritoneum, then treatment will be directed at the abdominal cavity as well.

RESEARCH AND NEW DIAGNOSTIC TESTS Many cancer researchers recognize the urgency of developing a new diagnostic test for ovarian cancer that is both sensitive and reliable. Some experts in the field look to proteomics, which is the large-scale identification and analysis of all the proteins in an organism or organ, to lead eventually to the development of a useful new test for ovarian cancer.

A group of researchers in Canada reported in 2003 that human kallikrein gene 14 (KLK14) might serve as a new biomarker for ovarian cancer. Kallikreins are a group of compounds that help to split up complex protein molecules into smaller units; prostate-specific antigen, or PSA, is a kallikrein. Early results of tests for KLK14 indicate that about 65% of women known to have ovarian cancer have elevated levels of this kallikrein.

Treatment team

A woman's treatment team may consist of her primary care physician, her gynecologist/surgeon, a

medical oncologist, a gynecologic oncologist, and a radiation oncologist. Professionals to address her psychological needs may also be part of the team, such as a medical social worker or a psychiatric nurse specializing in oncology. A case coordinator may also participate, as may individuals to address her spiritual and/or mind/body needs. The purpose of the team, versus seeing the various specialists independently, is to coordinate the care, treatments and appointments between the different team members. This allows all team members to know what everyone is doing, to coordinate appointments to minimize fatigue, and to make sure the physical, psychological, and spiritual needs of the patient are being addressed to the fullest degree possible.

Clinical staging, treatment, and prognosis

Clinical staging

Staging is the term used to determine if the cancer is localized or has spread, and if so, how far and to where. Staging helps define the cancer, and will determine the course of suggested treatment. Staging involves examining any tissue samples that have been taken from the ovary, nearby lymph nodes, as well as from any nearby organs or structures where **metastasis** was suspected. This may include the diaphragm, lungs, stomach, intestines and omentum (the tissue covering internal organs), and any fluid as described above.

The National Cancer Institute Stages for ovarian cancer are:

- Stage I: Cancer is confined to one or both ovaries.
- Stage II: Cancer is found in one or both ovaries and/or has spread to the uterus, fallopian tubes, and/or other body parts within the pelvic cavity.
- Stage III: Cancer is found in one or both ovaries and has spread to lymph nodes or other body parts within the cavity, such as the surfaces of the liver or intestines.
- Stage IV: Cancer is found in one or both ovaries and has spread to other organs such as the liver or lung.

The individual stages are also further broken down in detail, such as Ia, Ib, etc. Accurate staging is important for several reasons. Treatment plans are based on staging, in part because of trying to duplicate the best results achieved in prior research trials. When staging is inconsistent, it becomes more difficult to know how different research studies compare, so the results themselves cannot be relied upon.

Treatment

Treatment offered will primarily depend on the stage of the cancer and the woman's age. It is always appropriate to consider getting a second opinion, especially when treatment involves surgery, **chemotherapy**, and possible radiation. Before the patient makes her decision as to which course of treatment to take, she should feel that she has the information necessary with which to make an informed decision. The diagnostic tools mentioned above are used to determine the course of treatment. However, the treatment plan may need to be revised if the surgeon sees that the tumor has spread beyond the scope of what was seen during diagnostic tests.

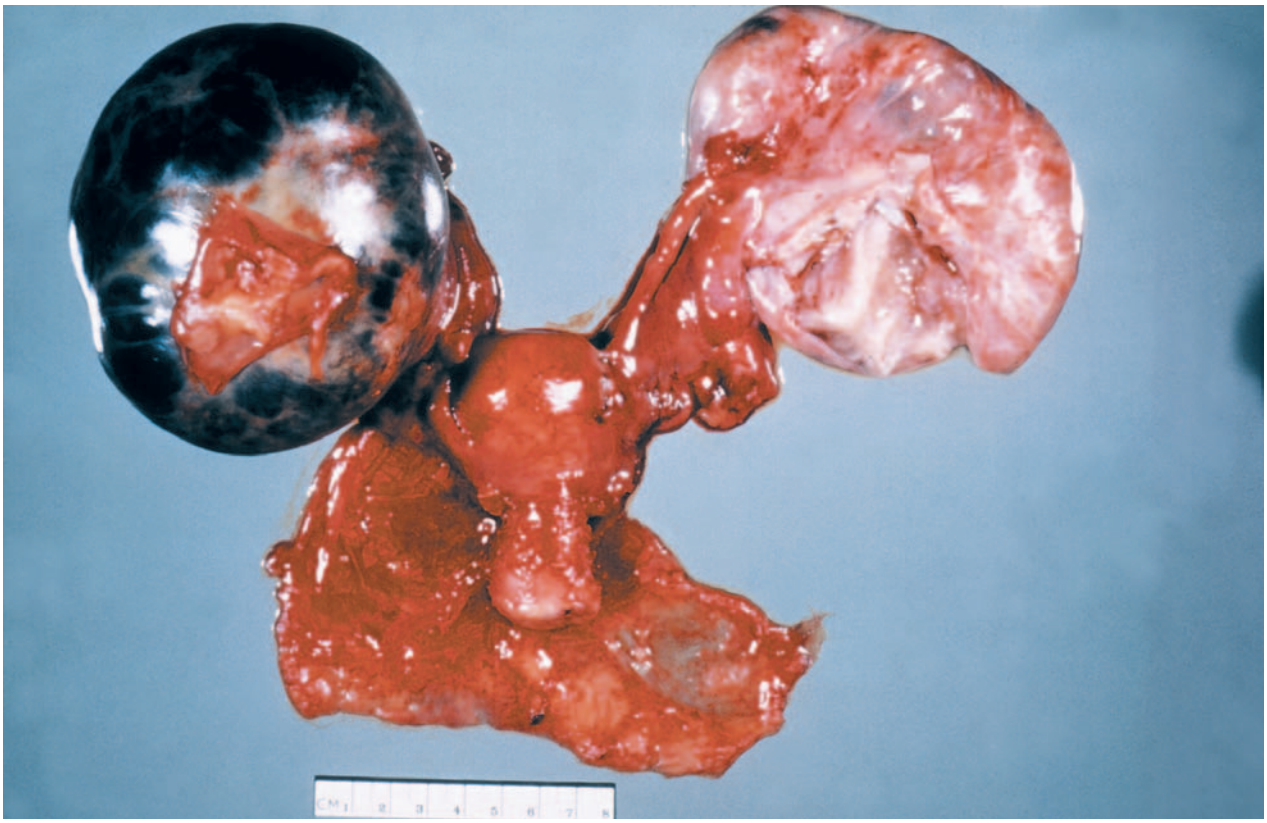
SURGERY Surgery is done to remove as much of the tumor as possible (called tissue debulking), utilizing chemotherapy and/or radiation to target cancer cells that have remained in the body, without jeopardizing the woman's health. This can be hard to balance once the cancer has spread. Removal of the ovary is called oophorectomy, and removal of both ovaries is called bilateral oophorectomy. Unless it is very clear that the cancer has not spread, the fallopian tubes are usually removed as well (salpingo-oophorectomy). Removal of the uterus is called hysterectomy.

If the woman is very young, all attempts will be made to spare the uterus. It is crucial that a woman discuss with her surgeon her childbearing plans prior to surgery. Unfortunately, ovarian cancer spreads easily and often swiftly throughout the reproductive tract. It may be necessary to remove all reproductive organs as well as part of the lining of the peritoneum to provide the woman with the best possible chance of long-term survival. Fertility-sparing surgery can be successful if the ovarian cancer is caught very early.

Side effects of the surgery will depend on the extent of the surgery, but may include pain and temporary difficulty with bladder and bowel function, as well as reaction to the loss of hormones produced by the organs removed. A hormone replacement patch may be applied to the woman's skin in the recovery room to help with the transition. An emotional side effect may be the feeling of loss stemming from the removal of reproductive organs.

Chemotherapy

Chemotherapy is used to target cells that have traveled to other organs, and throughout the body via the lymphatic system or the blood stream. Chemotherapy drugs are designed to kill cancer cells, but may also be harmful to healthy cells as well. Chemotherapy may be administered through a vein in the arm (intravenous, IV), may be taken in tablet form, and/or may be given through a thin tube called a catheter directly into the abdominal cavity (intraperitoneal). IV and oral chemotherapy drugs travel throughout the body; intraperitoneal chemotherapy is localized in the abdominal cavity.



Excised female reproductive organs, showing a cancerous ovary (left, black). *(©St. Bartholomew's Hospital, Science Source/ Photo Researchers, Inc. Reproduced by permission.)*

Side effects of chemotherapy can vary greatly depending on the drugs used. Currently, chemotherapy drugs are often used in combinations to treat advanced ovarian cancer, and usually the combination includes a platinum-based drug (such as **cisplatin**) with a taxol agent, such as **paclitaxel**. Some of the combinations used or being studied include: carboplatin/paclitaxel, cisplatin/paclitaxel, cisplatin/topotecan, and cisplatin/carboplatin. As new drugs are evaluated and developed, the goal is always for maximum effectiveness with minimum of side effects. Side effects include **nausea and vomiting**, **diarrhea**, decreased appetite and resulting **weight loss**, fatigue, headaches, loss of hair, and numbness and tingling in the hands or feet. Managing these side effects is an important part of cancer treatment.

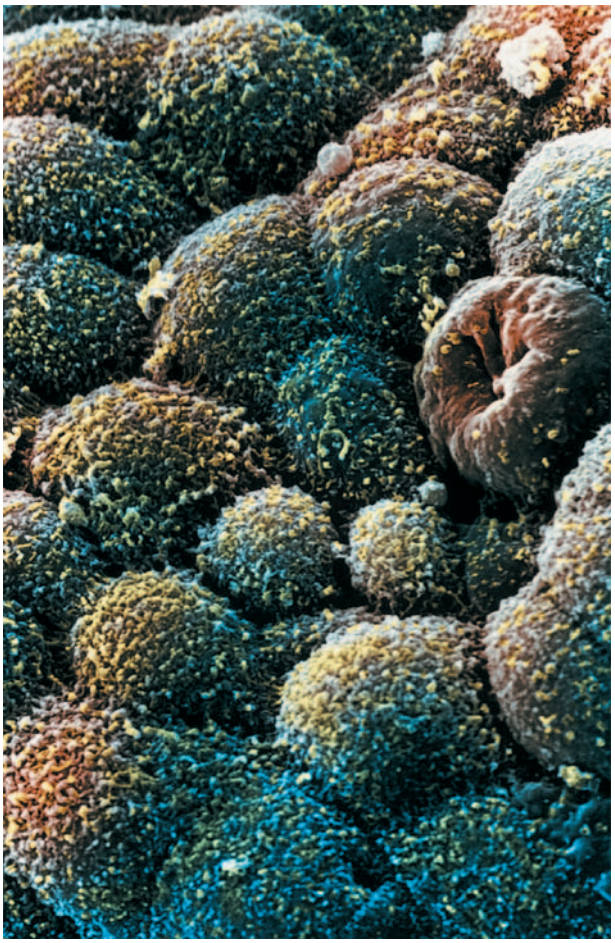
After the full course of chemotherapy has been given, the surgeon may perform a "second look" surgery to examine the abdominal cavity again to evaluate the success of treatment.

RADIATION Radiation uses high-energy, highly focused x rays to target very specific areas of cancer. This is done using a machine that generates an external beam. Very careful measurements are taken so that the targeted area can be as focused and small as possible. Another form of radiation uses a radioactive liquid that is administered into the abdominal cavity in the same fashion as intraperitoneal chemotherapy. Radiation is usually given on a daily Monday though Friday schedule and for several weeks continuously. Radiation is not painful, but side effects can include skin damage at the area exposed to the external beam, and extreme fatigue. The fatigue may hit suddenly in the third week or so of treatment, and may take a while to recover even after treatments have terminated. Other side effects may include nausea, vomiting, diarrhea, loss of appetite, weight loss and urinary difficulties. For patients with incurable ovarian cancer, radiation may be used to shrink tumor masses to provide pain relief and improve quality of life.

Once the full course of treatment has been undertaken, it is important to have regular follow-up care to monitor for any long-term side effects as well as for future relapse or metastases.

Alternative and complementary therapies

The term alternative therapy refers to therapy utilized instead of conventional treatment. By definition,



Colored scanning electron micrograph (SEM) of cancer cells in the ovary. These tumor cells are a variety of shapes and sizes, typical of the chaotic arrangement and growth of malignant cancer cells. *(Copyright Quest, Science Source/ Photo Researchers, Inc. Photo reproduced by permission.)*

these treatments have not been scientifically proven or investigated as thoroughly and by the same standards as conventional treatments. The terms complementary or integrative therapies denote practices used in conjunction with conventional treatment. Regardless of the therapies chosen, it is key for patients to inform their doctors of any alternative or complementary therapies being used or considered. (Some alternative and complementary therapies adversely affect the effectiveness of conventional treatments.) Some common complementary and alternative medicine techniques and therapies include:

- prayer and faith healing
- meditation
- mind/body techniques such as support groups, visualization, guided imagery and hypnosis
- energy work such as Therapeutic Touch and Reiki
- acupuncture and Chinese herbal medicine
- body work such as yoga, massage and t'ai chi
- vitamins and herbal supplements
- diets such as vegetarianism and macrobiotic

Mind/body techniques along with meditation, prayer, yoga, t'ai chi, and acupuncture have been shown to reduce stress levels, and the relaxation provided may help boost the body's immune system. The effectiveness of other complementary and alternative treatments is being studied by the National Institutes of Health's National Center for Complementary and Alternative Medicine (NCCAM). For a current list of the research studies occurring, results of recent studies, or publications available, patients can visit the NCCAM web site or call at (888) 644-6226.

Prognosis

Prognosis for ovarian cancer depends largely on the stage at which it is first diagnosed. While stage I cancer may have a 95% success rate, stages III and IV may have a survival rate of 17-30% at five years post-diagnosis. Early detection remains an elusive, yet hopeful, goal of research. Also, **clinical trials** are addressing new drug and treatment combinations to prolong survival in women with more advanced disease. Learning one's family history may assist in early detection, and genetic studies may clarify who is at greater risk for the disease.

Coping with cancer treatment

While the cancer may only be in part of the body, it is very much a full mind/body experience. Strategies for coping with the treatment need to address the entire range of the experience. Each woman will have different needs. She might want to create a personal support team of friends. They can provide support by:

- Finding helpful information in the library or on the Internet about clinical trials, new therapies or treatments, different treatment centers, etc.
- Providing transportation to and from appointments. A diagnosis of cancer can be overwhelming. In such a stressful and distracted state it is often hard to remember what a doctor has said, or even to remember the questions to be asked. Having a second set of ears during this stressful time can be helpful.
- Helping with household duties so that the woman can rest after treatments and have more energy to devote to her family.
- Assisting with child care. Children are very much affected by a parent's cancer diagnosis, whether they

KEY TERMS

Biomarker—A biochemical substance that can be detected in blood samples and indicates the presence of a cancerous tumor.

Gynecologic oncologist—A physician specializing in the treatment of cancers of the female reproductive tract.

Kallikrein—Any of a group of compounds in the body known as serine endopeptidases that help to break down proteins into smaller units. Prostate-specific antigen belongs to this group of chemicals. A recently discovered kallikrein may be useful as a biomarker for ovarian cancer.

Lymphatic system—A connected network of nodes, or glands that carry lymph throughout the body. Lymph is a fluid that contains the infection-fighting white blood cells that form part of the body's immune system. Because the network goes throughout the body, cancer cells that enter the lymphatic system can travel to and be deposited at any point into the tissues and organs and form new tumors there.

Pathologist—The pathologist is a doctor specializing in determining the presence and type of disease by looking at cells and tissue samples.

QUESTIONS TO ASK THE DOCTOR

- What tests will be used to look for and diagnose my cancer?
- How should I prepare for the tests?
- What will take place during the test? Will it be painful? What can I do to decrease the pain?
- When will I learn the results?
- Once the results are in: What do these results mean?
- What type and stage is my cancer?
- What are my treatment options?
- Who will be involved in my care?
- What clinical trials would benefit me?
- What changes in my ability to work or perform my daily functions should I expect during treatment?
- How long will my treatment last?
- What side effects should I expect from treatment?
- Are there any conventional or alternative therapies that can diminish these side effects?
- How soon after treatment will I be able to resume my regular activities?
- What is the plan for my follow-up care?

have been fully informed or not of what is taking place. For a child to go to a friend's house can provide a sense of normalcy and security.

- Being available to participate in activities and conversations not centering on the cancer. While in the midst of cancer treatments, it is important to talk about non-cancer issues as well, and to maintain social relationships and activities. It is important for the cancer patient to keep at least some of the social outlets she had before the diagnosis.

A woman may wish to join a support group of women with ovarian cancer. This group can provide the environment to talk about the diagnosis, the treatments, the side effects and the impact the diagnosis has on her life with others who can empathize. If there is no support group nearby, she may be able to start one, or use one on the Internet. Studies examining support groups for children of a parent with cancer have shown these groups to be helpful for the child as well.

Clinical trials

Clinical trials are human research studies. Their goal is to evaluate the effectiveness of new ways to treat cancer. There are many different designs, and they target different aspects of care. For example, some may investigate the response of different chemotherapy drugs, while another study may compare different types of treatment/chemotherapy combinations. The Cancer Information Service (CIS) is a division of the National Cancer Institute, the United States government agency for cancer research. Their web site contains information on all ongoing research trials, the areas being researched, and whether or not individuals can still participate.

Research studies are usually designed to compare a new treatment method against the standard method, or the effectiveness of a drug against a placebo (an inert substance that would be expected to have no effect on the outcome). Since the research is experimental in nature, there are no guarantees about the outcome. New drugs being used may have harmful, unknown side effects. Some people participate to help further knowledge about their disease. For others, the study may provide a possible treatment that is not yet available

otherwise. If one participates in a study and is in the group receiving the standard care or the placebo, and the treatment group gets clear benefit, it may be possible to receive the experimental treatment once one's original participation role is over. Participants will have to meet certain criteria before being admitted into the study. It is important to fully understand one's role in the study, and weigh the potential risks versus benefits when deciding whether or not to participate.

As of late 2004, the National Cancer Institute (NCI) had nearly 150 clinical trials related to ovarian cancer in its database. Most of these trials are devoted to combination chemotherapy or chemotherapy administered after surgery, but they also include studies of stem cell transplantation, newer drugs like amifostine, pain management and supportive care for advanced ovarian cancer, and cancer vaccines.

Prevention

Since the cause of ovarian cancer is not known, it is not possible to fully prevent the disease. However, there are ways to reduce one's risks of developing the disease.

DECREASE OVULATION. Pregnancy gives a break from ovulation, and multiple pregnancies appear to further reduce the risk of ovarian cancer. The research is not clear as to whether the pregnancy must result in a term delivery to have full benefit. Women who breastfeed their children also have a lower risk of developing the disease. Since oral contraceptives suppress ovulation, women who take birth control pills (BCPs), even for as little as 3 to 6 months have a lower incidence of the disease. It appears that the longer a woman takes BCPs, the lower her risk for ovarian cancer. Also, this benefit may last for up to 15 years after a woman has stopped taking them. However, since BCPs alter a woman's hormonal status, her risk for other hormonally related cancers may change. For this reason it is very important to discuss all the risks and benefits with one's health care provider.

GENETIC TESTING. **Genetic testing** is available which can help to determine whether a woman who has a family history of breast, endometrial, or ovarian cancer has inherited the mutated BRCA gene that predisposes her to these cancers. If the woman tests positive for the mutation, then she may be able to choose to have her ovaries removed. Even without testing for the mutated gene, some women with strong family histories of ovarian cancer may consider having their ovaries removed as a preventative measure (prophylactic oophorectomy). This procedure diminishes but does not completely remove the risk of cancer, as some women may still develop primary peritoneal carcinoma after oophorectomy.

SURGERY. Procedures such as tubal ligation (in which the fallopian tubes are blocked or cut off) and hysterectomy (in which the uterus is removed) appear to reduce the risk of ovarian cancer. However, any removal of the reproductive tract organs has surgical as well as hormonal side effects.

SCREENING. There are no definitive tests or screening procedures as of early 2005 to detect ovarian cancer in its early stages. Women at high risk should consult with their physicians about regular screenings, which may include transvaginal ultrasound and the blood test for the CA-125 protein.

The American Cancer Society recommends annual pelvic examinations for all women after age 40, in order to increase the chances of early detection of ovarian cancer.

Special concerns

Early detection remains the key focal point because the more ovarian cancer has spread, the poorer the chance for survival past a few years. As women and practitioners become more aware of the vague early warning signs, and seek out more accurate family histories, earlier screening can begin to lead to earlier detection and improved treatment success.

Ovarian epithelial cancer

Definition

Ovarian epithelial cancer is a type of cancer that develops in the cells that line the surface of the ovaries.

Description

Part of the female reproductive system, the ovaries are a pair of almond-shaped organs that are located on either side of the uterus, just above the pelvic bone. The ovaries produce estrogen and progesterone, which are female hormones. At birth, each ovary contains thousands of eggs. During a woman's fertile years, one ripened egg (or sometimes more) is released each month into a fallopian tube. As the egg takes its journey toward the uterus, a sperm can fertilize it. When a baby is conceived, it stays in the uterus until birth. During the birth process, powerful muscles in the uterus help to push the baby out through the cervix and vagina.

When an ovarian cell becomes cancerous, it tends to multiply quickly, forming a growth (or tumor). The resulting tumor may interfere with the way the ovary normally functions, but not in every case. Sometimes the cancer cells break off from the tumor and spread contiguously, which means they spread to nearby organs, such as to other areas of the pelvis.

Demographics

Although **ovarian cancer** rates differ significantly from country to country, Europe has been recognized as having one of the highest incidence rates of ovarian cancer in the world. Having carefully studied the ovarian cancer trends of twenty-eight European countries, Bray and colleagues reported in a 2004 article published by the *International Journal of Cancer* that European countries with the highest ovarian cancer rates in the past included the Nordic countries, Austria, Germany, and the United Kingdom, but current trends in these and other northern European countries showed a decline in ovarian cancer rates, especially with regard to mortality. However, the opposite was found to be true with regard to some of the southern and eastern European countries. In the Czech Republic and Hungry, there has been a drop in the mortality rates associated with ovarian cancer, but not a drop in the number of cases diagnosed. Bray a colleagues reported that "recent trends in ovarian cancer have led to a leveling of rates across various areas of the [European] continent, although a 2.5-fold variation was still observed in the late 1990s between the highest mortality rate of 9.3/100,000 in Denmark and the lowest one of 3.6 in Portugal."

The American Cancer Society estimates that 22,220 news cases of ovarian cancer will be diagnosed in the United States in 2005, resulting in approximately 16,210 deaths. Rarely seen in women under the age of 30, the risk of developing ovarian cancer increases with age. Nearly 90% of all the cases of ovarian cancer are ovarian epithelial cancer. Ranked fifth as the most

frequent cause of cancer death in women, ovarian epithelial cancer most commonly occurs in women over the age of 65.

Causes and symptoms

The presence of mutations in the BRCA1 and BRCA2 genes increase a woman's risk of developing breast or ovarian cancer, including ovarian epithelial cancer. When these gene mutations are not present in woman who has ovarian epithelial cancer, it is difficult to identify the cause. Several factors may increase a woman's risk of developing ovarian epithelial cancer, such as having a close relative with the disease or a personal history of **breast cancer**.

There seems to be a connection between the development of ovarian epithelial cancer and the number of times a woman ovulates in her lifetime. Statistics show that a woman who ovulates less seems to have less risk. For example, a woman who has had a child may have a decreased risk of developing ovarian epithelial cancer, because she has had a nine-month break in ovulation. On the other hand, a woman who has used birth control pills may lessen her risk for the same reason, because she, too, has had a break in ovulation.

Ovarian epithelial cancer often produces no symptoms in its early stages; therefore, by the time it is discovered, the disease is often widespread. In addition, women often ignore the symptoms, because they don't identify them with anything serious. Some of the symptoms include:

- gas and indigestion
- bloating
- swelling of the abdomen
- constipation, nausea, and vomiting
- fullness or pressure in the pelvis
- abnormal bleeding from the vagina
- lower abdominal pain (such as cramps)

Diagnosis

A variety of tests and examinations are used to diagnose ovarian epithelial cancer.

Pelvic Exam

Many women are familiar with this exam and schedule one on a yearly basis along with a pap smear. The exam is usually performed by a gynecologist, but is also sometimes performed by a physician specializing in family or internal medicine. Many women think a Pap smear will detect ovarian cancer, but, in truth, it is the pelvic examination that helps a physician diagnose ovarian epithelial cancer, whereas the Pap smear is useful in detecting **cervical cancer**.

To perform a pelvic examination, the physician inserts one or two lubricated, gloved fingers of one hand into a woman's vagina while pressing down on her abdomen with the other hand. By touch, the physician examines the uterus and ovaries, checking for any abnormalities in shape, size, or position. This examination only takes a few minutes and is not painful, although some women may feel some pressure or minor discomfort. The patient should tell the physician immediately if any pain is experienced. As part of the examination, the physician will also insert a lubricated, gloved finger into the rectum to feel for lumps.

Ultrasound

Often referred to as a sonogram, ultrasound is a completely painless procedure performed by radiologist in which high-energy sound waves are bounced off internal organs.

Magnetic Resonance Imaging (MRI)

Although an expense test, an MRI is often covered by many insurance plans. Using a magnetic field and imaging waves, an MRI scans a specific portion of the body from any angle. Painless and noninvasive, MRI testing does not require the use of contrast dye. However, the MRI is an unnerving machine for anyone claustrophobic, because the machine surrounds almost the entire body. Claustrophobic patients should ask their physician to refer them to the nearest Open Air MRI facility. The open design of an Open Air MRI provides access from all four sides and allows patients to feel more comfortable during their exam.

Blood Test

A test that measures the level of CA 125 in the blood is often recommended if ovarian epithelial cancer is suspected. An increased level of CA 125 may be a sign that cancer is present in the body.

Barium Enema

Sometimes referred to as a lower GI, a liquid that contains barium is put into the rectum, which coats the gastrointestinal tract so that x rays can be taken. It is usually performed by an x-ray technician or radiologist and is considered by many people to be as unpleasant as a normal enema.

Intravenous Pyelogram (IVP)

The purpose of this test, which normally takes about thirty minutes to an hour, is to see if any abnormalities exist in the kidneys and bladder. An IVP is essentially a series of x rays. A contrast dye, which is injected into the patient's vein, enhances the x-ray images that are taken to see if there are any blockages.

The night before the exam, the patient will be asked to fast (not eat any food) and to take a mild laxative, such as a teaspoon of castor oil. Patients who suspect they might be pregnant should inform their physicians prior to having an IVP. Although it is often not necessary for patients to remove their clothing, they will often be asked to remove any jewelry that might interfere with the images.

An IVP itself is painless, although some patients experience nausea and/or a metallic taste in their mouth as the dye is being inserted. Both the nausea and metallic taste tend to go away as the patient's body gets used to the dye. Some patients develop hives, which is an allergic reaction to the dye. The radiologist, who performs the test, will have medication on hand to treat the hives. When the test is completed, the radiologist will examine the x rays and write up a report for the referring physician who will deliver the results to the patient.

Computerized Tomography (CT Scan)

A CT scan, also referred to as a CAT scan, is a procedure that takes a series of detailed pictures of the inside of the body and is considered one of the best tools available for studying abdominal tissue, especially with regard to the presence of a tumor.

Like an IVP, a contrast dye is injected into a vein to help the organs and surrounding tissue show up more clearly. In some cases, the contrast dye is swallowed by the patient rather than injected. A computer linked to an x-ray machine generates the pictures. The test is painless and generally takes about thirty minutes to an hour, depending on how many images are needed. Unlike the IVP, however, the x-ray technician or radiologist will not remain in the room while the x rays are being taken. The patient will be able to hear and speak to the person performing the test, which is either an x-ray technician or radiologist. Because of the radiation used to perform a CT scan, patients that suspect they are pregnant should tell their physician prior to having the test. If the images show a tumor, many different specialists, such as a radiologist, oncologist, surgeon, and the referring physician, will often work together to arrive at a suitable course of treatment.

Biopsy

A physician may recommend that a **biopsy** be performed, which is a surgical procedure to remove tissue or cells from the surface of the ovary to see if they are cancerous.

Treatment team

The treatment team is comprised of physicians from a variety of medical specialties. For example, a patient diagnosed with ovarian epithelial cancer may have a treatment team that includes the patient's primary care physician and her gynecologist, as well as a radiologist, oncologist, surgeon, and **pain management** specialist. At-home caretakers are also part of the treatment team, providing important physical and emotional support to the patient. Physicians and patients that value a holistic approach to fighting cancer may add a variety of other advisors to the treatment team, such as psychologists, pastors, and alternative medicine specialists.

Clinical staging, treatments, and prognosis

Staging

After ovarian epithelial cancer has been diagnosed, it is classified as being in one of four stages based on whether the cancer cells have or have not spread within the ovaries or to other parts of the body. To determine the stage of the disease, the patient is placed under general anesthesia and a surgical procedure called a laparotomy is performed. By making an incision through the abdomen, the surgeon can inspect the ovaries and adjacent organs for cancer. A biopsy is often done at that time and the cells are viewed under a microscope by the surgeon who often specializes in oncology. If there are clear indications that cancerous tissue is present, the surgeon will usually remove it and any effected organs during the laparotomy. A tissue sample is also sent to a lab where a pathologist can further classify the sample and confirm the diagnosis. It can take several days to receive the pathologist's report.

The National Cancer Institute explains the four main stages of ovarian epithelial cancer as follows:

- Stage I: The cancer is present in one or both ovaries, but the cancer has not spread.
- Stage II: The cancer is present in one or both ovaries and has spread to the pelvis.
- Stage III: The cancer is present in one or both ovaries and has spread to other parts of the abdomen.
- Stage IV: The cancer is not only in one or both ovaries, but it has spread beyond the abdomen to other parts of the body.

KEY TERMS

Pap Smear—A procedure that involves taking cells from the cervix, which are examined under a microscope for signs of abnormality.

Peritoneum—The tissue that lines the abdomen.

QUESTIONS TO ASK YOUR DOCTOR

- What clinical trials do you recommend?
- Will I be able to have children?
- When will I be able to return to work?
- Are there any local cancer support groups?
- How will the treatment affect my sex life?
- Are there any medications that could alter the test or treatment results?
- What prescription and over-the-counter medications should be avoided during treatment?

All four stages have subcategories A, B, and C, which further indicate the characteristics and severity of the cancer within each stage. For example, according to the National Cancer Institute, in Stage IIIB, "The cancer has spread to the peritoneum but is 2 centimeters or smaller in diameter, whereas in Stage IIIC, the cancer has spread to the peritoneum and is larger than 2 centimeters and/or has spread to lymph nodes in the abdomen."

Treatment Options

Depending on the patient and the stage of the cancer, there are a variety of treatment options for patients with ovarian epithelial cancer. The three convention treatment options are surgery, **radiation therapy**, and **chemotherapy**. As the National Cancer Institute states, "Most patients have surgery to remove as much of the tumor as possible." Although ovarian epithelial cancer usually does not strike young women, it does pose a special concern for young women hoping to have a family. In the event that the disease is caught early enough, it might be possible to perform a unilateral salpingo-oophorectomy, which is the removal of only the involved ovary and fallopian tube, thereby giving the woman a chance to have children someday. However, in many cases, it is necessary to remove both ovaries, as well as the uterus, fallopian tubes, and nearby lymph glands. Sometimes it is even necessary to remove the omentum, which is a fold of the peritoneum.

Depending on the stage of cancer, radiation therapy may be recommended. There are generally two types of radiation therapy external radiation therapy, which comes from a machine outside of the body, and internal radiation therapy, such as implant radiation or brachytherapy. Chemotherapy is a commonly known cancer treatment that utilizes strong drugs to stop the growth of cancer cells. Chemotherapy is either given intravenously or orally; it often involves combination drug therapy. The administration and combination of chemotherapy drugs utilized is largely dependant on the extent of the cancer and the patient's medical profile.

Prognosis

The survival rate depends on a variety of factors, such as the patient's age and general health as well as the type and stage of tumor. When ovarian epithelial cancer is found early, the five-year survival rate is approximately 60% to 80%. However, because ovarian epithelial cancer is often found late in its development, the overall survival rate is 30% to 40%. In addition, ovarian epithelial cancer can recur after it has been treated.

Coping with cancer treatment

Patients having difficulty coping with the pain associated with cancer and chemotherapy might find it helpful to be referred to a physician who specializes in pain management or a pain clinic. Physicians specializing in the treatment of pain come from a variety of medical backgrounds, such as anesthesiology, obstetrics and gynecology, neurology, and surgery. Because of the complicated nature of cancer and cancer-related pain, ideally a pain management team should be formed that works with the patient's primary care physician, oncologist, and radiologist to provide comprehensive care to the patient.

Much has been written about coping with the physical side effects of cancer treatment; however, patients with ovarian epithelial cancer also face emotional challenges associated with their treatment. For example, women who are still in their reproductive years and need to have both ovaries removed must deal with an abrupt end to their reproductive choices. Women of all ages will have to deal with a variety of psychological issues, such as body image versus self-image. Some woman may need to be reminded, especially by family members and friends, that they are more than a collection of body parts. The spirit of their womanhood remains even if their ovaries do not.

It is important for cancer patients to understand that they are not alone. Support groups exist to help patients

cope not only with the physical aspects of having cancer, but with the psychological ones as well. Patients should be encouraged to talk about their feelings. The positive support (both emotional and otherwise) provided by caregivers can help to improve a patient's quality of life. In addition, support groups on the Internet have made it possible for women, even those in rural or remote areas, to reach out to one another in ways that allow anonymity.

Clinical trials

Patients should ask their doctor if there are any **clinical trials** being conducted in their areas that they should consider joining. Clinical trials are conducted to improve current methods of treatment or to develop new treatments. Patients with cancer who participate in clinical trials may improve their chances of survival.

Prevention

Women with a strong family history of ovarian epithelial cancer should be sure to have regular pelvic examinations, because an early diagnosis increases the chance of survival. However, there really is no way to prevent ovarian epithelial cancer, other than to have both ovaries removed before cancer has had a chance to grow, which is an extremely controversial prevention method. Nonetheless, some women with a high risk of developing ovarian epithelial cancer who have had the chance to have a family have elected to have a prophylactic **oophorectomy**, which is the medical name for the procedure that refers to the removal of healthy ovaries. Women considering this procedure need to know that it isn't necessarily a guarantee against ovarian cancer.

Oxaliplatin

Definition

Oxaliplatin is an investigational **chemotherapy** medicine used to treat certain types of cancer by destroying cancerous cells. Oxaliplatin is also known in other countries by its brand names Eloxatin and Transplatine. Other names for oxaliplatin include Oxalatoplatin, Oxalatoplatinum, 1-OHP or L-OHP, PR-54780.

Purpose

Oxaliplatin is not yet approved by the Food and Drug Administration in the United States. It is commercially available in Europe. Oxaliplatin has been used to treat metastatic colorectal cancer, and advanced **ovarian cancer** and has been tested with some results in head and neck cancers, skin cancer, lung cancer, and **non-Hodgkin's lymphomas**.

Description

Oxaliplatin is an analog of **cisplatin**, the first successful platinum-containing anticancer drug. It is one of the so-called DACH (1,2-Diamincyclohexane)-containing platinum complexes that exhibited activity in Murine L1210 leukemia tumor models possessing acquired resistance to cisplatin. These platinum-containing drugs interfere with the genetic material, or DNA, inside the cancer cells and prevent them from further dividing and growing more cancer cells.

Oxaliplatin has been used to treat cancer in **clinical trials** in the United States. It can be used alone to treat cancer or in combination with other chemotherapy medicines. Some of the other chemotherapy medicines that Oxaliplatin is commonly combined with include the drugs **fluorouracil** and calcium **leucovorin** and used in combination with cisplatin.

Recommended dosage

An oxaliplatin dose can be determined using a mathematical calculation that measures a person's body surface area (BSA). This number is dependent upon a patient's height and weight. The larger the person the greater the body surface area. Body surface area is measured in the units known as square meter (m^2). The body surface area is calculated and then multiplied by the drug dosage in milligrams per square meter (mg/m^2). This calculates the actual dose a patient is to receive.

Oxaliplatin is a clear colorless solution administered by an infusion into a vein. The infusion time period can vary. It can be given as a one-time dose every three weeks infused over 20 minutes up to six hours. There are multiple doses of oxaliplatin used in clinical trials dependent upon the type of cancer being treated. The doses have ranged from 20 mg per square meter daily for several days to 130 mg per square meter for one day every three weeks. Listed below are example dose recommendations for colorectal cancer and ovarian cancer.

To treat metastatic colorectal cancer

Oxaliplatin alone has been given at 130 mg per square meter administered into a vein for one day every three weeks. This did not have very good response rates.

Oxaliplatin is also given at a dose of 130 mg per square meter administered into a vein as a two- to six-hour infusion for one day every three weeks in combination with the chemotherapy drug fluorouracil.

To treat advanced ovarian cancer

Oxaliplatin alone has been given at 59 mg to 130 mg per square meter administered into a vein for one day as a 20-minute or two-hour infusion every three weeks.

Combination treatment of oxaliplatin at a dose of 130mg per square meter administered into a vein as a two-hour infusion every three weeks. The oxaliplatin must immediately follow a two hour-infusion of the chemotherapy drug cisplatin at a dose of 100 mg square meter every three weeks.

KEY TERMS

Anemia—A red blood cell count that is lower than normal.

Chemotherapy—Specific drugs used to treat cancer.

DNA—Genetic material inside of cells that allows for cells to function, separate into two cells and make more cells.

Food and Drug Administration—A government agency that oversees public safety in relation to drugs and medical devices. The FDA gives the approval to pharmaceutical companies for commercial marketing of their products.

Intravenous—To enter the body through a vein.

Metastatic—Cancer that has spread to one or more parts of the body.

Neutropenia—A white blood cell count that is lower than normal.

Precautions

When receiving the drug oxaliplatin it is important to avoid cold food and drinks.

Blood counts will be monitored regularly while on oxaliplatin therapy. During a certain time period after receiving oxaliplatin there is an increased risk of getting infections. Caution should be taken to avoid unnecessary exposure to germs.

Patients with a known previous allergic reaction to chemotherapy drugs should tell their doctors.

Patients who may be pregnant or trying to become pregnant should tell their doctors before receiving oxaliplatin.

Chemotherapy can cause men and women to be sterile or not able to have children.

Patients with existing or previous tingling or numbness in their hands and feet should tell their doctor before receiving oxaliplatin.

Patients should check with their doctors before receiving live virus **vaccines** while on chemotherapy.

Side effects

One of the most common side effects from receiving oxaliplatin is **nausea and vomiting**. Patients will be given medicines known as **antiemetics** before receiving

oxaliplatin to help prevent or decrease this side effect. **Diarrhea** and mouth sores have also been known to occur. The chance of these increase if the oxaliplatin is given along with the chemotherapy drug fluorouracil.

Oxaliplatin can commonly cause damage to nerves and nervous system tissues. Patients may feel tingling, numbness, and sometimes burning of the fingers and toes. This side effect is common, can be severe, and gets worse in the cold. The patient must inform the doctor if any of these symptoms are present. In addition, the patient may experience a tightness or spasm in their throat. The chance that this will happen increases if the patient is exposed to cold food or drinks while receiving oxaliplatin.

Low blood counts, referred to as **myelosuppression**, are expected due to oxaliplatin. The extent to which the blood counts fall due to oxaliplatin has been minimal. When the white blood cell count is low, this is called **neutropenia** and patients are at an increased risk of developing a **fever** and infections. There is a drug called Neupogen (filgrastim) that can be used to increase the white blood cell count.

Platelets are blood cells in the body that allow for the formation of clots. When the platelet count is low, patients are at an increased risk for bruising and bleeding. If the platelet count remains too low a platelet blood transfusion is an option. Low red blood cell counts, referred to as **anemia**, may also occur due to cisplatin administration. Low red counts make people feel tired and lacking energy. There is a drug called **erythropoietin** that can be used to increase the red blood cell count.

Oxaliplatin has caused severe allergic reactions known as anaphylaxis. The symptoms include difficulty breathing, drop in blood pressure, sweating, redness of the face, dizziness, headache, and a fast heart beat. This appears to be more common after several treatments with the drug oxaliplatin.

Less common side effects include hair loss (alopecia), fever, rash on hands and feet when given with fluorouracil, and fatigue. Oxaliplatin rarely causes kidney damage or hearing damage, unlike cisplatin chemotherapy.

All side effects a patient experiences should be reported to his or her doctor.

Interactions

Patients should avoid cold food and drinks while receiving oxaliplatin.

Oxaliplatin immediately followed by the chemotherapy drug **irinotecan** has caused overproduction of saliva and pain in the abdomen.

Oxycodone *see* **Opioids**

P

Paclitaxel

Definition

Paclitaxel is a drug used to treat certain types of cancer. It belongs to a category of anticancer drugs known as taxanes. Paclitaxel is available under the trade name Taxol.

Purpose

Paclitaxel is an antineoplastic agent used to treat **ovarian cancer**, **breast cancer**, non-small cell lung **carcinoma**, and AIDS-related **Kaposi's sarcoma**.

Description

Paclitaxel was approved by the Food and Drug Administration (FDA) in 1992.

Paclitaxel is a naturally occurring compound originally extracted from the bark of the Pacific yew tree (*Taxus brevifolia*). Due to high demand, paclitaxel is typically synthesized from the more abundant, naturally occurring compound 10-deacetyl baccatin III, which is extracted from the needles of yew plants. Paclitaxel belongs to a group of chemicals called taxoids. **Docetaxel**, a taxoid found in the English yew tree (*Taxus baccata*), is similar to paclitaxel in terms of chemical structure and biological action. Some researchers consider docetaxel to be preferable to paclitaxel in treating ovarian cancer because it has less severe side effects.

Paclitaxel (and docetaxel) disrupt microtubule function, inhibiting cell replication. One of the roles of normal microtubules is to aid in the replication of cells, and paclitaxel promotes the formation of microtubules that do not function properly, thus disrupting this function and inhibiting cell replication.

Paclitaxel is used in patients who have ovarian cancer carcinoma alone, and in combination with such platinum-containing drugs as **cisplatin** or carboplatin. Paclitaxel is also used to treat breast cancer that has recurred or progressed following treatment with other drugs. It is also used to treat non-small cell lung carcinoma in combination with cisplatin in cases where surgery or radiation is not possible. Paclitaxel is also used to treat AIDS-related Kaposi's sarcoma.

Recent trends in the treatment of ovarian cancer include the addition of a third drug to combination chemotherapy with carboplatin and paclitaxel; and the use of paclitaxel together with a new drug known as erlotinib (Tarceva). Erlotinib is an inhibitor of an enzyme known as tyrosine kinase, and appears to increase the antitumor effect of paclitaxel.

Recommended dosage

There is no known antidote for paclitaxel overdose, so patients should be carefully monitored during treatment for toxicity.

Paclitaxel is administered intravenously once every three weeks. Blood tests may be necessary to ensure that the bone marrow is functioning adequately to continue treatment at the recommended interval.

All patients should be pretreated prior to paclitaxel administration with **corticosteroids** and antihistamines to help prevent adverse side effects. These side effects include severe hypersensitivity to paclitaxel.

Precautions

Paclitaxel should only be used under the supervision of a physician experienced in the use of cancer chemotherapeutic agents. Special caution should be taken to monitor the toxic effects of paclitaxel, especially suppression of bone marrow function and hypersensitivity reactions. Premedication to prevent hypersensitivity reactions is recommended. Minor to severe hypersensitivity reactions are frequent and may occur within a few minutes of the start of treatment. Severe hypersensitivity

requires treatment to stop. Paclitaxel has a low therapeutic index. Certain complications will only be possible to manage if the necessary diagnostic and treatment resources are readily available.

Because paclitaxel is administered intravenously, and the site of infusion should be monitored for signs of inflammation.

Cardiac monitoring during paclitaxel administration is recommended in patients with a preexisting cardiac condition.

The occurrences of adverse effects of paclitaxel treatment in patients with significant liver dysfunction are more likely.

Paclitaxel should not be administered to patients who are known to have severe hypersensitivity to polyoxy 35 castor oil, which is a component of the treatment that helps dissolve the drug.

The safety of paclitaxel in children under 16 years of age has not been established.

Paclitaxel can cause harm to a fetus when administered to pregnant women. Only in life-threatening situations should this treatment be used during pregnancy. Women of childbearing age are advised not to become pregnant during treatment. Women should stop nursing before beginning treatment, due to the potential for serious adverse side effects in the nursing infants.

Side effects

Suppression of bone marrow function is the principal adverse side effect associated with paclitaxel treatment. Blood tests will allow a doctor to determine if there is adequate bone marrow function to begin or continue treatment. Hypersensitivity may also occur during treatment. Premedication is administered prior to treatment to help alleviate this side effect. Additional side effects, including **fever**, infection, nausea, vomiting, increase or decrease in blood pressure, **diarrhea**, **weight loss**, pain, and hair loss (alopecia) may occur.

Interactions

When used in combination with cisplatin, paclitaxel should be administered first. Paclitaxel may increase the level of **doxorubicin** (a DNA interactive anticancer drug) in the blood when used in combination. Drugs that may alter the metabolism of paclitaxel such as cyclosporine (immunosuppressant), terfenadine (antifungal), ketoconazole (antifungal), erythomycin (antibacterial), and troleandomycin (antibacterial) should be used with caution due to the potential for interactions.

KEY TERMS

10-deacetyl baccatin III—A naturally occurring compound that can be converted to paclitaxel and docetaxel.

Hypersensitivity—An abnormally sensitive reaction to a stimulus. Similar to an allergic reaction.

Microtubules—Tubular structures located in cells that help them to replicate.

Taxoid—A complex molecule that is chemically similar to paclitaxel.

Therapeutic index—A ratio of the maximum tolerated dose of a drug divided by the dose used in treatment.

Paget's disease of the breast

Definition

Paget's disease of the breast is a rare type of **breast cancer** that is characterized by a red, scaly lesion on the nipple and surrounding tissue (areola).

Description

Paget's disease of the breast, also called mammary Paget's disease, is a rare breast condition that is often associated with underlying breast cancer. It is believed that Paget's disease of the breast occurs when invasive **carcinoma** or intraductal carcinoma (cancer of the milk ducts) spreads through the milk ducts to the nipple.

Although in most cases the underlying breast cancer is extensive, in 10% of the cases, cancer only affects the nipple and surrounding tissue. Rarely, there is no detectable underlying breast cancer. Paget's disease located elsewhere on the body (extramammary Paget's disease) is rarely associated with an underlying invasive cancer. This type of Paget's disease, most commonly found on and around the genitals, is believed to arise directly from the cells lining certain sweat gland ducts. Possibly, the few cases of mammary Paget's disease without an underlying breast cancer have a similar origin.

Paget's disease of the breast accounts for 2% of all breast cancers. On average, women are 62 years old and men are 69 years old at diagnosis. Breast cancer rarely occurs in men.

Causes and symptoms

The causes of Paget's disease of the breast are unknown. The most common signs and symptoms of Paget's disease include redness, scaling, and flaking on and around the nipple and areola. Other symptoms include **itching**, tingling, burning, oversensitivity, or pain. The lesion may bleed or weep and open sores (ulcers) may be present.

Diagnosis

A thorough breast examination would be performed. A breast mass can be felt (palpated) in about half of the women with Paget's disease. **Mammography** and **ultrasonography** should be conducted to look for cancer within the breast that cannot be felt.

The definitive diagnosis of Paget's disease is the presence of a certain cell type, called Paget's cells, in the skin of the nipple. A tissue sample may be easily obtained by touching a microscope slide to a weeping lesion or by scraping a scaly or crusted lesion gently with a microscope slide. Alternatively, a sample of the lesion may be obtained by cutting out a small piece of nipple tissue (**biopsy**). The biopsy would be performed with local anesthetic in the physician's office. If a mass was felt, a breast biopsy would be performed.

Treatments and prognosis

Treatments

The traditional treatment of Paget's disease of the breast is to surgically remove the breast (**mastectomy**). Conservative surgery, (nipple-areolar sacrificing **lumpectomy**) in which just the nipple, areola, and underlying tissue are removed, may be sufficient in some cases. The underarm (axillary) lymph nodes are rarely sampled or removed (lymphadenectomy), unless an underlying invasive cancer is a concern.

Radiation therapy may be used as adjuvant therapy to complement the surgical treatment, and if a lumpectomy is performed, radiation must be employed. Radiation therapy uses high-energy radiation from x rays and gamma rays to kill the cancer cells. The skin in the treated area may become red and dry, and **fatigue** is also a common side effect.

Chemotherapy, also used as adjuvant therapy if an underlying invasive breast cancer is found, uses drugs to kill the cancer cells. The side effects of chemotherapy include stomach upset, vomiting, appetite loss (anorexia), hair loss (alopecia), mouth or vaginal sores, fatigue, menstrual cycle changes, premature menopause, and low white blood cell counts with an increased risk of infection.

Prognosis

As with other breast cancers, the prognosis of Paget's disease depends on the extent of the cancer and whether it has spread to the lymph nodes and other organs.

PAGET'S DISEASE ALONE The survival rate of women with Paget's disease of the breast alone is 99.5%.

PAGET'S DISEASE WITH INVASIVE BREAST CANCER The prognosis for Paget's disease and invasive cancer is based on the stage of the underlying breast cancer. Staging for breast cancer is as follows:

- Stage 1—The cancer is no larger than 2 cm (0.8 in) and no cancer cells are found in the lymph nodes.
- Stage 2—The cancer is between 2 cm and 5 cm, and the cancer has spread to the lymph nodes.

- Stage 3A—Tumor is larger than 5 cm (2 in) or is smaller than 5 cm, but has spread to the lymph nodes, which have grown into each other.
- Stage 3B—Cancer has spread to tissues near the breast, (local invasion), or to lymph nodes inside the chest wall, along the breastbone.
- Stage 4—Cancer has spread to skin and lymph nodes beyond the axilla (regional lymph nodes) or to other organs of the body.

The prognosis depends on the type and stage of cancer. Over 80% of stage I patients are cured by current therapies. Stage II patients survive overall about 70% of the time, those with more extensive lymph nodal involvement doing worse than those with disease confined to the breast. About 40% of stage III patients survive five years, and about 20% of stage IV patients do so.

Alternative and complementary therapies

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques such as biofeedback, visualization, meditation, and yoga, have not shown any effect in reducing cancer but they can reduce stress and lessen some of the side effects of cancer treatments.

A few studies found an association between longer survival time and a diet high in beta-carotene and fruits. Acupuncture has been found to relieve chemotherapy-induced **nausea and vomiting** and reduce pain. In some studies, mistletoe has been shown to reduce tumor size, extend survival time, and enhance immune function. Other studies have failed to show a response to mistletoe treatment.

For more comprehensive information, the patient should consult the book on complementary and alternative medicine published by the American Cancer Society listed in the Resources section.

Prevention

There are no specific factors that increase a person's risk of developing Paget's disease. Men who are at an increased risk of developing breast cancer include those who have had radiation exposure and those with Klinefelter's syndrome. Women's risk factors for breast cancer include:

- a personal history of breast cancer
- a family history of breast cancer
- alterations in certain genes (e.g. BRCA1 and BRCA2)
- changes in breast tissue (e.g. lobular carcinoma in situ or atypical hyperplasia)
- long-term exposure to estrogen (e.g. early age at first menstruation or late menopause), and possibly use of hormone replacement therapy
- exposure to diethylstilbestrol (DES) before birth
- first pregnancy after 30 years of age
- alcohol consumption

Regularly scheduled screening mammograms are recommended for all women over the age of 40 years. Those with a significant family history (one or more first-degree relatives who have been treated for breast cancer), should start annual mammograms 10 years younger than the youngest relative was when she was diagnosed, but not earlier than 35. Monthly breast self examinations and yearly clinical breast examinations are recommended for all women. Daily exercise, totalling two to four hours a week, decreases a woman's risk of breast cancer by 50% to 75%. Women with a high risk of breast cancer may take the drug **tamoxifen**, which has been shown to reduce the occurrence (or recurrence) of breast cancer. Women at a very high risk may choose to have a mastectomy to prevent breast cancer (prophylactic mastectomy).

Special concerns

Of special concern to the young woman with breast cancer is the impact that treatment will have on her fertility and **body image**. **Depression** is common. There is ongoing research investigating whether timing breast cancer surgery to coincide with the luteal phase (after

KEY TERMS

Areola—The darkened area that surrounds the nipple.

Diethylstilbestrol (DES)—A medication used between 1945 and 1970 to prevent miscarriage.

Extramammary Paget's disease—Paget's disease that is located anywhere on the body, excluding the breasts.

Luteal phase—That part of the menstrual cycle that begins after ovulation and ends at menstruation.

Mastectomy—Surgical removal of breast tissue. Mastectomy may be partial, when only some tissue is removed, or radical, when all breast tissue and adjacent tissues are removed.

QUESTIONS TO ASK THE DOCTOR

- What type of cancer do I have?
- What stage of cancer do I have?
- What is the five-year survival rate for women with this type and stage of cancer?
- Has the cancer spread?
- What are my treatment options?
- How much breast tissue will you be removing?
- Where will the scars be?
- What will my breast look like after surgery?
- When can I have breast reconstruction?
- What are the risks and side effects of these treatments?
- What medications can I take to relieve treatment side effects?
- Are there any clinical studies underway that would be appropriate for me?
- What effective alternative or complementary treatments are available for this type of cancer?
- How debilitating is the treatment? Will I be able to continue working?
- Are there any local support groups for breast cancer patients?
- What is the chance that the cancer will recur?
- Is there anything I can do to prevent recurrence?
- How often will I have follow-up examinations?

ovulation) of the menstrual cycle leads to an increased survival rate.

Pain management

Definition

Pain management in cancer care encompasses all the actions taken to keep people with cancer as free of pain as possible. It includes pharmacological, psychological, and spiritual approaches to prevent, reduce, or stop pain sensations.

Purpose

It is estimated that more than 800,000 new cases of cancer are diagnosed each year in the United States, and 430,000 cancer victims will die. Though recent figures are hopeful and suggest a decline in both the incidence of cancer and the number of people who die from it, studies have consistently shown that at least 70% of cancer patients in the advanced stage of the disease will experi-

ence significant pain. Pain is a localized sensation ranging from mild discomfort to an unbearable, excruciating experience. It is, in its origins, a protective mechanism, designed to alert the brain to injury or disease conditions. Unfortunately, when the cause of the pain is known, such as in diagnosed cancer, and treatment is initiated, pain can often continue.

Once the message of cancer has been received and interpreted by the brain, further pain can be counter-productive. Pain can have a negative impact on a person's quality of life, causing **depression** and impeding recovery. Unrelieved pain can become a syndrome in its own right and cause a downward spiral in a person's health and outlook. Proper pain management facilitates recovery, prevents additional health complications, and improves an individual's quality of life.

Several independent studies of the relief of pain have shown that pain is often under-treated by the medical profession. For this reason, in the spring and summer of 2000, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and the American Pain Society (APS) developed standards for proper pain management.

Description

What is pain?

The treatment of pain has been a major endeavor since ancient times. By 400 B.C., the father of modern medicine, Hippocrates, had theorized that the brain, not the heart, was the controlling center of the body, and Greek anatomists had begun to identify various nerves and their purposes. The pain-relieving properties of opium were already known and were being utilized to stop suffering. Two thousand years ago, in China, acupuncture was being used to reduce pain.

Pain is the means by which the peripheral nervous system (PNS) warns the central nervous system (CNS) of injury or potential injury to the body. The CNS comprises the brain and spinal cord, and the PNS is composed of the nerves that stem from and lead into the CNS. PNS includes all nerves throughout the body except the brain and spinal cord.

A pain message is transmitted to the CNS by special PNS nerve cells called nociceptors. Nociceptors are distributed throughout the body and respond to different stimuli depending on their location. For example, nociceptors that extend from the skin are stimulated by sensations such as pressure, temperature, and chemical changes.

When a nociceptor is stimulated, neurotransmitters are released from cells. Neurotransmitters are chemicals found within the nervous system that facilitate nerve cell communication. The nociceptor transmits its signal to nerve cells within the spinal cord, which conveys the pain message to the thalamus, a specific region in the brain.

Once the brain has received and processed the pain message and coordinated an appropriate response, pain has served its purpose. The body uses natural pain killers, called endorphins, that are meant to derail further pain messages from the same source. However, these natural pain killers may not adequately dampen a continuing pain message. Also, depending on how the brain has processed the pain information, certain hormones, such as prostaglandins, may be released. These hormones enhance the pain message and play a role in immune system responses to injury, such as inflammation. Certain neurotransmitters, especially substance P and **calcitonin** gene-related peptide, actively enhance the pain message at the injury site and within the spinal cord.

It has been hypothesized that uninterrupted and unrelenting pain can induce changes in the spinal cord. In the past, intractable pain (pain that can't be managed or cured) has been treated by severing a nerve's connection to the CNS. However, the lack of any sensory information being relayed by that nerve can cause pain transmission in the spinal cord to go into overdrive, as evidenced by the phantom limb pain experienced by amputees. Evidence is accumulating that unrelenting pain or the complete lack of nerve signals increases the number of pain receptors in the spinal cord. Nerve cells in the spinal cord may also begin secreting pain-amplifying neurotransmitters independent of actual pain signals from the body. Immune chemicals, primarily cytokines, may play a prominent role in such changes.

What is cancer pain?

The majority of cancer pain results from a cancerous tumor pressing on organs, nerves, or bone. However, several studies by pain-pioneer Dr. John Bonica and others have shown that a predictable 78% of all cancer pain is indeed related to the disease, but an impressive 19% was found to be caused instead by treatment of the cancer. Three percent of all complaints of pain were unrelated to either the disease or treatment.

Cancer pain is generally divided into three categories:

- *Visceral pain*, usually caused by pressure resulting from the invasiveness of the tumor, expansion of the

hepatic capsule, or injury caused by radiation or **chemotherapy**.

- *Somatic pain* often resulting from bone metastasis.
- *Neuropathic pain*, or pain caused by the pressure of a tumor on nerves, or the trauma to nerves resulting from either radiation, chemotherapy, or surgery.

Managing cancer pain

PHARMACOLOGICAL OPTIONS General guidelines developed by the World Health Organization (WHO) for pain management apply to cancer pain management as well. These guidelines follow a three-step ladder approach:

- Mild pain is alleviated with acetominophen or non-steroidal anti-inflammatory drugs (NSAIDs). NSAIDs and acetaminophen are available as over-the-counter and prescription medications, and are frequently the initial pharmacological treatment for pain. These drugs can also be used as adjuncts to the other drug therapies, which might require a doctor's prescription. NSAIDs include aspirin, ibuprofen (Motrin, Advil, Nuprin), naproxen sodium (Aleve), and ketoprofen (Orudis KT). These drugs are used to treat pain from inflammation and work by blocking production of pain-enhancing neurotransmitters, such as prostaglandins. Acetaminophen is also effective against pain, but its ability to reduce inflammation is limited. NSAIDs and acetaminophen are effective for most forms of acute (sharp, but of a short course) pain.
- Mild to moderate pain is eased with a milder opioid medication plus acetominophen or NSAIDs. **Opioids** are both actual opiate drugs such as morphine and codeine, and synthetic drugs based on the structure of opium. This drug class includes drugs such as oxycodone, methadone, and **meperidine** (Demerol). They provide pain relief by binding to specific opioid receptors in the brain and spinal cord, and thus block the perception of pain.
- Moderate to severe pain is treated with stronger opioid drugs plus acetominophen or NSAIDs. Morphine is sometimes referred to as the "Gold Standard" of palliative care as it is not expensive, can be given starting with smaller doses and gradually increased, and is highly effective over a long period of time. It can also be administered orally (by mouth), rectally, or by injection. A newer method of administering morphine involves a patient-controlled delivery system implanted in the covering of the spinal cord. Researchers in North Carolina reported in late 2003 that the new system not only provided more effective pain relief, but also lowered the patients' use of morphine and the complications associated with long-term use of morphine. In general, the development of implantable pumps has greatly improved pharmacological approaches to pain management.

Although antidepressant drugs were developed to treat depression, they are also effective in combating chronic headaches, cancer pain, and pain associated with nerve damage. Antidepressants shown to have analgesic (pain reducing) properties include **amitriptyline** (Elavil), trazodone (Desyrel), and imipramine (Tofranil). Anticonvulsant drugs share a similar background with antidepressants. Developed to treat epilepsy, anticonvulsants were found to relieve pain as well. Drugs such as **phenytoin** (Dilantin) and **carbamazepine** (Tegretol) are prescribed to treat the pain associated with nerve damage.

Close monitoring of the effects of pain medications is required in order to assure that adequate amounts of medication are given to produce the desired pain relief. When a person is comfortable with a certain dosage of medication, oncologists typically convert to a long-acting version of that medication. Transdermal fentanyl patches (Duragesic) are a common example of an long-acting opioid drug often used for cancer pain management. A patch containing the drug is applied to the skin where the drug is continuously absorbed by the body, usually for three days. Pumps are also available that provide an opioid medication upon demand when the person is experiencing pain. By pressing a button, they can release a set dose of medication into an intravenous solution or an implanted catheter. Another mode of administration involves implanted catheters that deliver pain medication directly to the spinal cord. Delivering drugs in this way can reduce side effects and increase the effectiveness of the drug. Research is underway to develop toxic substances that act selectively on nerve cells that carry pain messages to the brain, killing these selected cells, and thus stopping transmission of the pain message.

NON-PHARMACOLOGICAL OPTIONS Pain treatment options that do not involve drugs are often used as adjuncts to, rather than replacements for, drug therapy. One of the benefits of non-drug therapies is that an individual can take a more active stance against pain. Relaxation techniques, such as yoga and meditation, are used to shift the focus of the brain away from the pain, decrease muscle tension, and reduce stress. Tension and stress can also be reduced through biofeedback, in which an individual consciously attempts to modify skin temperature, muscle tension, blood pressure, and heart rate. A group of researchers in New York reported in 2003 that the hypnotic-like approaches—particularly imagery, relaxation techniques, and hypnotic suggestion—appear to be more effective in managing pain than other behavioral approaches.

KEY TERMS

Acute—A short-term pain in response to injury or other stimulus that resolves when the injury heals or the stimulus is removed.

Chemotherapy—The treatment of infections or malignant diseases by drugs that act selectively on the cause of the disorder, but which may have substantial side effects.

Chronic—Pain that endures beyond the term of an injury or painful stimulus. Also refers to cancer pain, pain from a chronic or degenerative disease, and pain from an unidentified cause.

CNS or central nervous system—The part of the nervous system that includes the brain and the spinal cord.

Hepatic capsule—The membranous bag enclosing the liver.

Iatrogenic—Resulting from the activity of the physician.

Metastasis—A secondary malignant tumor (one that has spread from a primary cancer to affect other parts of the body.

Neuropathy—Nerve damage.

Neurotransmitter—Chemicals within the nervous system that transmit information from or between nerve cells.

Nociceptor—A nerve cell capable of sensing pain and transmitting a pain signal.

Non-pharmacological—Therapy that does not involve drugs.

Palliative—Serving to relieve or alleviate the symptoms of a disease or disorder without curing the disease.

Pharmacological—Therapy that relies on drugs.

PNS or peripheral nervous system—Nerves that are outside of the brain and spinal cord.

Radiation—A treatment for cancer (and occasionally other diseases) by x rays or other sources of radioactivity, both of which produce ionizing radiation. The radiation, as it passes through diseased tissue, destroys or slows the development of abnormal cells.

Stimulus—A factor capable of eliciting a response in a nerve.

Virtual reality—The creation of a convincing environment by computer technology, displayed either on a computer screen or viewed through special stereoscopic goggles. Virtual reality is primarily a visual and auditory experience. It appears to be a useful approach to pain management in children.

Participating in normal activities and exercising can also help control pain levels. Through physical therapy, an individual learns beneficial exercises for reducing stress, strengthening muscles, and staying fit. Regular exercise has been linked to production of endorphins, the body's natural pain killers.

Acupuncture involves the insertion of small needles into the skin at key points. The acupuncturist will usually stimulate points on the ear when treating cancer pain. Acupressure uses these same key points, but involves applying pressure rather than inserting needles. Both of these methods may work by prompting the body to release endorphins. Applying heat or being massaged are very relaxing and help reduce stress. Transcutaneous electrical nerve stimulation (TENS) applies a small electric current to certain parts of nerves, potentially interrupting pain signals and inducing release of endorphins. To be effective, use of TENS should be medically supervised.

A new method for managing pain in children with cancer is virtual reality, which works by distracting the child's attention from the pain and accompanying anxiety. Virtual reality has been used successfully in the treatment of anxiety disorders, and shows great promise in treating children suffering from cancer pain. Larger-scale studies are under way as of late 2003.

Preparation

Assessment of cancer pain is absolutely essential to good pain management. Pain scales or questionnaires are sometimes used to attach an objective measure to a subjective experience. Objective measurements allow health care workers a better understanding of the pain being suffered by the patient. Pain has been called "the fifth vital sign," (temperature, pulse, respiration and blood pressure being the other four vital signs), by the Veterans Administration. Evaluation also includes physical examinations and diagnostic tests to determine underlying cause of the pain. Some evaluations require assessments from several viewpoints, including neurology, psychiatry and psychology, and physical therapy.

Risks

Owing to toxicity over the long term, even non-prescription drugs must be carefully monitored in chronic pain management. NSAIDs have the well-known side effect of causing gastrointestinal bleeding, and long-term use of acetaminophen has been linked to kidney and liver damage. Other drugs, especially narcotics, have side effects such as constipation, drowsiness, and nausea. Sedation can often be reduced by the timing of when medication is taken (such as at bedtime), and constipation can be reduced by increasing the amount of fruits, vegetables, and whole-grain foods in the diet, or by the use of **laxatives**, stool softeners, or even enemas. Serious side effects can also accompany antidepressants and anticonvulsants, which may discourage or prevent their use depending upon the circumstances. These side effects include mood swings, confusion, bone thinning, cataract formation, increased blood pressure, and other problems.

Non-pharmacological therapies carry little or no risks. However, it is advised that individuals recovering from serious illness or injury consult with their health care providers or physical therapists before making use of adjunct therapies. Invasive procedures carry risks similar to other surgical procedures, such as infection, reaction to anesthesia, iatrogenic injury (injury as a result of treatment), and heart failure.

A traditional concern about narcotics use has been the risk of promoting addiction or tolerance. As narcotic use continues over time, as in terminal cancer, the body becomes accustomed to the drug and adjusts normal functions to accommodate to its presence. Therefore, to elicit the same level of action, it is necessary to increase dosage over time. Tolerance can be defined as a gradual lessening of the effectiveness of an opioid drug from continued use.

Many studies involving cancer patients have indicated that proper dosage of narcotic medication does not create an addiction to it. A major concern for many cancer patients though, is that the medication will stop working for them. Evidence suggests this is not true. A simple increase in the dose will usually cause the medication to relieve pain again. One of the biggest dangers is abruptly stopping an opioid medication or reducing the dose, as the person can then go into withdrawal, a potentially serious medical condition characterized by agitation, rapid heart rate, profuse sweating and sleeplessness.

However, physical dependence is different from psychological addiction. Physical dependence is characterized by discomfort if drug administration suddenly stops, while psychological addiction is characterized by an overpowering craving for the drug for reasons other than pain relief. Psychological addiction is a very real and necessary concern in some instances, but it should not interfere with a genuine need for narcotic pain relief.

QUESTIONS TO ASK THE DOCTOR

- Does my type of cancer usually cause pain, and if so, how will the pain be treated?
- Does the radiation or chemotherapy that I may have cause pain?
- What are the side-effects of the medications you will order?
- What things can I do to help with my pain management?
- Does the pain necessarily mean that the cancer is getting worse?

Normal results

Effective application of pain management techniques reduces or eliminates cancer pain. This treatment can improve an individual's quality of life and aid in recovery.

Perhaps the best measure of the results of pain management for cancer patients would be the fulfillment of the recently developed Bill of Rights for Cancer Pain. It is as follows:

- You have the right to be believed about the severity of your pain.
- You have the right to have your pain controlled.
- You have the right to have pain resulting from treatments and procedures prevented, or at least minimized.
- You have the right to be treated with respect at all times when you need medication; to not be treated like a drug abuser.

Pancreatic cancer, endocrine

Definition

Endocrine pancreatic cancer is a disease in which cancerous cells originate within the tissues of the pancreas that produce hormones.

Description

The pancreas is a six- to eight-inch long, slipper-shaped gland located in the abdomen. It lies behind the stomach, within a loop formed by the small intestine. Other nearby organs include the gallbladder, spleen, and liver. The pancreas has a wide end (head), a narrow end (tail), and a middle section (body). A healthy pancreas is important for normal food digestion and plays a critical role in the body's metabolic processes. The pancreas has two main functions, each performed by distinct types of tissue. The exocrine tissue secretes fluids into the other organs of the digestive system, while the endocrine tissue secretes substances that are circulated in the bloodstream. The exocrine pancreas makes up the vast majority of the gland; it produces pancreatic juices containing enzymes that help break down proteins and fatty food. The endocrine tissue of the pancreas makes up only 2% of the gland's total mass. It consists of small patches of cells that produce hormones (like insulin) that control how the body stores and uses nutrients. These patches are called islets (islands) of Langerhans or islet cells and are interspersed evenly throughout the pancreas. Each islet contains approximately 1,000 endocrine cells and a dense network of capillaries (tiny blood vessels), which allows immediate entry of hormones into the circulatory system.

Pancreatic tumors are classified as either exocrine or endocrine tumors depending on which type of tissue they arise from within the gland. Endocrine tumors of the pancreas are very rare, accounting for only 5% of all pancreatic cancers. The majority of endocrine pancreatic tumors are functional **adenocarcinomas** that overproduce a specific hormone. There are several types of islet cells and each produces its own hormone or peptide (small protein molecule). Functional endocrine tumors are named after the hormone they secrete. Insulinoma is the most common tumor of the endocrine pancreas. Patients with this disease usually develop hypoglycemia due to increased insulin production that leads to abnormally low blood sugar levels. Gastrinoma, a disease in which gastrin (hormone which stimulates stomach acid production) is overproduced, causes multiple ulcers in the upper gastrointestinal (GI) tract. Gastrinoma was first described in patients with a rare form of severe peptic ulcer disease known as **Zollinger-Ellison syndrome** (ZES). The less common glucagonoma causes mild diabetes due to excess glucagon (hormone which stimulates glucose production) secretion. Other rare islet cell tumors include vipoma (vasoactive intestinal peptide) and somatostatinoma. Nonfunctional pancreatic endocrine tumors are not associated with an excess production of any hormone and can be difficult to distinguish from exocrine pancreatic cancer. Cancers of the endocrine pancreas are relatively slow-growing compared to the more common ductal adenocarcinomas of the exocrine pancreas.

Demographics

Between one and four cases of insulinoma occur per million people per year, and 90% of these tumors are benign. They occur mostly between the ages of 50 and

60 and affect men and women equally. Less than three cases of gastrinoma per million people are diagnosed each year, but it is the most common functional islet cell tumor in patients with multiple endocrine tumors, a condition known as multiple endocrine neoplasia (MEN) syndrome. Vipoma and glucagonoma are even rarer and they occur more frequently in women. Somatostatinoma is exceedingly uncommon, and less than 100 cases have been reported worldwide. Nonfunctional islet cell cancers account for approximately one-third of all cancers of the endocrine pancreas, and the majority of these are malignant.

Causes and symptoms

There are no known causes of islet cell cancer, but a small percentage of cases occur due to hereditary syndromes such as MEN. This is a condition that frequently causes more than one tumor in several endocrine glands, such as the parathyroid and pituitary, in addition to the islet cells of the pancreas. Twenty-five percent of gastrinomas and less than 10% of insulinomas occur in MEN patients. Von Hippel-Lindau (VHL) syndrome is another genetic disorder that causes multiple tumors, and 10% to 15% of VHL patients will develop islet cell cancer.

Symptoms vary among the different islet cell cancer types. Insulinoma causes repeated episodes of hypoglycemia, sweating, and tremors, while patients with gastrinoma have inflammation of the esophagus, epigastric pain, multiple ulcers, and possibly **diarrhea**. Symptoms of glucagonoma include a distinctive skin rash, inflammation of the stomach, glucose intolerance, **weight loss**, weakness, and **anemia** (less common). Patients with vipoma have episodes of profuse, watery diarrhea, even after fasting. Somatostatinoma causes mild diabetes, diarrhea/steatorrhea (fatty stools), weight loss, and gallbladder disease. Nonfunctional endocrine tumors frequently produce the same symptoms as cancer of the exocrine pancreas such as abdominal pain, jaundice, and weight loss.

Diagnosis

A thorough physical exam is usually performed when a patient visits a doctor with the above symptoms; however, functional endocrine tumors of the pancreas tend to be small and are not detected by palpating the abdomen. Once other illnesses such as infection are ruled out, the doctor will order a series of blood and urine tests. The functional endocrine tumors can be identified through increased levels of hormone in the bloodstream.

Functional endocrine tumors can occur in multiple sites in the pancreas and are often small (less than 1 cm), making them difficult to diagnose. Nonfunctional tumors tend to be larger, which makes them difficult to distinguish from tumors of the exocrine pancreas. Methods such as **computed tomography** (CT) scan and **magnetic resonance imaging** (MRI) are used to take pictures of the internal organs and allow the doctor to determine whether a tumor is present. Somatostatin receptor scintigraphy (trade name OctreoScan) is an imaging system used to localize endocrine tumors, especially gastrinomas and somatostatinomas. Endoscopic ultrasound (EUS) is a more sensitive technique that may be used if a CT scan fails to detect a tumor. Endocrine tumors usually have many blood vessels, so **angiography** may be useful in the doctor's assessment and staging of the tumor. Surgical exploration is sometimes necessary in order to locate very small tumors that occur in multiple sites. These techniques also help the doctor evaluate how far the tumor has spread. A **biopsy** can be taken to confirm diagnosis, but more often, doctors look at the size and local invasion of the tumor in order to plan a treatment strategy.

Treatment team

Patients with islet cell cancer are cared for by a number of specialists from different disciplines. Medical oncologists, gastroenterologists, radiologists, and surgeons all interact with the patient to develop an appropriate treatment plan. Endocrinologists play an important role in helping patients with diabetes maintain steady blood sugar levels. Much of the treatment of islet cell cancer focuses on relieving symptoms of the tumor through medication that inhibits hormone overproduction. It is best for patients to work with doctors who are experienced in treating this rare form of cancer.

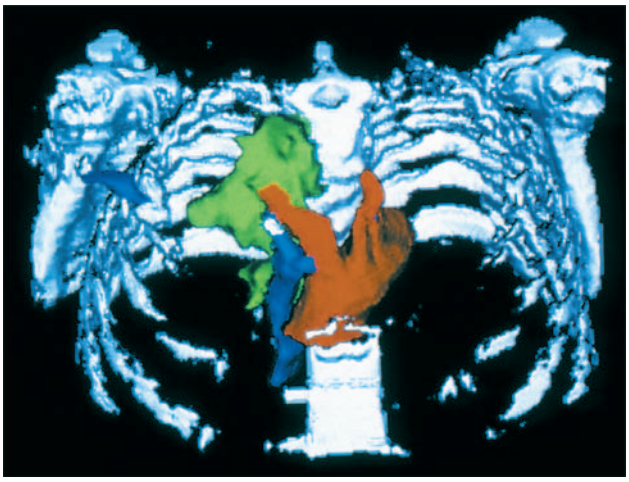
Clinical staging, treatments, and prognosis

Staging

The staging system for islet cell cancer is still evolving, but the tumors typically fall into three categories: cancers that arise in one location within the pancreas, cancers that arise in several locations within the pancreas, and cancers that have spread to nearby lymph nodes or to other organs in the body.

Treatments

Surgery is the only curative method for islet cell cancers, and studies have shown that an aggressive surgical approach can improve survival and alleviate symptoms of the disease. As with most forms of cancer, the earlier it is diagnosed, the greater the chance



Colorized computed tomography (CT) scan showing the location of a cancerous tumor of the pancreas (green). *(Copyright Clinique Ste Catherine/CNRI, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

for survival. With the exception of insulinoma, the majority of islet cell tumors are malignant at the time of diagnosis, and more than half are metastatic. However, surgery and **chemotherapy** have been shown to improve the outcome of patients even if they have metastatic disease. Surgery may include partial or total removal of the pancreas, and in patients with gastrinoma, the stomach may be removed as well. Streptozocin, **doxorubicin**, and 5-fluorouracil (5-FU, or fluorouracil) are chemotherapeutic agents commonly used in the treatment of islet cell cancer. Patients may experience **nausea and vomiting**, as well as kidney toxicity, from streptozocin, and bone marrow suppression from doxorubicin. Hormone therapy is used to relieve the symptoms of functional tumors by inhibiting excess hormone production. Other techniques may be used to block blood flow to the liver in an attempt to kill the cancer cells that have spread there. Abdominal pain, nausea, vomiting, and **fever** may result from this type of treatment. Radiation has little if any role in the treatment of islet cell cancer.

Prognosis

Islet cell cancers overall have a more favorable prognosis than cancers of the exocrine pancreas, and the median survival from diagnosis is three-and-half years. This is mainly due to their slow-growing nature. Insulinomas have a five-year survival rate of 80% and gastrinomas have 65%. When malignant, islet cell cancers do not generally respond well to chemotherapy, and the treatment is mainly palliative. Most patients with **metastasis** do not survive five years. Islet cell cancer tends to spread to the surrounding lymph nodes, stomach, small intestine, and liver.

KEY TERMS

Adenocarcinoma—A malignant tumor that arises within the tissues of a gland and retains its glandular structure.

Angiography—Diagnostic technique used to study blood vessels in a tumor.

Biopsy—Removal and microscopic examination of cells to determine whether they are cancerous.

Chemotherapy— Drug treatment administered to kill cancerous cells.

Endocrine—Refers to glands that secrete hormones circulated in the bloodstream.

Endoscopic Ultrasonography (EUS)—Diagnostic imaging technique where an ultrasound probe is inserted down a patient's throat to determine if a tumor is present.

Gastrinoma—Tumor that arises from the gastrin-producing cells in the pancreas.

Insulinoma—Tumor that arises from the insulin-producing cells in the pancreas.

Islets of Langerhans—Clusters of cells in pancreas that make up the endocrine tissue.

Coping with cancer treatment

Patients should discuss with their doctors any side effects they experience from treatment. Many drugs are available to relieve nausea and vomiting associated with cancer treatments and for combating **fatigue**. Insulin may be prescribed if patients develop diabetes as a result of partial or total removal of their pancreas. Special diets or fluids may be recommended if patients have more than one digestive organ removed. These patients may require intravenous feeding after surgery until they recover.

Clinical trials

Because this is such a rare disease, relatively few **clinical trials** are available to people with islet cell cancer. Most are investigating the efficacy of new chemotherapeutic drugs or combinations of drugs and biological therapies. R115777 is an agent being tested in combination with **trastuzumab** (Herceptin) for patients with advanced or metastatic adenocarcinoma. Two new drugs that are antineoplastons, A10 and

QUESTIONS TO ASK THE DOCTOR

- What type of islet cell cancer do I have?
- Do you have experience in treating this form of cancer?
- Is my tumor benign or malignant?
- What is my prognosis?
- Can my tumor be removed by surgery?
- What medication will I need to take?
- Am I at risk for developing other endocrine tumors?
- Is there a clinical trial I can participate in?
- Is there a support group available?

AS2-1, are being examined together as a treatment regimen for patients with metastatic or incurable **neuroendocrine tumors**. Patients should ask their doctors whether they qualify for these or other clinical trials.

Prevention

There are no known risk factors associated with sporadic islet cell cancer. Therefore, it is not clear how to prevent its occurrence. Individuals with MEN syndrome or VHL, however, have a genetic predisposition to developing islet cell cancer should be screened regularly in an effort to catch the disease early.

Special concerns

Many patients find it helpful to join support groups after being diagnosed with cancer. Discussing the condition with others who are experiencing a similar situation may help to relieve anxiety and **depression**, which are often associated with cancer and its treatment. Medication may also be prescribed to alleviate depression. Patients should learn as much as they can about their illness and find out what their treatment options are. It is important for patients to remember that each cancer has unique characteristics and responds differently to treatment depending on those characteristics.

Pancreatic cancer, exocrine

Definition

Exocrine pancreatic cancer is a disease in which cancerous cells originate within the tissues of the pancreas that produce digestive juices.

Description

The pancreas is a six- to eight-inch long, slipper-shaped gland located in the abdomen. It lies behind the stomach, within a loop formed by the small intestine. Other nearby organs include the gallbladder, spleen, and liver. The pancreas has a wide end (head), a narrow end (tail), and a middle section (body). A healthy pancreas is important for normal food digestion and also plays a critical role in the body's metabolic processes. The pancreas has two main functions, and each are performed by distinct types of tissue. The exocrine tissue makes up the vast majority of the gland and

secretes fluids into the other organs of the digestive system. The endocrine tissue secretes hormones (like insulin) that are circulated in the bloodstream, and these substances control how the body stores and uses nutrients. The exocrine tissue of the pancreas produces pancreatic (digestive) juices. These juices contain several enzymes that help break down proteins and fatty foods. The exocrine pancreas forms an intricate system of channels or ducts, which are tubular structures that carry pancreatic juices to the small intestine where they are used for digestion.

Pancreatic tumors are classified as either exocrine or endocrine tumors depending on which type of tissue they arise from within the gland. Ninety-five percent of pancreatic cancers occur in the tissues of the exocrine pancreas. Ductal adenocarcinomas arise in the cells that line the ducts of the exocrine pancreas and account for 80% to 90% of all tumors of the pancreas. Unless specified, nearly all reports on pancreatic cancer refer to ductal adenocarcinomas. Less common types of pancreatic exocrine tumors include acinar cell **carcinoma**, cystic tumors that are typically benign but may become cancerous, and papillary tumors that grow within the pancreatic ducts. Pancreatoblastoma is a very rare disease that primarily affects young children. Two-thirds of pancreatic tumors occur in the head of the pancreas, and tumor growth in this area can lead to the obstruction of the nearby common bile duct that empties bile fluid into the small intestine. When bile cannot be passed into the intestine, patients may develop yellowing of the skin and eyes (jaundice) due to the buildup of bilirubin (a component of bile) in the bloodstream. Tumor blockage of bile or pancreatic ducts may also cause digestive problems since these fluids contain critical enzymes in the digestive process. Depending on their size, pancreatic tumors may cause abdominal pain by pressing on the surrounding nerves. Because of its location deep within the abdomen, pancreatic cancer often remains undetected until it has spread to other organs such as the liver or lung. Pancreatic cancer tends to rapidly spread to other organs, even when the primary (original) tumor is relatively small.

Demographics

Though pancreatic cancer accounts for only 3% of all cancers, it is the fifth most frequent cause of cancer deaths. In 2001, an estimated 29,200 new cases of pancreatic cancer will be diagnosed in the United States. Pancreatic cancer is primarily a disease associated with advanced age, with 80% of cases occurring between the ages of 60 and 80. Men are almost twice as likely to develop this disease than women. Countries with the highest frequencies of pancreatic cancer include the U.S., New Zealand, Western European nations, and Scandinavia. The lowest occurrences of the disease are reported in India, Kuwait and Singapore. African Americans have the highest rate of pancreatic cancer of any ethnic group worldwide. Whether this difference is due to diet or environmental factors remains unclear.

Causes and symptoms

Although the exact cause for pancreatic cancer is not known, several risk factors have been shown to increase susceptibility to this particular cancer, the greatest of which is cigarette smoking. Approximately one-third of pancreatic cancer cases occur among smokers. People who have diabetes develop pancreatic cancer twice as often as non-diabetics. Numerous studies suggest that a family history of pancreatic cancer is another strong risk factor for developing the disease, particularly if two or more relatives in the immediate family have the disease. Other risk factors include chronic (long-term) inflammation of the pancreas (pancreatitis), diets high in fat, and occupational exposure to certain chemicals such as petroleum.

Pancreatic cancer often does not produce symptoms until it reaches an advanced stage. Patients may then present with the following signs and symptoms:

- upper abdominal and/or back pain
- jaundice
- weight loss
- loss of appetite (anorexia)
- diarrhea
- weakness
- nausea

These symptoms may also be caused by other illnesses; therefore, it is important to consult a doctor for an accurate diagnosis.

Diagnosis

Pancreatic cancer is difficult to diagnose, especially in the absence of symptoms, and there is no current screening method for early detection. The most sophisticated techniques available often do not detect very small tumors that are localized (have not begun to spread). At advanced stages where patients show symptoms, a number of tests may be performed to confirm diagnosis and to assess the stage of the disease. Approximately half of all pancreatic cancers are metastatic (have spread to other sites) at the time of diagnosis.

The first step in diagnosing pancreatic cancer is a thorough medical history and complete physical examination. The abdomen will be palpated to check for fluid

accumulation, lumps, or masses. If there are signs of jaundice, blood tests will be performed to rule out the possibility of liver diseases such as hepatitis. Urine and stool tests may be performed as well.

Non-invasive imaging tools such as **computed tomography** (CT) scans and **magnetic resonance imaging** (MRI) can be used to produce detailed pictures of the internal organs. CT is the tool most often used to diagnose pancreatic cancer, as it allows the doctor to determine if the tumor can be removed by surgery or not. It is also useful in staging a tumor by showing the extent to which the tumor has spread. During a CT scan, patients receive an intravenous injection of a contrast dye so the organs can be visualized more clearly. MRI may be performed instead of CT if a patient has an allergy to the CT contrast dye. In some cases where the tumor is impinging on blood vessels or nearby ducts, MRI may be used to generate an image of the pancreatic ducts.

If the doctor suspects pancreatic cancer and no visible masses are seen with a CT scan, a patient may undergo a combination of invasive tests to confirm the presence of a pancreatic tumor. Endoscopic ultrasound (EUS) involves the use of an ultrasound probe at the end of a long, flexible tube that is passed down the patient's throat and into the stomach. This instrument can detect a tumor mass through high frequency sound waves and echoes. EUS can be accompanied by fine needle aspiration (FNA), where a long needle, guided by the ultrasound, is inserted into the tumor mass in order to take a **biopsy** sample. **Endoscopic retrograde cholangiopancreatography** (ERCP) is a technique often used in patients with severe jaundice because it enables the doctor to relieve blockage of the pancreatic ducts. The doctor, guided by endoscopy and x rays, inserts a small metal or plastic stent into the duct to keep it open. During ERCP, a biopsy can be done by collecting cells from the pancreas with a small brush. The cells are then examined under the microscope by a pathologist, who determines the presence of any cancerous cells.

In some cases, a biopsy may be performed during a type of surgery called **laparoscopy**, which is done under general anesthesia. Doctors insert a small camera and instruments into the abdomen after a minor incision is made. Tissue samples are removed for examination under the microscope. This procedure allows a doctor to determine the extent to which the disease has spread and decide if the tumor can be removed by further surgery.

An **angiography** is a type of test that studies the blood vessels in and around the pancreas. This test may be done before surgery so that the doctor can determine the extent to which the tumor invades and interacts with the blood vessels within the pancreas. The test requires local anesthesia and a catheter is inserted into the patient's upper thigh. A dye is then injected into blood vessels that lead into the pancreas, and x rays are taken.

As of April 2001, doctors at major cancer research institutions such as Memorial Sloan-Kettering Cancer Center in New York were investigating CT angiography, an imaging technique that is less invasive than angiography alone. CT angiography is similar to a standard CT scan, but allows doctors to take a series of pictures of the blood vessels that support tumor growth. A dye is injected as in a CT scan (but at rapid intervals) and no catheter or sedation is required. A computer generates 3D images from the pictures that are taken, and the information is gathered by the surgical team who will develop an appropriate strategy if the patient's disease can be operated on.

Treatment team

Pancreatic cancer is a complex disease that involves specialists from a variety of medical disciplines. Patients are likely to interact with medical oncologists, gastroenterologists, radiologists, and surgeons to develop a suitable treatment plan. Treatment plans vary depending on the stage of the disease and the overall health of the patient. Cancers of the pancreas frequently cause intense pain by pressing on the surrounding network of nerves in the abdomen; therefore, anesthesiologists who specialize in pain management may play a role in making a patient more comfortable. Obstruction of the intestine or bowel can also be a cause of pain, but is usually relieved through surgery. Patients receiving **chemotherapy** meet with oncologists who determine the dose schedule and oncology nurses who administer the chemotherapy. Patients who undergo partial or total removal of their pancreas may develop diabetes, and an endocrinologist will prescribe insulin or other medication to help them manage this condition. It is important for patients to get proper nutrition during any treatment for cancer. Patients may wish to consult a nutritionist or dietician to assist them (this may require oral replacement of digestive enzymes).

Clinical staging, treatments, and prognosis

Staging

After cancer of the pancreas has been diagnosed, doctors typically use a TNM staging system to classify the tumor based on its size and the degree to which it has spread to other areas in the body. T indicates the size and local advancement of the primary tumor. Since cancers often invade the lymphatic system before

spreading to other organs, regional lymph node involvement (N) is an important factor in staging. M indicates whether the tumor has metastasized (spread) to distant organs. In stage I, the tumor is localized to the pancreas and has not spread to surrounding lymph nodes or other organs. Stage II pancreatic cancer has spread to nearby organs such as the small intestine or bile duct, but not the surrounding lymph nodes. Stage III indicates lymph node involvement, whether the cancer has spread to nearby organs or not. Stage IVA pancreatic cancer has spread to organs near the pancreas such as the stomach, spleen, or colon. Stage IVB is a cancer that has spread to distant sites (liver, lung). If pancreatic cancer has been treated with success and then appears again in the pancreas or in other organs, it is referred to as recurrent disease.

Treatments

Treatment of pancreatic cancer will depend on several factors, including the stage of the disease and the patient's age and overall health status. A combination of therapies is often employed in the treatment of this disease to improve the patient's chances for survival. Surgery is used whenever possible and is the only means by which cancer of the pancreas can be cured. However, less than 15% of pancreatic tumors can be removed by surgery. By the time the disease is diagnosed (usually at Stage III), therapies such as radiation and chemotherapy or both are used in addition to surgery to relieve a patient's symptoms and enhance quality of life. For patients with metastatic disease, chemotherapy and radiation are used mainly as palliative (pain-alleviating) treatments.

SURGERY Three types of surgery are used in the treatment of pancreatic cancer, depending on what section of the pancreas the tumor is located in. A Whipple procedure removes the head of the pancreas, part of the small intestine and some of the surrounding tissues. This procedure is most common since the majority of pancreatic cancers occur in the head of the organ. A total pancreatectomy removes the entire pancreas and the organs around it. Distal pancreatectomy removes only the body and tail of the pancreas. Chemotherapy and radiation may precede surgery (neoadjuvant therapy) or follow surgery (adjuvant therapy). Surgery is also used to relieve symptoms of pancreatic cancer by draining fluids or bypassing obstructions. Side effects from surgery can include pain, weakness, **fatigue**, and digestive problems. Some patients may develop diabetes or malabsorption as a result of partial or total removal of the pancreas.

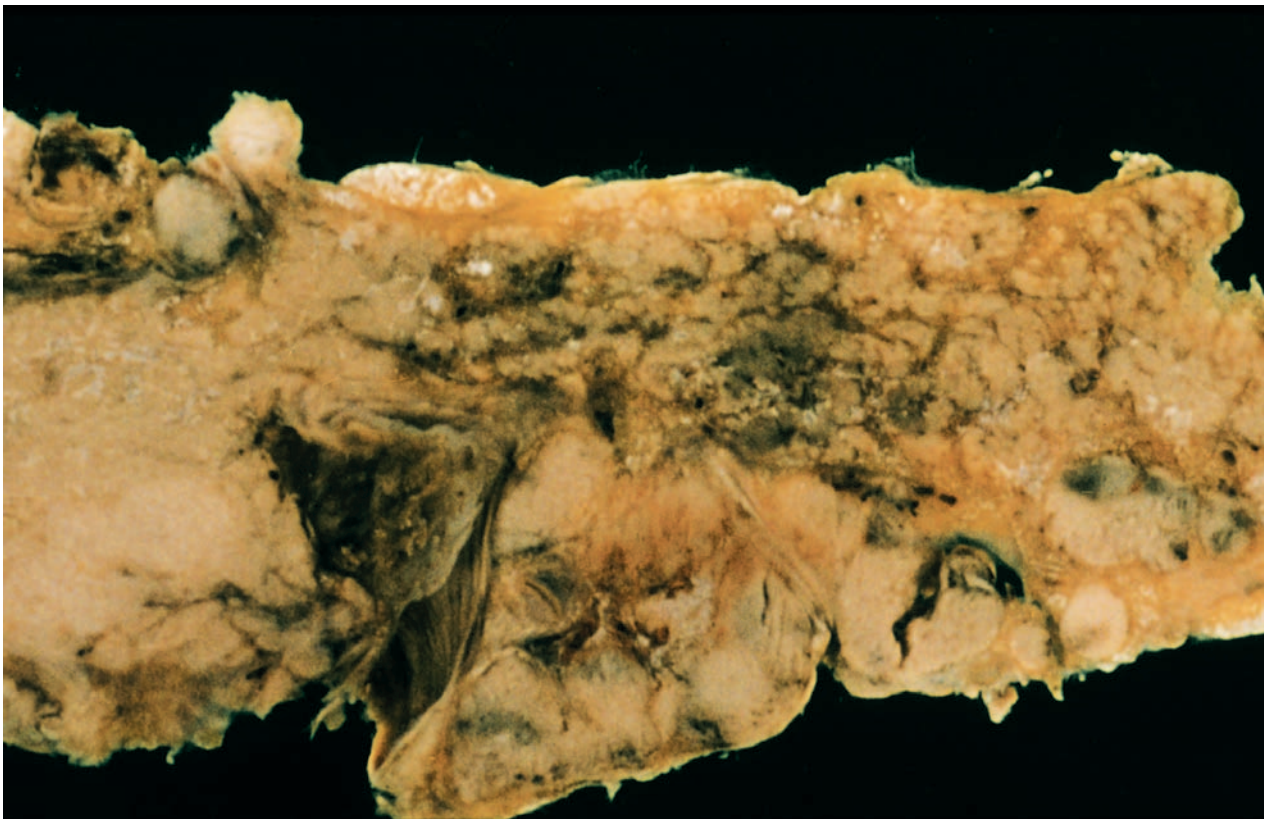
RADIATION THERAPY **Radiation therapy** is sometimes used to shrink a tumor before surgery or to remove remaining cancer cells after surgery. Radiation may also be used to relieve pain or digestive problems caused by the tumor if it cannot be removed by surgery. External radiation therapy refers to radiation applied externally to the abdomen using a beam of high-energy x rays. High-dose intraoperative radiation therapy is sometimes used during surgery on tumors that have spread to nearby organs. Internal radiation therapy refers to the use of small radioactive seeds implanted in the tumor tissue. The seeds emit radiation over a period of time to kill tumor cells. Radiation treatment may cause side effects such as fatigue, tender or itchy skin, nausea, vomiting, and digestive problems.

CHEMOTHERAPY Chemotherapeutic agents are powerful drugs that are used to kill cancer cells. They are classified according to the mechanism by which they induce cancer cell death. Multiple agents are often used to increase the chances of tumor cell death. **Gemcitabine** is the standard drug used to treat pancreatic cancers and can be used alone or in combination with other drugs, such as 5-fluorouracil (5-FU, or fluorouracil). Other drugs are being tested in combination with gemcitabine in several ongoing **clinical trials**, specifically **irinotecan** (CPT-11) and **oxaliplatin**. Chemotherapy may be administered orally or intravenously in a series of doses over several weeks. During treatment, patients may experience fatigue, nausea, vomiting, hair loss (alopecia), and mouth sores, depending on which drugs are used.

BIOLOGICAL TREATMENTS Numerous vaccine treatments are being developed in an effort to stimulate the body's immune system into attacking cancer cells. This is also referred to as immunotherapy. Another type of biological treatment involves using a targeted monoclonal antibody to inhibit the growth of cancer cells. The antibody is thought to bind to and neutralize a protein that contributes to the growth of the cancer cells. Investigational treatments such as these may be considered by patients with metastatic disease who would like to participate in a clinical trial. Biological treatments typically cause flu-like symptoms (chills, **fever**, loss of appetite) during the treatment period.

Prognosis

Unfortunately, cancer of the pancreas is often fatal, and median survival from diagnosis is less than six months, while the five-year survival rate is 4%. This is mainly due to the lack of screening methods available for early detection of the disease. Yet, even when localized tumors can be removed by surgery, patient survival after five years is only 10% to 15%. These statistics demonstrate the aggressive nature of most pancreatic cancers and their tendency to recur. Pancreatic cancers tend to be resistant to radiation and chemotherapy and



Carcinoma of the head of the pancreas. Tumors appear as gritty, gray, hard nodules, invading the adjacent gland. *(Copyright Biophoto Associates, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

these modes of treatment are mainly used to relieve pain and tumor burden.

Alternative and complementary therapies

Acupuncture or hypnotherapy may be used in addition to standard therapies to help relieve the pain associated with pancreatic cancer. Because of the poor prognosis associated with pancreatic cancer, some patients may try special diets with vitamin supplements, certain exercise programs, or unconventional treatments not yet approved by the FDA. Patients should always inform their doctors of any alternative treatments they are using as they could interfere with standard therapies. As of 2000, the National Cancer Institute (NCI) was funding phase III clinical trials of a controversial treatment for pancreatic cancer that involves the use of supplemental pancreatic enzymes (to digest cancerous cells) and coffee enemas (to stimulate the liver to detoxify the cancer). These theories remain unproven and the study is widely criticized in the medical community. It remains to been seen whether this method of treatment has any advantage over the standard chemotherapeutic regimen in prolonging patient survival or improving quality of life.

Coping with cancer treatment

Patients should discuss with their doctors any side effects they experience from treatment. Many drugs are available to relieve **nausea and vomiting** associated with cancer treatments and for combating fatigue. Special diets or supplements, including pancreatic enzymes, may be recommended if patients are experiencing digestive problems. Insulin or other medication may be prescribed if patients develop diabetes as a result of partial or total removal of their pancreas.

Clinical trials

A large number of clinical trials are underway to assess the therapeutic effect of new chemotherapy regimens and several new immunotherapies. Gemcitabine is being tested in combination with irinotecan (CPT-11) in patients with metastatic pancreatic disease. Other agents under investigation are DX-8951f and R115777. Some drugs are being tested in combination with radiation therapy or with biological therapies. Two preliminary studies using the vaccine G17DT showed a significant improvement in the survival of patients with advanced pancreatic

cancer. The monoclonal antibody cetuximab (IMC-C225) in combination with gemcitabine also showed positive preliminary results. There are trials available for patients with all stages of pancreatic cancer. Patients can find out which trials they are eligible for by talking with their doctors. Information about ongoing trials can be found at <http://cancernet.nci.nih.gov/trialsrch.shtml>. Many treatments given during clinical trials are considered experimental by **health insurance** companies and may not be covered by certain health plans. Patients should discuss their options with their doctors and health insurance providers.

Prevention

Although the exact cause of pancreatic cancer is not known, there are certain risk factors that may increase a person's chances of developing the disease. Quitting smoking will certainly reduce the risk for pancreatic cancer and many other cancers. The American Cancer Society recommends a diet rich in fruits, vegetables, and dietary fiber in order to reduce the risk of pancreatic cancer. According to the NCI, workers who are exposed to petroleum and other chemicals may be at greater risk for developing the disease and should follow their employer's safety precautions. People with a family history of pancreatic cancer are at greater risk than the general population, as a small percentage of pancreatic cancers are considered hereditary.

Special concerns

Pain control is probably the single greatest problem for patients with pancreatic cancer. As the cancer grows and spreads to other organs in the abdomen, it often presses on the surrounding network of nerves, which can cause considerable discomfort. In most cases, pain can be alleviated with analgesics or **opioids**. If medication is not enough, a doctor may inject alcohol into the abdominal nerve area to numb the pain. Surgical treatment of the affected nerves is also an option.

Pancreatic cancer patients frequently have difficulty maintaining their weight because food may not taste good or the pancreas is not releasing enough enzymes needed for digestion. Therefore, supplements of pancreatic enzymes may be helpful in restoring proper digestion. Other nutritional supplements may be given orally or intravenously in an effort to boost calorie intake. However, cachexia (severe muscle breakdown) caused by certain substances that the cancer produces, remains a significant problem to treat.

Patients with pancreatic cancer may experience anxiety and **depression** during their diagnosis and treatment. Statistics on the prognosis for the disease can be discouraging, however, there are many new treatments on the horizon that may significantly improve the outcome for this disease. Many patients find it helpful to join support groups where they can discuss their concerns with others who are also coping with the illness.

KEY TERMS

Acinar cell(s)—Cells that comprise small sacs terminating the ducts of some exocrine glands.

Acinar cell carcinoma—A malignant tumor arising from the acinar cells of the pancreas.

Angiography—Diagnostic technique used to study blood vessels in a tumor.

Biopsy—Removal and microscopic examination of cells to determine whether they are cancerous.

Cancer vaccines—A treatment that uses the patient's immune system to attack cancer cells.

Chemotherapy— Drug treatment administered to kill cancerous cells.

Ductal adenocarcinoma—A malignant tumor arising from the duct cells within a gland.

Endoscopic retrograde cholangiopancreatography (ERCP)—Diagnostic technique used to obtain a biopsy. Also a surgical method of relieving biliary obstruction caused by a tumor.

Endoscopic ultrasonography (EUS)—Diagnostic imaging technique in which an ultrasound probe is inserted down a patient's throat to determine if a tumor is present.

Exocrine—Refers to glands which secrete their products through a duct.

Laparoscopic surgery—Minimally invasive surgery in which a camera and surgical instruments are inserted through a small incision.

Pancreatectomy—Partial or total surgical removal of the pancreas.

Radiation therapy—Use of radioisotopes to kill tumor cells. Applied externally through a beam of x rays, intraoperatively (during surgery), or deposited internally by implanting radioactive seeds in tumor tissue.

Whipple procedure—Surgical removal of the head of the pancreas, part of the small intestine, and some surrounding tissue.

QUESTIONS TO ASK THE DOCTOR

- What is my prognosis?
- What is the standard course of treatment for my cancer at this stage?
- How long will the course of treatment take?
- What side effects will I experience?
- What can be done to relieve my abdominal pain?
- What should I do to prepare for surgery?
- Can you refer me to a nutritionist or dietician?
- Are there any alternative therapies you would recommend?
- Am I eligible to participate in a clinical trial?
- Will my health insurance cover costs associated with a clinical trial?
- Are there any support groups I can join?

Pap test

Definition

The Pap test is a procedure in which a physician scrapes cells from the cervix or vagina to check for **cervical cancer**, **vaginal cancer**, or abnormal changes that could lead to cancer. It often is called a Pap smear.

Purpose

The Pap test is used to detect abnormal growth of cervical cells at an early stage so that treatment can be started when the condition is easiest to treat. This microscopic analysis of cells can detect cervical cancer, precancerous changes, inflammation (vaginitis), infections, and some sexually transmitted diseases (STDs). The Pap test can occasionally detect endometrial (uterine) cancer or **ovarian cancer**, although it was not designed for this purpose.

Women should begin to have Pap tests at the age of 21 or within three years of becoming sexually active, whichever comes first. Young people are more likely to have multiple sex partners, which increases their risk of certain diseases that can cause cancer, such as human papillomavirus (HPV).

The American Cancer Society (ACS) updated its guidelines concerning Pap test frequency in late 2002. In brief, women should continue screening every year with

regular Pap tests until age 30, every two years if using the liquid-based Pap test. Once a woman age 30 and older has had three normal results in a row, she may get screened every two to three years. A doctor may suggest more frequent screening if a woman has certain risk factors for cervical cancer. Women who have had total hysterectomies including the removal of the cervix do not need Pap tests unless the hysterectomy resulted from cervical cancer. Those over age 70 who have had three normal results generally do not need to continue having Pap tests under the new guidelines.

Women with certain risk factors should always have yearly tests. Those at highest risk for cervical cancer are women who started having sex before age 18, those with many sex partners (especially if they did not use condoms, which protect against STDs), those who have had STDs such as genital herpes or genital warts, and those who smoke. Women older than 40 may have the test yearly, if experiencing bleeding after menopause. Women who have had a positive test result in the past may need screening every six months. Women who have had cervical cancer or precancer should have regular Pap smears.

Other women also benefit from the Pap test. Women over age 65 account for 25% of all cases of cervical cancer and 41% of deaths from this disease. Women over age 65 who have never had a Pap smear benefit the most from a Pap smear. Even a woman who has had a hysterectomy (removal of the uterus) should continue to have regular Pap tests at the discretion of the woman and the provider. If the surgery was for cancer, she may need to be examined more often than once a year. (Some women have the cervix left in place after hysterectomy.) Finally, a pregnant woman should have a Pap test as part of her first prenatal examination.

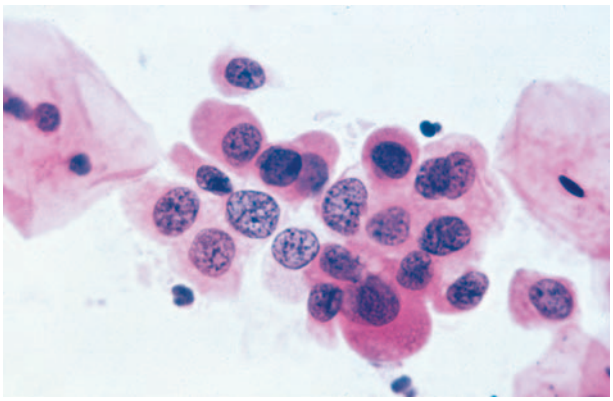
The Pap test is a **screening test**. It identifies women who are at increased risk of cervical dysplasia (abnormal cells) or cervical cancer. Only an examination of the cervix with a special lighted instrument (colposcopy) and samples of cervical tissue (biopsies) can actually diagnose these problems.

Precautions

The Pap test is usually not done during the menstrual period because of the presence of blood cells. The best time is in the middle of the menstrual cycle.

Description

The Pap test is an extremely cost-effective and beneficial test. Cervical cancer used to be a leading cause of cancer deaths in American women, but widespread use of this diagnostic procedure reduced the death rate from this disease by 74% between 1955 and 1992. A 2003 study reported that the test reduces rates of invasive cervical cancer by as much as 94%. In 2003, the FDA approved a new screening test that combines DNA testing for the HPV type that causes the most cases of cervical cancer with the standard Pap test, increasing its screening value.



These malignant cells were taken from a woman's cervix during a Pap test. *(Photograph by Parviz M. Pour, Photo Researchers, Inc. Reproduced by permission.)*

The Pap test, sometimes called a cervical smear, is the microscopic examination of cells scraped from both the outer cervix and the cervical canal. (The cervix is the opening between the vagina and the uterus, or womb.) It is called the "Pap" test after its developer, Dr. George N. Papanicolaou. This simple procedure is performed during a gynecologic examination and is usually covered by insurance. For those with coverage, Medicare will pay for one screening Pap smear every three years.

During the pelvic examination, an instrument called a speculum is inserted into the vagina to open it. The doctor then uses a tiny brush, or a cotton-tipped swab and a small spatula to wipe loose cells off the cervix and to scrape them from the inside of the cervix. The cells are transferred or "smeared" onto glass slides, the slides are treated to stabilize the cells, and the slides are sent to a laboratory for microscopic examination. The entire procedure is usually painless and takes five to ten minutes at most.

The newer method called liquid-based cytology, or the liquid-based Pap test, involves spreading the cells more evenly on a slide after removing them from the sample. The liquid-based method prevents cells from drying out and becoming distorted. Studies show that liquid-based testing slightly improves cancer detection and greatly improves detection of precancers, but it costs more than the traditional Pap test. Trade names in 2003 for liquid-based Pap smears were ThinPrep and AutoCyte.

Preparation

The Pap test may show abnormal results when a woman is healthy or normal results in women with cervical abnormalities as much as 25% of the time. It may even miss up to 5% of cervical cancers. Some simple preparations may help to ensure that the results are reliable. Among the measures that may help increase test reliability are:

- Avoiding sexual intercourse for two days before the test.
- Not using douches for two or three days before the test.
- Avoiding using tampons, vaginal creams, or birth control foams or jellies for two to three days before the test.
- Scheduling the Pap smear when not menstruating. However, most women are not routinely advised to make any special preparations for a Pap test.

If possible, women may want to ensure that their test is performed by an experienced gynecologist, physician, or provider and sent to a reputable laboratory. The physician should be confident in the accuracy of the chosen lab.

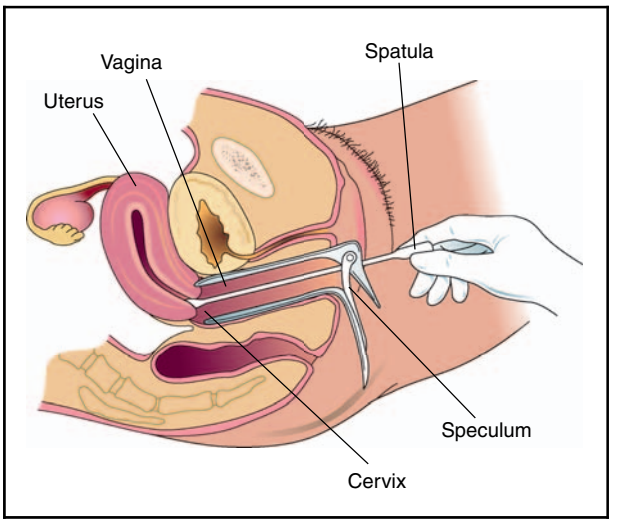
Before the exam, the physician will take a complete sexual history to determine a woman's risk status for cervical cancer. Questions may include date and results of the last Pap test, any history of abnormal Pap tests, date of last menstrual period and any irregularity, use of hormones and birth control, family history of gynecologic disorders, and any vaginal symptoms. These topics are relevant to the interpretation of the Pap test, especially if any abnormalities are detected. Immediately before the Pap test, the woman should empty her bladder to avoid discomfort during the procedure.

Aftercare

Harmless cervical bleeding is possible immediately after the test; a woman may need to use a sanitary napkin. She should also be sure to comply with her doctor's orders for follow-up visits.

Risks

No appreciable health risks are associated with the Pap test. However, abnormal results (whether valid or due to technical error) can cause significant anxiety. Women may wish to have their sample double-checked, either by the same laboratory or by the new technique of computer-assisted rescreening. The Food and Drug Administration (FDA) has approved the use of AutoPap and PAPNET to doublecheck samples that have been examined by technologists. AutoPap may also be used to perform initial screening of slides, which are then checked by a technologist. Any abnormal Pap test should be followed by colposcopy, not by double checking the Pap test.



The Pap test is a procedure used to detect abnormal growth of cervical cells that may be a precursor to cancer of the cervix. It is administered by a physician who inserts a speculum into the vagina to open and separate the vaginal walls. A spatula is then inserted to scrape cells from the cervix. These cells are transferred onto glass slides for laboratory analysis. The Pap test may also identify vaginitis, some sexually transmitted diseases, and cancers of the uterus and ovaries. *(Illustration by Electronic Illustrators Group. Reproduced by permission of The Gale Group.)*

Normal results

Normal (negative) results from the laboratory exam mean that no atypical, dysplastic, or cancer cells were detected, and the cervix is normal.

Abnormal results

Terminology

Abnormal cells found on the Pap test may be described using two different grading systems. Although this can be confusing, the systems are quite similar. The "Bethesda" system is based on the term "squamous intraepithelial lesion" (SIL). Precancerous cells are classified as "atypical squamous cells of undetermined significance," "low-grade" SIL, or "high-grade" SIL. Low-grade SIL includes mild dysplasia (abnormal cell growth) and abnormalities caused by HPV; high-grade SIL includes moderate or severe dysplasia and carcinoma in situ (cancer that has not spread beyond the cervix).

KEY TERMS

Carcinoma in situ—Malignant cells that are present only in the outer layer of the cervix.

Cervical intraepithelial neoplasia (CIN)—A term used to categorize degrees of dysplasia arising in the epithelium, or outer layer, of the cervix.

Dysplasia—Abnormal changes in cells.

Human papillomavirus (HPV)—The most common STD in the United States. Various types of HPV are known to cause cancer.

Neoplasia—Abnormal growth of cells, which may lead to a neoplasm, or tumor.

Squamous intraepithelial lesion (SIL)—A term used to categorize the severity of abnormal changes arising in the squamous, or outermost, layer of the cervix.

QUESTIONS TO ASK THE DOCTOR

- How will paracentesis benefit me?
- Will I have to have this procedure more than once?
- How soon after this procedure can I resume my normal activities?
- Will paracentesis cure my problem?
- Will I require hospitalization?

Another term that may be used is "cervical intraepithelial neoplasia" (CIN). In this classification system, mild dysplasia is called CIN I, moderate is CIN II, and severe dysplasia or carcinoma in situ is CIN III.

Regardless of terminology, it is important to remember that an abnormal (positive) result does not necessarily indicate cancer. Results may be falsely abnormal after infection or irritation of the cervix. Up to 40% of mild dysplasia reverts to normal tissue without treatment, and only 1% of mild abnormalities ever develop into cancer.

Treatment

CHANGES OF UNKNOWN CAUSE The most common abnormality found in Pap tests is atypical squamous cells of undetermined significance (ASCUS), which are found in 4% of all Pap tests. Sometimes these results are described further as either reactive or precancerous. Reactive changes suggest that the cervical cells are responding to inflammation, such as from a yeast infection. These women may be treated for infection and then undergo repeat Pap testing in three to six months. If those results are negative, no further treatment is necessary. This category may also include atypical "glandular" cells, which could imply a more severe type of cancer and requires repeat testing and further evaluation.

DYSPLASIA The next most common finding (in about 25 of every 1,000 tests) is low-grade SIL, which includes mild dysplasia or CIN I and changes caused by HPV. Unlike cancer cells, these cells do not invade normal tissues. Women are most susceptible to cervical dysplasia between the ages of 25 and 35. Typically, dysplasia causes no symptoms, although women may experience abnormal vaginal bleeding. Because dysplasia is precancerous, it should be treated if it is moderate or severe.

Treatment of dysplasia depends on the degree of abnormality. In women with no other risk factors for cervical cancer, mild precancerous changes may be simply observed over time with repeat testing, perhaps every four to six months. This strategy works only if women are diligent about keeping later appointments. Premalignant cells may remain that way without causing cancer for five to ten years, and may never become malignant.

In women with positive results or risk factors, the gynecologist must perform colposcopy and **biopsy**. A colposcope is an instrument that looks like binoculars, with a light and a magnifier, used to view the cervix. Biopsy, or removal of a small piece of abnormal, cervical or vaginal tissue for analysis, is usually done at the same time.

High-grade SIL (found in three of every 50 Pap tests) includes moderate to severe dysplasia or carcinoma in situ (CIN II or III). After confirmation by colposcopy and biopsy, it must be removed or destroyed to prevent further growth. Several outpatient techniques are available: conization (removal of a cone-shaped piece of tissue), laser surgery, **cryotherapy** (freezing), or the "loop electrosurgical excision procedure." Cure rates are nearly 100% after prompt and appropriate treatment of carcinoma in situ. Of course, frequent checkups are then necessary.

CANCER HPV, the most common STD in the United States, may be responsible for many cervical cancers. Cancer may be manifested by unusual vaginal bleeding or discharge, bowel and bladder problems, and pain. Women are at greatest risk of developing cervical cancer between the ages of 30 and 40 and between the ages of 50 and 60. Most new cancers are diagnosed in women between 50

and 55. Although the likelihood of developing this disease begins to level off for Caucasian women at the age of 45, it increases steadily for African-Americans for another 40 years. Biopsy is indicated when any abnormal growth is found on the cervix, even if the Pap test is negative.

Doctors have traditionally used **radiation therapy** and surgery to treat cervical cancer that has spread within the cervix or throughout the pelvis. In severe cases, post-operative radiation is administered to kill any remaining cancer cells, and **chemotherapy** may be used if cancer has spread to other organs. Recent studies have shown that giving chemotherapy and radiation at the same time improves a patient's chance of survival. The National Cancer Institute has urged physicians to strongly consider using both chemotherapy and radiation to treat patients with invasive cervical cancer. The survival rate at five years after treatment of early invasive cancer is 91%; rates are below 70% for more severe invasive cancer. That is why prevention, risk reduction, and frequent Pap tests are the best defense for a woman's gynecologic health.

Paracentesis

Definition

Also known as peritoneal tap or abdominal tap, paracentesis consists of drawing fluid from the abdomen through a needle.

Purpose

Although little or no fluid is present in the abdominal (peritoneal) cavity of a healthy man, more than half an ounce may accumulate at certain times during a woman's menstrual cycle. Any cancer that originates in or spreads to the abdomen can result in fluid accumulation (malignant **ascites**).

Doctors remove fluid (ascites) from the abdomen to analyze its composition and determine its origin, to relieve the pressure and discomfort it causes, and to check for signs of internal bleeding This procedure should be performed whenever an individual experiences sudden or worsening abdominal swelling or when ascites is accompanied by **fever**, abdominal pain, confusion, or coma.

Paracentesis in cancer patients

When performed on a patient who has been diagnosed with cancer, paracentesis helps doctors determine the extent (stage) of the disease and whether conservative or radical treatment approaches would most effectively relieve symptoms or lengthen survival.

Precautions

Before undergoing paracentesis, a patient must make the doctor aware of any allergies, bleeding problems or use of anticoagulants, pregnancy, or possibility of pregnancy.

Description

Paracentesis is performed in a doctor's office or a hospital. The puncture site is cleansed and, if necessary,

shaved. The patient may feel some stinging as a local anesthetic is administered, and pressure as the doctor inserts a special needle (tap needle) into the abdomen. Occasionally, guidance with CT or ultrasound may be used.

When paracentesis is performed for diagnostic purposes, less than an ounce of fluid is drawn from the patient's abdomen into a syringe. As much as 15 ounces may be needed to determine whether ascites contains cancer cells. When the purpose of the procedure is to relieve pressure or other symptoms, many quarts of ascites may be drained from the abdomen. Because removing large amounts of fluid in a short time can cause dizziness, lightheadedness, and a sudden drop in blood pressure, the doctor may drain fluid slowly enough that the patient's circulatory system has time to adapt.

Laboratory analysis of abdominal fluid can detect blood, cancer cells, infection, and elevated protein levels often associated with malignant ascites. Results of these tests can help doctors determine the most appropriate course of treatment for a particular patient.

Preparation

No special preparations are required before this procedure. Patients should ask their doctors about special preparation requirements, but usually may eat, drink and take medications normally prior to paracentesis.

Aftercare

After removing the tap needle, the doctor may use a stitch or two to close any incision made (to ease the needle's entry into the abdomen) and applies an adhesive dressing to the puncture site.

Risks

Paracentesis occasionally causes infection. There is also a slight chance of the tap needle puncturing the bladder, bowel, or blood vessels in the abdomen. If large amounts of ascites are removed, the patient may need to be hospitalized and given intravenous (IV) fluids to prevent or correct severe fluid, protein, or electrolyte imbalances. A patient who has undergone extensive paracentesis should be warned about the possibility of fainting (syncope) episodes.

Normal results

Paracentesis is designed to establish the cause of, or to relieve symptoms associated with, an abnormal accumulation of fluid in the abdomen.

KEY TERMS

Appendicitis—Inflammation of the appendix.

Cirrhosis—Scarring of the liver (from infection or tumor) resulting in liver dysfunction

Lymphoma—Cancer of the lymph system.

Abnormal results

Laboratory tests of ascites may indicate the presence of:

- appendicitis
- cancer
- cirrhosis
- damaged bowel
- disease of the heart, kidneys, or pancreas
- infection

Ascites that contains cancer cells is usually bloody. Cloudy abdominal fluid has been found in patients with extensive intraabdominal lymphomas. Ascites will continue to accumulate until its cause is identified and eliminated. Some patients need to undergo paracentesis repeatedly.

Paranasal sinus cancer

Definition

Paranasal sinus cancer is a disease in which cancer (malignant) cells are found in the tissues of the paranasal sinuses—the four hollow pockets of bone surrounding the nasal cavity.

Description

The paranasal sinuses, which are arranged symmetrically around the nasal cavity, include the:

- frontal sinuses (in the forehead, directly above the nose)
- ethmoidal sinuses (on each side of the nasal cavity, just behind the upper part of the nose)
- maxillary sinuses (on each side of the nasal cavity, in the upper region of the cheek bones)
- sphenoidal sinuses (behind the ethmoidal sinuses, in the center of the skull)

The paranasal sinuses, which normally contain air, are lined by mucous membranes that moisten the air entering the nose. Because they contain air, the sinuses allow the voice to echo and resonate.

Because the paranasal sinus area lies in an anatomically complex region, tumors in the paranasal sinuses can invade a variety of structures—such as the orbit (the bony cavity protecting the eyeball), the brain, the optic nerves, and the carotid arteries—even before symptoms appear.

The pharynx (throat) is divided into three sections: the nasopharynx, oropharynx, and laryngopharynx. The nasopharynx is the area behind (posterior to) the nose. The oropharynx is the area posterior to the mouth. The laryngopharynx opens into the larynx and esophagus. Usually, cancers of the paranasal sinuses originate in the lining of the nasopharynx or oropharynx. In rare cases, melanomas—a type of cancer arising from dark pigment-producing cells called melanocytes—may appear in the naso- or oropharynx. There is also an area of specialized sensory epithelium (surface layer of cells) through which the terminal branches of the olfactory nerve enter the roof of the nasal cavity, which gives rise to a very rare malignant neoplasm (growth) known as an esthesioneuroblastoma, or olfactory **neuroblastoma**.

Infrequently, a cancer may arise from the muscles or the soft tissues of the paranasal sinus region; these lesions are called **sarcomas**. Occasionally, lesions called midline granulomas (a granular-type tumor usually from lymphoid or epithelioid cells) occur; these lesions arise in the nose or paranasal sinuses and spread to surrounding tissues. Also rare are slow-growing cancers called inverting papillomas (papillae are tiny, nipple-like protuberances).

Demographics

Malignant growths of the paranasal sinuses are uncommon in the general population. Paranasal sinus cancer represents 3% of all cancers in the upper aerodigestive tract (air and food passages) and less than 1% of all malignancies in the body. The incidence of paranasal sinus cancer is about one case per 100,000 people per year in the United States. Only about 200 new cases a year are diagnosed in the United States. The disease is more common in Asia Minor and China than in Western countries. The incidence of maxillary sinus cancer is highest in the South African Bantus and in Japan.

Paranasal sinus tumors occur about two to three times more frequently in men than women, and diagnosis usually occurs between the ages of 50 and 70. Cancers of the maxillary sinus are the most common of the paranasal sinus cancers, occurring in about 80% of individuals. Tumors of the ethmoidal sinuses are less common (about 20%), and tumors of the sphenoidal and frontal sinuses are rarest (less than 1%).

Squamous cell carcinoma (cancer that originates from squamous keratinocytes in the epidermis, the top layer of the skin) is the most frequent type of malignant tumor in the paranasal sinuses (about 80%). **Adenocarcinomas** (cancer that begins in cells that line certain internal organs and that have glandular, or secretory, properties) constitute 15%, and the remaining 5% are composed of all other types.

Causes and symptoms

Although the causes of paranasal sinus cancer are not known, several occupational groups have been found to have an increased risk of developing these tumors. These groups include leather and textile workers, nickel refiners, woodworkers, and manufacturers of isopropyl alcohol, chromium, and radium. Also, snuff and thorium dioxide (a radiological contrast agent) have been associated with an increased incidence of paranasal sinus cancer. It is unclear whether these factors cause cancer by direct **carcinogenesis** (cancer production) or by altering the normal nasal epithelial physiology.

Nickel workers primarily develop squamous cell carcinomas, which usually arise in the nasal cavity. Woodworkers, however, usually develop adenocarcinomas that usually arise in the ethmoidal sinuses. The incidence of adenocarinomas in these workers is 1,000 times higher than that of the general population. Tobacco and alcohol use have not been demonstrated conclusively as a causative factor in the development of paranasal sinus tumors. However, viral agents, especially the **human papilloma virus** (HPV), may also play a causative role.

In patients with cancer of the head and neck, the immune system is often not functioning properly. Malignant cells are not recognized as foreign, or when recognized, the immune system does not effectively destroy

cancer cells. Causes of the failure of the immune system include severe malnutrition, substances in the tumor that deactivate the immune system, or a genetic predisposition.

The symptoms of paranasal sinus cancer vary with the type, location, and stage of cancer present. Symptoms typical of early lesions often resemble those of an upper respiratory tract infection and include nasal obstruction, facial pain, and thin, watery nasal discharge (rhinorrhea), which can at times be blood-tinged. The key factor that differentiates the symptoms of an upper respiratory infection from a malignant lesion, however, is the duration of the symptoms. An upper respiratory infection generally clears up or improves dramatically in several weeks with appropriate medical care, but symptoms associated with a malignancy persist.

The most common symptoms of paranasal sinus cancer include:

- persistently blocked nose
- feeling of recurrent "sinus infections"
- bleeding without apparent cause from the nose or the paranasal sinuses
- progressive pain and swelling of the upper region of the face or around the eyes
- closing up of one eye, blurred vision, or visual loss
- persistent pain in the forehead, the front of the skull, or over the cheekbones
- swelling in the roof of the mouth
- loosening of teeth, poorly fitting dentures, or bleeding from upper teeth sockets

Tumors in the nasal cavity and paranasal sinuses metastasize (spread) to the cervical lymph nodes (lymph nodes in the neck) in about 15% of individuals.

Diagnosis

There are several steps in establishing a diagnosis of paranasal sinus cancer. The first step is a thorough medical history, followed by a physical examination. The physical examination may reveal a lesion in the nose or a submucosal (below the mucous membrane) mass arising in an adjacent sinus.

After the history and physical examination, a series of tests are performed to determine the precise nature of the suspicious growth and the extent of its spread. These tests may include:

- **Biopsy** (the removal of a sample of tissue that appears to be suspicious) is performed after a lesion is identified. The tissue is studied under the pathologist's microscope.
- **Computed tomography** (CT) scan, which is a series of detailed pictures with thin cross-sectional slices taken radiologically through the body and interpreted with a computer.
- Nasoscopy, which utilizes an instrument called the nasoscope for examining the nasal cavity and the paranasal sinuses.
- **Magnetic resonance imaging** study (MRI), an imaging study that consists of detailed pictures, but instead of using x rays, a powerful magnet is used to polarize electrons inside the body to obtain images, which are then interpreted by a computer.
- Posterior rhinoscopy, in which the nasopharynx and the rear portion of the nose are examined using a light and a special mirror.

Although endoscopic techniques (visualizing the nasal cavity with an endoscope—a tube-like device to which an optical system is attached) have greatly improved the ability to examine the nasal cavities and the paranasal sinuses, radiographic studies are also necessary in completing the evaluation. The most important radiographic studies include CT and MRI scans, usually used in combination. The MRI scan has become the most essential radiographic test for accurate delineation of pretreatment tumor extent, and also for following up patients after treatment.

However, each scanning technique has its own advantages and limitations. The CT scan is preferred in evaluating the bony structures in the paranasal sinus area. The MRI better assesses soft-tissue differences, enabling not only the differentiation of tumor from inflammatory changes in the nose and sinuses, but also the determination of involvement of the soft tissues in, for example, the orbit, the brain, and the optic nerve.

Obtaining a biopsy is crucial to diagnosis. Endoscopic sinus surgery is widely used for obtaining tissue for biopsy. Combining endoscopic surgery with CT imaging, however, allows the surgeon access into small recesses of the nose and sinuses and along the base of the skull, making biopsy not only more accurate but also safer for the patient.

Treatment team

Patients with paranasal sinus cancer are usually treated by a team of specialists using a multifaceted approach. Each patient receives a treatment plan that is tailored to fit his or her requirements, specifically the patient's overall constitution, grade, and stage of disease. Usually, however, the treatment team includes:

- an otorhinolaryngologist (ear, nose, and throat specialist)

- an oncologist (cancer specialist)
- a radiotherapist (x-ray treatment specialist)

If extensive surgery is required, a plastic and reconstructive surgeon may also serve as part of the treatment team.

Clinical staging, treatments, and prognosis

Paranasal sinus cancer staging involves carefully establishing the degree of cancer spread. If the cancer has spread, it is also necessary to establish the extent of spread and organ involvement.

Cancer grading is a microscopic issue; the pathologist determines the degree of aggressiveness of the cancer. The term well-differentiated means less aggressive; the terms moderately differentiated, intermediately aggressive, and poorly differentiated mean more aggressive.

Both grading and staging help the physician establish the prognosis (degree of seriousness of the disease) and likely outcome.

Staging

Staging may involve additional imaging tests such as CT scan of the brain, abdominal ultrasound, bone scan, or chest **x ray**. Although no clear-cut staging protocol exists for the relatively uncommon cancers of the paranasal sinuses, the following practical staging exists for cancer of the maxillary sinuses, the most common cancer of this area:

- Stage I: The cancer is confined to the maxillary sinus, with no bony erosion or spread to the lymph nodes.
- Stage II: The cancer has begun to destroy the surrounding bones but without spread to the lymph nodes.
- Stage III: The cancer has spread no farther than the bones around the sinus and to one node on the same side of the neck, and is no greater than 3 cm (1.1 in) in size, or has spread to the cheek, the rear portion of the sinus, the eye socket, or the ethmoidal sinus (spread to lymph nodes on the same side of the neck may or may not be present).
- Stage IV: The cancer has spread to the eye, other sinuses, or tissues adjacent to the sinuses (spread to lymph nodes on the same side of the neck may or may not be present). The cancer may have spread within the sinus itself or to surrounding tissues, to lymph nodes in the neck on one or both sides, to any node larger than 6 cm (2.3 in), or to other parts of the body. Recurrent maxillary sinus cancer—either in the same location or in a different one after primary treatment has been completed—is also in this category.

Treatment options

The major treatment options for paranasal sinus cancer include:

- Surgery. May be necessary for the removal of a section of the nasal cavity or the paranasal sinus at any stage of the disease. Also, some **lymph node dissection** may be required in the neck, depending upon the staging and grading. May be combined with radiotherapy at any stage, depending on the type of cancer and its location.
- Radiotherapy. Also called **radiation therapy**, radiotherapy is sometimes used alone in stage I and II disease, or in combination with surgery in any stage of the disease. In the early stages of paranasal sinus cancer, radiotherapy is considered the alternative local therapy to surgery. Radiotherapy involves the use of high energy, penetrative rays to destroy cancer cells in the zone treated. Radiation therapy is also employed for palliation (control of symptoms) in patients with advanced cancer. Teletherapy (external radiation) is administered via a machine remote from the body while internal radiation (brachytherapy) is given by implanting a radioactive source into the cancerous tissues. Patients may or may not require both types of radiation. Radiotherapy usually takes just five to ten minutes per day, five days a week for about six weeks, depending upon the type of radiation used.
- **Chemotherapy**. Usually reserved for stage III and IV disease. Besides local therapy, the best attempt to control cancer cells circulating in the body is by using systemic therapy (therapy that affects the entire body) in the form of injections or oral medications. This form of treatment, called chemotherapy, is given in cycles (each drug or combination of drugs is usually administered every three to four weeks). Chemotherapy may also be used in combination with surgery, radiotherapy, or both.

At the forefront of research into head and neck cancer, molecular biology and gene therapy are providing new insights into the basic mechanisms of cancer genesis and treatment. The detection of various oncogenes (genes that can induce tumor formation) in head and neck cancer is also progressing rapidly. Gene therapy trials, still in their infancy as of 2005, are also introducing genetic material to help the immune system recognize cancer cells.

Alternative and complementary therapies

Alternative and complementary therapies may also be used at any stage of the disease. Alternative treatments are treatments used instead of conventional treatments. Complementary therapies are used in addition to

conventional treatments. Although not specifically used in treating paranasal sinus cancer, there is much anecdotal (nonscientific) evidence for a number of alternative cancer therapies. Some insurance plans cover complementary therapies, such as acupuncture.

The safest and most accepted of these complementary therapies include:

- acupuncture
- biofeedback
- diet that includes fresh fruit, vegetables, and whole grains
- massage
- meditation, prayer, or creative visualization
- vitamins (especially **antioxidants** A, E, and C), minerals, and herbs

The National Center for Alternative and Complementary and Alternative Medicine, part of the National Institutes of Health, discusses some alternative and complementary cancer treatments on its web site <http://www.nccam.nih.gov>.

Prognosis

The high mortality rate and poor prognosis association with paranasal sinus cancer is related to late diagnosis. Most lesions (75%) are at an advanced stage at the time of definitive diagnosis. Surgical treatment alone may be sufficient for stage I or II lesions if adequate surgical margins are obtained. However, for advanced tumors, combined therapy with radical surgical excision and postoperative radiotherapy has been demonstrated to improve the five-year survival rate.

The primary cause of death is failure of local control. Most paranasal sinus cancers grow rapidly and invade nearby tissues but are slow to spread to distant sites. Thus, patients with advanced disease usually die from a local recurrence of the tumor, even after aggressive treatment.

Coping with cancer treatment

Cancer treatments such as radiotherapy and chemotherapy not only destroy cancer cells but also damage healthy tissue. The effects of radiation depend upon the dose of radiation, the size of the area radiated, and the number and size of each fraction. When doses are fractionated, the total dose of radiation therapy is divided into several smaller, equal doses delivered over a period of several days.

The most common side effect of radiotherapy is extreme **fatigue**. Although rest is encouraged, most radiotherapists advise patients to move around as much as possible. Another common side effect is radiation dermatitis—the skin covering the radiated area becomes red, dry, itchy, and may show signs of scaling. This skin problem is associated only with teletherapy (external radiation therapy).

Radiation also may cause **nausea and vomiting**, **diarrhea**, and urinary discomfort. There may also be a decrease in white blood cells, which are needed to fight infection. Usually the radiotherapist can suggest the drugs and diet necessary to alleviate these problems.

Chemotherapy drugs may cause a wide spectrum of side effects. The severity of these symptoms vary with

KEY TERMS

Adenopathy—Large or swollen lymph glands.

Adjuvant therapy—Treatment (such as chemotherapy, radiation therapy, or hormone therapy) given after the primary treatment to increase the chances of a cure.

Adenocarcinoma—Cancer that begins in cells that line certain internal organs and that have glandular (secretory) properties.

Angiogenesis inhibitor—A substance that prevents the growth of new blood vessels.

Antimetabolite—A chemical very similar to one required in normal biochemical reactions in cells; an antimetabolite can stop or slow down the reaction.

Antineoplaston—A substance isolated from normal human blood and urine and tested as a type of treatment for some tumors and AIDS. Treatment is considered experimental in 2001.

Epithelium—A thin layer of tissue that covers organs, glands, and other structures within the body.

Monoclonal antibody—Laboratory-produced substance that can locate and bind to cancer cells.

Nasal cavity—The cavity between the floor of the cranium and the roof of the mouth.

Neoplasm—Any new and abnormal formation of tissue, as a tumor or growth.

Radiotherapy—Radiation treatment (external or internal).

each drug and with each individual. Some of the most common side effects of chemotherapy include:

- diarrhea
- hair loss (**alopecia**)
- hearing loss
- skin rashes
- tingling and numbness in the fingers and toes
- vomiting

Most of these side effects are treatable, temporary, and recede after therapy ends. However, the attitude of the patient is very important during cancer therapy. The better psychologically prepared the patient is for treatment, the better the chances of experiencing decreased side effects.

QUESTIONS TO ASK THE DOCTOR

- What kinds of treatments will I receive?
- What benefits can be expected from this therapy?
- What are the risks and side effects of these treatments?
- Will my treatments be covered by health insurance?
- What clinical trials are available for this type of cancer? Am I a candidate?
- Are there any complementary treatments that would benefit me?

If extensive surgery is required, reconstruction and rehabilitation by specialized physicians can improve the patient's quality of life.

Clinical trials

As of 2005, 35 **clinical trials** involving paranasal sinus cancer were operating in the United States. Clinical trials can be located at the web site <http://www.clinicaltrials.gov>, a service of the National Institutes of Health and the National Library of Medicine.

Some of the new drugs under investigation for advanced, recurrent, or metastatic head and neck cancer—either alone, in combination, with concurrent radiotherapy, or with standard chemotherapy drugs such as **fluorouracil** (5-FU), **paclitaxel**, or **cisplatin**—include:

- A10 and AS2-1 (antineoplastons)
- Dimesna (chemoprotective agent)
- Fenretinide (retinoid, or vitamin A derivative)
- **Filgrastim** (G-CSF or granulocyte colony-stimulating factor; increases white blood cells)
- Flavopiridol (cyclin-dependent kinase [Cdk] inhibitor; kinases plays a role in cell cycle regulation and tumor formation)
- Gemcitabine (antimetabolite)
- ONYX-015 (genetically engineered cold virus)
- C225/cetuximab (monoclonal antibody)
- Oxaliplatin (platinum compound; chemotherapeutic agent)
- SU5416 (angiogenesis inhibitor)

Prevention

The causes of paranasal sinus cancer are unknown. However, avoiding environmental risk factors such as heavy smoking or drinking, or inhaling wood dust or other toxic substances (such as isopropyl alcohol, chromium, or radium) on a regular basis may decrease the chances of developing this form of cancer.

Special concerns

Although surgical treatment of squamous cell carcinoma of the head and neck offers the best chance for cure in many patients, the results of the surgery have often been extremely disfiguring and functionally debilitating. The changes in facial appearance and loss of ability to speak, swallow, and breathe normally can be devastating, both physically and psychologically.

If the anticipated surgical defect is large, often a reconstructive team will harvest tissue from a distant site in the body to use as a graft while the oncology team is removing the cancer. Initially, reconstructive teams were more concerned with simply closing the surgical defect and re-establishing a more natural form. Increasingly, the focus has been to re-establish normal function.

Paraneoplastic syndromes

Description

Paraneoplastic syndromes are rare disorders caused by substances that are secreted by a benign tumor, a malignant (cancerous) tumor, or a malignant tumor's metastases. The disturbances caused by paraneoplastic syndromes occur in body organs at sites that are distant or remote from the primary or metastatic tumors. Body systems that may be affected by paraneoplastic syndromes include neurological, endocrine, cutaneous, renal, hematologic, gastrointestinal, and other systems. The most common manifestations of paraneoplastic syndromes are cutaneous, neurologic, and endocrine disorders. An example of a cutaneous paraneoplastic disorder are telangiectasias, which can be caused by **breast cancer** and lymphomas. Lambert-Eaton myasthenic syndrome (LEMS, and also known as Eaton-Lambert syndrome) is a neurologic paraneoplastic syndrome that can be caused by a variety of tumors including small cell lung cancer, **lymphoma**, breast, colon and other cancers. **Syndrome of inappropriate antidiuretic hormone** (SIADH) is an endocrine paraneoplastic syndrome, which is seen in as many as 40% of patients diagnosed with small cell lung cancer.

Approximately 15% of patients already have a paraneoplastic disorder at the time of initial diagnosis with cancer. As many as 50% of all cancer patients will develop a paraneoplastic syndrome at some time during the course of their disease. Some clinicians categorize the **anorexia**, cachexia, and **fever** which occur as a result of cancer as metabolic paraneoplastic syndromes. Virtually all patients diagnosed with cancer are affected by at least one of these metabolic paraneoplastic syndromes.

Paraneoplastic syndromes can occur with any type of malignancy. However, they occur most frequently with lung cancer, specifically small-cell lung **carcinoma**. Other types of cancer that commonly cause paraneoplastic syndromes are breast cancer and stomach cancer. With the exception of **Wilms' tumor** and **neuroblastoma**, paraneoplastic syndromes do not usually occur in children diagnosed with cancer.

In general, paraneoplastic syndromes may be present in the patient before a diagnosis of cancer is made, or, as stated earlier, may be present at the time the patient is first diagnosed with cancer. Most paraneoplastic syndromes appear in the later stages of the disease. Frequently, the presence of a paraneoplastic syndrome is associated with a poor prognosis. Paraneoplastic syndromes are difficult to diagnose and are often misdiagnosed. Some paraneoplastic syndromes may be confused with metatastic disease or spread of the cancer. The presence of the syndrome may be the only indication that a patient has a malignancy or that a malignancy has recurred. Paraneoplastic syndromes may be useful as clinical indicators to evaluate the response of the primary cancer to the treatment. Resolution of the paraneoplastic syndrome can be correlated with tumor response to treatment. That is, if the paraneoplastic syndrome resolves, the tumor has usually responded to the treatment.

KEY TERMS

Anorexia—Loss of appetite.

Cachexia—Severe malnutrition, emaciation, muscle wasting and debility associated with the inability to absorb the nutritional value of food eaten.

Cutaneous disorders—Disorders affecting the skin.

Hypokalemia—Decreased levels of the electrolyte potassium in the blood.

Hyponatremia—Decreased levels of the electrolyte sodium in the blood.

Metastasis—Tumors which originate from the primary or original tumor at distant locations in the body; secondary tumors.

Neurologic disorders—Disorders affecting the nervous system.

Causes

Paraneoplastic syndromes occur when the primary or original tumor secretes substances such as hormones, proteins, growth factors, cytokines, and antibodies. The substances are referred to as mediators. These mediators have effects at remote or distant body organs, which are termed target organs. Mediators interfere with communication between cells in the body. This miscommunication results in abnormal or increased activity of the cell's normal function. For example, a lung tumor may cause the paraneoplastic syndrome, ectopic **Cushing's syndrome**, which is the result of abnormal functioning of the pituitary gland located in the brain. In this example, the lung cancer is the primary tumor and the pituitary gland is the target organ. Ectopic Cushing's Syndrome is caused by overproduction of the mediator, adrenocorticotropic hormone (ACTH).

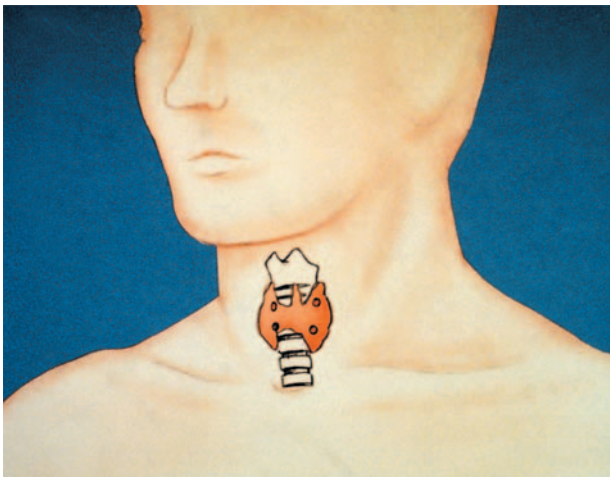
Treatment

There are usually two approaches taken in the treatment of paraneoplastic syndromes. The first step is treatment of the cancer that is causing the syndrome. This treatment can be surgery, administration of **chemotherapy**, biotherapy, **radiation therapy**, or a combination of these therapies. The next approach is to suppress the substance or mediator causing the paraneoplastic syndrome. Often treatment targeted to the underlying cancer and to the paraneoplastic syndrome occur at the same time. However, even with treatment, irreversible damage to the target organ can occur.

Selected Paraneoplastic Syndromes

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE (SIADH) SIADH is a common paraneoplastic syndrome that affects the endocrine system. This syndrome is most often associated with small cell lung cancer; however, other cancers such as brain tumors, leukemia, lymphoma, colon, prostate, and **head and neck cancers** can lead to SIADH. SIADH is caused by the inappropriate production and secretion of arginine vasopressin or antidiuretic hormone (ADH) by tumor cells. Patients with SIADH may not have symptoms, especially in the early stages. When symptoms do occur they are usually related to hyponatremia, which leads to central nervous system toxicity if left untreated. Signs and symptoms associated with hyponatremia include **fatigue**, anorexia, headache and mild alteration in mental status in early stages. If SIADH remains untreated, symptoms can progress to confusion, delirium, seizures, coma, and death. Treatment approaches for SIADH are to treat the underlying tumor and restriction of fluids. More severe cases may require the administration of medications.

LAMBERT-EATON MYASTHENIC SYNDROME Lambert-Eaton myasthenic syndrome, also known as LEMS and Eaton-Lambert syndrome, has been associated with a



The parathyroid glands, embedded in the thyroid gland but separate from the thyroid in function, control calcium metabolism in the body by producing parathyroid hormone (PTH). Cancer of the parathyroid glands is rare. *(Photograph by Rick Hall. Custom Medical Stock Photo. Reproduced by permission.)*

number of cancers including small-cell lung cancer, lymphoma, breast, stomach, colon, and prostate cancers. Potential mediators associated with paraneoplastic LEMS are antibodies that interfere with release of acetylcholine at the neuromuscular junction. This interference prevents the flow of calcium, which results in decreased or absent impulse transmission to muscle. The disruption in muscular impulse transmission leads to mild symptoms including weakness in the legs and thighs, muscle aches, muscle stiffness, and muscle fatigue. Treatment of LEMS includes administration of **corticosteroids**, intravenous immunoglobulin, and plasmapheresis. Depending on the extent of damage, irreversible loss of function may occur even with treatment.

ECTOPIC CUSHING'S SYNDROME Cushing's Syndrome is most often associated with small cell lung cancer, **ovarian cancer**, and medullary cancers of the thyroid. ACTH precursors are activated by tumor cells that results in overproduction of ACTH by the pituitary gland. Signs and symptoms of ectopic Cushing's Syndrome include hypertension, hyperglycemia, hypokalemia, edema, muscle weakness, and **weight loss**. The primary approach to treating ectopic Cushing's Syndrome is to treat the underlying cancer. In early stages, surgery is the treatment of choice. However, surgery is not usually an option for patients diagnosed with small cell cancer of the lung. If the tumor is unable to be removed or controlled, or if the patient has severe symptoms, then treatment targeted to the syndrome is initiated. Medical therapy is usually focused on inhibiting cortisol production and involves the use of medications such as ketoconazole and **aminoglutethimide**.

Parathyroid cancer

Definition

Parathyroid cancer is a rare, slow-growing tumor of a parathyroid gland in the neck.

Description

The four parathyroid glands in the human body are designated as the right superior, right inferior, left superior, and left inferior glands. They usually lay adjacent to the thyroid, but rarely can be found in the upper chest. The parathyroid glands secrete parathyroid hormone, which plays a central role in regulating calcium levels in the blood. In the condition called primary hyperparathyroidism, excess production of parathyroid hormone leads to abnormally high levels of calcium (**hypercalcemia**). Adenomas, or hyperplasia, of the parathyroid glands are responsible for about 99% of all cases of primary hyperparathyroidism. Parathyroid cancer accounts for the remaining 1%.

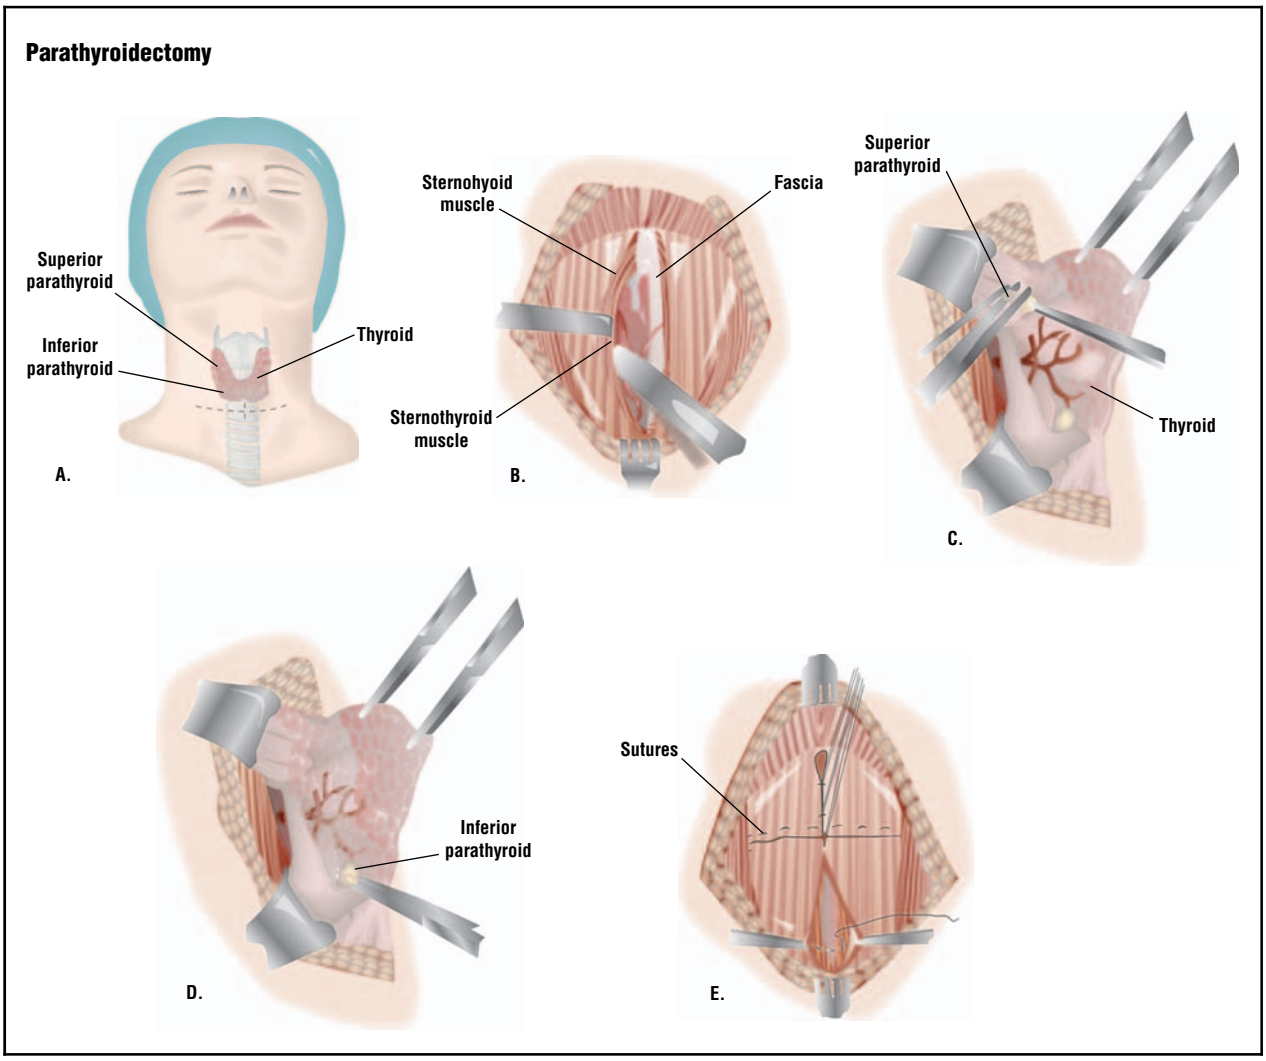
Parathyroid cancer is a slow-growing tumor that manifests itself mainly by production of parathyroid hormone.

Demographics

Only a few hundred cases of parathyroid cancer have been reported in medical literature. It is more common in Japan than in Western countries. No gender preference has been reported. The average age of the patient with parathyroid cancer is in the fifth decade.

Causes and symptoms

Unlike some cancers, there are no predisposing factors that have been found to clearly increase the risk for



(Illustration by Argosy Publishing. Reproduced by permission of The Gale Group.)

parathyroid cancer. There are some reported cases of parathyroid cancer arising in patients with adenomas or hyperplasia of the parathyroid.

Most parathyroid cancers are functioning tumors, in that they overproduce parathyroid hormone. Thus, the signs and symptoms of parathyroid cancer are chiefly related to hyperparathyroidism and the resultant hypercalcemia. Common complaints are weakness, **fatigue**, **weight loss**, **anorexia**, constipation, nausea, and vomiting. Patients may also report frequent urination and extreme thirst. Since excess parathyroid hormone causes bones to release too much calcium into the bloodstream, patients may experience **bone pain** and fractures. The extra calcium in the blood can be deposited in the kidneys, leading to the formation of painful kidney stones. Pancreatitis is another consequence of hypercalcemia. The levels of parathyroid hormone and calcium in patients with parathyroid cancer are usually dramatically elevated—much more so than in patients with benign causes of hyperparathyroidism.

Sometimes the parathyroid cancer is large enough to form a mass in the neck that can be easily felt. If the mass is large enough, it can impinge upon a nerve that controls the vocal cords, leading to hoarseness. In contrast, these features are uncommon in benign hyperparathyroidism.

Diagnosis

The diagnosis of parathyroid cancer can be difficult because it produces symptoms similar to those of benign hyperparathyroidism due to adenomas or hyperplasia. However, the symptoms of parathyroid cancer are generally more severe and the levels of parathyroid hormone

KEY TERMS

Adenoma—Benign tumor derived from glandular structures.

Biopsy—Obtaining a piece of tissue from a living being for diagnostic examination.

Computed tomography—A radiology test by which images of cross-sectional planes of the body are obtained.

Diuretic—A drug that promotes the excretion of urine.

Hyperplasia—Generalized overgrowth of a tissue or organ due to excess number of cells.

Magnetic resonance imaging—A radiology test that reconstructs images of the body based on magnetic fields.

Pancreatitis—Inflammation of the pancreas.

Peptic ulcer—Distinct erosions of the inner layer of the stomach or small intestine.

Scintigraphy—A radiology test that involves injection and detection of radioactive substances to create images of body parts.

Ultrasound—A radiology test utilizing high-frequency sound waves.

and calcium are usually higher. The presence of a neck mass or hoarseness also suggests cancer. Beyond this, there are no biochemical or radiological tests that can definitively diagnose parathyroid cancer.

There are four general scenarios for the diagnosis of parathyroid cancer:

- Parathyroid cancer is suspected, based on symptoms and signs. Surgery is performed with the intent to remove the cancer.
- A patient with hyperparathyroidism undergoes surgery to remove one or more glands that are thought to contain an **adenoma** or hyperplasia. During surgery, it is discovered that the underlying lesion is most likely cancer.
- Similarly, a patient with hyperparathyroidism undergoes surgery to remove one or more glands that are thought to contain an adenoma or hyperplasia. After the surgery is complete, the resected specimen is found to contain cancer.
- When symptoms of hyperparathyroidism reappear after surgery, it should raise the suspicion of an incompletely treated parathyroid cancer. This cancer may be localized to the neck or may have spread to distant organs. Several imaging tests can be helpful in this situation. Scintigraphy and ultrasound are useful in detecting recurrent tumors in the neck. **Computed tomography** (CT scan) and **magnetic resonance imaging** (MRI) can detect cancer at distant organs, such as the lungs or liver. Sometimes, careful **biopsy** of a suspected tumor may confirm the diagnosis of cancer.

Clinical staging, treatments, and prognosis

Parathyroid cancer begins in the parathyroid gland and extends to adjacent structures. Late in the course of the disease, it spreads to lymph nodes and ultimately to the lungs and liver.

The best treatment for parathyroid cancer is surgical removal of the cancerous gland. In order to assure complete resection of the cancer, part of the thyroid gland, nearby lymph nodes, and other adherent tissue must be removed with the specimen. Cancer that has spread to distant organs should be removed if possible.

Surgical cure is not possible if the cancer has spread too widely. Therapy then becomes focused on controlling hypercalcemia. General measures include infusing saline solution intravenously to restore lost fluid and to encourage urinary excretion of calcium. Diuretics are drugs that further stimulate urinary excretion of calcium. Bisphosphonates and plicamycin both inhibit the release of calcium from the bone. Other agents, such as **gallium nitrate**, have shown promise in the treatment of hypercalcemia associated with parathyroid cancer. However, further studies must be conducted to confirm their effectiveness and safety.

The prognosis of parathyroid cancer depends upon the stage of the cancer and the completeness of the surgical resection. If the cancer is detected early and completely removed, cure is possible, but the cancer has been reported to recur up to 20 years after surgery. Cure is unlikely after recurrence. Even so, survival can be signficantly extended by surgery aimed at removing as much recurrent or distant cancer as possible. In general, parathyroid cancer grows and spreads slowly, so that oversecretion of parathyroid hormone is more clinically evident than the actual growth of the cancer.

Alternative and complementary therapies

There have been a few cases in which **radiation therapy** or **chemotherapy** have been reported to partially control the growth and symptoms of parathyroid cancer. In the majority of patients, these interventions have not been successful.

PC-SPES

Definition

PC-SPES is an herbal mixture of eight botanical compounds adapted from traditional Chinese medicine that is used to treat **prostate cancer**, particularly the forms that do not respond to anti-androgen (hormone) therapy.

As PC-SPES is considered an alternative treatment for cancer, the National Center for Complementary and Alternative Medicine (NCCAM) began to conduct four separate clinical trials of the compound in the early 2000s. These studies were put on hold in June 2002, after the Food and Drug Administration (FDA) determined that samples of PC-SPES were contaminated with "undeclared prescription drug ingredients that could cause serious health effects if not taken under medical supervision." The California distributors of the product voluntarily recalled it, and closed their business at the end of 2002.

Because the early trials of PC-SPES gave promising results, NCCAM is interested in funding newer studies of the product, but will not do so until a fully standardized and uncontaminated product using the original formulation becomes available.

Purpose

PC-SPES is an herbal remedy that has been marketed as an over-the-counter drug for the treatment of prostate cancer. Anecdotal evidence of greatly reduced prostate-specific antigen (PSA) levels in patients taking this preparation prompted more formal testing of its effect. Laboratory studies show that PC-SPES has the ability to slow growth of both hormone-sensitive and hormone-insensitive prostate cancer cell lines in the test tube. Studies done with mice that have been implanted with prostate cancer cells indicate that the treatment triggers apoptosis (programmed cell death) in the artificially created hormone-insensitive tumors.

PC-SPES was shown in three clinical studies to reduce the serum prostate-specific antigen (PSA) levels in the overwhelming majority of patients suffering from prostate cancer that is unresponsive to androgen therapy. The treatment also reduces prostate acid phosphatase (PAP) levels, an enzyme often elevated with hormone-resistant disease. Treatment with the mixture has been shown to decrease pain, decrease narcotic use, and increase perceived quality of life. Researchers noted bone scan improvements, indicating a reduction in the size of cancer metastases to the bone. The majority of the work with this treatment has been done with patients having advanced disease, characterized by elevated PSA values and Gleason tumor scores.

According to one Japanese study, PC-SPES also shows promise in treating Leukemia.

Description

PC-SPES is a mixture of eight herbs used in Chinese medicine: *Ganoderma lucidum*, *Scutellaria baicalensis*, *Rabdosia rubescens*, *Isatis indigotica*, *Dendranthema morifolium*, *Seronoa repens* (**saw palmetto**), *Panax pseudoginseng*, and *Glycyrrhiza uralensis* (licorice). The "PC" portion of the name stands for prostate cancer, while SPES is Latin for "hope." It has been commercially available since 1996. Manufacturers claim it stimulates the immune system and has anti-tumor activity. The mixture appears to act like estrogen against the tumors, and the side effects are very similar for the two therapies. Yet an analysis using liquid chromatography shows that diethylstilbestrol (DES), estrone, or estradiol are all absent. Additionally, some patients who did not respond to traditional estrogen therapy and alkylating agents did respond to PC-SPES, suggesting the mechanism may be unique from that used by DES or **estramustine** (nitrogen mustard, an alkylating agent). Researchers plan a clinical trial that will directly compare the action of DES and PC-SPES in an effort to compare and contrast the two treatment methods.

Recommended dosage

In the **clinical trials**, PC-SPES was given either in a dosage of nine tablets per day, three before each mealtime or six tablets a day, three before breakfast and three before dinner. As there was essentially no difference in the anti-tumor effect for the studies, six tablets a day might be a recommended starting dosage.

With herbal medications, such as PC-SPES, potency of herb per tablet and recommended dosage may vary from manufacturer to manufacturer.

KEY TERMS

Alkylating agent—A chemical that alters the composition of the genetic material of rapidly dividing cells, such as cancer cells, causing selective cell death; used as a chemotherapeutic agent to treat prostate cancer.

Androgen—Hormones responsible for male characteristics that can be necessary for growth of prostate tumors; blocking the action of androgens can treat prostate cancer.

Apoptosis—An innate process of a cell that brings about its death at the end of the cell's useful lifetime; when malfunctioning can cause cancer.

Gleason grading system—A method of predicting the tendency of a tumor in the prostate to metastasize based on how similar the tumor is to normal prostate tissue; the higher the number the greater the predicted tendency of the tumor to metastasize.

Prostate-specific antigen (PSA)—A protein produced by the cells of the prostate that can be elevated in patients suffering from prostate cancer, abbreviated PSA.

Precautions

As PC-SPES has been used only in relatively small clinical trials, the full spectrum of precautions has yet to be determined. The clinical trials required taking the tablets on an empty stomach. Furthermore, despite the small sample size, experience does suggest that patients with known heart disease or stroke tendencies should take this medicine with caution, as it might aggravate these conditions.

Side effects

The side effects for PC-SPES are relatively mild and include, from most frequent to least frequent, nipple tenderness, **nausea and vomiting**, **diarrhea**, **fatigue**, gynecomastia (swelling of the male breast), leg cramps or swelling, angina, increased hot flashes, and blood clots. The incidence of angina occurred in a patient with preexisting coronary disease and was treated by altered heart medications and a reduction in PC-SPES administered.

Interactions

There have been no studies of drug interactions between PC-SPES and other medications. The lack of information about potential adverse interactions suggests caution in adding PC-SPES to other more traditional treatment methods for prostate cancer.

Pegaspargase

Definition

Pegaspargase (also known as PEG-L-asparaginase and Oncaspar) is a medicine used to stop growth of cancer and formation of new cancer cells.

Purpose

Pegaspargase is used as part of induction regimen for the treatment of **acute lymphocytic leukemia** (ALL) in children who developed an allergy to **asparaginase**.

Description

Pegaspargase is a slightly changed version of the native form of asparaginase (*E. coli* asparaginase) that is linked to polyethylene glycol (PEG) molecule. This medicine was made available in 1994 under the brand name Oncaspar. It is more expensive than the native form and is mainly used in patients who developed an allergy to the native form. The advantage of pegaspargase over asparaginase is that it is less likely to cause an allergic reaction and has a longer duration in the body and can be given less frequently. Pegaspargase kills cancer cells by depleting a certain amino acid in the blood (L-asparagine), which is needed for survival and growth of tumor cells in patients with acute lymphocytic leukemia. Fortunately, normal cells can make their own L-asparagine and are not dependent on L-asparagine from the blood for survival.

Pegaspargase is mainly given in combination with other drugs **vincristine** (a vinca alkaloid anticancer drug) and steroids (either prednisone or **dexamethasone**). Other **chemotherapy** medicines are added to this regimen if a patient is at a high risk for disease recurrence.

Recommended dosage

Adults and children with body surface area greater than 0.6 square meters

In induction chemotherapy for acute lymphocytic leukemia, doses vary between different chemotherapy protocols. The usual dose is 2500 international units (IU) per square meter of body surface area given every 14 days.

Children with body surface area less than 0.6 square meters

In induction chemotherapy for acute lymphocytic leukemia, the usual dose is 82.5 IU per kg given every 14 days.

Administration

This medicine can be given directly into the muscle (intramuscular) or into the vein (intravenous). Intramuscular injection of pegaspargase is preferred over the intravenous route because of lower risk of liver disease, blood clotting problems, stomach, and kidney problems. When used intramuscularly, it must be administered as deep injection into a large muscle. When given intravenously, it must be infused over one to two hours. Patients will be monitored closely by a physician for 30 to 60 minutes.

Precautions

The use of this medication should be avoided in patients with active pancreatitis (inflammation of the pancreas) or history of pancreatitis and in patients who have had a serious allergic reaction to pegaspargase in the past.

Pegaspargase should only be administered in a hospital, and a patient will need to be observed by a physician for the first hour.

This medication can lower the body's ability to fight infections. Patients should avoid contact with any individuals that may have a cold, flu, or other infection.

Pegaspargase should be used with caution in the following populations:

- People with gout (it may increase uric acid levels and worsen gout).
- People with diabetes (it may increase blood sugar).
- Breast-feeding mothers (it is not known if asparaginase crosses into breast milk).
- Women who are pregnant or may become pregnant (unless benefits to the mother outweigh the risks to the baby).

Patients should contact a doctor immediately if any of these symptoms develop:

- **fever**, chills, sore throat
- chest pain or heart palpitations
- yellowing of the skin or eyes
- puffy face, skin rash, trouble breathing, joint pain
- drowsiness, confusion, hallucinations, convulsions
- unusual bleeding or bruising
- stomach pain with nausea and vomiting, and loss of appetite (anorexia)

A physician will be doing blood tests before starting therapy and during therapy to monitor complete blood count, blood sugar, pancreas, kidney, and liver functions.

Side effects

Pegaspargase is a very potent medicine that can cause serious side effects. An allergic reaction with skin rash, **itching**, joint pain, puffy face, and difficulty breathing is a side effect that happens very quickly after the drug is injected. The allergic reaction to pegaspargase is less common than with asparaginase. The severe type of this allergic reaction (anaphylaxis) can result in death. Other common side effects include nausea, vomiting, **diarrhea**, loss of appetite, stomach cramps, yellow-

KEY TERMS

Acute lymphocytic leukemia (ALL)—This is the most common cancer in children. Patients with ALL can present with fever, weakness, fatigue, pallor, unusual bleeding and easy bruising, pinpoint dots on the skin, large lymph nodes, and large liver and spleen. ALL in children has a much better prognosis than in adults, with over 90% of children going into remission and an over 80% cure rate with chemotherapy.

Induction therapy—The first stage in treatment of ALL. The purpose of this stage is to quickly cause remission of the disease. The combination of vincristine, asparaginase, and steroids make up the foundation of induction regimen.

Nonsteroidal anti-inflammatory drugs (NSAIDS)—Drugs such as ibuprofen (Advil, Motrin) and naproxen (Aleve) that reduce pain, fever, and inflammation.

ing of the eyes or skin, swelling of hands or feet, and pain at the injection site. Less frequent side effects include high blood sugar, chest pain, heart palpitations, headache, chills, **night sweats**, convulsions, decreased kidney function, increased blood clotting, mouth sores, and decreased body's ability to fight infections. Usually the side effects of pegaspargase are more severe in adults than in children.

Interactions

Pegaspargase can decrease effectiveness of **methotrexate** (an antimetabolite, or compound that prevents the synthesis and utilization of normal cellular metabolite, anticancer drug) in killing cancer cells when given right before and together with methotrexate. The use of these two medicines together should be avoided.

Pegaspargase can decrease breakdown and increase toxicity of **cyclophosphamide** (a DNA alkylating anticancer drug).

Risk of liver disease may be increased in patients getting both pegaspargase and **mercaptopurine** (a purine analog antimetabolite anticancer drug).

This medicine can increase blood sugar, especially when given with steroids.

Pegaspargase should be given after vincristine instead of before or with vincristine because it can increase the risk of numbing, tingling, and pain in hands and feet.

People taking blood thinners (**warfarin**, **heparin**, or its derivatives), aspirin, and non-steroidal anti-inflammatory drugs (ibuprofen, naproxen) may be at an increased risk of bleeding. A physician and a pharmacist must be informed about any prescription or over-the-counter medications the patient is taking.

Olga Bessmertny, Pharm.D.

PEG-L-asparaginase *see* **Pegaspargase**

Pemetrexed

Definition

Pemetrexed is an anticancer drug that is used to treat malignant pleural **mesothelioma** and **non-small cell lung cancer**.

Purpose

Malignant pleural mesothelioma (MPM) is a rare type of cancer of the mesothelium (the lining of the chest cavity around the lungs and the abdomen). About 2,000–2,500 new cases of MPM are diagnosed in the United States annually. Twice that many cases occur in Europe. MPM usually is caused by exposure to asbestos. Inhaled asbestos fibers attach to the outer lining of the lung and the chest wall, causing tumor growth. The disease takes years to develop after asbestos exposure. Symptoms of MPM usually are not apparent or are misdiagnosed until after the disease is well-advanced and difficult to treat with surgery or **radiation therapy**. Average survival time is 9–13 months after diagnosis. Pemetrexed is used for patients with MPM that cannot be treated surgically.

Lung cancer—usually caused by smoking—is the most common cause of cancer death in the United States. Almost 174,000 people develop lung cancer each year and more than 160,000 die from it annually. Non-small cell lung cancer (NSCLC) accounts for about 80% of all lung cancers and includes squamous cell **carcinoma**, **adenocarcinoma**, and large cell carcinoma. Pemetrexed is used to treat stage III or IV NSCLC in patients whose cancer has recurred following **chemotherapy** and is advancing or has spread (metastasized). Pemetrexed does not improve rates of survival over the standard second-line treatment drug **docetaxel** but has fewer side effects and thus may improve the quality of life. Neither drug cures recurrent lung cancer.

Description

During the 1980s a new class of drugs called multi-targeted anti-folates (MTA) were developed. These drugs limited the ability of cancer cells to obtain **folic acid**, a member of the B-vitamin complex that is required for cell growth and reproduction. However, these drugs were considered too toxic to use until pemetrexed was discovered by a Princeton University biochemist in the 1990s.

Pemetrexed disodium heptahydrate (Alimta), manufactured by Eli Lilly, was approved by the U.S. Food and Drug Administration (FDA) in February of 2004 for use in combination with the anticancer drug **cisplatin** to treat MPM. Pemetrexed, also known as LY231514, was the first drug for treating this type of cancer and, as an orphan drug for a rare disease, received priority review from the FDA. The Orphan Drug Act granted Eli Lilly seven years of exclusive marketing. In August of 2004 the FDA approved pemetrexed for the treatment of NSCLC.

Pemetrexed is a member of a large group of chemotherapy drugs known as antineoplastics or antimetabolites; it sometimes is referred to as an antifolate antineoplastic agent. It inhibits three folate-dependent enzymes that mesothelioma and lung cancer cells need for the synthesis of the nucleotides that make up DNA and RNA. Fast growing cancer cells have a much higher requirement for nucleotides than normal cells.

Effectiveness

The effectiveness of pemetrexed for treating MPM was established in a single clinical trial with 448 patients, comparing combined treatment with pemetrexed and cisplatin to treatment with cisplatin alone. Patients receiving the combined treatment lived three months longer than those receiving cisplatin alone—12 months versus nine months. Patients also had improved lung function. Tumors shrank in 41% of the patients treated with the combined drugs, compared with 17% of those treated with cisplatin alone.

In an earlier clinical trial pemetrexed combined with the chemotherapy drug **carboplatin**, which is similar to cisplatin, increased the average survival time of mesothelioma patients to 15 months and some patients were still alive after nearly three years. More than two-thirds of the treated patients had reduced pain and improvement in other symptoms. Tumors shrank in almost one-third of the patients.

In a clinical trial of 571 patients with recurrent NSCLC, those treated with either pemetrexed or docetaxel had a one-year survival rate of 30%; however, those receiving pemetrexed were significantly less likely to experience the following:

- fever
- infections
- hospitalizations
- hair loss
- numbness in the arms and legs

Recommended dosage

Pemetrexed is supplied as a sterile powder in single-dose vials of 500 mg pemetrexed and 500 mg mannitol. Pemetrexed is given in a single 10-minute intravenous infusion, once every three weeks. The dose depends on body size and may be adjusted or delayed depending on the patient's blood counts, kidney and liver function, and general condition.

For treating MPM, cisplatin is infused for two hours, beginning about 30 minutes after the end of pemetrexed infusion. As much fluid as possible is taken before and after treatment with cisplatin to keep the kidneys functioning properly. Intravenous fluids usually are given during cisplatin infusion.

Since pemetrexed interferes with both folic acid and vitamin B_{12}, these nutrients are always taken as supplements to prevent severe side effects. Folic acid—350–1000 micrograms—is taken every day for at least five out of seven days prior to pemetrexed treatment. It is continued daily until 21 days after the final treatment. Folic acid is available over-the-counter as well as in many multivitamins. Vitamin B12 is injected during the week before the first pemetrexed treatment and once every nine weeks during treatment.

Patients also take a corticosteroid such as **dexamethasone** twice a day for three days, beginning the day before pemetrexed infusion, to lower the risk of skin reactions.

Precautions

Pemetrexed causes birth defects if administered to a woman during the conception period or during pregnancy or to a man near the time of conception. Birth control must be used by patients while they receive pemetrexed treatment. Women should not breastfeed while being treated with pemetrexed. Like many other chemotherapy drugs, pemetrexed may cause sterility.

Medical conditions that may interfere with the use of pemetrexed include the following:

- chicken pox or exposure to chicken pox
- gout

- heart disease
- congestive heart failure
- shingles
- kidney stones or kidney disease
- liver disease
- third space fluid (extra body fluid such as **ascites** in the stomach area or **pleural effusion** in the lungs and chest)
- other types of cancer

Other precautions during pemetrexed treatment include avoiding the following:

- touching the eyes or inside of the nose without first washing the hands
- cuts or bleeding
- contact sports, bruising, or injury

It is important to avoid vaccinations during and after pemetrexed treatment. It also is important to avoid contact with those who have taken oral polio vaccine within the past several months. A protective face mask that covers the nose and mouth may be used if contact is unavoidable. If possible, people with any infection should be avoided.

Side effects

Pemetrexed has fewer side effects than many anticancer drugs; however, the most common side effects are as follows:

- anemia (low red blood cell count) that may cause **fatigue**, paleness, or shortness of breath
- a temporary decline in white blood cells, particularly during the first 10–14 days after each treatment
- a decline in blood platelets
- nausea and vomiting
- diarrhea
- constipation
- loss of appetite
- weight loss
- heartburn
- dry mouth
- redness or sores in the mouth or throat or on the lips a few days after treatment
- rash or **itching** between treatments
- wrinkled or peeling skin
- burning, tingling, numbness, or pain in the extremities
- muscle aches, cramping, stiffness, or pain
- joint swelling or pain
- difficult or rapid breathing
- pain or burning in the throat
- difficult or painful swallowing
- stuffy or runny nose
- sunken eyes
- irritability
- mood swings or depression
- lightheadedness or dizziness
- confusion
- insomnia
- difficulty concentrating
- hair loss
- increased heart rate
- decreased urination

KEY TERMS

Cisplatin—An anticancer drug that is used together with pemetrexed to treat MPM.

Docetaxel—An anticancer drug, belonging to the drug family called mitotic inhibitors, that was the standard treatment for recurrent NSCLC prior to pemetrexed.

Folic acid, folate—A member of the vitamin B complex that is a required cell nutrient.

Malignant pleural mesothelioma, MPM—A cancer of the mesothelium that lines the chest cavity; caused by exposure to asbestos.

Multitargeted anti-folate, MTA—A drug that targets various folate-dependent enzymes.

Non-small cell lung cancer, NSCLC—The most common type of lung cancer; includes squamous cell carcinoma, adenocarcinoma, and large cell carcinoma.

Orphan drug—A drug that treats a rare condition; such drugs receive special treatment by the FDA under the Orphan Drug Act.

Vitamin B12—Cobalamin; a protein complex of animal origin that is required for the formation of red blood cells.

White blood cells (WBC)—Blood cells, including lymphocytes, neutrophils, eosinophils, marcrophages, and mast cells, that are produced in the bone marrow and help the body fight infection and disease.

- severe weakness and fatigue for a few days after treatment
- liver problems, as indicated by fluctuating liver function blood tests

Blood counts are taken before and after each pemetrexed treatment. Rare side effects of pemetrexed include a severe allergic reaction or blood clots.

Pemetrexed suppresses production of blood cells by the bone marrow and decreases the white blood cell count. Symptoms of infection caused by decreased white blood cells include the following:

- fever above 100.5°F (38°C)
- chills
- cough
- hoarseness
- lower back or side pain
- difficult or painful urination

Pemetrexed can reduce blood platelets, thereby increasing the risk of the following:

- unusual bleeding or bruising
- nosebleeds
- bleeding gums when teeth are being cleaned
- black, tarry stools
- tiny red spots on the skin
- blood in the urine or stool

Other serious side effects of pemetrexed can include:

- swollen glands
- increased thirst
- swelling of the eyes, face, fingers, or lower legs
- pain in the chest, groin, or legs, especially in the calves
- sudden severe headaches
- sudden changes in vision
- sudden slurred speech
- fast or irregular breathing
- chest tightness or wheezing
- increased blood pressure
- loss of coordination
- fainting or loss of consciousness
- weight gain

Interactions

Known interactions of pemetrexed with other drugs include:

- oral contraceptives
- vitamins and herbal supplements
- nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, ibuprofen such as Motrin, naproxen such as Aleve, celecoxib (Celebrex), rofecoxib (Vioxx)

Margaret Alic, Ph.D.

Penile cancer

Definition

Penile cancer is the growth of malignant cells on the external skin and in the tissues of the penis.

Description

Penile cancer is a disease in which cancerous cells appear on the penis. If left untreated, this cancer can grow and spread from the penis to the lymph nodes in the groin and eventually to other parts of the body.

Demographics

Penile cancer is a rare form of cancer that develops in about one out of 100,000 men per year in the United States. Penile cancer is more common in other parts of the world, particularly Africa and Asia. In Uganda, penile cancer is the most common form of cancer for men.

Causes and symptoms

The cause of penile cancer is unknown. The most common symptoms of penile cancer are:

- A tender spot, an open sore, or a wart-like lump on the penis.
- unusual liquid discharges from the penis.
- Pain or bleeding in the genital area.

Diagnosis

In order to diagnose penile cancer, the doctor examines the patient's penis for lumps or other abnormalities. A tissue sample, or **biopsy**, may be ordered to distinguish cancerous cells from syphilis and penile warts. If the results confirm a diagnosis of cancer, additional tests are done to determine whether the disease has spread to other parts of the body.

Carcinoma of penis. *(Custom Medical Stock Photo. Reproduced by permission.)*

Treatment team

A doctor who specializes in the genitourinary tract (urologist) is usually the first point of contact for the patient and makes the diagnosis of penile cancer. Once a diagnosis of cancer is made, a specialist in cancer (oncologist) will become involved to determine the stage of the cancer and recommend appropriate treatments.

Clinical staging, treatments, and prognosis

In Stage I penile cancer, malignant cells are found only on the surface of the head (glans) and on the foreskin of the penis. If the cancer is limited to the foreskin, treatment may involve wide local excision and circumcision. Wide local excision is a form of surgery that removes only cancer cells and a small amount of normal tissue adjacent to them. Circumcision is removal of the foreskin.

If the Stage I cancer is only on the glans, treatment may involve the use of a **fluorouracil** cream (Adrucil, Efudex), and/or microsurgery. Microsurgery removes cancerous tissue and the smallest possible amount of normal tissue. During microsurgery, the doctor uses a special instrument that provides a comprehensive view of the area where cancer cells are located and makes it possible to determine that all malignant cells have been removed.

In Stage II, the penile cancer has spread to the surface of the glans, tissues beneath the surface, and the shaft of the penis. The treatment recommended may be **amputation** of all or part of the penis (total or partial penectomy). If the disease is diagnosed early enough, surgeons are often able to preserve enough of the organ for urination and sexual activity. Treatment may also include microsurgery and external **radiation therapy**, in which a machine provides radiation to the affected area. Laser surgery is an experimental treatment for Stage II cancers. Laser surgery uses an intense precisely focused beam of light to dissolve or burn away cancer cells.

In Stage III, malignant cells have spread to lymph nodes in the groin, where they cause swelling. The recommended treatment may include amputation of the penis and removal of the lymph nodes on both sides. Radiation therapy may also be suggested. More advanced disease requires systemic treatments using drugs (**chemotherapy**). In chemotherapy, medicines are administered intravenously or taken by mouth. These drugs enter the bloodstream and kill cancer cells that have spread to any part of the body.

In Stage IV, the disease has spread throughout the penis and lymph nodes in the groin, or has traveled to other parts of the body. Treatments are similar to that for Stage III cancer.

Recurrent penile cancer is disease that recurs in the penis or develops in another part of the body after treatment has eradicated the original cancer cells.

Cure rates are high for cancers diagnosed in Stage I or II, but much lower for Stages III and IV, by which time cancer cells have spread to the lymph nodes.

Alternative and complementary therapies

In addition to the treatments previously described, biological therapy is another treatment that is currently being studied. Biological therapy is a type of treatment that is sometimes called biological response modifier (BRM) therapy. It uses natural or artificial substances to boost, focus, or reinforce the body's disease-fighting resources.

Coping with cancer treatment

Medical side effects of treatment include constipation, **fatigue**, and sleep disorders. These effects may be

KEY TERMS

Circumcision—Surgical removal of the foreskin of the penis. It is usually performed shortly after birth.

Fluorouracil—A cell-killing (cytotoxic) medication that can be applied in cream form to treat cancer of the penis.

QUESTIONS TO ASK THE DOCTOR

- What stage is my cancer?
- What treatment alternatives do I have?
- Do I qualify for an experimental trial of a new treatment?

managed through a combination of diet and environment as well as supplemental drug treatments. The patient should seek support resources for the psychological effects that treatment for penile cancer may cause, such as **depression**, decreased **sexuality**, anxiety, or feelings of grief.

Clinical trials

New treatments for penile cancer that are in **clinical trials** include chemotherapy with the drugs **methotrexate**, **bleomycin**, interferon, or **cisplatin**.

Prevention

Conditions which increase a person's chance of getting penile cancer include:

- Infection with genital warts (human papillomavirus, or HPV).
- a skin disease called psoriasis
- a condition called phimosis, in which the foreskin becomes difficult to retract
- other conditions that result in repeated irritation of the penis
- a history of smoking

There appears to be a connection between development of the disease and lack of personal hygiene. Failure to regularly and thoroughly cleanse the part of the penis covered by the foreskin increases the risk of developing the disease. Penile cancer is also more common in uncircumcised men.

Special concerns

The treatment or amputation of the penis may have a significant psychological impact on the patient. Thorough patient education and appropriate counseling or support resources are a must.

Pentamidine *see* **Antibiotics**

Pentostatin

Definition

Pentostatin is an anticancer (antineoplastic) agent belonging to the class of drugs called antimetabolites (compounds that prevent the synthesis and utilization of normal cellular metabolite). It is a natural product isolated from *Streptomyces antibioticus*. It also acts as a suppressor of the immune system. It is available under the brand name Nipent. Other common names for pentostatin include 2'-deoxycoformycin and 2'DCF.

Purpose

Pentostatin is primarily used to treat a particular type of cancer of the blood called **hairy cell leukemia**. It is also used in the treatment of low-grade lymphomas. **Clinical trials** are underway to determine the effectiveness of pentostatin in fighting **cutaneous T-cell lymphoma** (CTCL), **chronic lymphocytic leukemia** (CLL), **non-Hodgkin's lymphomas** (NHL), and prolymphocytic leukemia.

Description

Pentostatin chemically interferes with the synthesis of genetic material (DNA and RNA) of cancer cells, which prevents these cells from being able to reproduce and continue the growth of the cancer.

Recommended dosage

Pentostatin may be taken only as an injection. It is generally given once every two weeks. A typical dosage is four mg per square meter of body surface area. However, the dosage prescribed can vary widely depending on the patient, the cancer being treated, and whether or not other medications are also being taken.

Precautions

Pentostatin should be taken on an empty stomach. If stomach irritation occurs, it should be taken with small amounts of food or milk. Pentostatin should always be taken with plenty of fluids.

Pentostatin can cause an allergic reaction in some people. Patients with a prior allergic reaction to pentostatin should not take pentostatin.

Pentostatin can cause serious birth defects if either the man or the woman is taking this drug at the time of conception or if the woman is taking this drug during pregnancy.

Because pentostatin is easily passed from mother to child through breast milk, breast feeding is not recommended while pentostatin is being taken.

Pentostatin suppresses the immune system and interferes with the normal functioning of certain organs and tissues. For these reasons, it is important that the prescribing physician is aware of any of the following preexisting medical conditions:

- a current case of, or recent exposure to, chicken pox
- herpes zoster (shingles)
- a current case, or history of, gout or kidney stones
- all current infections
- kidney disease.
- liver disease

Also, because pentostatin is such a potent immunosuppressant, patients taking this drug must exercise extreme caution to avoid contracting any new infections. They should do their best to:

- avoid any person with any type of infection
- avoid bleeding injuries, including those caused by brushing or flossing the teeth
- avoid contact of the hands with the eyes or nasal passages (inside of the nose) unless the hands have just been washed and have not touched anything else since this washing
- avoid contact sports or any other activity that could cause a bruising or bleeding injury

KEY TERMS

Antineoplastic—A drug that prevents the growth of a neoplasm by interfering with the maturation or proliferation of the cells of the neoplasm.

Hairy cell leukemia—A rare form of cancer in which hairy cells grow out of control in the blood, liver, and spleen.

Lymphoma—A malignant tumor of the lymphatic system.

Neoplasm—New abnormal growth of tissue.

Side effects

The most common side effects of pentostatin are: cough, extreme **fatigue**, increased susceptibility to infection, loss of appetite (anorexia), skin rash or **itching**, nausea, temporary hair loss (alopecia), vomiting, and **weight loss**.

Less common side effects include anxiety or nervousness; changes in vision; nosebleed; sores in the mouth or on lips; sore, red eyes; trouble sleeping (insomnia); numbness or tingling in the hands and/or feet; and swelling in the feet or lower legs.

A doctor should be consulted immediately if the patient experiences shortness of breath, chest or abdominal pain, persistent cough, **fever** and chills, pain in the lower back or sides, painful or difficult urination, unusual bleeding or bruising, blood in the urine or stool, or tiny red dots on the skin.

Interactions

Pentostatin should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician. It is particularly important that the prescribing physician be aware of the use of any of the following drugs or any **radiation therapy** or **chemotherapy** medicine:

- amphotericin B
- antithyroid agents
- azathioprine

- chloramphenicol
- colchicine
- flucytosine
- fludarabine
- ganciclovir
- interferon
- plicamycin
- probenecid
- sulfinpyrazone
- vidarabine
- zidovudine

Percutaneous transhepatic cholangiography

Definition

Percutaneous transhepatic cholangiography (PTHC) is an x-ray test used to identify obstructions either in the liver or bile ducts that slow or stop the flow of bile from the liver to the digestive system.

Purpose

Because the liver and bile ducts are not normally seen on x rays, the doctor injects the liver with a special dye that will show up on the resulting picture. This dye distributes evenly to fill the whole liver drainage system. If the dye does not distribute evenly, this is indicative of a blockage, which may caused by a gallstone or a tumor in the liver, bile ducts, or pancreas.

Precautions

Patients should report allergic reactions to:

- anesthetics
- dyes used in medical tests
- iodine
- shellfish

PTHC should not be performed on anyone who has cholangitis (inflammation of the bile duct), massive **ascites**, a severe allergy to iodine, or a serious uncorrectable or uncontrollable bleeding disorder. Patients who have diabetes should inform their doctors.

Description

PTHC is performed in a hospital, doctor's office, or outpatient surgical or x-ray facility. The patient lies on a movable x-ray table and is given a local anesthetic. The patient will be told to hold his or her breath, and a doctor, nurse, or laboratory technician will inject a special dye into the liver as the patient exhales.

The patient may feel a twinge when the needle penetrates the liver, a pressure or fullness, or brief discomfort in the upper right side of the back. Hands and feet may become numb during the 30-60 minute procedure.

The x-ray table will be rotated several times during the test, and the patient helped to assume a variety of positions. A special x-ray machine called a fluoroscope will track the dye's movement through the bile ducts and show whether the fluid is moving freely or if its passage is obstructed.

PTHC costs about $1,600. The test may have to be repeated if the patient moves while x rays are being taken.

Preparation

An intravenous antibiotic may be given every 4–6 hours during the 24 hours before the test. The patient will be told to fast overnight. Having an empty stomach is a safety measure in case of complications, such as bleeding, that might require emergency repair surgery. Medications such as aspirin, or non-steroidal anti-inflammatory drugs that thin the blood, should be stopped for some three to seven days prior to taking the PRHC test. Patients may also be given a sedative a few minutes before the test begins.

Aftercare

A nurse will monitor the patient's vital signs and watch for:

- itching
- flushing
- nausea and vomiting
- sweating
- excessive flow of saliva
- possible serious allergic reactions to contrast dye

The patient should stay in bed for at least six hours after the test, lying on the right side to prevent bleeding from the injection site. The patient may resume normal eating habits and gradually resume normal activities. The doctor should be informed right away if pain develops in the right abdomen or shoulder or in case of **fever**, dizziness, or a change in stool color to black or red.

KEY TERMS

Ascites—Abnormal accumulation of fluid in the abdomen.

Bile ducts—Tubes that carry bile, a thick yellowish-green fluid that is made by the liver, stored in the gallbladder, and helps the body digest fats.

Cholangitis—Inflammation of the bile duct.

Fluoroscope—An x-ray machine that projects images of organs.

Granulomatous disease—Characterized by growth of tiny blood vessels and connective tissue.

Jaundice—Disease that causes bile to accumulate in the blood, causing the skin and whites of the eyes to turn yellow. Obstructive jaundice is caused by blockage of bile ducts, while non-obstructive jaundice is caused by disease or infection of the liver.

Risks

Septicemia (blood poisoning) and bile peritonitis (a potentially fatal infection or inflammation of the membrane covering the walls of the abdomen) are rare but serious complications of this procedure. Dye occasionally leaks from the liver into the abdomen, and there is a slight risk of bleeding or infection.

Normal results

Normal x rays show dye evenly distributed throughout the bile ducts. Obesity, gas, and failure to fast can affect test results.

Abnormal results

Enlargement of bile ducts may indicate:

- obstructive or non-obstructive jaundice
- cholelithiasis (gallstones)
- hepatitis (inflammation of the liver)
- cirrhosis (chronic liver disease)
- granulomatous disease
- pancreatic cancer
- bile duct or gallbladder cancers

Pericardial effusion

Definition

A pericardial effusion is a fluid collection that develops between the pericardium, the lining of the heart, and the heart itself. Pericardial effusions can be found in up to 20% of cancer patients at autopsy, but of those, only about 30% would have had symptoms from their effusions.

Description

Most of the organs of the body are covered by thin membranes. The membrane that surrounds the heart is called the pericardium. Normally, only a few milliliters of fluid sit between the pericardium and the muscle of the heart. Any larger, abnormal collection of fluid in that space is called a pericardial effusion.

A pericardial effusion can interfere with the normal contraction and expansion of the heart muscle, which decreases the heart's ability to pump blood effectively. A large or rapidly developing effusion can cause a condition called cardiac tamponade. Tamponade is a medical emergency and can be fatal if not diagnosed and treated promptly. Symptoms of tamponade include shortness of breath, rapid pulse, cough, and chest discomfort. As tamponade progresses, low blood pressure and shock develop and cardiac arrest can follow.

A smaller or more slowly developing pericardial effusion also causes chest discomfort. Other symptoms, such as shortness or breath, difficulty swallowing, hoarseness or hiccups result from pressure from the enlarged, fluid-filled pericardium pressing against nearby organs. Although chronic or smaller effusions are not emergencies, they do cause discomfort and can become more serious.

The diagnosis of pericardial effusion is made on the basis of patient history, physical examination and appropriate laboratory studies. Heart sounds can be muffled, the veins in the neck engorged and the pulse rapid. A chest **x ray** shows enlargement of the silhouette of the heart. An echocardiogram or cardiac ultrasound will show the fluid surrounding the heart, as will CT and MRI scans.

Causes

A pericardial effusion in a cancer patient is caused either by the disease itself or by the treatment for the disease.

Many cancers can metastasize or spread to the pericardium or the heart itself. They include:

- Lung
- Breast
- Thyroid
- Esophagus
- Kidney
- Pancreas
- Endometrium
- Larynx
- Cervix
- Stomach
- Mouth
- Liver
- Ovary
- Colon
- Prostate
- Leukemia
- Melanoma
- **Lymphoma**
- Sarcoma
- Myeloma

The presence of the cancerous cells on the pericardium is an irritant and causes a reactive fluid buildup, much as a blister forms under the skin due to irritation. Some cancers cause less fluid buildup, instead thickening the pericardium and making it less elastic. This can also cause symptoms of tamponade.

Another cause of pericardial effusion in a cancer patient is previous **radiation therapy** to the chest, especially in the case of lung cancer or lymphoma. While such effusions are less likely to produce tamponade, it is possible.

Many of the drugs that are used to treat cancer can cause pericardial disease and can thus potentially cause pericardial effusions. Some of the chemotherapeutic drugs that can affect the pericardium are **cytarabine**, **fluorouracil**, **cyclophosphamide**, **doxorubicin** and **daunorubicin**. Granulocyte-macrophage colony-stimulating factor (**sargramostim**), often given to help increase the population of white blood cells during intensive **chemotherapy**, is also a pericardial irritant.

Other causes of pericardial effusions are heart failure, liver disease, and kidney disease. Any of these can also affect cancer patients.

Treatments

Treatment of pericardial effusion depends on the presence or absence of cardiac tamponade. Tamponade is a medical emergency and symptoms such as cyanosis, a blue tinge to the lips and skin, shock, or a change in mental status require urgent drainage of the fluid. This drainage is accomplished with a procedure called **pericardiocentesis**, in which a needle is inserted into the pericardial space and the fluid withdrawn into a large syringe. Chronic effusions can be drained electively, and some need not be drained at all. If a patient's prognosis is poor and the pericardial effusion is not compromising the function of the heart, the risks of a drainage procedure may outweigh its benefits and the effusion may be left alone. Effusions caused by lymphoma often resolve after aggressive chemotherapy and need no further treatment.

Elective drainage of a pericardial effusion is done by one of several surgical procedures. The surgeon might open the chest, make a small incision under the bottom of the breastbone, or use a video-assisted technique called **thoracoscopy**. In addition to permitting drainage of the pericardial fluid, these procedures permit the surgeon to take a pericardial **biopsy**, which can confirm the diagnosis of metastatic cancer.

Sometimes a catheter is placed in the pericardium and connected to an external drainage system to collect any fluid that might reaccumulate.

Occasionally, sclerosing agents—drugs that cause scarring—are infused into the pericardium through a catheter. These agents, such as tetracycline, minocycline or **bleomycin**, irritate the pericardium, causing it to thicken and adhere to the heart muscle. This scarring prevents the further accumulation of fluid. Some malignant pericardial effusions resolve after the instillation of chemotherapeutic drugs such as **thiotepa** or platinum directly into the pericardial cavity. Others resolve after radiation therapy directed at the pericardium.

Alternative and complementary therapies

No complementary or alternative treatments are aimed specifically at treating pericardial effusions, but

KEY TERMS

Pericardium—The thin membrane that surrounds the heart.

Sclerosing agents—Drugs that are instilled into parts of the body to deliberately induce scarring.

Tamponade—A medical emergency in which fluid or other substances between the pericardium and heart muscle compress the heart muscle and interfere with the normal pumping of blood.

Thoracoscopy—Chest surgery done with the guidance of special video cameras that permit the surgeon to see inside the chest.

practitioners of acupressure and acupuncture designate a pressure point for the pericardium at two and a half finger breadths above the wrist crease on the inner aspect of the arm. Acupressure and acupuncture do offer some relief of symptoms to those suffering from shortness of breath and might offer benefit to those with pericardial effusions.

Marianne Vahey, M.D.

Pericardiocentesis

Definition

Pericardiocentesis is a therapeutic and diagnostic procedure in which fluid is removed from the pericardium, the sac that surrounds the heart.

Purpose

The pericardium normally contains only a few milliliters (less than a teaspoon) of fluid to cushion the heart. Many illnesses cause larger volumes of fluid, called pericardial effusions, to develop. Spread of cancer to the pericardium is a frequent cause of pericardial effusions. If an effusion is too large, pressure develops within the sac that can interfere with the normal pumping action of the heart. Should that interference become severe, a life-threatening condition called cardiac tamponade can develop, which can lead to shock or death.

Pericardiocentesis is a procedure to remove that fluid, which allows the heart to pump normally again. The fluid is analyzed for the presence of cancer cells or microorganisms. If cardiac tamponade is present, pericardiocentesis must be done on an urgent basis. If tamponade is not present, an elective surgical pericardial drainage procedure can be scheduled.

Precautions

The presence of tamponade is a medical emergency and requires urgent treatment. The blood pressure can be low and breathing compromised. Fluids and intravenous medications might be needed to raise the blood pressure until the pericardiocentesis can be performed.

Description

When possible, pericardiocentesis is performed in the cardiac catheterization laboratory of the hospital, but it can be done at the bedside or in the emergency department. The patient lies on his or her back with the head elevated at about 45 degrees. The skin is sterilized and local anesthetic given. A long needle attached to a large sterile syringe is inserted under the breastbone into the pericardium. If available, an echocardiogram or cardiac ultrasound is done to guide the physician to the pericardium. Once the needle is in the pericardium, the doctor withdraws the pericardial fluid into the syringe. The fluid can then be tested for cancer cells. If the volume of the fluid is large or likely to reaccumulate, a catheter or drain is placed with one end in the pericardial space and the other outside the chest, attached to a collecting bag.

This can stay in place for several days, until there is no more fluid to drain. After withdrawing either the needle or the catheter, the doctor will apply direct pressure to the site.

If a pericardiocentesis is unsuccessful at draining the **pericardial effusion**, other procedures are available such as percutaneous balloon pericardiotomy, in which a balloon-tipped catheter is inserted through the skin and then used to puncture a hole in the pericardium. This is a painful procedure and should be done under anesthesia. The pericardial fluid is allowed to drain into the chest cavity, into the pleural space, the area between the pleura, the membranes that line the lungs, and the lungs themselves. The pleural space can accommodate more fluid than the pericardium without significant discomfort.

Alternatively, if emergent pericardiocentesis is unsuccessful, the patient can be taken to the operating room for a surgical procedure that will drain the fluid. These elective surgical procedures are similar to pericardiocentesis; however, for open surgical procedures, image guidance is not necessary. These are typically performed under general anesthesia. These procedures present the surgeon with the opportunity to perform a **biopsy** of the pericardium, to confirm the suspicion that the patient's cancer has metastasized there. The operation can also be performed as a thoracoscopic procedure.

Finally, if necessary, a pericardiectomy, sometimes called a pericardial stripping, can be performed. This is a surgical procedure to remove the pericardium and is reserved for the most refractory cases. Pericardiectomy tends to carry more risk than other procedures.

Preparation

For a scheduled pericardiocentesis, a patient will take nothing by mouth for several hours before the procedure. The patient will undergo preoperative blood tests, an electrocardiogram, and an echocardiogram or ultrasound of the heart.

Aftercare

Most patients are admitted to an intensive care unit for monitoring after a pericardial drainage procedure. Frequent checks of blood pressure and pulse will be done, and the neck veins will be examined for bulging. Such bulging might indicate a bleeding complication. If a drain has been placed, the fluid collected will be measured, and the site checked for signs of bleeding or infection. Most patients spend several days in the hospital after pericardial drainage, but a few who do not have drains placed can go home the next day.

Risks

There is about a 5% risk of complications with a pericardiocentesis. These risks include:

- cardiac arrest
- myocardial infarction or heart attack
- abnormal heart rhythms
- laceration or puncture of the heart muscle
- laceration of the coronary arteries
- laceration of the lungs
- laceration of the stomach, colon or liver
- air embolism, in which a pocket of air becomes trapped in a blood vessel, blocking blood flow

When a pericardial effusion is caused by the presence of cancer cells, there is also a risk that the fluid might reaccumulate. Injecting irritants into the pericardial sac can initiate scarring of the pericardium. This causes it to adhere to the surface of the heart and prevents fluid from collecting there again. The irritating or sclerosing agents that are

KEY TERMS

Pericardium—The thin membrane that surrounds the heart.

Sclerosing agents—Drugs that are instilled into parts of the body to deliberately induce scarring.

Tamponade—A medical emergency in which fluid or other substances between the pericardium and heart muscle compress the heart muscle and interfere with the normal pumping of blood.

Thoracoscopy—Chest surgery done with the guidance of special video cameras that permit the surgeon to see inside the chest.

QUESTIONS TO ASK THE DOCTOR

- What is a pericardiocentesis?
- Why do I need this procedure?
- What are the risks?
- What are the risks of not having a pericardiocentesis?
- What sort of anesthesia will I have?
- What do you expect to find?
- What can I expect after the test?
- How long will I need to stay in the hospital?

instilled into the pericardial space through a catheter include tetracycline, minocycline, and **bleomycin**. The injection of these drugs into the pericardium can cause pain. Sometimes, the simple presence of a drainage catheter will introduce the desired scarring, and this method is preferred, when possible, to the use of the irritant drugs.

Normal results

The most important result is the relief of tamponade or other symptoms of heart failure from excess pericardial fluid. The blood pressure should return to normal, chest pain should be relieved, and breathing should become easier.

The fluid will be analyzed. Normal pericardial fluid is clear, has no cancer cells, no evidence of infection, and fewer than 1,000 white blood cells.

Abnormal results

On rare occasions, the pressure changes surrounding the heart that occur after pericardial drainage can cause temporary worsening of symptoms. This is called pericardial shock.

The most likely cause of a pericardial effusion in a person with cancer is spread of cancer to the pericardium. Thus, the fluid might, upon analysis, contain cancerous cells, high levels of protein, and many white blood cells. This can make the fluid thick and viscous. If the pericardial biopsy is performed, as can be done with a surgical drainage procedure, that biopsy might also reveal the presence of cancer cells.

Peritoneovenous shunt

Definition

A peritoneovenous shunt (PVS) is a device that is inserted surgically into the body to create a passage between the peritoneum (abdominal cavity) and the jugular vein to treat refractory cases of peritoneal **ascites**. Ascites is a condition in which an excessive amount of fluid builds up within the abdominal cavity.

KEY TERMS

Abdomen—The part of the body which lies between the diaphragm and the rim of the pelvis.

Circulatory system—The circulatory system consists of the heart and blood vessels. It serves as the body's transportation system.

Esophagus—The part of the digestive tract that brings food from the mouth to the stomach.

Jugular veins—Large veins returning the blood from the head to the heart into two branches (external and internal) located on each side of the neck.

Lymph—Colorless liquid that carries the white blood cells in the lymphatic vessels.

Lymphatic system—A subsystem of the circulatory system, it consists of lymphatic fluid, lymphatic vessels, and lymphatic tissues (lymph nodes, tonsils, spleen, and thymus). It returns excess fluid to the blood and defends the body against disease.

Peritoneum—Smooth membrane which lines the cavity of the abdomen and which surrounds the viscera (large interior organs) forming a nearly closed bag.

Peritonitis—Inflammation of the peritoneum.

Vena cava—Very large veins. There are two vena cava in the body. The superior vena cava returns blood from the upper limbs, head, and neck to the heart and the inferior vena cava returns blood from the lower limbs to the heart.

QUESTIONS TO ASK THE DOCTOR

- What are the benefits of PVS for my condition?
- Why is medication not possible?
- What complications are possible?
- What happens if the PVS device gets blocked?
- How experienced is the surgeon with PVS surgery?

Purpose

The abnormal build-up of fluid in the spaces found between the tissues and organs of the abdominal cavity is a common symptom of liver disease such as cirrhosis of the liver, but approximately 10% of the diagnosed cases occur as a side effect of several types of cancers, such as ovarian, gastric, exocrine pancreatic, and colorectal cancers, and **lymphoma**. This condition is known as ascites and it causes pain and discomfort in patients. When doctors can not treat advanced ascites with medication, they recommend an operation such as the PVS procedure as a means to empty the abdomen of the accumulated fluid.

The ascites that results from cancer contains high levels of proteins. It occurs because of functional imbalances in the cells of the organs affected by the cancer and because the walls of the capillaries containing the normal abdominal fluid start leaking. Depending on the type of cancer, there may also be a decrease in the ability of the lymphatic system of the body to absorb fluids.

Precautions

The PVS procedure is restricted to patients with livers that function normally. Additionally, the required veins must be healthy so as to allow the insertion of the shunt device. The PVS insertion is not performed in the following cases:

- patients having undergone previous extensive abdominal surgery
- patients diagnosed with bacterial peritonitis
- patients with diseased veins in the esophagus
- patients with heart disease
- patients with a diseased major organ

In cases of ascites due to cancer (malignant ascites), there is a concern that the use of a PVS could enhance the spread of the cancer. In evaluating a cancer patient as a candidate for a PVS, the risk of cancer spread must be balanced against pain/discomfort relief, quality of life issues, and the expected survival period.

Description

The most common PVS device is the LeVeen shunt, used since the 1970s to relieve ascites due to liver disease and since the 1980s for cancer-related ascites. It consists of a plastic or silicon rubber tube fitted with a pressure-activated one-way polypropylene valve that connects the peritoneal space where the fluid is collecting to a large vein located in the neck called the jugular vein. The tube enters the jugular vein and terminates in another large vein called the superior vena cava that returns blood to the heart. Thus, the fluid goes from the abdominal cavity to the venous blood circulatory system and is then eliminated by the kidneys. The function of

the one-way valve is to prevent blood from flowing back into the peritoneal space.

The PVS is inserted under the skin of the chest under local or general anesthesia, depending on the general health condition of the patient.

An alternative option to treat ascites due to cirrhosis is to use a transjugular intrahepatic portosystemic shunt (TIPS). This is also a tube that is passed through the skin of the neck and into the jugular vein but it is pushed all the way through the liver and into the portal vein, which drains into the liver. It thus creates a shunt of blood across the liver in an attempt to reduce pressure and fluid formation.

Preparation

Abdominal computed tomography (CT) scans are used to determine the extent of the ascites. Lab tests are usually performed to determine if the excess abdominal fluid is infected and other **imaging studies** such as ultrasound may be performed to assess the general condition of the veins selected for insertion of the PVS tube. For the operation, the patient is usually injected with a mild sedative and local anesthetic. The surgeon uses a puncture needle to create the opening required for insertion of the PVS device so as to avoid surgical incisions which take longer to heal.

Aftercare

Antibiotics are usually prescribed for approximately four days after surgery. Any **fever** or chills that the patient experiences should be reported to the doctor without delay.

Risks

Complications following PVS insertion are very common and include infection, leakage of fluid, fluid build-up in the lungs, problems with blood coagulation, heart failure and blockage of the PVS device.

Normal results

The PVS insertion is considered successful when the abdominal fluid build-up gradually disappears after the operation.

Abnormal results

The most common complication resulting from PVS insertion is obstruction of the valve or tube, which can be due to a blood clot or to scar tissue forming around the shunt and eventually blocking it. This complication occurs in approximately 60% of cases during the first year of follow-up.

Peutz-Jeghers syndrome

Definition

Peutz-Jeghers syndrome (PJS) is a rare familial cancer syndrome that causes intestinal polyps, skin freckling, and an increased risk for cancer.

Description

Peutz-Jeghers syndrome affects both males and females. The characteristic, or pathognomonic, features of PJS are unusual skin freckling and multiple polyps of the small intestine. The skin freckles, which are bluish to brown to black in color, can be found on the lips, inside the mouth, around the eyes, on the hands and feet, and on the genitals. The freckles are called benign hyperpigmented macules and do not become cancerous. The polyps in PJS are called hamartomatous polyps, and are found in the small intestine, small bowel, stomach, colon, and sometimes in the nose or bladder. Hamartomatous polyps are usually benign (not cancerous), but occasionally become malignant (cancerous). Dozens to thousands of hamartomatous polyps may develop. A person with PJS with benign hamartomatous polyps can have abdominal pain, blood in the stool, or complications such as colon obstruction or intussusception (a condition in which one portion of the intestine telescopes into another). Surgery may be required to remove the affected part of the colon. A person with PJS is at increased risk for cancer of the colon, small intestine, stomach and pancreas. Women with PJS are also at increased risk for breast and **cervical cancer**, and a specific type of benign ovarian tumor called SCTAT (sex cord tumors with annular tubules). Men with PJS are also at increased risk for benign testicular tumors.

Diagnosis

The diagnosis of Peutz-Jehgers syndrome can be made clinically in a person with the characteristic

freckles and at least two hamartomatous polyps. A pathologist needs to confirm that the polyps are hamartomatous instead of another type of polyp. If a person has a family history of PJS, the diagnosis can be made in a person who has either freckles or hamartomatous polyps. When someone is the first person in his/her family to be diagnosed with PJS, it is important for all first-degree relatives to be carefully examined for clinical signs of PJS. About half of all persons with PJS will have family members with symptoms of PJS. Symptoms can vary between families and between members of the same family. Some family members may just have freckling and others may have more serious medical problems such as bowel obstruction or cancer diagnosis. The freckles in PJS usually appear in childhood and fade as a person gets older, so it may be necessary to look at childhood photos in an adult who is being examined for signs of PJS.

Risks

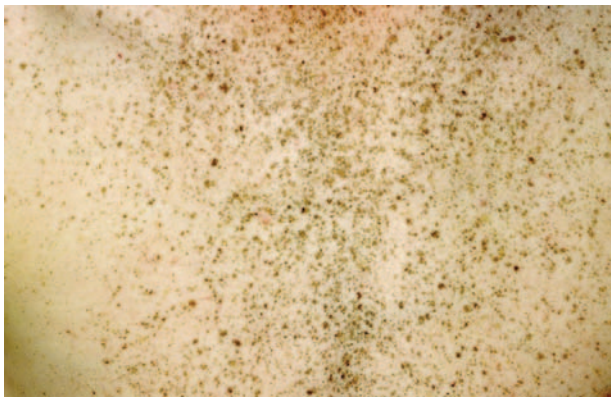
Hamartomatous polyps may be diagnosed from early childhood to later in adulthood. On average, a person with PJS develops polyps by his or her early 20s. The lifetime risk for cancer is greatly increased over the general population, and cancer may occur at an earlier age. Early and regular screening is important to try to detect any cancers at an early stage. The benign ovarian tumors in women with PJS may cause early and irregular menstruation. The benign testicular tumors in men may cause earlier growth spurts and gynecomastia (development of the male breasts).

Causes

PJS is a genetic disease caused by a mutation of a tumor suppressor gene called LBK1 (or STK11) on chromosome 19. The exact function of LBK1 is unknown at this time. PJS is inherited as an autosomal dominant condition, which means that a person with PJS has a 50% chance of passing it on to each of his or her children. Screening and/or **genetic testing** of family members can help sort out who has PJS or who is at risk for developing PJS. Identification of a person with PJS in a family may result in other family members with more mild symptoms being diagnosed, and then receiving appropriate screening and medical care.

Genetic Testing

Fifty percent of people clinically diagnosed with PJS will have a mutation in the LBK1/STK11 gene detected in the lab. The other half will not have a detectable mutation at that time, but may have other PJS-causing genetic mutations discovered in the future.



The unusual skin freckling of Peutz-Jeghers syndrome. Here, the freckles are shown on the chest. *(Custom Medical Stock Photo. Reproduced by permission.)*

In families where a mutation is known, family members can be tested for the same mutation. A person who tests positive for the family mutation will be diagnosed with PJS (even if he or she does not currently show signs of PJS), will need to have the recommended screening evaluations, and is able to pass on the mutation to his or her children. A person who tests negative for a known family mutation will be spared from screening, and his or her children will not be at risk for PJS. When the mutation cannot be found in a family, genetic testing is not useful, and all persons at risk for inheriting PJS will need to have screening for PJS throughout their life span.

Screening and treatment

Regular medical examinations and special screening tests are needed in people with PJS. The age at which screening begins and the frequency of the tests is best determined by a physician familiar with PJS. Screening schedules depend on symptoms and family history. **Colonoscopy**, used to search for polyps in the colon, usually begins in adolescence. X rays and/or upper gastrointestinal endoscopy are used to screen for polyps in the stomach and small intestine. The goal of screening is to remove polyps before they cause symptoms or become cancerous. Surgery may be necessary. Females with PJS need to have annual gynecologic examinations by age 18, and breast **mammography** starting between the ages of 25 and 35. Males with PJS need to have annual testicular examinations. If a person with PJS develops cancer, it is treated as it would be in the general population.

See also Cancer genetics; Familial cancer syndromes.

KEY TERMS

Gynecomastia—Overdevelopment of the mammary glands in males; male breast development.

Intussusception— The folding of one segment of the intestine into another segment of the intestine.

Pathognomonic—Characteristic of a disease; a pattern of symptoms not found in any other condition.

Polyp—A mushroom-like growth that may be a precursor to cancer.

Phenytoin

Definition

Phenytoin is an anticonvulsant, a drug that acts to prevent seizures. In the United States, phenytoin is sold under the brand name Dilantin.

Purpose

Phenytoin helps prevent some types of seizure activity. It is often used to aid in controlling nerve pain associated with some cancers and cancer treatments. Nerve pain causes a burning, tingling sensation. Phenytoin also may be ordered to control a rapid or irregular heart rate. Phenytoin may be given to stop uncontrolled seizures. It may be used during brain surgery to prevent seizure activity. In 2003 a group of researchers in California reported that phenytoin is effective in controlling the acute mania associated with bipolar disorder. Additional uses are under study.

Description

Phenytoin works on areas of the brain to limit electrical discharges and stabilize cellular activity. Like many drugs that control seizures, it also has proven helpful in managing nerve pain.

Recommended dosage

The dose ordered depends on blood levels of the drug determined during routine monitoring. For pain, doctors usually order 200–500 mg per day, either at bedtime or in divided doses. Patients usually start on a low dose. Depending on the patient's response and drug blood levels, the dose may be increased. For seizures, patients are usually started at 100 mg, three times per day. Blood is drawn to check the level of phenytoin in seven to 10 days. The dose is adjusted accordingly. The doctor may prescribe a dose based on an older person's weight. A child's dose also is based on his or her weight.

It is very important that this drug be used exactly as directed. This medication should be taken at the same time every day. Patients should take a missed dose as soon as it is noted. But patients should not take two doses within four hours of each other. This medication should be stored in a dry place, not in the bathroom.

Precautions

Patients should not suddenly stop taking this medication. The abrupt withdrawal of phenytoin could trigger seizures. Patients should not crush or break extended-release drugs. Chewable tablets should be chewed before swallowing. Other pills should be swallowed whole. Older adults may be more prone to adverse effects than younger people. Patients should not change brands without approval of the doctor.

Phenytoin should not be taken by patients who are allergic to this drug. People with slow heart rates, certain other heart conditions, or a flaking, open skin condition also should not take it. Phenytoin may be used cautiously for patients with asthma, allergies, limited kidney or liver function, heart disease, and blood disorders. It also should be used with caution in those with alcoholism, diabetes
