mellitus, lupus, poor thyroid function, or porphyria, a rare metabolic disorder. Pregnant women should discuss the risks and benefits of this medication with the doctor. It has been associated with birth defects and possibly cancer in children born to women taking the drug; one study done in 2003 suggests that phenytoin interferes with the normal development of the baby's blood circulation. Expectant mothers who are taking it to prevent seizures should not abruptly stop the drug. Those using it for pain control should discuss its continued use with the doctor. Patients on this drug should not breast feed.

Side effects

Drowsiness is a common side effect of phenytoin. Patients should exercise caution when driving or operating machinery. Alcohol may increase drowsiness. Patients should not consume alcoholic beverages while taking this drug. Other, less frequent effects related to the central nervous system include an unsteady gait, slurred speech, confusion, and dizziness. Patients may experience **depression**, difficulty sleeping, nervousness, irritability, tremors, and numbness. Twitching, headache, mental-health problems including psychotic episodes, and more seizure activity may occur. This medication may also cause **nausea and vomiting**, stomach upset, **diarrhea**, constipation, and swollen gum tissue. Side effects also include a rash, hair loss (**alopecia**) or excessive hair growth, vision changes, uncontrolled eye movements, and inflammation of the surface of the eye. Patients may develop chest pain, swelling, **fever**, increase in weight, enlarged lips, or joint or muscle pain. Patients should practice good dental hygiene to decrease the risk of gum disease. With the doctor's approval, it may be taken with food to decrease stomach upset.

Phenytoin may produce changes in the normal makeup of the blood, including high blood sugar levels and **anemia**. It may trigger disorders of the lymphatic system and cause liver damage. If the liver is not able to properly break down phenytoin, it can produce toxic effects, even at small doses. Doctors typically assess kidney and liver function prior to ordering it. The tests are repeated at regular intervals. Patients should notify the doctor promptly of any side effects. If a skin rash develops, the doctor will instruct the patient how to taper off and stop the drug.

Interactions

Many drugs interact with phenytoin and may increase or decrease its blood levels. Phenytoin may alter the effectiveness of other drugs. The list of interactions is long and varied. Drugs that interfere with phenytoin include anticoagulants (blood thinners), sulfa and other **antibiotics**, antifungal agents, drugs used to treat ulcers, methadone, antidepressants, and disulfiram, which is used to treat alcoholism. It also interacts with **corticosteroids**, estrogen hormones, birth control pills and injections, drugs to treat hypoglycemia, asthma drugs, such other anticonvulsants as carbamazepine, lidocaine, heart medications, Parkinson's disease drugs, anti-inflammatory drugs, narcotic pain relievers, and anticancer drugs. Additionally, taking phenytoin with certain antidepressants may cause seizures in some patients.

Phenytoin has also been reported to interact with certain herbs, including evening primrose (*Oenothera biennis*), gingko (*Gingko biloba*), wormwood (*Artemisia pontica*), and an Ayurvedic preparation known as Shankapulshpi. Patients should always tell their doctors about any herbal preparations they may be taking as well as other prescription medications.

Alcohol ingestion can interfere with maintaining proper blood levels of phenytoin. Patients should not drink alcoholic beverages while taking this medication, as phenytoin can accumulate to toxic levels in the body of noncompliant patients. Antacids and calcium can lower the effectiveness of phenytoin. These drugs should be taken two to three hours apart from phenytoin. Tube feeding may decrease the amount of phenytoin absorbed. Patients should not give tube feedings for two hours before and after taking this drug. Patients should talk to the doctor before taking **folic acid**. It may interfere with this drug.

KEY TERMS

Anticonvulsant—A type of medication given to prevent seizures. Phenytoin is an anticonvulsant.

Bipolar disorder—A mood disorder in which the patient experiences both periods of mania and periods of depression.

Epilepsy—Disorder of the nervous system that causes seizures.

Lymph system—a part of the immune system that includes lymph nodes and tissue.

Mania—The phase of bipolar disorder in which the patient is easily excited, hyperactive, agitated, and unrealistically cheerful. Phenytoin appears to be a useful treatment for mania.

Pheochromocytoma

Definition

Pheochromocytoma is a tumor of special cells (called chromaffin cells), most often found in the middle of the adrenal gland.

Description

Because pheochromocytomas arise from chromaffin cells, they are occasionally called chromaffin tumors. Most (90%) are benign tumors so they do not spread to other parts of the body. However, these tumors can cause many problems and if they are not treated and can result in death.

Pheochromocytomas can be found anywhere chromaffin cells are found. They may be found in the heart and in the area around the bladder, but most (90%) are found in the adrenal glands. Every individual has two adrenal glands that are located above the kidneys in the back of the abdomen. Each adrenal gland is made up of two parts: the outer part (called the adrenal cortex) and the inner part (called the adrenal medulla). Pheochromocytomas are found in the adrenal medulla. The adrenal medulla normally secretes two substances, or hormones, called norepinephrine and epinephrine. These two substances, when considered together, are known as adrenaline. Adrenaline is released from the adrenal gland, enters the bloodstream and helps to regulate many things in the body including blood pressure and heart rate. Pheochromocytomas cause the adrenal medulla to secrete too much adrenaline, which in turn causes high blood pressure. The high blood pressure usually causes the other symptoms of the disease.

Demographics

Pheochromocytomas are rare tumors. They have been reported in babies as young as 5 days old as well as adults as old as 92 years old. Although they can be found at any time during life, they usually occur in adults between 30-40 years of age. Pheochromocytomas are somewhat more common in women than in men.

Causes and symptoms

The cause of most pheochromocytomas is not known. A small minority (about 10-20%) of pheochromocytomas arise because a person has an inherited susceptibility to them. Inherited pheochromocytomas are associated with four separate syndromes: Multiple Endocrine Neoplasia, type 2A (MEN2A), Multiple Endocrine Neoplasia, type 2B (MEN2B), von Hippel-Lindau disease (VHL), and Neurofibromatosis type 1 (NF1).

Individuals with pheochromocytomas as part of any of these four syndromes usually have other medical conditions, as well. People with MEN2A often have cancer (usually **thyroid cancer**) and other hormonal problems. Individuals with MEN2B can also have cancer and hormonal problems, but also have other abnormal physical features. Both MEN2A and MEN2B are due to genetic alterations or mutations in a gene called RET, found at chromosome 10q11.2. Individuals with VHL often have other benign tumors of the central nervous system and pancreas, and can sometimes have renal cell cancer. This syndrome is caused by a mutation in the VHL gene, found at chromosome 3p25-26. Individuals with NF1 often have neurofibromas (benign tumors of the peripheral nervous system). NF1 is caused by mutations in the NF1 gene, found at chromosome 17q11.

All of these disorders are inherited in an autosomal dominant inheritance pattern. With autosomal dominant inheritance, men and women are equally likely to inherit the syndrome. In addition, children of individuals with the disease are at 50% risk of inheriting it. **Genetic test-**

ing is available for these four syndromes (MEN2A, MEN2B, VHL and NF1) but, due to the complexity, genetic counseling should be considered before testing.

Most people (90%) with pheochromocytoma have hypertension, or high blood pressure. The other symptoms of the disease are extremely variable. These symptoms usually occur in episodes (or attacks) called paroxysms and include:

- headaches
- excess sweating
- racing heart
- rapid breathing
- anxiety/nervousness
- nervous shaking
- pain in the lower chest or upper abdomen
- nausea
- heat intolerance

The episodes can occur as often as 25 times a day or, as infrequently as once every few months. They can last a few minutes, several hours or days. Usually, the attacks occur several times a week and last for about 15 minutes. After the episode is over, the person feels exhausted and fatigued.

Between the attacks, people with pheochromocytoma can experience the following:

- increased sweating
- cold hands and feet
- weight loss
- constipation

Diagnosis

If a pheochromocytoma is suspected, urine and/or a blood tests are usually recommended. A test called "24-hour urinary catacholamines and metanephrines" will be done. This test is designed to look for adrenaline and the break-down products of adrenaline. Since the body gets rid of these hormones in the urine, those testing will need to collect their urine for 24 hours. The laboratory will determine whether or not the levels of hormones are too high. This test is very good at making the diagnosis of pheochromocytoma. Another test called "serum catacholamines" measures the level of adrenaline compounds in the blood. It is not as sensitive as the 24-hour urine test, but can still provide some key information if it shows that the level of adrenaline compounds is too high.

One of the difficulties with these tests is that a person needs to have an attack of symptoms either during the 24-hour urine collection time period or shortly before the blood is drawn for a serum test to ensure the test's accuracy. If a person did not have an episode during that time, the test can be a "false negative." If a doctor suspects the patient has gotten a "false negative" test, additional tests called "pharmacologic tests" can be ordered. During these tests, a specific drug is given to the patient (usually through an IV) and the levels of hormones are monitored from the patient's blood. These types of tests are only done rarely.

Once a person has been diagnosed with a pheochromocytoma, he or she will undergo tests to identify exactly where in the body the tumor is located. The imaging techniques used are usually **computed tomography** scan (CT scan) and magnetic resonance imaging (MRI). A CT scan creates pictures of the interior of the body from computer-analyzed differences in x rays passing through the body. CT scans are performed at a hospital or clinic and take only a few minutes. An MRI is a computerized scanning method that creates pictures of the interior of the body using radio waves and a magnet. An MRI is usually performed at a hospital and takes about 30 minutes.

Treatment team

A pheochromocytoma will usually be treated by an internist (general medical doctor) an anesthesiologist (doctor who administers anesthesia for surgery) and a specialized surgeon (doctor who removes the tumor from the body). If the tumor is found to be malignant, a radiation oncologist (doctor who specializes in radiation treatment for cancer) and medical oncologist (doctor who specializes in **chemotherapy** treatment for cancer) may be consulted.

Clinical staging, treatments and prognosis

Once a pheochromocytoma is found, more tests will be done to see if the tumor is benign (not cancer) or malignant (cancer). If the tumor is malignant, tests will be done to see how far the cancer has spread. There is no accepted staging system for pheochromocytoma; but an observation of the tumor could provide one of these four indications:

- Localized benign pheochromocytoma means that the tumor is found only in one area, is not cancer, and cannot spread to other tissues of the body.
- Regional pheochromocytoma means that the tumor is malignant and has spread to the lymph nodes around the original cancer. Lymph nodes are small structures that are found all over the body that make and store infection-fighting cells.

- Metastatic pheochromocytoma means that the tumor is malignant and has spread to other, more distant parts of the body.
- Recurrent pheochromocytoma means that a malignant tumor that was removed has come back.

Treatment in all cases begins with surgical removal of the tumor. Before surgery, medications such as alpha-adrenergic blockers are given to block the effect of the hormones and normalize blood pressure. These medications are usually started seven to ten days prior to surgery. The surgery of choice is laparoscopic laparotomy, which is a minimally invasive outpatient procedure performed under general or local anesthesia. A small incision is made in the abdomen, the laparoscope is inserted and the tumor is removed. The patient can usually return to normal activities within two weeks. If a laparoscopic laparotomy cannot be done, a traditional laparotomy will be performed. This is a more invasive surgery done under spinal or general anesthesia and requires five to seven days in the hospital. Usually patients are able to return to normal activities after four weeks. After surgery, blood and urine tests will be done to make sure hormone levels return to normal. If the hormone levels are still above normal, it may mean that some tumor tissue was not removed. If not all tumor can be removed (as in malignant pheochromocytoma, for example) drugs will be given to control high blood pressure.

If a pheochromocytoma is malignant, **radiation therapy** and/or chemotherapy may be used. Radiation therapy uses high-energy x rays to kill cancer cells and shrink tumors. Because there is no evidence that radiation therapy is effective in the treatment of malignant pheochromocytoma, it is not often used for treatment. However, it is useful in the treatment of painful bone metastases if the tumor has spread to the bones. Chemotherapy uses drugs to kill cancer cells. Like radiation therapy, it has not been shown to be effective in the treatment of malignant pheochromocytoma. Chemotherapy, therefore, is only used in rare instances.

Untreated pheochromocytoma can be fatal due to complications of the high blood pressure. In the vast majority of cases, when the tumor is surgically removed, pheochromocytoma is cured. In the minority of cases (10%) where pheochromocytoma is malignant, prognosis depends on how far the cancer has spread, and the patient's age and general health. The overall median five-year survival from the initial time of surgery and diagnosis is approximately 43%.

Coping with cancer treatment

If laparascopic laparotomy is done and no further treatment is necessary, patients usually return to normal activity within two weeks. If more extensive surgery is performed, normal activity is delayed for a few weeks and can be emotionally difficult. In rare cases where radiation and/or chemotherapy are needed, coping can be very difficult. Consultation with physicians, nurses, social workers, and psychologists may be beneficial.

KEY TERMS

Adrenal medulla—The central core of the adrenal gland.

Laparoscope—An instrument used to examine body cavities during certain types of surgery; for example, surgeries to remove fibroid tumors, or gall bladders, are often removed through the navel rather than cutting into the body.

Paroxysm—A sudden attack of symptoms.

Prevention

Unfortunately, little is known about environmental and other causes of pheochromocytoma. Some of the tumors are due to inherited predisposition. Because of these factors, pheochromocytoma cannot be prevented.

Special concerns

Pheochromocytoma in children

Pheochromocytoma is rare in children, but occurs most commonly between the ages of 8 and 14 years. Diagnosis of pheochromocytoma can be more difficult at this age, because other **childhood cancers** (e.g. **neuroblastoma**) can also elevate adrenaline compounds in the body. Pheochromocytomas in children are more likely to be bilateral (on both the left and right sides of the body) and outside the adrenal glands. For this reason, transabdominal surgery is usually performed to remove the tumor.

Pheochromocytoma in pregnancy

Although rare, pheochromocytoma in pregnancy can be very dangerous. Because x rays are to be avoided in pregnancy, MRI and/or ultrasound is used to locate the tumor. Alpha-adrenergic blocking agents to reduce blood pressure are given to the woman as soon as the diagnosis is made. If the woman is in the first two trimesters of pregnancy, most often the tumor is removed. In the third trimester, the woman usually remains on alpha-adrenergic blocking agents until a cesarean section can be safely performed.

Pheresis

Definition

Pheresis is a blood purification process that consists of:

- drawing blood,
- separating red cells, plasma, platelets, and cryoprecipitated antihemophilic factor,
- isolating the blood component needed to diagnose a suspected abnormality or treat a known disease,
- and returning the remaining blood to the donor.

Purpose

Because most of the blood is returned to the donor, pheresis enables an individual to donate more of a specific component. The two main types of pheresis are removal of platelets (plateletpheresis) and removal of plasma (plasmapheresis).

Plateletpheresis

Cancer and cancer treatments can deplete the body's supply of platelets, the colorless particles that stick to the lining of blood vessels and make it possible for blood to clot. Patients who have leukemia or aplastic **anemia**, are receiving **chemotherapy**, or undergoing **bone marrow transplantation** need platelets donated by healthy volunteers to prevent potentially fatal bleeding problems.

Plasmapheresis

Also known as therapeutic plasma exchange, plasmapheresis removes cells from the straw-colored liquid portion of the blood, which contains clotting factors, infection-fighting antibodies, and other proteins. Plasma regulates blood pressure and maintains the body's mineral balance.

Frozen immediately after collection and thawed when needed for transfusion, fresh frozen plasma is sometimes given to control **disseminated intravascular coagulation** (DIC). A particular problem for cancer patients, this rare condition causes large numbers of blood clots to form, then dissolve.

Leukapheresis

Also known as apheresis, leukapheresis may be used to treat certain leukemia and to collect cells for autologous stem cell transplant. Performed before chemotherapy is administered, leukapheresis increases the treatment's impact by reducing the number of cancer cells in the bloodstream and permitting the medication to circulate more freely.

Precautions

The American Red Cross will not accept blood or blood products from anyone who is:

- less than 17 years old
- not in good health
- taking **antibiotics** or insulin
- unable to meet other requirements established to ensure the safety of donated blood

In general, cancer survivors who were treated surgically or with radiation and have been cancer-free for at least five years may donate blood. Because of the remote danger of contracting cancer as the result of a transfusion, blood donations are not accepted from cancer survivors who have been treated with chemotherapy or hormonal therapy or diagnosed with leukemia or **lymphoma**.

The Food and Drug Administration (FDA) requires every blood donor to provide a detailed health history

KEY TERMS

Babesiosis—Infection transmitted by the bite of a tick and characterized by fever, headache, nausea, and muscle pain.

Blood typing—Technique for determining compatibility between donated blood products and transfusion recipients.

Chagas disease—Acute or chronic infection caused by the bite of a tick and characterized by fever, swollen glands, rapid heartbeat, and other symptoms.

QUESTIONS TO ASK THE DOCTOR

- If I make a pheresis donation, can I still donate whole blood?
- What should I do if I change my mind about making a pheresis donation?
- What should I do if I make a pheresis donation and later realize my blood might not be safe?
- How can I find out if I could be a pheresis donor?
- Can I make a pheresis donation for myself, a friend, or a member of my family?

and have a physical examination. All donated blood is tested for babesiosis, bacterial infections, Chagas disease, human immunodeficiency virus (HIV), Lyme disease, malaria, syphilis, and viral hepatitis.

Description

Throughout the procedure, which lasts between 90 minutes and three hours, the pheresis donor relaxes in a specially contoured chair and watches movies or listens to music. A flexible tube inserted into the donor's arm slowly draws blood into a sophisticated machine (centrifuge) which separates the various blood components, collects whichever component is being donated, and returns the remaining blood through a vein in the donor's other arm. Each pheresis donation is typed and designated for a specific patient.

Inserting the needle can cause mild, momentary discomfort. Some pheresis donors feel a slight tingling around the lips and nose, but this sensation disappears as soon as the procedure is completed.

Plasmapheresis and plateletpheresis can be performed in a hospital or blood collection center. Leukapheresis should be performed in a hospital where bone marrow transplantation is frequently performed.

Preparation

Before undergoing pheresis, a donor should get a good night's sleep, eat a well-balanced meal, and drink plenty of caffeine-free liquids. A donor should not take aspirin within 72 hours or ibuprofen within 24 hours before undergoing plateletpheresis, because these medications would make the platelets less beneficial to the patient receiving the transfusion. The donor's physician will determine whether any other medications should be discontinued in preparation for the procedure.

Aftercare

A pheresis donor may feel tired for a few hours and should not plan on driving home after the procedure. Although the donor may resume normal activities right away, heavy lifting or strenuous exercise should be avoided until the following day.

Photodynamic therapy

Definition

Photodynamic therapy (PDT) is a form of nonsurgical cancer treatment available since the early 1990s that

combines a photosensitizing medication with exposure to a laser or other specific light wavelength to kill cancer cells. It can be used before or after surgery and other forms of cancer treatment. In some cases, PDT can even be administered during surgery to kill any cancer cells that were not removed by excision.

Purpose

Photodynamic therapy is still evolving, both in terms of the types of cancer it is approved to treat and the specific drugs that are used. PDT with a drug called **porfimer sodium** (Photofrin) was first approved as a treatment for **esophageal cancer** in 1995. The Food and Drug Administration (FDA) then extended its approval of this drug to cover **non-small cell lung cancer** in 1998. As of the early 2000s, the FDA has also approved porfimer sodium for the treatment of tumors located in the bronchi of the lungs and for palliative treatment of advanced cancers of the esophagus. Some cancer centers in the United States administer PDT with porfimer sodium for the treatment of certain types of skin cancer (squamous cell **carcinoma**, **basal cell carcinoma**, and Bowen's disease), recurrences of **breast cancer** following **mastectomy**, colorectal cancer, and cancers of the vulva and cervix, but these applications of PDT are still considered experimental as of early 2005.

In December 1999, the FDA approved a compound called aminolevulinic acid (ALA or Levulan Kerastick) for the treatment of actinic keratosis, a precancerous skin disorder caused by sun exposure. Experimental uses of ALA, as of the early 2000s, include treatment of **mycosis fungoides** and cancerous tumors on the surface of the skin.

Porfimer sodium and ALA are the only photosensitizing agents approved by the FDA for use in the United States as of 2005; however, several newer drugs for PDT are being tested in cancer centers in the United States and Europe. The most important of these will be described below.

In addition to cancer therapy, PDT is used to treat such conditions as wet macular degeneration, an eye disorder that can lead to blindness, as well as such benign skin conditions as psoriasis, acne, and skin disorders caused by the **human papilloma virus**. In addition, PDT is under investigation as a possible treatment for certain forms of coronary artery disease.

Precautions

Precautions for porfimer sodium (Photofrin):

- Porfimer sodium cannot be used in patients who are allergic to hematoporphyrin, a blood pigment used to make the drug.
- It cannot be used in pregnant or nursing women because its safety during pregnancy or lactation has not been established.
- It cannot be used to treat children.
- Lung tumors treated with Photofrin must be located in an airway where the doctor can reach them with a brochoscope.
- Photofrin cannot be used to treat tumors in the esophagus or bronchi that are beginning to break into the patient's windpipe or a major blood vessel. The drug should also be used cautiously in treating bronchial tumors that could block the airway if they develop inflammation following PDT.
- Patients who are receiving radiotherapy should not have PDT with porfimer sodium until 4 weeks after their last radiation treatment. They should also not be treated with radiotherapy until 2–4 weeks after a PDT treatment.

Precautions for aminolevulinic acid (ALA):

- Patients being treated with ALA must protect their skin from exposure to sunlight or bright indoor light in the short time period between application of the drug to the skin and the PDT treatment.
- ALA should be used cautiously in pregnant women or nursing mothers.
- If a second treatment is necessary, it should not be done before eight weeks after the first treatment.

Description

How PDT works

Photodynamic therapy is based on a series of chemical reactions involving a specific wavelength of visible light, a photosensitizing drug, and oxygen. There is no standard wavelength of light, light source, exposure period, or method of administering the medication that covers all forms of PDT. Most photosensitizing drugs are given intravenously, but some are applied to the skin or taken by mouth. Photosensitizers given by injection are activated by light in the red portion of the visible light spectrum, around 630–700 nanometers (nm; a nanometer is a measure of length, one billionth of a meter), while those applied to the skin are usually activated by blue light.

In general, cancerous tumors inside the body need more concentrated doses of light than abnormal growths on the body surface. Lasers are usually used to deliver highly concentrated light at one specific wavelength, while light sources that provide a larger area of illumination, such as light-emitting diodes (LEDs), are more efficient for treating skin tumors.

In contrast to their uses in surgery, lasers are not used in PDT to remove tissue or seal blood vessels with heat; rather they are used to start a chemical reaction. As a result, they do not become hot enough to burn tissue. The burning or stinging sensation that some patients experience during PDT is caused by the release of oxygen stimulating nearby nerve endings rather than heat from the laser itself.

Lasers can be attached to fiberoptics for treating tumors inside the body. Fiberoptics are thin strands of plastic or glass with special optical properties that can be threaded through a bronchoscope or endoscope, which are special tubes that allow the doctor to see into the patient's lungs or esophagus. Light from the laser is then transmitted along the special fibers to the tumor, thus allowing the doctor to activate the photosensitizing medication in a very small area of tissue without damaging normal tissue nearby.

PDT is a two-step form of therapy. First, the photosensitizing medication is injected into a vein or applied to the skin several days or hours before the scheduled treatment. The drug is absorbed by all body tissues but remains in cancer cells longer than in normal cells because the cancer cells are multiplying faster. After the medication has had time to collect in the malignant cells, the doctor directs a light source of the proper wavelength on the targeted area. When the light source strikes tissue containing the photosensitizing medication in the presence of oxygen, the medication is activated and produces free radicals and a highly reactive form of oxygen called singlet oxygen. The free radicals and singlet oxygen interact with the cell membranes of the cancer cells to destroy the energy-producing structures inside the cancer cells. In addition to killing the cancer cells directly, PDT works by closing blood vessels inside the tumor, thereby shutting off its supply of nutrients, and by stimulating the immune system to produce interleukins (nonantibody proteins) and other substances that attack the cancer.

Photosensitizing drugs

PORFIMER SODIUM Porfimer sodium, or Photofrin, was the first medication used for PDT. It is a purified derivative of hematoporphyrin, a dark reddish-purple pigment found in blood. Photofrin is activated by red light at a wavelength of 630 nm; one disadvantage of this short wavelength is that it cannot penetrate tissue deeper than about a third of an inch, thus making Photofrin unsuitable for treating tumors that lie deep beneath the surface. The light used to activate Photofrin is usually generated by a laser.

Porfimer sodium has several other disadvantages for PDT: It is a complex chemical mixture that tends to break down over time; it has limited ability to penetrate tissue; and it takes 4–6 weeks to be cleared from the skin, thus leaving patients susceptible to a photosensitivity reaction for a long period of time after their PDT treatment. A photosensitivity reaction occurs when sensitized skin is exposed to sunlight or other bright light and is characterized by redness, swelling, and blistering of the exposed skin. As a result of Photofrin's disadvantages, researchers have been studying other photosensitizers with the following characteristics:

- They are single compounds rather than mixtures of chemicals.
- They are more effective in absorbing the red region of the visible light spectrum.
- They are more selective in targeting malignant tissue.
- They are more efficient in generating singlet oxygen.

AMINOLEVULINIC ACID Aminolevulinic acid, or ALA, is a short-lived photosensitizer that is applied to the skin as a 5–20% oil-in-water mixture. It is activated by either a special blue light illuminator or by light at 630–635 nm.

SECOND-GENERATION PHOTOSENSITIZERS Newer photosensitizing agents that are being used in **clinical trials** as of 2005 include:

- HPPH (2-[1-hexyloethyl]-2-devinyl-pyropheophorbide-a; brand name Photochlor). HPPH is a photosensitizer that is activated by light more efficiently than Photofrin. In addition, patients treated with HPPH do not have the long-term photosensitivity reactions associated with Photofrin. HPPH has been used experimentally since 2003 at the Roswell Park Cancer Institute in Buffalo, New York, to treat esophageal cancer, Barrett's esophagus, basal cell carcinoma, and recurrent breast cancer following mastectomy. It is also undergoing clinical trials in schools of veterinary medicine as a possible treatment for cancers in cats and dogs. Like Photofrin, HPPH is given intravenously.
- Verteporfin (also known as BPD-MA [benzoporphyrin derivative monoacid ring A]; brand name Visudyne). Verteporfin is a second-generation photosensitizer used primarily to treat eye disorders, including age-related macular degeneration, other abnormal formations of blood vessels within the eye, and histoplasmosis (an eye infection caused by a fungus). Verteporfin is also being investigated as a possible treatment for skin cancer and psoriasis.
- Temoporfin (Meta-tetra hydroxyphenyl chlorin; brand name Foscan). Temoporfin is a chlorin-type photosensitizer developed in the United Kingdom. It was approved by the European Union in 2001 for the treatment of **head and neck cancers** and certain types of

lung cancer, but is categorized as an orphan drug in the United States. The FDA lists temoporfin as an orphan drug for the palliative treatment of inoperable head and neck cancers.

- Motexafin lutetium (brand name Lu-Tex). Lu-Tex is an injectable dye that has been used in clinical trials to treat malignant **melanoma**. It has a high degree of selectivity for cancer cells. It also shows promise as a treatment for recurrent breast cancer and atherosclerosis.

Clinical trials

Although the National Cancer Institute (NCI) is not conducting trials of new PDT drugs as of 2005, there are several cancer centers in the United States and Canada that are investigating Photochlor and other second-generation photosensitizers.

Preparation

PDT for skin conditions

A patient receiving PDT for skin cancer or a precancerous skin disorder will have ALA applied to the affected area 3–6 hours before the scheduled treatment. The skin may or may not be covered with a dressing. The patient does not need to fast or make any other special preparations. If the affected area of skin is on the face, the patient may be given goggles to wear to protect the eyes from the blue light used to activate the drug.

PDT for internal cancers

The photosensitizing agents used for PDT or palliative treatment of esophageal or lung cancers are given by injection, usually 2–3 days before treatment. The patient may return home after the injection, but must avoid sunlight and bright light indoors before the light treatment. The patient does not need to fast or discontinue other medications, but should cover the windows and skylights in their home before receiving the light treatment to prevent exposure to bright light after returning home.

Patients undergoing PDT for esophageal or lung cancers are given a local or general anesthetic before the doctor inserts the bronchoscope or endoscope. They may also be given a mild tranquilizer to relieve anxiety.

Aftercare

Aftercare following PDT with porfimer sodium involves 4–6 weeks of protection from sunlight and other sources of bright light, including tanning lamps or the examination lamps found in doctors' and dentists' offices. During this period, the patient should wear dark glasses; long-sleeved shirts of light-colored, and tightly woven fabric long pants or slacks; and a wide-brimmed hat to protect the skin and eyes outdoors for at least 30 days after treatment. Sunscreen creams and lotions do not provide enough protection. It is best to run necessary errands after sundown or ask someone else in the household to drive the car. Women should not use helmet-type hair dryers or hand-held dryers on a high setting, as the drug remains in the scalp for several weeks and may cause burns if exposed to high heat. Exposure to low levels of indoor light is necessary, however, in order to break down the Photofrin remaining in the skin. After 30 days, the doctor will give the patient instructions on testing the skin for any remaining sensitivity to light.

Patients who have received PDT for cancers in the lining of the bronchi must return two days after the treatment for a follow-up **bronchoscopy**, in which the doctor will remove dead tumor cells and other pieces of tissue from the treated area. This follow-up procedure is necessary to prevent inflammation and possible blockage of the patient's airway. Treated tumor sites require between 4 and 8 weeks for complete healing.

Patients who receive PDT with ALA do not need to take special precautions regarding sun exposure after treatment because the drug is short-lived. The treated skin will usually form a crust or scale for several days before healing completely.

Risks

Porfimer sodium

Risks of PDT with porfimer sodium include photosensitivity reactions if the patient fails to observe the guidelines for aftercare; chest pain or a burning sensation in the chest or throat; difficulty swallowing; **itching**; the formation of ulcers or scar tissue; and discomfort in the eyes when exposed to sunlight, bright lights, or car headlights. Breast cancer and lung cancer patients who have severe chest pain after PDT can be given medications to control the pain.

Aminolevulinic acid

Some patients experience a stinging or burning sensation in the skin during the blue light treatment, but this usually goes away as soon as the light is turned off. Some patients also report temporary swelling or redness of the skin in the treated areas, or minor changes in the pigmentation of their skin.

Normal results

Normal results of PDT of the esophagus or the lining of the bronchi are shrinkage of the tumor and

KEY TERMS

Actinic keratosis (plural, keratoses)—A type of precancerous skin growth with a scaly or bumpy surface caused by overexposure to the sun.

Barrett's esophagus—A precancerous condition of the esophagus that may develop as a complication of gastroesophageal reflux disease (GERD).

Bronchi (singular, bronchus)—The larger air passages inside the lungs.

Fiberoptics—Bundles of specially treated glass or plastic fibers that intensify light from a light source by internal reflection. Fiberoptics can be attached to lasers for use in PDT.

Free radicals—Molecules that contain at least one unpaired electron. They are highly reactive and can destroy cells by disrupting their normal biological processes. Free radicals are released during PDT and help to kill tumor cells.

Hematoporphyrin—A dark reddish-purple pigment found in blood. A purified form of hematoporphyrin is used to make porfimer sodium.

Nanometer—A measurement of length equal to 10^{-9} meters, or one billionth of a meter. It is used as a unit of measurement for light waves.

Orphan drug—A drug that treats a rare disease—"rare disease" being defined by the Food and Drug Association as one affecting fewer than 200,000 Americans. The category of orphan drug includes experimental as well as approved medications. Some photosensitizing drugs used in Europe are considered orphan drugs in the United States.

Palliative—Referring to treatment used to relieve the symptoms of a disease or disorder rather than to cure it.

Singlet oxygen—A highly reactive form of the oxygen molecule (O_2) formed during PDT that helps to destroy cancer cells by attacking their cell membranes.

destruction of cancer cells. Normal results of palliative treatment for cancer of the esophagus are sufficient shrinkage of the tumor to allow the patient to swallow again.

Normal results for PDT of the skin include shrinkage and destruction of the tumor, although large skin tumors may require a second treatment for complete removal.

QUESTIONS TO ASK YOUR DOCTOR

- Is photodynamic therapy a possible treatment option for my cancer?
- Are you experienced in treating patients with PDT?
- Should I consider enrolling in a clinical trial of a new PDT drug?

Abnormal results

Abnormal results include allergic reactions to the photosensitizing medication or failure of the tumor to respond to PDT.

Pilocarpine

Definition

Pilocarpine is a medicine used to treat **xerostomia**, or dryness of the mouth, caused by a decrease in saliva production following radiation or due to **Sjögren's syndrome**, a disorder of the immune system characterized by the failure of the exocrine glands. Pilocarpine is also known as pilocarpine hydrochloride or Salagen.

Purpose

Pilocarpine is used to treat side effects arising from radiation treatment for **head and neck cancers**. It alleviates dryness of the mouth and throat and aids in chewing, tasting, and swallowing. It may also be given to treat dryness of the eyes resulting from cancer treatment.

Pilocarpine is also used in the form of eye drops or eye gel to treat glaucoma; it works by lowering the pressure of the fluid inside the eye.

Description

Pilocarpine is a naturally occurring substance found in the leaflets of *Pilocarpus jaborandi*, a South American shrub.

Pilocarpine works by stimulating the function of the exocrine glands, including the glands that produce saliva, sweat, tears, and digestive secretions. It also stimulates smooth muscles, such as those found in the bronchus, gallbladder, bile ducts, and intestinal and urinary tracts.

Pilocarpine was approved by the United States Food and Drug Administration as a sialogogue, or medication to increase the flow of saliva, in 1994. Pilocarpine was effective in relieving xerostomia symptoms after twelve weeks in over half the patients studied; however, the medication may not work for everyone.

Recommended dosage

Pilocarpine is taken orally. It is available in round white tablets containing 5 mg. Different patients may require different dosages of the drug. The usual dose for adults is five milligrams taken three times a day. If necessary, the physician may increase the dosage to 10 mg, three times a day. Since increasing the dose increases the likelihood of side effects, the lowest dose that is effective should be used for treatment.

Pilocarpine begins to act 20 minutes after ingestion. It will continue to act for three to five hours, with the maximum effect taking place one hour after ingestion. Twelve weeks of regular use may be required for an improvement of symptoms.

If a dose is missed, it should be taken as soon as possible; however, if it is almost time for the next dose, only the next dose should be taken.

Precautions

Patients may wish to take this medication with a meal to avoid stomach upset; however, pilocarpine will have reduced effectiveness if it is taken with a meal that is high in fat. Patients should drink plenty of water to avoid dehydration due to increased sweating. Alcohol and antihistamines should not be used while taking pilocarpine. Due to the possibility of visual disturbances or dizziness, people using this medication should avoid driving or operating machinery, particularly at night. Patients should continue to see a dentist regularly during treatment even though symptoms may be improved, since xerostomia may increase the likelihood of tooth decay and other dental problems.

Studies have not been done to test the safety of pilocarpine use in pregnant or nursing women; very high doses of the drug may cause birth defects in animals. Studies have also not been done to test the use of pilocarpine by children.

Pilocarpine should not be taken by people who are sensitive to it or who have uncontrolled asthma, or such eye problems as inflammation of the iris or angle-closure glaucoma. It should be used with caution by people with breathing problems, gallbladder disease, kidney problems, peptic ulcer, psychological disturbances, retinal disease, or heart or blood vessel disease.

Side effects

The most common side effect of pilocarpine use is increased sweating. Other less common side effects are as follows: **nausea and vomiting**, irritated nose, chills, flushing, frequent urination, dizziness, weakness, headache, difficulty with digestion, increased tear production, **diarrhea**, bloating, abdominal pain, and visual problems.

Symptoms of overdose include irregular heartbeat, chest pain, fainting, confusion, stomach cramps or pain, and trouble breathing. Unusually severe or continuing side effects such as diarrhea, headache, weakness, trembling, visual difficulties, nausea, and vomiting may also indicate overdose.

Interactions

Pilocarpine may interact with other medications, reducing or increasing their effects or, sometimes, increasing the side effects of the other medications. Pilocarpine may also be less effective as a result of interaction with other medications. The following drugs may cause interactions:

- amantadine
- anticholinergics
- antidepressants
- antidyskinetics
- antihistamines
- antimyasthenics
- antipsychotics
- beta-adrenergic blocking agents
- bethanecol
- buclizine
- carbamazepine
- cyclizine
- cyclobenzaprine
- disopyramide
- flavoxate
- glaucoma medications
- ipratropium
- meclizine
- methylphenidate
- orphenadrine
- oxybutynin
- physostigmine
- procainamide
- promethazine
- quinidine

Pilocarpine may also interact with alcohol, cocaine, and marijuana.

KEY TERMS

Exocrine—Referring to a gland that secretes outward by way of a duct.

Sialogogue—A medication given to increase the flow of saliva. Pilocarpine may be used as a sialogogue.

Xerostomia—The medical term for dry mouth.

Pineoblastoma

Definition

A pineoblastoma is an aggressive primary brain tumor that develops in the pineal body (sometimes called

the epiphysis cerebri or pineal gland), which is a small cone-shaped organ located in the midbrain. The pineal body secretes melatonin, a hormone that regulates moods and the sleep-wake cycle in humans. Pineoblastomas are also known as pinealoblastomas.

Description

Pineoblastomas are rapidly growing tumors, and thereby distinguished from pineocytomas, which grow relatively slowly. They are defined by the World Health Organization (WHO) as primitive neuroectodermal tumors (PNETs) in the pineal gland; the word *primitive* in this context means that these tumors are composed of cells that have not yet separated into more specialized types of cells. The word *neuroectodermal* means that these tumors develop out of a layer of cells in the embryo that eventually gives rise to the baby's nervous system.

Pineoblastomas are considered highly malignant. They may invade nearby areas of brain tissue as well as spread into the cerebrospinal fluid, although they rarely metastasize to other parts of the body. In addition, pineoblastomas sometimes cause bleeding into the ventricles of the brain. The child's radiologist may be able to see areas of dying tissue in the brain when **imaging studies** are performed.

Demographics

Pineoblastomas are extremely rare, accounting for only 0.5–2 percent of childhood tumors of the central nervous system (CNS). About 2200 children below the age of 15 are diagnosed with malignant tumors of the brain and spinal cord each year in the United States; between 10 and 40 of these children will be diagnosed with pineoblastomas.

It is difficult to evaluate the statistical significance of racial or gender differences in such a small group; however, the available evidence from American cancer registries suggests that these cancers occur more frequently in Caucasian children than in African Americans, and more frequently in males than in females.

Pineoblastomas occur almost exclusively in younger children, with very few cases reported in adolescents or adults. The slower-growing pineocytomas, by contrast, are most likely to develop in adults between the ages of 25 and 35.

Causes and symptoms

The cause of pineoblastomas is unknown, as of early 2005, but may be associated with gene mutations. A group of British radiologists reported in 2004 that the chances of survival in children diagnosed with pineoblastoma who had inherited a mutation of the **retinoblastoma** (RB) gene are much lower than the chances of children who did not inherit the RB mutation. The researchers suggested that this mutation may cause pineoblastomas as well as reduce or inhibit their response to therapy.

The symptoms of a pineoblastoma result from blockage of the flow of cerebrospinal fluid and increased pressure on the brain. Depending on the size of the tumor, symptoms may include the following:

- headache
- double vision
- **nausea and vomiting**
- weakness or loss of sensation on one side of the body
- seizures
- developmental delays or failure to thrive (in younger children)
- lowered energy level or unusual need for sleep
- personality changes
- unexplained changes in weight or appetite

Parents should note, however, that these symptoms are not unique to pineoblastomas; they may be produced by other types of brain tumors, head trauma, meningitis, migraine headaches, or several other medical conditions. In any event, a child with these symptoms should be seen by a doctor at once.

Diagnosis

The diagnosis of a pineoblastoma begins with a review of the child's medical history and a thorough physical examination. The child may be given several vision tests if he or she is seeing double or having other visual disturbances. The child's doctor will then order both laboratory tests and imaging studies. The laboratory tests are done to rule out such diseases as meningitis and to see whether the child's liver and other organs are functioning normally. The imaging studies are performed to determine the extent of the cancer and to assign the child to a risk group.

Unless surgical removal of the tumor is considered too risky, a neurosurgeon will perform what is known as an open **biopsy** to confirm the diagnosis of pineoblastoma. He or she will remove a small piece of the tumor for examination by a pathologist.

Laboratory tests

Standard laboratory tests for children with brain tumors include a complete blood count (CBC), electrolyte analysis, tests of kidney, liver, and thyroid function,

and tests that determine whether the child has been recently exposed to certain viruses. In addition, a **lumbar puncture** will be performed to look for cancer cells in the child's spinal fluid.

Imaging tests

Imaging tests for pineoblastomas include the following:

- Magnetic resonance imaging (MRIs).
- Computed tomography (CT) scan. Doctors usually order MRIs and CT scans that cover the full length of the spinal column as well as the brain, because pineoblastomas are more likely than other PNETs to spread into the cerebrospinal fluid.
- Chest x ray.
- Bone scan. This test is necessary to determine whether the tumor has spread beyond the central nervous system.

Treatment team

Since the 1960s, most children diagnosed with brain tumors have been treated in specialized children's cancer centers. A child with pineoblastoma will usually have a pediatric oncologist as his or her primary doctor, along with one or more specialists. These specialists may include a neurosurgeon, pathologist, neuroradiologist, radiation oncologist, medical oncologist, endocrinologist, nutritionist, physical therapit or rehabilitation specialist, and psychologist or psychiatrist. The team will also include social workers, clergy, and other professionals to help the parents cope with the stresses of their child's illness and treatments.

Clinical staging, treatments, and prognosis

Staging

Pineoblastomas are not staged in the same way as cancers elsewhere in the body. Instead, children with these tumors are divided as of the early 2000s into two risk groups, average risk and poor risk. Assignment to these groups is based on the following factors:

- child's age
- size and location of the tumor
- whether the tumor has spread to other parts of the central nervous system
- whether the tumor has spread beyond the CNS to other parts of the body

Average-risk children are those older than three years, with most or all of the tumor removed by surgery and no evidence that the cancer has spread beyond the pineal body. Poor-risk children are those who are younger than three years, whose cancer was located near the center of the brain or could not be removed completely by surgery, and whose cancer has spread to or beyond other parts of the CNS. The risk of recurrence is higher for children in the poor risk group.

Treatments

Treatments for pineoblastoma depend on the child's age and his or her risk group. Children younger than three years are not usually given **radiation therapy** because it can affect growth and normal brain development; they are usually treated with surgery to remove as much of the tumor as possible, followed by **chemotherapy** if they are considered poor-risk patients. The drugs most commonly used to treat PNETs include **lomustine**, **cisplatin**, **carboplatin**, and **vincristine**.

In addition to removing the tumor, the surgeon may also place a shunt to reduce pressure on the child's brain if the tumor is blocking the flow of cerebrospinal fluid. The shunt is a plastic tube with one end placed within the third ventricle of the brain. The rest of the shunt is routed under the skin of the head, neck, and chest with the other end placed in the abdomen or near the heart. Shunts are used very conservatively in children with pineoblastomas, however, because there have been reports of these tumors spreading into the abdomen via the shunt.

Children three years and older are treated with surgery first, followed by radiation treatment of the entire brain and spinal cord. Those considered poor risks may also be given chemotherapy. Recurrent pineoblastomas are treated with further surgery and an additional course of chemotherapy.

Treatments for pineoblastoma that are considered experimental as of 2005 include the following:

- Gamma knife surgery (GKS). One group of neurosurgeons in Florida has reported good results in treating children with tumors in the pineal body with GKS. The advantages of GKS include more complete tumor removal and quicker recovery for the patient.
- Gene therapy.
- High-dose chemotherapy.
- **Photodynamic therapy**.
- Stem cell and **bone marrow transplantation**.
- Newer drugs: **Irinotecan**, tipifarnib, lapatinib, ixabepilone, cilengitide, and tariquidar.

Prognosis

The prognosis for children with pineoblastomas depends largely on their risk group. In general, however,

these tumors have a poorer prognosis than other types of brain tumors, in part because of the difficulty of removing the complete tumor due to the location of the pineal body deep within the brain. The overall five-year survival rate of children with pineoblastoma is reported to be 50–60 percent, but is much lower in children younger than three years and in older children who do not respond to radiation therapy.

Recurrent pineoblastomas are almost always fatal; there are no effective therapies for recurrent PNETs, as of the early 2000s.

Alternative and complementary therapies

Some complementary therapies that are reported to help children with pineoblastomas include pet therapy, humor therapy, and music therapy. All of these can be pleasurable for the child as well as relaxing. Ginger or peppermint may help to relieve the nausea and vomiting associated with chemotherapy.

Coping with cancer treatment

Children can be given additional medications to treat nausea and other side effects of chemotherapy. With regard to homesickness and other emotional reactions to being away from home, children's cancer centers have social workers and child psychologists who can educate the child's family about the cancer as well as help the child deal with separation issues.

The side effects of radiation therapy in children with brain tumors may include the formation of dead tissue at the site of the tumor. This formation is known as radiation necrosis. It occurs in about 5 percent of children who receive radiation therapy and may require surgical removal. Radiation necrosis, however, is not as serious as recurrence of the tumor.

Children who have difficulty speaking after brain surgery, or who experience physical weakness, difficulty walking, visual impairment, or other sensory problems, are given physical therapy and/or speech therapy on either an inpatient or outpatient basis.

Clinical trials

Because pineoblastomas are so rare, the American Cancer Society recommends that children diagnosed with these tumors be enrolled in an appropriate clinical trial. As of early 2005, there are about 30 **clinical trials** in the United States for children with pineoblastomas and other PNETs. Some of these trials involve gene testing to improve diagnosis of children with brain tumors, while others are exploring various combinations of chemotherapy (including new agents), photodynamic therapy, stem cell transplantation, and bone marrow transplantation as treatments for pineoblastomas.

KEY TERMS

Blastoma—An abnormal growth of embryonic cells. A pineoblastoma is a blastoma that develops in the pineal body.

Endocrinologist—A doctor who specializes in diagnosing and treating disorders that affect the balance of hormones in the body or the organs that produce these hormones.

Melatonin—A hormone that regulates moods and the sleep-wake cycle in humans. It is produced by the pineal body.

Pineal body—A small cone-shaped endocrine gland attached to the roof of the third ventricle of the brain. The pineal body, which is also known as the pineal gland or epiphysis, secretes melatonin.

Pineocytoma—A slower-growing tumor of the pineal body found more commonly in adults.

Primary brain tumor—A tumor that starts in the brain, as distinct from a metastatic tumor that begins elsewhere in the body and spreads to the brain. A pineoblastoma is one type of primary brain tumor.

Primitive—Simple or undifferentiated. Pineoblastomas are classified as primitive tumors because they arise from cells that have not yet separated into groups of more specialized cells.

Shunt—A tube inserted by a surgeon to relieve pressure on the brain from blocked cerebrospinal fluid. The tube allows the fluid to bypass the tumor that is blocking its flow.

Ventricle—One of the small cavities located within the brain. The pineal body is attached to the roof of the third ventricle.

Prevention

There is no way to prevent pineoblastomas as of the early 2000s because their cause is still unknown.

Special concerns

Children diagnosed with pineoblastomas, like children with other long-term illnesses, may develop emotional problems in reaction to restrictions on their activities, uncomfortable treatments, or being treated in a cancer center away from home. These children may

QUESTIONS TO ASK YOUR DOCTOR

- Which risk group has my child been assigned to?
- What treatments would you recommend for a child in that group, and why would you recommend them?
- Is my child eligible for any current clinical trials for children with pineoblastoma?
- Would you recommend any of the treatments currently considered experimental?
- What is my child's life expectancy? What can I do to make the remaining time as pain-free and enjoyable as possible?

withdraw from others, become angry or bitter, or feel inappropriately guilty about their illness. It is important to reassure the child that he or she did not cause the cancer or deserve it as a punishment for being "bad." Parents may benefit from consulting a child psychiatrist about these and other emotional problems.

Another special concern is the task of explaining the child's illness and treatments to other family members and friends in ways that they can understand. Members of the child's treatment team can be helpful in providing simplified descriptions for siblings or schoolmates.

A third area of concern with **childhood cancers** is the parents' relationships with their other children and with each other. Siblings may resent the amount of time and attention given to the child with cancer, or they may fear that they too will develop a brain tumor. Support groups for families of children with cancer can help by sharing strategies for coping with these problems as well as allowing members to express anxiety and other painful feelings in a safe setting.

Pituitary tumors

Definition

Pituitary tumors are abnormal growths in the pituitary gland.

Description

Located in the brain, the pituitary gland is often referred to as the "master gland" of the body. This is because it makes and releases (secretes) at least nine distinct hormones (including oxytocin, antidiuretic hormone [ADH], prolactin, thyroid-stimulating hormone [TSH], adrenocorticotropic hormone [ACTH], follicle-stimulating hormone [FSH], luteinizing hormone [LH], and human growth hormone [HGH]) that regulate the activities of several other endocrine glands and influence a number of physiological processes including growth, sexual development and functioning, and the fluid balance of the body. The pituitary is divided into two parts: front (anterior) and rear (posterior). Each half of the pituitary gland secretes specific hormones. Tumors in the anterior part are common and are usually noncancerous (benign). Tumors rarely develop in the posterior portion. Between 10% and 15% of all tumors in the skull are pituitary tumors, which makes them the third most common type of brain tumor.

Virtually all pituitary tumors arise from a single cell which, for unknown reasons, has grown out of control. Tumors that have originated from a single cell are called monoclonal. Some tumors secrete hormones normally made by the pituitary gland. Because the tumor cells are uncontrolled, they secrete large amounts of hormones. As a result, hormone imbalance occurs. The symptoms caused by the hormone imbalance are often the first sign of a pituitary tumor.

There are several different types of pituitary tumors. Pituitary adenomas (adenomas are tumors that grow from gland tissues) are the most common type. Most pituitary adenomas are benign, although they may spread to nearby tissues. Pituitary adenomas can be further classified based on which, if any, hormones are secreted by the tumor. Thirty-five percent of pituitary adenomas do not secrete hormones, 27% secrete prolactin (prolactinomas), and 21% secrete growth hormone. The remaining pituitary adenomas secrete sex hormones (6%), thyroid hormones (1%), or adrenal (adrenocorticotropic) hormones (8%). Plurihormonal adenomas secrete more than one type of hormone. Tumors that secrete adrenocorticotropic hormone cause **Cushing's syndrome** and Nelson's syndrome.

Craniopharyngiomas are benign tumors that originate in tissues next to the pituitary gland. Technically speaking, they are not pituitary tumors although they affect the pituitary gland. They are extremely difficult to remove and radiation does not stop craniopharyngiomas from spreading throughout the pituitary gland. Craniopharyngiomas account for less than 5% of all brain tumors.

Pituitary **carcinoma** is a very rare condition. Fewer than 100 cases have ever been reported. It is usually diagnosed when a pituitary tumor, which was believed to be an **adenoma**, spreads (metastasizes) to distant organs. These pituitary tumors may or may not release hormones. Because pituitary carcinoma is often diagnosed late, it has a high death rate.

Demographics

Pituitary tumors occur more frequently in women than in men. They usually develop between the ages of 30 and 40. Half of all craniopharyngiomas occur in children, with symptoms most often appearing between the ages of five and ten.

Causes and symptoms

The cause of pituitary tumors is not known. Most pituitary tumors presumably result from changes to the DNA of one cell, leading to uncontrolled cell growth. The genetic defects, multiple endocrine neoplasia syndrome type I (MEN I or Wermer's syndrome), McCune-Albright syndrome, and the Carney complex, are associated with pituitary tumors. However, these defects account for only a small percentage of the cases of pituitary tumors. Also, a pituitary tumor may result from the spread (**metastasis**) of cancer from another site. **Breast cancer** in women and lung cancer in men are the most common cancers to spread to the pituitary gland. Other cancers that spread to the pituitary gland include kidney cancer, **prostate cancer**, **melanoma**, and **gastrointestinal cancers**.

Symptoms related to tumor location, size, and pressure on neighboring structures include:

- persistent headache on one or both sides, or in the center of the forehead
- blurred or double vision; loss of side (peripheral) vision
- drooping eyelid (ptosis) caused by pressure on nerves leading to the eye
- numb feeling on the face
- dementia
- drowsiness
- enlarged head

- eating excessive (hyperphagia) or abnormally small (hypophagia) amounts of food
- seizures

The specific symptoms associated with hormone-secreting tumors will vary depending on which hormones are being over-produced. Symptoms related to hormonal imbalance include:

- excessive sweating
- loss of appetite
- loss of interest in sex
- inability to tolerate cold temperatures
- nausea
- menstrual problems
- excessive thirst
- frequent urination
- dry skin
- constipation
- premature or delayed puberty
- delayed growth in children
- milk secretion in the absence of pregnancy or breast feeding (galactorrhea)
- reduced strength
- mood alterations (**depression**, anxiety, unstable emotions)
- muscle pain
- low blood sugar (sudden occurrence of shakiness and sweating)

Patients who have sudden pituitary failure caused by bleeding or tissue death (pituitary apoplexy also known as Sheehan's syndrome) may experience very severe headaches, confusion, loss of sight, and drowsiness. This condition is considered an emergency.

Tumors that secrete growth hormone cause a condition called acromegaly. This long-term condition is characterized by enlargement of the nose, ears, jaws, toes, and fingers. Joint pain, blood sugar imbalances, high blood pressure, carpal tunnel syndrome, and airway blockages can result.

Diagnosis

As many as 40% of all pituitary tumors do not release excessive quantities of hormones into the blood. Known as clinically nonfunctioning, these tumors are difficult to distinguish from tumors that produce similar symptoms. They may grow to be quite large before they are diagnosed.

The diagnosis of pituitary tumors is based on:

- the patient's own observations and medical history
- physical examination
- laboratory studies of the patient's blood and brain/spinal fluid (cerebrospinal fluid)
- x rays of the skull and other studies that provide images of the inside of the brain (CT, MRI)
- vision tests
- urinalysis

Treatment team

The treatment team for pituitary tumors may include a neuroendocrinologist, endocrinologist, neurosurgeon, oncologist, radiation oncologist, nurse oncologist, psychiatrist, psychological counselor, and social worker.

Clinical staging, treatments, and prognosis

Clinical staging

Because most pituitary tumors are benign, there is no clinical staging system.

Treatments

Treatment is determined by the type of tumor, the type of hormone being released, and whether or not the tumor has invaded tissues next to the pituitary gland. The goals of treatment are to normalize hormone levels and reduce the size of (or remove) the tumor. Treatment options include surgery, radiation, and/or medication. Some pituitary tumors stabilize without treatment. Small tumors that are not causing significant symptoms may be watched only.

Surgery is usually used to remove all or part of a tumor within the gland or the area surrounding it. Surgery may be combined with **radiation therapy** to treat tumors that extend beyond the pituitary gland. A neurosurgeon will operate immediately to remove the tumor or pituitary gland (hypophysectomy) of a patient whose vision is deteriorating rapidly. Approximately 96% of the surgeries are performed through the nose (transsphenoidal). If the tumor is large, the skull may be opened (**craniotomy**) for tumor removal. Removal or destruction of the pituitary gland requires life-long hormone replacement therapy. The most common complications of surgery are leakage of cerebrospinal fluid through the nose and inflammation of the membranes that surround the brain and spinal column (meningitis).

Radiation therapy is not as effective as surgery and is usually reserved for tumors that have not responded to other treatments and those that recur. Radioactive pellets

KEY TERMS

Adenoma—A tumor that is derived from glandular tissue.

Agonist—A drug that increases the effectiveness of another drug or chemical.

Benign—A term used to describe a noncancerous growth.

Carney complex—A genetic disorder characterized by myxomas, spotty pigmentation of the skin and mucous membranes, and endocrine overactivity.

Dopamine—A neurotransmitter that is a chemical messenger in the brain.

Hormone—A chemical that is produced and released by one organ to regulate the function of another organ.

Invasive—A descriptive term for tumors that spread to nearby structures.

McCune-Albright syndrome—A genetic disorder that includes bone, endocrine, and skin abnormalities. Some individuals with this syndrome show the effects of excessive secretion of pituitary growth hormone.

Multiple endocrine neoplasia syndrome type I—An inherited disorder that affects the endocrine glands. The pituitary gland becomes overactive in about one-sixth of the individuals with this syndrome.

Nelson's syndrome—An endocrine disorder characterized by increase secretion of ACTH and melanocyte stimulating hormone by the pituitary gland.

can be implanted in the brain to treat the tumor. Selected patients are treated with proton beam radiosurgery that uses high energy particles in the form of a high energy beam to destroy an overactive pituitary gland. **Fatigue**, upset stomach, **diarrhea**, and nausea are common complaints of patients having radiation therapy. Radiation therapy to the brain can damage certain brain tissues.

Dopamine agonists, drugs that increase the effect of the brain chemical dopamine, are effective in treating tumors that release hormones. These drugs can reduce symptoms caused by a pituitary tumor and reduce the size of the tumor. Commonly used dopamine agonists include bromocriptine, pergolide, and cabergoline. Cabergoline is the most effective and produces fewer side effects than the other two drugs. Side effects associated with dopamine agonists include nausea, vomiting, and light-headedness when rising (postural hypotension). Acromegaly may be treated with somatostatin and other drugs derived from somatostatin (analogues). Tumors, and the symptoms they are causing, return when drug use is stopped. Patients should wear medical identification tags identifying their condition and the hormonal replacement medicines they take.

The common treatments for specific pituitary tumors are:

- Prolactin-secreting adenoma. Prolactinomas are treated with a dopamine agonist. Surgical treatment is used if the drug fails or causes intolerable side effects.
- Gonadotropin-secreting adenoma. Small tumors are not treated unless they are causing symptoms. Large tumors and small tumors that are causing symptoms are treated surgically. Radiation therapy may be used.
- Adrenocorticotropic hormone-secreting adenoma. Surgery is the treatment of choice. Medications that prevent adrenal hormone production or radiation therapy may be used if surgery fails.
- Growth hormone-secreting adenoma. Surgery is the treatment of choice. Medications (dopamine agonists, somatostatins) or radiation therapy may be used.
- Thyroid stimulating hormone-secreting adenoma. Surgery, with or without radiation therapy, is the treatment of choice. Although somatostatin treatment may reduce hormone levels, it fails to shrink the tumor.
- Nonsecreting adenoma. Surgery is the treatment of choice. In general, medications are not effective for this type of tumor. Radiation therapy may be used to prevent tumor recurrence.
- Pituitary carcinoma. Carcinoma is treated with standard cancer radiation therapy and chemotherapy.
- Craniopharyngiomas. These tumors are difficult to treat. Due to the nature of craniopharyngiomas, surgery is often incomplete and needs to be complemented by radiation therapy.

Prognosis

Pituitary tumors are usually curable. Pituitary adenomas that secrete adrenocorticotropic hormone are frequently persistent and have a high rate of recurrence. Approximately 5% of pituitary adenomas invade nearby tissues and grow to large sizes, making them more difficult to treat and subject to frequent recurrences. Metastasis of most pituitary tumors is very rare. However, pituitary carcinomas can metastasize and are associated with a poor prognosis.

Alternative and complementary therapies

Alternative and complementary therapies have not been shown to be effective in treating pituitary tumors.

QUESTIONS TO ASK THE DOCTOR

- Is my tumor cancerous? Is it invasive?
- What are my treatment options?
- What are the risks and side effects of these treatments?
- Is surgery really necessary?
- Which surgical approach will you use?
- How experienced are you at performing pituitary surgery?
- How will I feel immediately following surgery?
- Will I need to take medication for the rest of my life?
- How long will it take for my symptoms to go away?
- Will I be able to have children?
- Is it safe to become pregnant while taking this medication?
- How will pregnancy affect my tumor?
- What medications can I take to relieve treatment side effects?
- Are there any clinical studies underway that would be appropriate for me?
- What is the chance that the tumor will recur?
- How will recurrence be detected?
- How often will I have follow-up examinations?

For more comprehensive information, the patient should consult the book on complementary and alternative medicine published by the American Cancer Society listed in the Resources section.

Coping with cancer treatment

The patient should consult his or her treatment team regarding any side effects or complications of treatment. Patients may want to consult a psychotherapist and/or join a support group to deal with the emotional consequences of cancer and its treatment.

Clinical trials

There are two active **clinical trials** studying pituitary tumors are studying the safety and effectiveness of antineoplastons. Study #BRI-BT-9 is open to patients with serious or life-threatening brain tumors. Study #BRI-NE-2 is open to patients who have metastatic or incurable **neuroendocrine tumors**. The National Cancer Institute web site has information on these and other studies. Patients should consult with their treatment teams to determine if they are candidates for these or any other ongoing studies.

Special concerns

Long-term low levels of sex hormones (hypogonadism) can have negative effects on bone density and the cardiovascular system. The effect a pituitary tumor has on fertility is a concern for both men and women. Women taking medications to treat pituitary tumors need to question their physicians regarding the potential effect the medications may have on an unborn baby.

Pleural biopsy

Definition

The pleura is the membrane that lines the lungs and chest cavity. A pleural **biopsy** is the removal of pleural tissue for examination and eventual diagnosis.

Purpose

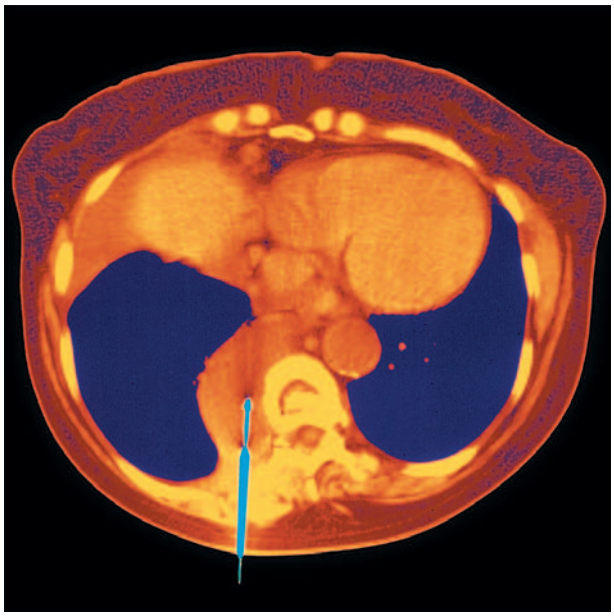
Pleural biopsy is performed to differentiate between benign (noncancerous) and malignant (cancerous) disease, to diagnose viral, fungal, or parasitic diseases, and to identify a condition called collagen vascular disease of the pleura. It is also ordered when a chest **x ray** indicates a pleural-based tumor, reaction, or thickening of the pleura.

Precautions

Because pleural biopsy—especially open pleural biopsy—is an invasive procedure, it is not recommended for patients with severe bleeding disorders.

Description

Pleural biopsy is usually ordered when pleural fluid obtained by another procedure called **thoracentesis** (aspiration of pleural fluid) suggests infection, signs of cancer, or tuberculosis. However, the procedure is most successful in diagnosing pleural tuberculosis (with a sensitivity up to 75%) rather than pleural malignancy (40–50% sensitivity).



Colored computed tomography (CT) scan of an axial section through the chest, showing a lung biopsy being taken by bronchoscope. The front of the chest is at the top, and the heart is at the lower center (appearing orange). The bronchoscope (blue) has penetrated the back of the patient and has entered a tumor (orange). At the tip of the bronchoscope is a biopsy needle. *(Copyright Mehau Kulyk, Science Source/Photo Researchers, Inc. Photo reproduced by permission.)*

The procedure most often performed for pleural biopsy is called a percutaneous (passage through the skin by needle puncture) needle biopsy or closed needle biopsy. This procedure can only sample the outer pleural membrane (parietal pleura), and the size of the tissue sample obtained is relatively small.

Although the biopsy needle itself remains in the pleura for less than one minute, the procedure takes 30–45 minutes. This type of biopsy is usually performed by a physician at bedside if the patient is hospitalized or in an outpatient setting under local anesthesia.

The actual procedure begins with the patient in a sitting position, shoulders and arms elevated and supported. The skin overlying the biopsy site is anesthetized and a small incision is made to allow insertion of the biopsy needle. This needle is inserted with a cannula (a plastic or metal tube) until fluid is removed. Then the inner needle is removed and a trocar (an instrument for withdrawing fluid from a cavity) is inserted to obtain the actual biopsy specimen. As many as three separate specimens are taken from different sites during the procedure. These specimens are then placed into a fixative solution and sent to the laboratory for tissue (histologic) examination.

Although used less frequently than the closed needle biopsy, an open pleural biopsy may be performed surgi-

KEY TERMS

Aspiration—Drawing out of fluid from a cavity by suction.

Endotracheal—Placed within the trachea, also known as the windpipe.

Pulmonary—Pertaining to the lungs.

QUESTIONS TO ASK THE DOCTOR

- What is the purpose of this test?
- Is the test dangerous?
- How do I prepare for the test?
- How long will the test take?
- How soon will I get my test results?

cally, in the operating room, when a larger tissue sample is required. The incision is larger than that required for a closed needle biopsy, and an endotracheal tube is inserted through the windpipe to assure proper breathing during the procedure. The procedure takes two to three hours, is more invasive, and requires general anesthesia and hospitalization for one or more days. Open biopsy is sometimes performed when there is no **pleural effusion** (an accumulation of fluid between the pleural layers) or when a direct view of the pleura and lungs is required.

Another procedure, called **thoracoscopy**, involves pleural biopsy under direct visualization through a thoracoscope. This procedure is highly accurate (sensitivity as high as 91%) in diagnosing both benign and malignant pleural disease. As in open needle biopsy, however, it requires general anesthesia and is usually used only after other diagnostic procedures fail.

Preparation

Preparations for this procedure vary, depending on the type of procedure requested. Closed needle biopsy requires little or no preparation. Open pleural biopsy, which is performed in a hospital, requires fasting (no solids or liquids) for 8–12 hours before the procedure because the stomach must be empty before general anesthesia is administered.

Aftercare

Potential complications of this procedure include bleeding or injury to the lung, or a condition called pneumothorax, in which air enters the pleural cavity (the space between the two layers of pleura lining the lungs and the chest wall). Because of these possibilities, a chest x ray is always performed after the procedure (closed or open biopsy). Also, it is important for the patient is to report any shortness of breath and for the nurses to note any signs of bleeding, decreased blood pressure, or increased pulse rate during the recovery period.

Risks

Risks for this procedure include respiratory distress on the side of the biopsy, as well as bleeding, possible shoulder pain, infection, pneumothorax (immediate), or **pneumonia** (delayed). Risk increases with stress, obesity, smoking, chronic illness, and the use of some medications (such as insulin, tranquilizers, and antihypertensives).

Normal results

Normal findings indicate no evidence of any pathologic or disease conditions in the pleural cavity.

Abnormal results

Abnormal findings include tumors called neoplasms (any new or abnormal growth) that can be either benign or malignant. Pleural tumors are divided into two categories: primary (**mesothelioma**), or metastatic (spreading to the pleural cavity from a site elsewhere in the body). These tumors are often associated with pleural effusion, which itself may be caused by pneumonia, heart failure, cancer, or blood clot in the lungs (pulmonary embolism).

Other causes of abnormal findings include viral, fungal, or parasitic infections, and tuberculosis.

Janis O. Flores

Pleural effusion

Description

Pleural effusion is the accumulation of fluid in the pleural space. The pleural space is the region between the outer surface of each lung (visceral pleurae) and the membrane that surrounds each lung (parietal pleurae). Under normal conditions, the pleurae are kept wet with pleural fluid to allow movement of the lungs within the chest. The pleural fluid comes from cells that make up the pleurae. Pleural fluid is continuously being produced and removed, a process that is precisely controlled by many factors. Cancer can interfere with this delicate balance within the pleural space causing fluid to accumulate.

Cancer is responsible for 40% of all pleural effusions, which are then called malignant pleural effusions. Pleural effusion is the first symptom of cancer for up to 50% of the patients. Thirty-five percent of the cases of malignant pleural effusion are caused by lung cancer, 23% by **breast cancer**, and 10% by **lymphoma**.

Chest x rays and computed tomography scans may be performed to diagnose pleural effusion. **Thoracentesis**, the removal of pleural fluid through a long needle, is usually performed for diagnostic purposes. Fluid removed by thoracentesis will be sent to the lab to be thoroughly evaluated. **Thoracoscopy**, in which a wand-like lighted camera (endoscope) is inserted through the chest, may be conducted to diagnose pleural effusion. During thoracoscopy, samples (**biopsy**) of pleura may be taken.

Pleural effusion can hinder the normal function of the lungs. Symptoms of pleural effusion include chest pain, chest heaviness, breathing difficulties, and a dry cough. Patients with malignant pleural effusions tend to be weak and have a short-span life expectancy. The prognosis depends on the type of cancer. Sixty-five percent of patients with malignant pleural effusions die within three months and 80% die within six months. However, patients with pleural effusion related to breast cancer have a longer life expectancy.

Causes

Malignant pleural effusions are most often associated with lymphomas, leukemia, breast cancer, gastrointestinal cancer, lung cancer, and **ovarian cancer**. For the majority of patients, pleural effusion occurs in the lung on the same side as the cancer. For one third of the patients, pleural effusion occurs in both lungs.

Pleural effusion in cancer patients can be caused by several different conditions. Blockage of the lymphatic system, a series of channels for drainage of body fluids, interferes with the removal of pleural fluid. Blockage of the veins of the lungs increases the pressure at the pleurae which causes fluid accumulation. Cancerous cells may seed onto pleurae and cause inflammation which increases fluid in the pleural space. High numbers of cancerous cells may collect in the pleural space (tumor cell suspensions) which causes extra fluid to be released. Accumulation of fluid in the abdominal cavity may cross over to the pleural space.

Treatments

Management of pleural effusion strives to relieve symptoms and improve quality of life. Cure is not always possible. The treatment method depends on the patient's age, prognosis, and location of the first tumor. Treatment for patients with pleural effusion who are asymptomatic (do not have symptoms) consists solely of observation.

Treatment options for pleural effusion include:

- Thoracentesis. Removal of the excess pleural fluid often relieves the symptoms of pleural effusion. However, effusion usually recurs within a few days. Repeat thoracentesis is not recommended, unless the patient has end-stage disease.
- Tube thoracostomy. A tube is inserted through the chest and into the pleural space to drain pleural fluid. When used alone, recurrence is very common.
- Indwelling pleural catheters. A thin flexible tube (catheter) is placed between the pleural cavity and the chest skin to allow drainage of pleural fluid. This method allows for continual drainage of pleural fluid without much pain.
- **Pleurodesis**. After tube thoracostomy, one of any number of chemicals (sclerosing agents) is put into the

KEY TERMS

Parietal pleurae—The membrane that surrounds each lung.

Pleural space—The space between the visceral and parietal pleurae.

Visceral pleurae—The outer surface of each lung.

pleural space to cause the visceral and parietal pleurae to stick together. Chemical pleurodesis is considered to be the treatment of choice for patients with malignant pleural effusion.

- Pleurectomy. Surgical removal of the parietal pleura through an incision in the chest wall (**thoracotomy**) is nearly 100% effective. Pleurectomy is not routinely performed and is reserved for patients for whom other treatments have failed. To be eligible for pleurectomy, the patient must have a long life expectancy and be able to tolerate major surgery.
- Pleuroperitoneal shunt. This procedure places a rubber tube between the pleural space and the abdominal cavity. A pump is used to move excess fluid out of the pleural space and into the abdominal cavity, where it would be absorbed. The patient must press the pump for several minutes four times daily. Although not frequently used, this is an effective treatment for cases that failed tube thoracostomy and pleurodesis.
- External radiation. Patients who have pleural effusion caused by blockage of a lymph duct may be treated by **radiation therapy**. External radiation therapy is successful for patients with pleural effusion related to lymphoma.
- Supportive care. Patients with end-stage cancer may not receive treatment for pleural effusion. Pain medications and oxygen therapy can be provided to keep the patient comfortable.

Pleural fluid analysis *see* **Thoracentesis**

Pleurodesis

Definition

Pleurodesis is the adherence of the outer surface of a lung to the membrane surrounding that lung, which is performed to treat the buildup of fluid around the lung.

Purpose

The pleural space is the region between the outer surface of each lung (visceral pleurae) and the membrane that surrounds each lung (parietal pleurae). Under normal conditions, the pleurae are kept wet with pleural fluid to allow movement of the lungs within the chest. **Pleural effusion**, the accumulation of fluid in the pleural space, is most commonly caused by cancer. Pleurodesis causes the pleurae to stick together, thereby eliminating the pleural space and preventing fluid accumulation. Chemical pleurodesis is considered to be the standard of care for patients with malignant pleural effusion.

Description

Before pleurodesis is conducted, all pleural fluid must be removed. This is achieved by inserting a chest tube through the skin and into the pleural space (thoracostomy). Insertion of the chest tube is carried out in the hospital. The patient is awake during the procedure. The skin is sterilized and a local pain killer is injected into the skin and underlying tissue. A small cut is made into the skin and a tube is placed into the pleural space. Fluid is withdrawn and the tube remains in place until all pleural fluid is drained, which usually takes two to five days. After the chest tube is inserted, the patient may either remain in the hospital or be allowed to return home with instructions on how to care for the tube. A chest **x ray** may be taken to ensure that all the fluid has been drained.

Pleurodesis is achieved by putting one of any number of chemicals (sclerosing agents or sclerosants) into the pleural space. The sclerosant irritates the pleurae which results in inflammation (pleuritis) and causes the pleurae to stick together. The patient is given a narcotic pain reliever and lidocaine, a local pain killer, is added to the sclerosant. A variety of different chemicals are used as sclerosing agents. There is no one sclerosant that is more effective or safer than the others. Commonly used sclerosants and their success rates are:

- Talc: 90% to 96%
- Nitrogen mustard: 52%
- Doxycycline: 90%
- **Bleomycin**: 84%
- Quinacrine: 70% to 90%

After the sclerosant has been put through the chest tube, the tube is closed. The patient may be asked to change position every 15 minutes for a two-hour time period. This was believed to be necessary to achieve an even distribution of sclerosant in the pleural space. However, recent evidence suggests that the sclerosant spreads

KEY TERMS

Pleural effusion—The abnormal buildup of fluid within the pleural space.

Pleural space—The space between the outer surface of each lung and the membrane that surrounds each lung.

Sclerosant—A chemical that causes the membranes of the pleural space to stick together.

throughout the pleural space immediately. Afterward, the chest tube is reopened and the sclerosant is sucked out of the pleural space. The tube remains in place for several days to allow all fluid to drain. Once drainage slows down, the chest tube is removed and the wound edges stitched (sutured) back together.

Aftercare

The patient should keep the wound from the chest tube clean and dry until it heals. Also, the patient should watch for signs of wound infection such as redness, swelling, and/or drainage, and be alert to symptoms indicating that the effusion recurred.

Risks

Complications of pleurodesis are uncommon and include infection, bleeding, acute respiratory distress syndrome, collapsed lung (pneumothorax), and respiratory failure. In addition, other complications may be specific for each sclerosant. Talc and doxycycline can cause **fever** and pain. Quinacrine can cause low blood pressure, fever, and hallucination. Bleomycin can cause fever, pain, and nausea. Severe respiratory complications can be fatal.

Normal results

Tube thoracostomy with pleurodesis is the most effective method to treat malignant pleural effusion. Successful pleurodesis prevents the recurrence of pleural effusion which relieves symptoms thereby improving quality of life.

Abnormal results

If drainage of sclerosant from the chest tube exceeds approximately one cup, the pleurodesis was unsuccessful and needs to be repeated. Pleurodesis may fail because of:

QUESTIONS TO ASK THE DOCTOR

- Will I be hospitalized the entire time?
- How long will I be hospitalized?
- Is it possible to do this on an outpatient basis?
- How uncomfortable is the chest tube?
- Will I be given pain medication as needed?
- Will having a chest tube limit my movements in any way?
- Will I be confined to bed?
- Which sclerosant will you be using?
- Why are you using this sclerosant?
- What are the side effects of this sclerosant?
- What is the success rate associated with this sclerosant?
- How painful is the pleurodesis process?

- trapped lung, in which the lung is enclosed in scar or tumor tissue
- formation of isolated pockets (loculation) within the pleural space
- loss of lung flexibility (elasticity)
- production of large amounts of pleural fluid
- extensive spread (**metastasis**) of pleural cancer
- improper positioning of the tube
- blockage or kinking of the tube

Plicamycin

Definition

Plicamycin is an antibiotic also known as mithramycin; it is sold under the trade name Mithracin. The medicine kills cancer cells. It may be used to treat cancer of the testicles. In addition, it may be used as treatment for **hypercalcemia**. Hypercalcemia is a condition characterized by high levels of calcium in the blood.

Purpose

Plicamycin is a drug used to treat **testicular cancer** in patients who are not good candidates for either surgery or x-ray therapy. It was first approved for this use by the Food and Drug Administration (FDA) in May 1970.

Plicamycin is also used to treat hypercalcemia. Many patients with hypercalcemia also have elevated levels of calcium in the urine. As treatment for this condition, plicamycin may not be a doctor's first choice. The reason for this is that plicamycin may cause serious side effects. Newer medicines, known as **bisphosphonates**, can effectively resolve hypercalcemia and these have fewer side effects. However, some patients cannot tolerate bisphosphonates. These patients may be given plicamycin.

Description

Plicamycin is produced by a bacterium known as *Streptomyces argillaceus*. It interacts chemically with the DNA in cells and so interferes with the production of RNA. It is thought that plicamycin also works by making tumor cells more sensitive to tumor necrosis factor (TNF), a nonantibody protein secreted by cells in the immune system that kills tumor cells. Plicamycin lowers levels of calcium in the blood by affecting the formation of new bone cells and interfering with the activities of certain hormones.

A new form of plicamycin, mithramycin SK, was developed at the University of Kentucky in 2003 from a genetically modified form of *S. argillaceus*. Mithramycin SK is a more effective antitumor drug than the original plicamycin.

Recommended dosage

For testicular cancer, some doctors give 25 micrograms per kilograms of body weight every two to four days to start. However, if the patient has kidney or liver problems, these doctors may give 12.5 micrograms per kilogram instead. Others administer 25 to 30 micrograms per kilograms of body weight every eight to ten days. Others may give as much as 50 micrograms per kilogram of body weight per dose for approximately eight doses every other day.

For high levels of calcium in the blood and urine, fifteen to twenty-five micrograms per kilogram of body weight may be given every day for three or four days. Following this, additional medication may be required approximately once a week.

Precautions

This medication is often not given to patients with problems with blood clotting or with the bone marrow. Plicamycin should not be given to pregnant women, nursing mothers, or children younger than fifteen years of age. The medicine should be used with caution in patients with liver or kidney problems. To lessen side effects to the digestive tract, the medicine may be administered over the course of four to six hours. Additional precautions should be followed to minimize the chances that the medicine will cause blistering.

Since people taking plicamycin are at increased risk of developing an infection and of having bleeding problems, they should avoid people who do have an infection. In addition, they should wash their hands before touching the inside of their mouth, their eyes, or their nose. Also, they should not take aspirin or over-the-counter preparations containing aspirin. In addition, they should attempt not to cause bleeding, for example when they brush and floss their teeth or when they shave.

Doctors should carefully monitor blood counts, liver function, and kidney function for patients given more than one dose of plicamycin.

Certain precautions should be followed by all patients. For example, plicamycin probably should not be taken by anyone who is living is a household with someone who has recently received oral polio vaccine, as there is a risk of transmission of the polio virus. The

KEY TERM

Hypercalcemia—A condition characterized by high levels of calcium in the blood.

person receiving plicamycin should wear a face mask if she or he is going to be in close proximity to anyone who has recently received the oral polio vaccine for an extended period. In addition, vaccines containing live organisms should not be given to anyone who is taking plicamycin or anyone who recently took plicamycin.

Side effects

The side effects of plicamycin include a tendency for abnormal bleeding. There may be low levels of calcium, potassium, and phosphorous in the blood, as well as other blood problems. The face may become flushed. Kidney or liver problems may develop. If bleeding does occur there may be damage to the surrounding skin.

Other side effects may include **diarrhea**, loss of appetite (anorexia), nausea and vomiting, and soreness of the mouth. Muscle cramps and abdominal cramps may develop, although these are likely to disappear as the body gets used to the medication. Uncommon side effects include pain, soreness at the injection side, **fever**, weakness, headache, depressed mood, **fatigue**, and drowsiness.

The side effects of this medicine tend to increase as the dose of the medicine exceeds 30 micrograms per kilogram.

It is important to notify the doctor if any of the following symptoms of plicamycin overdose appear: vomiting of blood; yellow eyes or skin; bloody, or black, tarry stools; swelling of the face or redness of the face; skin rash; or the appearance of tiny red spots on the skin.

Ploidy analysis

Definition

Ploidy analysis is a test that measures the amount of DNA in tumor cells. It is also called DNA ploidy analysis.

Purpose

DNA ploidy analysis is used in addition to the traditional grading system as another way to evaluate how malignant a tumor might be. The advantage of this test is that it provides a numeric, and therefore objective, evaluation of how aggressive the cancer might be. Because this test was relatively new in 2001, and the significance of information gained by this test was not completely understood, this test had not yet replaced traditional systems of **tumor grading**. It would be used only to supplement those tests in order to give the doctor as much information about the nature of the tumor as possible. Doctors may also use this test to help predict how a tumor may respond to the planned therapy.

Precautions

This test requires a certain sample size in order to be performed; the specimens acquired in some biopsies may

KEY TERMS

Aneuploid—Any number of chromosomes except the normal two sets.

Diploid—Two sets of 23 chromosomes. The normal amount in a human cell.

Ploidy—The number of sets of 23 chromosomes a human cell has.

Tetraploid—Four sets of chromosomes. The normal amount in a human cell that is about to divide to form two new cells.

QUESTIONS TO ASK THE DOCTOR

- Why did you order this test? What are you hoping it will tell us?
- What do the results mean?
- How much faith should I put in these results?
- Am I taking any medications that could influence the results of this test?
- Will my insurance company pay for this test?

not provide enough material to run the test. It is also important in this test that only tumor material is used to create the population of cells which are analyzed, as any healthy tissue included can significantly affect the results. Interpretation of the numeric results of this test is still somewhat controversial. There is no commonly accepted system for interpreting the results; in addition, the results of the test can vary greatly from one part of a tumor to another.

The way the test should be used for optimum results in the management of cancer patients remained questionable due to many unexplored issues, and results due to the lack of data accumulated so early into its history. Although research has shown that in general, patients whose tumors have lots of cells with abnormal amounts of DNA have shorter survival times, the results of the test have not, for the most part, been that successful in predicting how an individual patient will do.

Description

Ploidy analysis is performed on a sample of the tumor to determine how many of the cells have the normal amount of DNA and how many have more or less than the normal amount (called aneuploid). Cancerous cells are rapidly dividing cells. When cells divide there is a period before the actual division during which the cells have twice the normal amount of DNA. Tumors with higher proportions of aneuploid cells are generally considered to be more aggressive tumors.

Taking a sample of a tumor is called a **biopsy**. How and where that is done depends on where the tumor is located. Tissue from the surface of body cavities like the mouth or the vagina can be easily sampled from a simple scraping, in a doctor's office. For some types of tumors (such as in **breast cancer**) it is possible to extract enough cells with a needle and syringe. Often, however, a surgical biopsy will need to be performed in the hospital. The tissue removed will be taken to a laboratory and analyzed.

Preparation

Patient preparation for the collection of a tumor sample through biopsy will vary depending on the site of the tumor. Most biopsies call for little that the patient will need to do. For biopsies of internal organs the patient may need to avoid eating after midnight before the test, in case a complication occurs and surgery may be necessary. Patients should try not be fearful of the collection of the sample. Doctors will make the procedure as painless as possible by using appropriate anesthetic.

Aftercare

There can be a little soreness at the biopsy site for a few days following the procedure; acetominophen or another over-the-counter painkiller can be used if the patient feels a need for pain relief. If the site becomes swollen, red, or hot to the touch it may be infected and the patient should contact a physician.

Risks

The risks involved in this test are only the risks inherent in having a biopsy. Since this procedure uses tissue obtained through a biopsy already being performed for the purpose of grading the tumor, there are no additional risks to the patients involved as a result of the test. This test can also be performed on stored biopsy tissues that were obtained at some previous time.

Normal results

Normal cells, most of the time, have two sets of 23 chromosomes, one from each parent, for a total of 46 chromosomes. Normal cells contain four sets–or 92 total chromosomes–for a very brief time right before they divide. Normal tissues have a largely homogenous population of cells containing 46 chromosomes, with a very small percentage of dividing cells that contain 92.

Abnormal results

Tumors have lots of cells that are in the process of reproducing, so tumor tissues typically have a significant population of cells, containing 4 sets of chromosomes, that are about to divide, in addition to the large population of normal cells containing 2 sets of chromosomes. Tumor cells can also contain numerous other variations of normal. Any tissue comprised of significant numbers of cells that have anything but two sets of chromosomes would be considered abnormal.

Pneumonectomy

Definition

Pneumonectomy is the surgical removal of a lung.

Purpose

Pneumonectomy is most often used to treat lung cancer when less radical surgery cannot achieve satisfactory results. It also may be the most appropriate treatment for a tumor that is located near the center of the lung and that affects the pulmonary artery or veins, which transport blood between the heart and lungs. For the treatment of cancer, pneumonectomy may be combined with **chemotherapy** or **radiation therapy**. Pneumonectomy may also be the treatment of choice when traumatic chest injury has damaged the main air passage (bronchus) or the lung's major blood vessels so severely that they cannot be repaired. A form of this procedure known as extrapleural pneumonectomy is often used to treat malignant **mesothelioma**.

Precautions

Before scheduling a pneumonectomy, the surgeon reviews the patient's medical and surgical history and orders a number of tests to determine how successful the surgery is likely to be.

Blood tests, a bone scan, and **computed tomography** (CT) scans of the head and abdomen reveal whether the cancer has spread beyond the lungs. Positron emission tomography scanning (PET) is also used to help "stage" the disease. Cardiac screening indicates how well the patient's heart will tolerate the procedure, and extensive pulmonary testing (breathing tests and quantitative ventilation/perfusion scans) predicts whether the remaining lung will be able to compensate for the body's diminished breathing capacity.

Because extrapleural pneumonectomy is such an invasive operation, the patient must have no serious illness other than the cancer the surgery is designed to treat.

Description

Traditional pneumonectomy removes only the diseased lung. A more complex surgery generally performed in specialized medical centers, extrapleural pneumonectomy also removes:

- a section of the membrane (pericardium) covering the heart
- a portion of the muscular partition (diaphragm) that separates the chest and abdomen
- the membrane (parietal pleura) that lines the affected side of the chest cavity

General anesthesia is given to a patient undergoing either of these procedures. An intravenous (IV) line inserted into one arm supplies fluids and medication throughout the operation, which usually lasts between one and three hours; extrapleural pneumonectomies may last up to six hours.

The surgeon begins the operation by cutting a large opening on the side of the chest where the diseased lung is located. This posterolateral **thoracotomy** incision extends from below the shoulder blade, around the side of the patient's body, and along the curvature of the ribs at the front of the chest. Sometimes removing part of the fifth rib gives the surgeon a clearer view of the lung and makes it easier to remove the diseased organ.

A surgeon performing a traditional pneumonectomy then:

- deflates (collapses) the diseased lung
- ties off the lung's major blood vessels to prevent bleeding into the chest cavity
- clamps the main bronchus to prevent fluid from entering the air passage

KEY TERMS

Bronchopleural fistula—An abnormal connection between an air passage and the membrane that covers the lungs.

Empyema—Accumulation of pus in the lung cavity, usually as a result of infection.

Pleural space—A small space between the two layers of the membrane that covers the lungs and lines the inner surface of the chest.

Pulmonary embolism—Blockage of a pulmonary artery by a blood clot or foreign matter.

QUESTIONS TO ASK THE DOCTOR

- Why is it necessary to remove the whole lung?
- Why might I also need chemotherapy or radiation therapy?
- What should I do to prepare for this operation?
- How long will I have to stay in the hospital?
- Why is recovery such a slow process?

- cuts through the bronchus
- removes the lung
- staples or sutures the end of the bronchus that has been cut
- makes sure that air is not escaping from the bronchus
- inserts a temporary drainage tube between the layers of the pleura (pleural space) to draw air, fluid, and blood from the surgical cavity
- closes the chest incision

Besides removing the diseased lung, a surgeon performing an extrapleural pneumonectomy:

- cuts the pleura away from the chest wall
- removes parts of the pericardium and diaphragm on the affected side of the chest
- substitutes sterile synthetic patches for the tissue that has been removed
- closes the incision

Preparation

A patient who smokes must stop as soon as the disease is diagnosed.

A patient who takes aspirin or any other other blood-thinning medication must stop taking the medication about a week before the scheduled surgery, and patients may not eat or drink anything after midnight on the day of the operation.

Aftercare

Chest tubes drain fluid from the incision and a respirator helps the patient breathe for at least 24 hours after the operation. The patient may be fed and medicated intravenously. If no complications arise, the patient is transferred from the surgical intensive care unit (ICU) to a regular hospital room within one to two days.

A traditional pneumonectomy patient will probably be discharged within 10 days. A patient who has had an extrapleural pneumonectomy is likely to remain in the hospital between 10 and 12 days after the operation. While the patient is hospitalized, care focuses on:

- relieving pain
- monitoring to ensure that concentrations of oxygen in the blood do not become dangerously low (hypoexemia)
- encouraging the patient to walk in order to prevent formation of blood clots
- encouraging the patient to cough productively in order to clear accumulated lung secretions. If the patient cannot cough productively, the doctor uses a flexible tube (bronchoscope) to remove lung secretions and fluids (**bronchoscopy**).

Recovery is usually a slow process, with the remaining lung gradually taking on the tasks of the lung that has been removed and the patient gradually resuming normal, non-strenuous activities. Within eight weeks, a pneumonectomy patient who does not experience postoperative problems may be well enough to return to a job that is not physically demanding, but 60% of all pneumonectomy patients continue to experience marked shortness of breath six months after having surgery.

Risks

In the United States, the immediate survival rate from the surgery for patients who have had the left lung removed is between 96% and 98%. Due to the greater risk of complications involving the stump of the cut bronchus in the right lung, between 88% and 90% of patients survive removal of this organ.

Between 40% and 60% of pneumonectomy patients experience such short-term postoperative difficulties as:

- prolonged need for a mechanical respirator
- abnormal heart rate (cardiac arrhythmia), heart attack (myocardial infarction), or other heart problems
- pneumonia
- infection at the site of the incision
- a blood clot in the remaining lung (pulmonary embolism)
- an abnormal connection between the stump of the cut bronchus and the pleural space due to a leak in the bronchus stump (bronchopleural fistula)
- accumulation of pus in the pleural space (empyema)
- kidney or other organ failure

Over time, the chest's remaining organs may move toward the space created by the surgery. This condition is called postpneumonectomy syndrome, and a surgeon can correct it by inserting a fluid-filled prosthesis into the space the diseased lung occupied.

Normal results

The doctor will probably advise the patient to refrain from strenuous activities for a few weeks after the operation. Ribs that were cut during surgery will remain sore for some time.

A patient whose lungs have been weakened by noncancerous diseases like emphysema or chronic bronchitis may experience long-term shortness of breath as a result of this surgery.

Abnormal results

A patient who experiences a **fever**, chest pain, persistent cough, or shortness of breath, or whose incision bleeds or becomes inflamed, should notify his or her doctor immediately.

Pneumonia

Description

One of the most common pulmonary complications affecting cancer patients, pneumonia is a potentially life-threatening inflammation of one or both lungs.

Causes

Serious side effects in cancer patients most often occur in the lungs and may indicate that the cancer is progressing or that the patient has developed a new problem. Both cancer and the therapies used to treat it can injure the lungs or weaken the immune system in ways that make cancer patients especially susceptible to the bacteria, fungi, viruses, and other organisms that cause pneumonia.

Tumors and infections can block the patient's airway or limit the lungs' ability to rid themselves of fluid and other accumulated secretions that make breathing difficult. Other factors that increase a cancer patient's risk of developing pneumonia include:

- radiation therapy
- chemotherapy
- surgery
- depressed white blood cell count (neutropenia)
- **antibiotics**
- steroids
- malnutrition
- limited mobility
- splenectomy-immune system deficits

The risk of developing pneumonia is greatest for a cancer patient who has one or more additional health problems.

Treatments

Pneumonia in cancer patients must be treated promptly in order to speed recovery and prevent complications that could arise if the inflammation were allowed to linger. Treatment always includes bed rest and coughing to expel phlegm and other fluids from the lungs (productive cough). To determine which course of treatment would be most appropriate, a doctor considers when symptoms first appeared, what pattern the illness has followed, and whether cancer or its treatments have diminished the patient's infection-fighting ability (**immune response**).

A doctor generally prescribes broad-spectrum oral antibiotics if:

- the patient has had a **fever** for less than a week
- pneumonia has not spread beyond the lung area where it originated
- the patient's cancer is responding to treatment
- the patient is otherwise in good health

The doctor uses a flexible tube (bronchoscope) to examine the lungs and airway (**bronchoscopy**) for inflammation, swelling, obstruction, and other abnormalities and washes the lungs (bronchoalveolar lavage) with a mucus-dissolving solution if:

- pneumonia is extensive, aggressive, or severe
- antibiotics don't clear the infection
- the patient is very ill

The doctor may also remove a small piece of lung tissue (transbronchial **biopsy**) for microscopic examination and cultures, and prescribe medication to combat fungal and viral organisms that might be responsible for the patient's symptoms. If the patient's condition continues to worsen, the doctor may remove additional lung tissue (thoracic needle biopsy or open lung biopsy) for microscopic analysis and cultures.

Alternative and complementary therapies

Non-medical treatments will not cure pneumonia but may relieve symptoms and make the patient more comfortable. All of these therapies require the treating doctor's approval.

ACCUPUNCTURE Accupuncture may relieve congestion and reduce **fatigue**.

ESSENTIAL OILS Added to a warm bath or vaporizer, essential oils of eucalyptus (*Eucalyptus globus*), lavender (*Lavandula officinalis*), or pine (*Abies sibirica*) can create a fragrant steam that helps the patient breathe more easily. Because steam inhalations can irritate the lungs, individuals who have asthma should not use them.

POSTURAL DRAINAGE A strenuous exercise that can help clear phlegm from the lungs, postural drainage should be practiced only with a doctor's approval and in the presence of a person who can provide support for a patient who becomes tired or weak.

Leaning over the side of the bed with forearms braced on the floor, the patient coughs up phlegm and spits it into a container. If the patient cannot cough productively enough to dislodge phlegm, the support person can help clear lung secretions by pounding gently on the patient's upper back. Postural drainage should be performed three times a day. Each session should last between five and 15 minutes, unless the patient tires or weakens sooner.

KEY TERMS

Antineoplastic—An agent that inhibits or prevents the maturation and proliferation of malignant cells.

Free radicals—Highly reactive molecules that act as agents of tissue damage.

Necrosis—The sum of all the morphological changes that indicate cell death.

Oncologist—A physician who specializes in the diagnosis and treatment of cancer patients.

Photodynamic therapy—Cancer treatment that uses the interaction between laser light and an agent that makes cells more sensitive to light.

Photosensitizing agents—Ultraviolet or sunlight-activated drugs used in the treatment of certain cancer types.

Porphyrins—Pigments found in the body that have an active affinity for metals.

Radiologically occult—Radiologically unapparent or undefined.

MASSAGE After the patient's fever has broken, gently massaging the upper back may relieve congestion and encourage productive cough.

HERBAL REMEDIES Homemade cough medicines (expectorants) containing licorice (*Glycyrrhiza glabra*), black cherry (*Prunus serotina*) bark, raw onions, honey, and other natural ingredients can relieve congestion and encourage productive cough. Because natural substances can be poisonous, they should be used only with a doctor's approval and according to label directions.

Eating raw garlic (*Allium sativum*) or taking garlic supplements is believed to strengthen the immune system. Echinacea, brewed as tea or taken in liquid or capsule form, may help some patients recover more quickly.

VITAMINS Zinc supplements and large doses of **Vitamins** A, C, and E may strengthen the patient's immune system. Because large doses of some vitamins can cause **diarrhea** and other serious side effects, they should not be taken without a doctor's approval. Additionally, large doses of vitamins and herbal remedies may interfere with the primary cancer treatment programs. Approval from the treating doctor is imperative.

Porfimer sodium

Definition

Porfimer sodium (trade name Photofrin) is a photosensitizing agent that belongs to a group of medicines known as antineoplastics. Porfimer sodium is sometimes called a hematoporphyrin derivative.

Purpose

Porfimer is used in a treatment called photodynamic therapy (PDT). This form of cancer treatment is for patients presenting with obstructing esophageal and endobronchial non-small cell lung cancers (NSCLC) and early stage radiologically occult endobronchial cancer. As of the early 2000s, PDT is considered an experimental treatment for cancer of the esophagus. In 2003, however, the Food and Drug Administration (FDA) added Barrett's esophagus to the list of conditions for which Photofrin is an approved treatment. Some patients with Barrett's esophagus develop precancerous lesions that respond well to treatment with porfimer sodium.

As of 2004, PDT is being studied as a treatment for breast cancer that has progressed to the chest wall. Of one group of 14 patients, nine demonstrated a complete response to PDT.

Another new development is the use of porfimer sodium to treat cancers in the abdominal cavity and the brain. A group of researchers in Boston have used a needle to insert a small-diameter quartz optical fiber that transmits laser light to the pancreas, liver, and spleen to activate the Photofrin. A second team in Salt Lake City has used a new light-delivery device based on light-emitting diode (LED) technology to administer PDT to patients with recurrent brain tumors.

Description

The FDA granted its original approval to porfimer sodium in December 1995. Porfimer is a chemical mixture of up to eight porphyrin units. The freeze-dried compound exists as a dark red to reddish-brown cake or powder and is typically reconstituted with 5% dextrose or 0.9% sodium chloride. Porfimer sodium's antitumor effects are dependent upon its activation by a specific wavelength of light that results in the subsequent release of highly toxic oxygen-free radicals. Additionally, PDT using porfimer produces a significant decrease in blood flow to the treatment area that enhances necrosis in certain tumor cells. Clinical test results suggest that use of porfimer sodium for the palliative management of **esophageal cancer**, and NSCLC yields a statistically significant improvement after a single course of therapy. Porfimer sodium and the associated laser treatment have not been formally tested in conjunction with other photosensitizing compounds. However, it may be speculated that an increase in the photosensitive reaction would result.

Recommended dosage

The dose of porfimer sodium will vary among patients. The oncologist will make a final dose determination based on a number of factors, including body weight. An appropriate starting regimen for adults would be:

- 2mg porfimer per kg of body weight injected into a vein.
- Approximately 48 hours post injection, tumor illumination with a laser light source set at 630nm wavelength.
- Two to three days post tumor illumination, the physician will remove the destroyed cancer cells.
- If prescribed, a second laser treatment may be given 96–120 hours after the initial porfimer injection followed by subsequent removal of destroyed cancer cells.
- Patients may receive a second dose of porfimer at a minimum of 30 days from the initial treatment for up to three cycles, each 30 days apart.

Precautions

All patients who have received PDT must avoid exposure of the skin and eyes to direct sunlight and bright indoor lighting for a minimum of 30 days. In July 2000, the FDA added the following to patient information labeling of Photofrin: "Some patients may remain photosensitive for up to 90 days or more." Sensitivity is produced from the residual porfimer that has not cleared the patient's system; therefore, ambient indoor lighting will help to gradually quench the photosensitive effect. Intermittent exposure trials of a small patch of skin to direct sunlight should be conducted in

10-minute segments beginning 30 days after PDT, and before returning to normal outdoor activities. If no photosensitive reaction (redness, edema, blistering) is apparent 24 hours after exposure, cautious and gradually increased exposure may continue. If the test results are positive, patients should continue precautions for an additional two weeks before repeating the exposure test. Over-the-counter sunscreens are of no use because the photo activation of porfimer occurs in the visible light range. Patient eye sensitivity should be guarded for a minimum of 30 days by wearing dark sunglasses that allow for no greater than 4% of available white light to pass through the lenses. PDT treatment scheduling before or after **radiation therapy** should be properly spaced to avoid any cumulative inflammatory response from one treatment regimen to the next. A two- to four-week recovery phase between treatment types is recommended. Careful monitoring of endobronchial lesion patients is required to reduce the risk of respiratory distress caused by necrotic tissue obstructing the airway. These patients are also at risk from bleeding problems associated with erosion into a major blood vessel. As with all **antineoplastic agents**, pregnancy should be avoided. If the patient is pregnant, PDT should only be used if the potential benefits outweigh the risks to the fetus.

Side effects

Side effects are associated with all antineoplastic drugs, and patients should be instructed to discuss any concerns. Side effects produced with porfimer that may engender patient concern, but do not typically require medical attention, may include mild **diarrhea** or constipation, mild **nausea and vomiting**, blistering, redness or swelling of the skin, difficulty sleeping, weakness, and vision changes. These conditions usually subside as the body adjusts to the porfimer. Side effects associated with porfimer sodium that do require immediate medical attention include:

- shortness of breath or trouble breathing
- fast or irregular heartbeat
- high or low blood pressure
- spitting blood
- severe stomach, abdominal, or chest pain
- chills or fever
- dizziness or fainting
- coughing or wheezing
- unusual weight gain
- excessive fatigue or weakness
- swelling in the face, feet, neck, or lower legs
- white patches in the mouth
- tightness in the chest
- yellow coloration of the eyes or skin

KEY TERMS

Benign growth—A noncancerous cell growth that does not metastasize and does not recur after treatment or removal.

Cancer screening—A procedure designed to detect cancer even though a person has no symptoms, usually performed using an imaging technique.

CT scan—An imaging technique that uses a computer to combine multiple x-ray images into a two-dimensional cross-sectional image.

Electron—One of the small particles that make up an atom. An electron has the same mass and amount of charge as a positron, but the electron has a negative charge.

Gamma ray—A high-energy photon, emitted by radioactive substances.

Half-life—The time required for half of the atoms in a radioactive substance to disintegrate.

Malignant growth— A cell growth or tumor that becomes progressively worse and that can metastasize elsewhere in the body.

Metabolism—The sum of all physical and chemical processes occurring in the body to maintain its integrity and also the transformations by which energy is made available for its uses.

MRI—A special imaging technique used to image internal parts of the body, especially soft tissues.

Photon—A light particle.

Positron—One of the small particles that make up an atom. A positron has the same mass and amount of charge as an electron, but the positron has a positive charge.

Interactions

There have been no formal interaction studies between porfimer and other drugs. One may speculate on the possible synergistic effects of porfimer in conjunction with other photosensitizing agents, such as phenothiazines, chlorpropramide, **demeclocycline**, doxycycline, and tetracycline. Animal research studies suggest certain compounds decrease the effectiveness of porfi-

mer used in PDT. These inhibitors include drug compounds such as dimethyl sulfoxide (DMSO) and ethanol that act by inhibiting the formation of free radicals. Other drug groups, such as thromboxane A_2 inhibitors, inhibit by decreasing clotting, vasoconstriction, or platelet aggregation. Other pre-clinical trial data suggests a decrease in porfimer efficacy in PDT in response to glucocorticoids hormones, calcium channel blockers, and prostagladin synthesis inhibitors. As with any course of treatment, patients should first notify their doctors of any medications they are taking.

Positron emission tomography

Definition

Positron emission tomography (PET) is a highly specialized imaging technique using short-lived radiolabeled substances to produce powerful images of the body's biological function.

Purpose

Besides being used to investigate the metabolism of normal organs, PET has also become the technique of choice to investigate various neurological diseases and disorders, including stroke, epilepsy, Alzheimer's disease, Parkinson's disease, and Huntington's disease. Various psychiatric disorders, such as schizophrenia, **depression**, obsessive-compulsive disorder, attention-deficit/hyperactivity disorder, and Tourette syndrome, are also imaged by PET.

PET is especially useful in the context of cancer because it can detect metastatic tumors that may not be visualized by other imaging techniques. It is also being increasingly used not only as a cancer diagnostic tool, but also to help physicians design the most beneficial therapies. For example, it may be used to assess response to **chemotherapy**. PET imaging is very accurate in differentiating malignant from benign cell growths, and in assessing the spread of malignant tumors. PET is also used to detect recurrent brain tumors and cancers of the lung, colon, breast, lymph nodes, skin, and other organs.

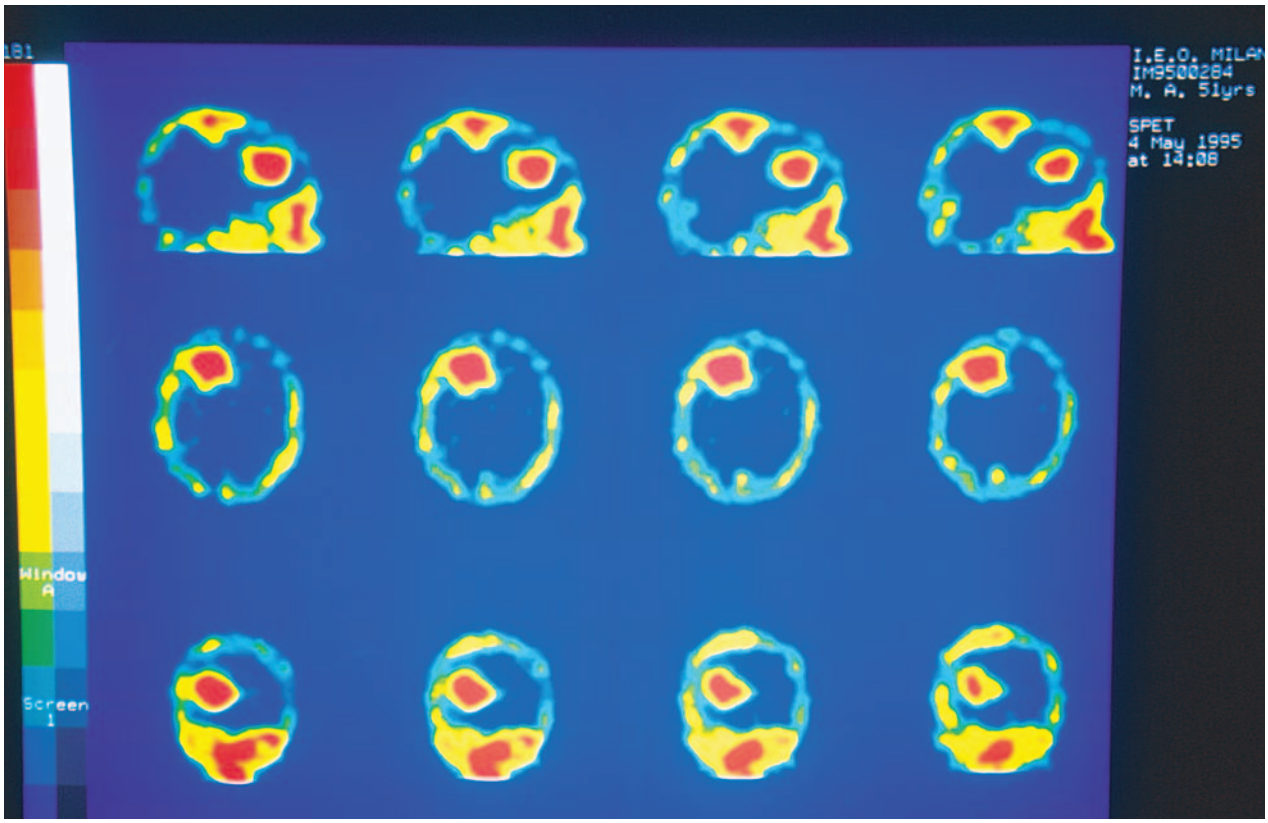
Precautions

In some cases, patients may be allergic to the radioactive agents used for PET. A patient with known allergies should discuss this with his or her specialist before undergoing the PET scan.

Description

PET is used in conjunction with compounds that closely resemble a natural substance used by the body, such as a simple sugar (e.g. glucose), labeled with a radioactive atom and injected into the patient. These compounds (radionuclides or **radiopharmaceuticals**) emit particles called positrons. As positrons emitted from the radionuclides encounter electrons in the body, they produce high-energy photons (gamma rays) that can be recorded as a signal by detectors surrounding the body. The radionuclides move through the body and accumulate in the organs targeted for examination. A computer collects the distribution of radioactivity and reassembles them into actual images.

By further defining a lesion seen on other imaging modalities, PET may enhance assessment of tumors exceedingly well. This is because of its operating principle. The radiolabeled sugars injected into the patient will be used by all body cells, but more sugar will be used by cells that have an increased metabolism. Cancer cells are highly



Positron emission tomography (PET) images of an oncology patient's brain. PET imaging can be used to differentiate between malignant and benign cell growths, assess the spread of malignant tumors, and detect recurrent brain tumors. *(Custom Medical Stock Photo. Reproduced by permission.)*

metabolic, meaning that they use more sugar than healthy nearby cells, and they are easily seen on the PET scan. PET images thus show the chemical functioning of an organ or tissue, unlike **x ray**, computed tomography, or magnetic resonance imaging, which show only body structure.

Preparation

The radiopharmaceutical is given by intravenous injection or inhaled as a gas a few minutes before the PET procedure. How it is administered depends on the radiopharmaceutical used and which one is selected depends on what organ or body part is being scanned. During the scan, the patient lies comfortably; the only discomfort involved may be the pinprick of a needle used to inject the radiopharmaceutical.

Aftercare

No special aftercare measures are indicated for PET.

Risks

Some of radioactive compounds used for PET scanning can persist for a long time in the body. Even though only a small amount is injected each time, the long half-lives of these compounds can limit the number of times a patient can be scanned. However, PET is a relatively safe procedure. PET scans using radioactive fluorine result in patients receiving exposures comparable to (or less than) those from other medical procedures, such as the taking of x rays. Other scanning radiopharmaceuticals—for instance, 6-F-dopa or radioactive water—normally cause even less exposure.

Normal results

The PET scan of a healthy organ or body part will yield images without contrasting regions, because the radiolabeled sugar will have been metabolised at the same rate.

Abnormal results

The PET scan of a diseased organ or body part however, will yield images showing contrasting regions, because the radiolabeled sugar will not have been metabolized at the same rate by the healthy and diseased cells.

QUESTIONS TO ASK THE DOCTOR

- How many PET scans will I have to undergo?
- Are there any risks associated with the radiopharmaceuticals that will be injected?
- How reliable are PET scans for my type of cancer?

Prednimustine

Definition

Prednimustine is one of a group of antineoplastic (antitumor) drugs known as alkylating agents. As of mid-2001, it is an **investigational drug**.

Purpose

Prednimustine has been used in the treatment of **chronic lymphocytic leukemia**, **non-Hodgkin's lymphomas**, and other malignant conditions including **breast cancer**.

Description

Prednimustine is one of a group of drugs based on the mustard gas used as a weapon in World War I. Like many antineoplastic (antitumor) therapies, prednimustine acts by killing quickly growing cells. Since cancerous cells are generally growing faster than normal cells, drugs that kill quickly growing cells generally affect tumors more than normal cells. However, some normal cells, such as white blood cells and platelets, also grow quickly and can be severely affected by antineoplastic drugs. Antitumor therapies create a situation in which the drug is racing to kill the tumor before it causes irreparable damage to normal tissues. The ideal situation is one in which the growth of the tumor is severely affected, but the growth of normal cells is unaffected. However, not every situation is ideal. Some patients taking antitumor drugs may have to discontinue treatment due to the severity of the drug's side effects.

Prednimustine probably kills rapidly growing cells by modifying cell's DNA with a chemical structure called an alkyl group. Thus, it is included in the group of alkylating agents. Prednimustine is a combination of two drugs joined together: **chlorambucil** (an alkylating agent) and methylprednisolone (a steroid).

Prednimustine is an investigational drug in the United States. This means that the FDA has not approved this drug for marketing in the U.S., as of mid-2001. Generally, investigational drugs are made available through participation in research studies.

Many drugs have toxic side effects, some of which are difficult to detect. **Clinical trials** are used to determine the side effects, drug interactions, and precautions for medicines, as well as their efficacy. Successful completion of multi-step clinical trials results in FDA approval of a drug. Many drugs that are used in clinical trials never gain FDA approval, however, possibly because of severe side effects which outweigh the benefits of the medication, or because the medication does not perform the function for which it was tested. Final approval of a drug is also expensive. Some drugs may not receive the financial support necessary to achieve final approval.

Recommended dosage

Since prednimustine is investigational, there is no recommended dosage. Various dosing schedules have been reported in the literature for different cancers.

Precautions

Patients who take this drug should avoid pregnancy, since this drug may cause fetal abnormalities.

KEY TERM

Investigational drug—A drug that has not been approved for marketing by the FDA. These drugs are generally available to patients through participation in research studies.

Side effects

In the published reports of prednimustine use, the most common side effect is myelosuppression, the damage to white blood cells and platelets. Such damage may result in infection and bleeding, respectively. Steroid side effects, such as fluid retention and high glucose, have also been reported.

Interactions

As of mid-2001, information on the interactions of prednimustine is not available.

See also Chlorambucil.

Pregnancy and cancer

Definition

For the most part, cancer that strikes during a pregnancy is unrelated to the pregnancy. The exception is choriocarcinoma. This cancer is only found in pregnancy.

Description

Pregnancy can be a joyous time for a woman, but when cancer is diagnosed, a tremendous dilemma can arise, both for the woman and for her health care providers. Cancer is not common in pregnancy, and is rarely the cause of maternal mortality. However, in any pregnancy there are always two patients to consider—the mother and the fetus. When a pregnant woman has cancer, the health of the mother may be pitted against the well-being of the fetus. For women who do not have regular medical visits, pregnancy may be a time for regular prenatal visits. For them, screenings done in pregnancy may serve as an opportunity to detect a hidden cancer.

Interestingly, pregnancy also has some protective effects against breast cancer. Studies have firmly established that early full-time pregnancy helps lower risk for breast cancer for a woman's lifetime.

Choriocarcinoma arises from embryonic fetal tissue called the chorion and chorionic villi. It may be associated with a molar pregnancy, an ectopic pregnancy, and may even develop after the delivery of a normal fetus. It may be referred to as gestational trophoblastic disease (GTD), or gestational trophoblastic tumor. A non-malignant form is a hydatiform mole, but the tissue can become cancerous. Vaginal bleeding and high beta human chorionic gonadotropin (hCG) levels characterize the condition.

Ultrasound is effective in evaluating the mass to establish the presence or absence of a fetus and of a fetal heartbeat. The tissue must be evacuated and sent to pathology for evaluation. If cancerous cells are found, **chemotherapy** is begun. Chemotherapy has been shown to be extremely effective in treating choriocarcinoma. If left untreated, choriocarcinoma readily metastasizes, or spreads to other organs.

Incidence of GTD rises with maternal age. Women who desire future pregnancies should discuss this as part of the treatment plan to ensure fertility-sparing choices. Some women normally have high hCG levels. If they have some abnormal vaginal bleeding they can be incorrectly diagnosed as having choriocarcinoma if they have a high hCG level without other evidence of a pregnancy. Before undergoing chemotherapy or surgery, women should have a urine pregnancy test done as well, and/or have blood hCG tests done that are able to discriminate between various forms of hCG. Some laboratory hCG tests have a high false-positive rate, and are not designed to screen for hCG that is associated with cancer.

The most common cancers occurring during pregnancy, in descending order are:

- **Cervical cancer**. About 0.5 to 5.0% of cervical cancers occur in pregnant women, and about one-third of women are under 35 when given the diagnosis. Survival rates for pregnant versus non-pregnant women are similar. It is safe to have a Pap smear during a prenatal visit. Suspicious findings may lead to a colposcopy and **biopsy**. There may be increased bleeding from the biopsy site in the pregnant woman. If cervical cancer is found, the stage of cancer and trimester of pregnancy will determine if immediate surgery is needed or if treatment can be postponed until the fetus matures. With cervical cancer a cesarean delivery will be

recommended, perhaps before full term of 40 weeks if the fetus' lungs are sufficiently mature.

- **Breast cancer**. Breast cancer occurs in about one out of every 3,000 pregnancies. As in non-pregnant women, infiltrating ductal carcinoma is the most prevalent type. When determining the type and stage, the tumor also will be evaluated for being estrogen receptor positive or negative (ER-positive, ER-negative). Pregnancy hormones accelerate the growth of ER-positive tumors. Pregnancy has less of an impact on ER-negative tumors. The pregnancy hormones can alter the test results and increase the number of false negatives of hormone receptor testing. Because of the normal breast changes in pregnancy, it is more difficult to detect a lump when pregnant, so diagnosis may be delayed while the tumor continues to grow. Pregnancy also increases the density of the breast and makes **mammography** less sensitive. Ultrasound can be used to differentiate between a fluid-filled lump and a solid tumor. About 67% of pregnant women with breast cancer have positive lymph nodes versus 38% of non-pregnant women. Studies indicate that about 47% of pregnant women with positive lymph nodes reach five-year survival versus 59% of non-pregnant women with positive nodes. For lactating women, some of the signs of mastitis are similar to the signs of inflammatory breast cancer. The diagnosis of cancer may be delayed because of the confusion. Some studies indicate that if an abscess is drained from a breast with mastitis, a sample should be sent to pathology. Pregnant women may experience bleeding from any procedures done on the breast due to increased vascularity.
- **Melanoma**. The average age for malignant melanoma is 45. About 30–40% of cases appear during the childbearing years. About 8% of women are pregnant at the time of diagnosis. During pregnancy the thickness of the lesion is greater, and nodal metastases more frequently occur. If there has been nodal **metastasis**, survival may be less than three years. Melanoma also can spread to the placenta and to the fetus. However, prognosis for the pregnant woman is greater if she carries to term (66.5% survival at five years), than if the pregnancy is terminated following diagnosis (33.5% survival at five years). Because most lesions appear on the extremities, treatment may begin during the pregnancy.
- Hodgkin's disease. Hodgkin's occurs about one in six thousand pregnancies. The average age for a diagnosis of Hodgkin's is 30. However, the prognosis for the pregnant woman is about the same as for a non-pregnant woman. Signs such as **fever**, **night sweats**, and unexplained **weight loss** indicate a higher stage of disease. A nodal biopsy can safely be done during pregnancy, but pregnancy can alter the test results. Treatment may include a short course of chemotherapy and radiation to the affected nodal area if the fetus can be adequately shielded. If this cannot be done safely, radiation may wait until after delivery. Nodal sclerosis is a common subtype of Hodgkin's and is frequently seen in adolescents and young adults. Non-Hodgkin's lymphoma is usually seen after the childbearing years.
- **Ovarian cancer** is extremely rare during pregnancy; only 1:10,000 to 1:100,000 full term deliveries are cases of this cancer. It is usually low grade and low stage (Stage 1) cancer. Germ cell malignancies are the most common form of ovarian cancer in young women. Germ cell cancer can grow very rapidly, so immediate chemotherapy will be discussed. During pregnancy alpha-fetoprotein levels are tested to check if the fetus may have a neural tube defect. However, this same test is used in the non-pregnant woman as a screening for germ cell cancer. Older women are more prone to epithelial and low malignancy potential ovarian cancers. It may be the prenatal ultrasound that first alerts a woman to her having ovarian cancer. The cancer tumor marker CA-125 is unreliable in pregnancy, as the levels go up during this time. Ovarian tumors may undergo torsion, or twisting, creating extreme pain that may be mistaken for appendicitis or an ectopic pregnancy if gestation is still early.
- Colorectal cancer is the third most common cancer in women, with 67,000 cases in 1999. About 10% of cases occur in patients under the age of 40; only about 2% of cases occur under the age of 30. Early occurrence is linked with high risk. There may be a delay in diagnosis, as some of the symptoms of colorectal cancer overlap symptoms seen in pregnancy. Because of the delay, a higher degree of disease may present at diagnosis. Women considering pregnancy should request screening prior to becoming pregnant. Signs of colorectal cancer include: nausea, abdominal bloating, backache, rectal bleeding, pain, and a change in bowel habits.
- Leukemia is quite rare during pregnancy, occurring in one out of 75,000 pregnancies. During pregnancy, acute myelocytic leukemia is usually the form seen. If treatment is begun right away, the prognosis for the pregnant woman is similar to that of the non-pregnant woman. Complete remission rates are also similar. Untreated, the disease can be rapidly fatal. The woman with leukemia is at greater risk for miscarriage, fetal growth retardation, prematurity and stillbirth.

Causes

As women delay their childbearing years into their forties and even fifties, an increase of cancer during pregnancy is occurring. This is due to the overlap of

KEY TERMS

Cesarean section—This procedure to deliver a baby involves an incision made through the abdominal wall and into the uterus to extract the baby.

Colposcopy—During a colposcopy a practitioner uses a special lighted instrument with magnification lenses (called a colposcope) to clearly visualize and examine the vagina and cervix. This procedure may be done when a Pap smear has come back showing suspicious or abnormal cells. If an area of the vagina or cervix looks suspicious in any way the practitioner may take a sample of tissue, called a biopsy, for further review by a pathologist.

Ectopic pregnancy—A pregnancy that occurs outside the uterus, most commonly in a fallopian tube. Early detection is important to avoid potential rupture of the fallopian tube as the fetus grows.

Hydatiform mole—A hydatiform mole is characterized by a larger-than-normal-for-dates uterus, vaginal bleeding, and the presence of multiple cysts stemming from the degeneration of chorionic villi, the early fetal tissue that imbedded into the uterine lining with placental and embryo implantation.

Interdisciplinary team—A group of health care providers from a variety of specialties that meet as a team to address the various needs of a patient. For a woman with cancer, the team may consist of an obstetrician, gynecologic oncologist, radiologist, neonatologist, social worker, nurse specialists, as well as others specific to the needs of a particular patient.

Microcephaly—Microcephaly is a congenital anomaly in which the head is small in proportion to the body. The brain is also underdeveloped, and there is some mental retardation.

Molar pregnancy—A molar pregnancy may be either complete or partial. In a partial mole, there may be a fetal sac, and even initial fetal heart tones. However, the fetus has multiple anomalies, does not grow properly, and eventually dies. When vaginal bleeding occurs the molar pregnancy is discovered, and needs to be evacuated to avoid retention of the tissue. In a complete mole, the ovum is fertilized but contains no genetic material. The embryo is unable to survive for very long. Complete evacuation of the uterus in necessary to avoid the development of choriocarcinoma.

Teratogenic—A substance or process affecting normal fetal development, leading to congenital malformations. Teratogens include alcohol, certain medications, and radiation.

childbearing with the usual times of occurrence of certain cancers. The exact cause of most cancers is not yet known. However, estrogen is known to play a role in the development of endometrial and ovarian cancers. Research has shown that smoking increases the risk of developing cervical cancer, as well as other cancers.

Special concerns

Decisions need to be made about commencing treatment, or delaying treatment until after the pregnancy is finished. Accurate staging of the tumor will be critical. The woman will be asked if the pregnancy is desired. If not, and if the gestation is less than 24 weeks, therapeutic abortion may be considered. Depending on the type and stage of the cancer, a delay in treatment might not affect the mother's prognosis. Fetal lung maturity may be monitored, so that a safe early delivery can be planned. As the fetus nears term, there is a significant decrease in morbidity and mortality for every extra two weeks it remains in utero.

A pregnant woman with cancer has a great need for an interdisciplinary team of experienced practitioners. Oncologists who have experience with treatment during pregnancy may be able to offer more choices for treating the cancer while maintaining a viable pregnancy. Practitioners also need experience in managing the treatment side effects in a safe way for the fetus. For example, corticosteroid use can increase the incidence of cleft palate, and affect maternal glucose intolerance.

Pregnant women should not take any over-the-counter medication, including herbal supplements, without first consulting their obstetrical provider. Medications and supplements considered safe for a non-pregnant woman may have harmful effects on the fetus.

Treatments

Cancer treatment usually involves some combination of surgery, radiation and chemotherapy. During the first trimester, or the first 12 weeks of gestation, the fetus' organs are developing and are very susceptible to teratogenic substances (substances that affect normal fetal development). When treatment is undertaken, it is most commonly in the second trimester, when early fetal development has already taken place.

When contemplating surgery during pregnancy, the risks for both mother and fetus must be considered. Abdominal surgery poses the greatest risk to the pregnancy, however some women can successfully have an ovary removed and still bring a healthy fetus to term. The removal of the ovary needs to take place after the first trimester, once the placenta has taken over the progesterone hormone production of the corpus luteum. General anesthesia is often chosen for surgery. The safest time for surgery is during the second trimester, but the risk of preterm labor, intrauterine growth retardation, and fetal death still exists. **Mastectomy** is often recommended for the treatment of breast cancer during pregnancy, although breast-conserving surgery may also be an option.

In the first 10 days following conception, radiation may kill the fetus, or may have no effect at all. From 10 days to 14 weeks, a fetus exposed to radiation is at risk for:

- intrauterine growth retardation
- central nervous system (CNS) abnormalities
- microcephaly
- severe mental retardation
- eye anomalies

From eight weeks until term, the fetus is still at risk for CNS abnormalities and milder forms of microcephaly and mental retardation from radiation. If the mother receives high doses of radiation, intrauterine death may occur. Because of the scarcity of research data, the *threshold dose* is unknown. **Childhood cancers**, other cancers later in life, and cancer appearing in later generations are also of concern. Research evaluating the outcome of the children of pregnant women exposed to the atomic bomb in Japan indicates the effects of radiation exposure may show up even five generations later.

When deciding on chemotherapy during pregnancy, several factors are considered:

- which chemotherapy drugs are effective for the woman's particular type of cancer, and of these which are safe for the developing fetus
- the stage of fetal development
- how long the chemotherapy will be administered
- how often it will be administered
- whether the chemotherapeutic agent crosses the placental barrier to the fetus

There are also maternal factors to consider. During pregnancy a woman's blood volume and cardiac output increase, which affects the drugs' concentration levels. If the woman has hyponatremia, this increases the drug concentration in her system. Maternal obesity can affect lipid-soluble drugs. As with radiation, the fetus is most susceptible during the first trimester. Congenital malformations and miscarriage are the most common consequences.

Fortunately, some chemotherapy drugs seem to be well tolerated by the fetus during the second and third trimesters. These drugs include **fluorouracil**, **doxorubicin** (Adriamycin), **bleomycin**, **vinblastine**, **dacarbazine**, and **cyclophosphamide**. Even so, the fetus is at risk for low birthweight, miscarriage, and premature birth. Chemotherapy is rarely administered near term. Treatment at this point may be delayed until after delivery, and during this time period the placenta is less able to effectively excrete the drug(s). Drugs that may not harm the fetus *in utero* may be harmful if consumed via the breast milk. For this reason, breastfeeding is usually discouraged. **Methotrexate** is known to be teratogenic and so is not given in pregnancy. **Daunorubicin** and **cytarabine** are teratogenic in the first trimester. There is not enough known about **paclitaxel** and pregnancy to consider its use. Of additional concern for the pregnant woman receiving treatment for cancer is the effects on the fetus

QUESTIONS TO ASK THE DOCTOR

- What type and stage is my cancer?
- If I were not pregnant how would you treat it?
- Since I am pregnant, how do you suggest treating it?
- What is the expected effect on my baby from the treatment?
- What is my prognosis?
- What part of the treatment can safely wait until after I deliver?
- What side effects can I expect from the treatment?
- What are the risks to me from this treatment?
- How will these treatments be managed?
- What long-term effects will my treatment have on my child?
- What alternative treatments are available to help me?
- Which members of my team are experienced in cancer and pregnancy?

of any medications that may be used to deal with treatment side effects.

Alternative and complementary therapies

A pregnant woman has many limitations on taking medications during pregnancy in order to protect the fetus. Medication that would ordinarily be available to deal with the side effects of cancer treatment may be harmful to the fetus. A helpful resource on the patient's interdisciplinary team is a practitioner with experience in the safe use of complementary therapies for cancer during pregnancy. Mind/body techniques such as guided imagery and meditation can help decrease some of the stress of this time. Acupuncture has been shown to be effective in dealing with the nausea associated with chemotherapy. Support groups can also be a great source of strength and information.

The area in which a cancer originates in the body. Once cancer spreads (metastasizes), the new tumors are called secondary tumors, or metastases.

Kate Kretschmann

Procarbazine

Definition

Procarbazine is an anticancer agent that kills cancer cells, also known by the brand name Matulane. It has received approval by the Food and Drug Administration (FDA) for the treatment of advanced **Hodgkin's disease** in combination with other anticancer drugs.

Purpose

Procarbazine is used in the treatment of various cancers, although the best established usage is with Hodgkin's disease. Other cancers in which procarbazine is sometimes used include other lymphomas, brain tumors, skin cancer, lung cancer, and **multiple myeloma**.

Description

Procarbazine is a cytotoxic drug, which means that it kills cancer cells. Procarbazine works by interfering with way the DNA and RNA in cells produce proteins by binding to it in the cells.

KEY TERMS

Cytotoxic drug—An anticancer drug that acts by killing or preventing the division of cells.

DNA (deoxyribonucleic acid)—An acid found in all living cells that contains tiny bits of genetic information.

Platelets—Components of the blood involved in clotting.

RNA (ribonucleic acid)—The tiny substances that transmit messages in the DNA to other elements in the cell.

Recommended dosage

Procarbazine is often given at a dose of 60 to 100 mg per square meter of body surface area for ten to fourteen days of each course of therapy. In addition, patients who have had pre-existing problems with liver, kidney, or bone marrow function may receive reduced doses.

Precautions

While on therapy with procarbazine, patients should not drink alcohol because it may interact with the drug to cause a flushed and hot sensation. Certain foods such as chocolate, fava beans, imported beer, Chianti wines, and ripe cheeses (camembert, cheddar, emmenthaler, stilton), caviar, pickled herring, fermented sausages (bologna, pepperoni, salami, summer sausage), should be avoided as they may cause a dangerous increase in blood pressure if eaten while receiving procarbazine.

Side effects

A carefully monitored side effect of procarbazine is a decrease in the white blood cells that fight infection and the platelet cells that prevent bleeding. The most severe side effect is **nausea and vomiting**. Patients should adhere to the antiemetic regimen prescribed for them to prevent this side effect. There may be neurologic side effects such as confusion, sleepiness, **depression**, nightmares, agitation, and nervousness. Patients may have reproductive dysfunction.

Interactions

Procarbazine has numerous drug interactions. Therefore, it is important that patients alert their physicians to all medications they are taking (prescription, over-the-counter, or herbal) prior to starting treatment with procarbazine or any other drug.

Prochlorperazine *see* **Antiemetics**

Promethazine *see* **Antiemetics**

Prostate cancer

Definition

Prostate cancer is a disease in which cells in the prostate gland become abnormal and start to grow uncontrollably, forming tumors.

Description

Prostate cancer is a malignancy of one of the major male sex glands. Along with the testicles and the seminal vesicles, the prostate secretes the fluid that makes up semen. The prostate is about the size of a walnut and lies just behind the urinary bladder. A tumor in the prostate interferes with proper control of the bladder and normal sexual functioning. Often the first symptom of prostate cancer is difficulty in urinating. However, because a very common, non-cancerous condition of the prostate, benign prostatic hyperplasia (BPH), also causes the same problem, difficulty in urination is not necessarily due to cancer.

Cancerous cells within the prostate itself are generally not deadly on their own. However, as the tumor grows, some of the cells break off and spread to other parts of the body through the lymph or the blood, a process known as **metastasis**. The most common sites for prostate cancer to metastasize are the seminal vesicles, the lymph nodes, the lungs, and various bones around the hips and the pelvic region. The effects of these new tumors are what can cause death.

Demographics

Prostate cancer is the most commonly diagnosed malignancy among adult males in Western countries. Although prostate cancer is often very slow growing, it can be aggressive, especially in younger men. Given its slow growing nature, many men with the disease die of other causes rather than from the cancer itself.

Prostate cancer affects African-American men twice as often as white men; the mortality rate among African-

Americans is also two times higher. African-Americans have the highest rate of prostate cancer of any world population group.

Causes and symptoms

The precise cause of prostate cancer is not known. However, there are several known risk factors for disease including age over 55, African-American heritage, a family history of the disease, occupational exposure to cadmium or rubber, and a high-fat diet. Men with high plasma **testosterone** levels may also have an increased risk for developing prostate cancer.

Frequently, prostate cancer has no symptoms and the disease is diagnosed when the patient goes for a routine screening examination. However, when the tumor is big or the cancer has spread to the nearby tissues, the following symptoms may be seen:

- weak or interrupted flow of the urine
- frequent urination (especially at night)
- difficulty starting urination
- inability to urinate
- pain or burning sensation when urinating
- blood in the urine
- persistent pain in lower back, hips, or thighs (bone pain)
- painful ejaculation

Diagnosis

Prostate cancer is curable when detected early. Yet the early stages of prostate cancer are often asymptomatic, so the disease often goes undetected until the patient has a routine physical examination. Diagnosis of prostate cancer can be made using some or all of the following tests.

Digital rectal examination (DRE)

In order to perform this test, the doctor puts a gloved and lubricated finger (digit) into the rectum to feel for any lumps in the prostate. The rectum lies just behind the prostate gland, and a majority of prostate tumors begin in the posterior region of the prostate. If the doctor does detect an abnormality, he or she may order more tests in order to confirm these findings.

Blood tests

Blood tests are used to measure the amounts of certain protein markers, such as prostate-specific antigen (PSA), found circulating in the blood. The cells lining the prostate generally make this protein and a small amount can be detected normally in the bloodstream. In contrast, prostate cancers produce a lot of this protein, significantly raising the circulating levels. A finding of a PSA level higher than normal for the patient's age group therefore suggests that cancer is present.

Transrectal ultrasound

A small probe is placed in the rectum and sound waves are released from the probe. These sound waves bounce off the prostate tissue and an image is created. Since normal prostate tissue and prostate tumors reflect the sound waves differently, the test is an efficient and accurate way to detect tumors. Though the insertion of the probe into the rectum may be slightly uncomfortable, the procedure is generally painless and only takes 20 minutes.

Prostate biopsy

If cancer is suspected from the results of any of the above tests, the doctor will remove a small piece of prostate tissue with a hollow needle. This sample is then checked under the microscope for the presence of cancerous cells. Prostate **biopsy** is the most definitive diagnostic tool for prostate cancer, and this procedure is done quickly and with little pain or discomfort.

Prostate cancer can also be diagnosed based on the examination of the tissue removed during a transurethral resection of the prostate (TURP). This procedure is performed to help alleviate the symptoms of BPH, a benign enlargement of the prostate. Like a biopsy, this is a definitive diagnostic method for prostate cancer.

X rays and imaging techniques

A chest **x ray** may be ordered to determine whether the cancer has spread to the lungs. Imaging techniques (such as **computed tomography** (CT) scans and **magnetic resonance imaging** (MRI)), where a computer is used to generate a detailed picture of the prostate and areas nearby, may be done to get a clearer view of the internal organs. A bone scan may be used to check whether the cancer has spread to the bone.

Treatment team

Prostate cancer is often treated by a team of specialists including a urologist (who may or may not perform surgery), a surgeon (if surgical treatment is used and it is not performed by the urologist), a medical oncologist, and, if **radiation therapy** is used, a radiation oncologist.

Clinical staging, treatments, and prognosis

Once cancer is detected during the microscopic examination of the prostate tissue during a biopsy or TURP, doctors will determine two different numerical scores that will help define the patient's treatment and prognosis.

Tumor grading

Initially, the pathologist will grade the tumor based on his or her examination of the biopsy tissue. The pathologist scores the appearance of the biopsy sample using the Gleason system. This system uses a scale of one to five based on the sample's similarity or dissimilarity to normal prostate tissue. If the tissue is very similar to normal tissue, it is still well differentiated and given a low grading number, such as one or two. As the tissue becomes more and more abnormal (less and less differentiated), the grading number increases, up to five. Less differentiated tissue is considered more aggressive and more likely to be the source of metastases.

The Gleason grading system is best predictive of the prognosis of a patient if the pathologist gives two scores to a particular sample—a primary and a secondary pattern. The two numbers are then added together and that is the Gleason score reported to the patient. Thus, the lowest Gleason score available is two (a primary and secondary pattern score of one each). A typical Gleason score is five (which can be a primary score of two and a secondary score of three or visa-versa). The highest score available is 10, with a pure pattern of very undifferentiated tissue, that is, of grade five. The higher the score, the more abnormal behavior of the tissue, the greater the chance for metastases, and the more serious the prognosis after surgical treatment. A study found that the ten-year cancer survival rate without evidence of disease for grade two, three, and four cancers is 94% of patients. The rate is 91% for grade five cancers, 78% for grade six, 46% for grade seven, and 23% for grade eight, nine, and ten cancers.

Cancer staging

The second numeric score determined by the doctor will be the stage of the cancer, which takes into account the grade of the tumor determined by the pathologist. Based on the recommendations of the American Joint Committee on Cancer (AJCC), two kinds of data are used for staging prostate cancer. Clinical data is based on the external symptoms of the cancer, while histopathological data is based on surgical removal of the prostate and examination of its tissues. Clinical data is most useful to make treatment decisions, while pathological data is the best predictor of prognosis. For this reason, the staging of prostate cancer takes into account both clinical and histopathologic information. Specifically, doctors look at tumor size (T), lymph node involvement (N), the presence of visceral (internal organ) involvement (metastasis = M), and the grade of the tumor (G).

The classification of tumor as T1 means the cancer that is confined to the prostate gland and the tumor that is too small to be felt during a DRE. T1 tumors are often found after examination of tissue removed during a TURP. The T1 definition is subdivided into those cancers that show less than 5% cancerous cells in the tissue sample (T1a) or more than 5% cancerous cells in the tissue sample (T1b). T1c means that the biopsy was performed based on an elevated PSA result. The second tumor classification is T2, where the tumor is large enough to be felt during the DRE. T2a indicates that only the left or the right side of the gland is involved, while T2b means both sides of the prostate gland has tumor.

With a T3 tumor, the cancer has spread to the connective tissue near the prostate (T3a) or to the seminal vesicles as well (T3b). T4 indicates that cancer has spread within the pelvis to tissue next to the prostate such as the bladder's sphincter, the rectum, or the wall of the pelvis. Prostate cancer tends to spread next into the regional lymph nodes of the pelvis, indicated as N1. Prostate cancer is said to be at the M1 stage when it has metastasized outside the pelvis in distant lymph nodes (M1a), bone (M1b) or organs such as the liver or the brain (M1c). Pain, **weight loss**, and **fatigue** often accompany the M1 stage.

The grade of the tumor (G) can be assessed during a biopsy, TURP surgery, or after removal of the prostate. There are three grades recognized: G1, G2, and G3, indicating the tumor is well, moderately, or poorly differentiated, respectively. The G, LN, M descriptions are combined with the T definition to determine the stage of the prostate cancer.

- Stage I prostate cancer comprises patients who are T1a, N0, M0, G1.
- Stage II includes a variety of condition combinations including T1a, N0, M0, G2, 3 or 4; T1b, N0, M0, Any G; T1c, N0, M0, Any G; T1, N0, M0, Any G or T2, N0, M0, Any G.
- Stage III prostate cancer occurs when conditions are T3, N0, M0, any G.
- Stage IV is T4, N0, M0, any G; any T, N1, M0, any G; or any T, any N, M1, Any G.

Prognosis

The prognosis for cancers at Stages I and II is very good. For men treated with stage I or stage II disease, over 95% are alive after five years. Although the cancers

of Stage III are more advanced, the five-year prognosis is still good, with 70% of men diagnosed at this stage still living. The spread of the cancer into the pelvis (T4), lymph (N1), or distant locations (M1) are very significant events, as the five-year survival rate drops to 30% for Stage IV.

Treatment options

The doctor and the patient will decide on the treatment mode after considering many factors. For example, the patient's age, the stage of the disease, his general health, and the presence of any co-existing illnesses have to be considered. In addition, the patient's personal preferences and the risks and benefits of each treatment protocol are also taken into account before any decision is made.

SURGERY For stage I and stage II prostate cancer, surgery is the most common method of treatment because it theoretically offers the chance of completely removing the cancer from the body. Radical **prostatectomy** involves complete removal of the prostate. The surgery can be done using a perineal approach, where the incision is made between the scrotum and the anus, or using a retropubic approach, where the incision is made in the lower abdomen. Perineal approach is also known as nerve-sparing prostatectomy, as it is thought to reduce the effect on the nerves and thus reduce the side effects of impotence and **incontinence**. However, the retropubic approach allows for the simultaneous removal of the pelvic lymph nodes, which can give important pathological information about the tumor spread.

The drawback to surgical treatment for early prostate cancer is the significant risk of side effects that impact the quality of life of the patient. Even using nerve-sparing techniques, studies by the National Cancer Institute (NCI) found that 60% to 80% of men treated with radical prostatectomy reported themselves as impotent (unable to achieve an erection sufficient for sexual intercourse) two years after surgery. This side effect can be sometimes countered by prescribing sildenafil citrate (Viagra). Furthermore, 8% to 10% of patients were incontinent in that time span. Despite the side effects, the majority of men were reported as satisfied with their treatment choice. Additionally, there is some evidence that the skill and the experience of the surgeon are central factors in the ultimate side effects seen.

A second method of surgical treatment of prostate cancer is cryosurgery, or cryotherapy. Guided by ultrasound, surgeons insert up to eight cryoprobes through the skin and into close proximity with the tumor. Liquid nitrogen (temperature of -320.8 degrees F, or -196 C) is circulated through the probe, freezing the tumor tissue. In prostate surgery, a warming tube is also used to keep the urethra from freezing. Patients currently spend a day or two in the hospital following the surgery, but it could be an outpatient procedure in the near future. Recovery time is about one week. Side effects have been reduced in recent years, although impotence still affects almost all who have had cryosurgery for prostate cancer. Cryosurgery is considered a good alternative for those too old or sick to have traditional surgery or radiation treatments or when these more traditional treatments are unsuccessful. There is limited amount of information about the long-term efficacy of this treatment for prostate cancer.

RADIATION THERAPY Radiation therapy involves the use of high-energy x rays to kill cancer cells or to shrink tumors. It can be used instead of surgery for stage I and II cancer. The radiation can either be administered from a machine outside the body (external beam radiation), or small radioactive pellets can be implanted in the prostate gland in the area surrounding the tumor, called brachytherapy or interstitial implantation. Pellets containing radioactive iodine (I-125), palladium (Pd 103), or iridium (Ir 192) can be implanted on an outpatient basis, where they remain permanently. The radioactive effect of the seeds last only about a year.

The side effects of radiation can include inflammation of the bladder, rectum, and small intestine as well as disorders of blood clotting (coagulopathies). Impotence and incontinence are often delayed side effects of the treatment. A study indicated that bowel control problems were more likely after radiation therapy when compared to surgery, but impotence and incontinence were more likely after surgical treatment. Long-term results with radiation therapy are dependent on stage. A review of almost 1,000 patients treated with megavoltage irradiation showed 10-year survival rates to be significantly different by T-stage: T1 (79%), T2 (66%), T3 (55%), and T4 (22%). There does not appear to be a large difference in survival between external beam or interstitial treatments.

HORMONE THERAPY Hormone therapy is commonly used when the cancer is in an advanced stage and has spread to other parts of the body, such as stage III or stage IV. Prostate cells need the male hormone testosterone to grow. Decreasing the levels of this hormone or inhibiting its activity will cause the cancer to shrink. Hormone levels can be decreased in several ways. **Orchiectomy** is a surgical procedure that involves complete removal of the testicles, leading to a decrease in the levels of testosterone. Another method tricks the body by administering the female hormone estrogen. When estrogen is given, the body senses the presence of a sex hormone and stops making the male hormone testosterone. However, there are some unpleasant side effects to hormone therapy. Men may have "hot flashes," enlarge-

ment and tenderness of the breasts, or impotence and loss of sexual desire, as well as blood clots, heart attacks, and strokes, depending on the dose of estrogen. Another side effect is osteoporosis, or loss of bone mass leading to brittle and easily fractured bones.

WATCHFUL WAITING Watchful waiting means no immediate treatment is recommended, but doctors keep the patient under careful observation. This is often done using periodic PSA tests. This option is generally used in older patients when the tumor is not very aggressive and the patients have other, more life-threatening, illnesses. Prostate cancer in older men tends to be slow-growing. Therefore, the risk of the patient dying from prostate cancer, rather than from other causes, is relatively small.

Alternative and complementary therapies

Alternative treatments that have been found helpful in coping with the emotional stress associated with prostate cancer include meditation, guided imagery, and relaxation techniques. Acupuncture is effective in relieving pain in some patients.

A variety of herbal products have been used to treat prostate cancer, including various compounds used in traditional Chinese medicine as well as single agents like Reishi mushrooms (*Ganoderma lucidum*). One herbal compound that was under investigation by the National Center for Complementary and Alternative Medicine (NCCAM) as a possible treatment for prostate cancer was PC-SPES, a mixture of eight herbs adapted from traditional Chinese medicine. In the summer of 2002, however, NCCAM put its studies of PC-SPES on hold when the Food and Drug Administration (FDA) determined that samples of the product were contaminated with undeclared prescription drug ingredients. PC-SPES was withdrawn from the American market in late 2002.

Coping with cancer treatment

The treatment process for prostate cancer can be a physically and emotionally exhausting time. Here are six general suggestions that can help make the process easier. Patients should:

- put their faith and trust in their doctors once a treatment course has been chosen
- remember that a patient is never without power and rights during the course of treatment
- put practical affairs in order
- closely monitor each step of the treatment
- keep close family and friends informed and delegate responsibilities as necessary
- work to make visits pleasant and comfortable

This patient's prostate cancer has metastasized, swelling the lymph nodes in the left groin. *(Photograph by Dr. P. Marazzi. Photo Researchers, Inc. Reproduced by permission.)*

- be careful to eat, sleep, exercise, and conduct daily activities in a healthy manner

Clinical trials

Patients with extraprostatic disease are suitable candidates for **clinical trials**. One trial is the testing of a vaccine (GVAX) that causes the body to mount an **immune response** against all prostate cells. As the prostate is a nonessential organ, the destruction of the normal cells with the tumor cells is not a problem. The vaccine was made using cancer cells from a tumor that had been genetically engineered to express granulocyte/macrophage colony-stimulating factor (GM-CSF), a potent activator of the entire immune system. The additional protein jumpstarted the immune response against the prostate cells upon vaccination and resulted in antitumor immune response.

Other trials for prostate cancer include evaluation of combination therapies, such as postoperative radiation delivery, use of cytotoxic agents, and hormonal treatment using luteinizing hormone-releasing hormone (LHRH) agonists and/or **antiandrogens** to shut down the growth of the hormone-dependent tumors. Other drugs that are being tested as of 2003 are chemoprotective agents like amifostine (Ethyol), which are given to prostate cancer patients to counteract the harmful side effects of radiation treatment.

Prevention

Because the cause of the cancer is not known, there is no definite way to prevent prostate cancer. Given its common occurrence and the low cost of screening, the American Cancer Society (ACS) and the National Comprehensive Cancer Network (NCCN) recommends that all men over age 40 have an annual rectal exam and that men

KEY TERMS

Antiandrogen—A substance that blocks the action of androgens, the hormones responsible for male characteristics. Used to treat prostate cancers that require male hormones for growth.

Benign Prostate Hyperplasia (BPH)—A non-cancerous swelling of the prostate.

Brachytherapy—A method of treating cancers, such as prostate cancer, involving the implantation near the tumor of radioactive seeds.

Gleason Grading System—A method of predicting the tendency of a tumor in the prostate to metastasize based on how similar the tumor is to normal prostate tissue.

Granulocyte/macrophage colony stimulating factor (GM-CSF)—Also known as sargramostim, a substance produced by cells of the immune system that stimulates the attack upon foreign cells. Used to treat prostate cancers as a genetically engineered component of a vaccine that stimulates the body to attack prostate tissue.

Histopathology—The study of diseased tissues at a minute (microscopic) level.

Luteinizing hormone releasing hormone (LHRH) agonist—A substance that blocks the action of LHRH, a hormone that stimulates the production of testosterone (a male hormone) in men. Used to treat prostate cancers that require testosterone for growth.

Orchiectomy—Surgical removal of the testes that eliminates the production of testosterone to treat prostate cancer.

Prostate-Specific Antigen—A protein made by the cells of the prostate that is increased by both BPH and prostate cancer.

Radical Prostatectomy—Surgical removal of the entire prostate, a common method of treating prostate cancer.

Transurethral resection of the prostate (TURP)—Surgical removal of a portion of the prostate through the urethra, a method of treating the symptoms of an enlarged prostate, whether from BPH or cancer.

have an annual PSA test beginning at age 50. African-American men and men with a family history of prostate cancer, who have a higher than average risk, should begin annual PSA testing even earlier, starting at age 45.

QUESTIONS TO ASK THE DOCTOR

- How do my age, general health, and other medical conditions affect my treatment choices?
- What are the T, N, and M stages of my cancer and how do they influence my treatment options?
- How do the Gleason score of my cancer and my blood prostate-specific antigen (PSA) level predict my outlook for survival and affect treatment options?
- What are the likely side effects of each proposed therapy and how will they affect my quality of life?
- What can be done to help manage the side effects of treatment?

However, mandatory screening for prostate cancer is controversial. Because the cancer is so slow growing, and the side effects of the treatment can have significant impact on patient quality of life, some medical organizations question the wisdom of yearly exams. Some organizations have even noted that the effect of screening is discovering the cancer at an early stage when it may never grow to have any outward effect on the patient during this lifetime. Nevertheless, the NCI reports that the current aggressive screening methods have achieved a reduction in the death rate of prostate cancer of about 2.3% for African-Americans and about 4.6% for Caucasians since the mid-1990s, with a 20% increase in overall survival rate during that period.

A low-fat diet may slow the progression of prostate cancer. To reduce the risk or progression of prostate cancer, the American Cancer Society recommends a diet rich in fruits, vegetables and dietary fiber, and low in red meat and saturated fats.

Special concerns

The availability of an early detection system for prostate cancer with the development of the PSA serum test has complicated the treatment of this disease. Early detection of an often slow-growing cancer, where treatment can significantly impact the quality of life of the patient, can be complicated. Long-term studies are currently in progress that should provide the first real quantitative information about the relative efficacy of the different treatment options, the actual occurrence of side effects, and the comparative benefits of watchful

waiting treatment compared with more aggressive action.

Prostatectomy

Definition

Prostatectomy is surgical removal of part of the prostate gland (transurethral resection, a procedure performed to relieve urinary symptoms caused by benign enlargement), or all of the prostate (radical prostatectomy, the curative surgery most often used to treat **prostate cancer**).

Purpose

Benign disease

When men reach their mid-40s, the prostate gland begins to enlarge. This condition, benign prostatic hyperplasia (BPH) is present in more than half of men in their 60s and as many as 90% of those over 90. Because the prostate surrounds the urethra, the tube leading urine from the bladder out of the body, the enlarging prostate narrows this passage and makes urination difficult. The bladder does not empty completely each time a man urinates, and, as a result, he must urinate with greater frequency, night and day. In time, the bladder can overfill, and urine escapes from the urethra, resulting in **incontinence**. An operation called transurethral resection of the

prostate (TURP) relieves symptoms of BPH by removing the prostate tissue that is blocking the urethra. No incision is needed. Instead a tube (retroscope) is passed through the penis to the level of the prostate, and tissue is either removed or destroyed, so that urine can freely pass from the body.

Malignant disease

Prostate cancer is the single most common form of non-skin cancer in the United States and the most common cancer in men over 50. Half of men over 70 and almost all men over the age of 90 have prostate cancer, and the American Cancer Society estimates that 198,000 new cases will be diagnosed in a given year. This condition does not always require surgery. In fact, many elderly men adopt a policy of "watchful waiting," especially if their cancer is growing slowly. Younger men often elect to have their prostate gland totally removed along with the cancer it contains—an operation called radical prostatectomy. The two main types of this surgery, radical retropubic prostatectomy and radical perineal prostatectomy, are performed only on patients whose cancer is limited to the prostate. If cancer has broken out of the capsule surrounding the prostate gland and spread in the area or to distant sites, removing the prostate will not prevent the remaining cancer from growing and spreading throughout the body.

Precautions

Potential complications of TURP include bleeding, infection, and reactions to general or regional anesthesia. About one man in five will need to have the operation again within 10 years.

Open (incisional) prostatectomy for cancer should not be done if the cancer has spread beyond the prostate, as serious side effects may occur without the benefit of removing all the cancer. If the bladder is retaining urine, it is necessary to insert a catheter before starting surgery. Patients should be in the best possible general condition before radical prostatectomy. Before surgery, the bladder is inspected using an instrument called a cystoscope to help determine the best surgical technique to use, and to rule out other local problems.

Description

TURP

This procedure does not require an abdominal incision. With the patient under either general or spinal anesthesia, a cutting instrument or heated wire loop is inserted to remove as much prostate tissue as possible and seal blood vessels. The excised tissue is washed into the bladder, then flushed out at the end of the operation. A catheter is left in the bladder for one to five days to drain urine and blood. Advanced laser technology enables surgeons to safely and effectively burn off excess prostate tissue blocking the bladder opening with fewer of the early and late complications associated with other forms of prostate surgery. This procedure can be performed on an outpatient basis, but urinary symptoms do not improve until swelling subsides several weeks after surgery.

Radical prostatectomy

RADICAL RETROPUBIC PROSTATECTOMY This is a useful approach if the prostate is very large, or cancer is suspected. With the patient under general or spinal anesthesia or an epidural, a horizontal incision is made in the center of the lower abdomen. Some surgeons begin the operation by removing pelvic lymph nodes to determine whether cancer has invaded them, but recent findings suggest there is no need to sample them in patients whose likelihood of lymph node metastases is less than 18%. A doctor who removes the lymph nodes for examination will not continue the operation if they contain cancer cells, because the surgery will not cure the patient. Other surgeons remove the prostate gland before examining the lymph nodes. A tube (catheter) inserted into the penis to drain fluid from the body is left in place for 14–21 days.

Originally, this operation also removed a thin rim of bladder tissue in the area of the urethral sphincter—a muscular structure that keeps urine from escaping from the bladder. In addition, the nerves supplying the penis often were damaged, and many men found themselves impotent (unable to achieve erections) after prostatectomy. A newer surgical method called potency-sparing radical prostatectomy preserves sexual potency in 75% of patients and fewer than 5% become incontinent following this procedure.

RADICAL PERINEAL PROSTATECTOMY This procedure is just as curative as radical retropubic prostatectomy but is performed less often because it does not allow the surgeon to spare the nerves associated with erection or, because the incision is made above the rectum and below the scrotum, to remove lymph nodes. Radical perineal prostatectomy is sometimes used when the cancer is limited to the prostate and there is no need to spare nerves or when the patient's health might be compromised by the longer procedure. The perineal operation is less invasive than retropubic prostatectomy. Some parts of the prostate can be seen better, and blood loss is limited. The absence of an abdominal incision allows patients to recover more rapidly. Many urologic surgeons have not been trained to perform this procedure.

Radical prostatectomy procedures last one to four hours, with radical perineal prostatectomy taking less time than radical retropubic prostatectomy. The patient remains in the hospital three to five days following surgery and can return to work in three to five weeks. Ongoing research indicates that laparoscopic radical prostatectomy may be as effective as open surgery in treatment of early-stage disease.

Cryosurgery

Also called **cryotherapy** or cryoablation, this minimally invasive procedure uses very low temperatures to freeze and destroy cancer cells in and around the prostate gland. A catheter circulates warm fluid through the urethra to protect it from the cold. When used in connection with ultrasound imaging, cryosurgery permits very precise tissue destruction. Traditionally used only in patients whose cancer had not responded to radiation, but now approved by Medicare as a primary treatment for prostate cancer, cryosurgery can safely be performed on older men, on patients who are not in good enough general health to undergo radical prostatectomy, or to treat recurrent disease. Recent studies have shown that total cryosurgery, which destroys the prostate, is at least as effective as radical prostatectomy without the trauma of major surgery.

Preparation

As with any type of major surgery done under general anesthesia, the patient should be in optimal condition. Most patients having prostatectomy are in the age range when cardiovascular problems are frequent, making it especially important to be sure that the heart is beating strongly, and that the patient is not retaining too much fluid. Because long-standing prostate disease may cause kidney problems from urine "backing up," it also is necessary to be sure that the kidneys are working properly. If not, a period of catheter drainage may be necessary before doing the surgery.

Aftercare

Following TURP, a catheter is placed in the bladder to drain urine and remains in place for two to three days. A solution is used to irrigate the bladder and urethra until the urine is clear of blood, usually within 48 hours after surgery. Whether **antibiotics** should be routinely given remains an open question. Catheter drainage also is used after open prostatectomy. The bladder is irrigated only if blood clots block the flow of urine through the catheter. Patients are given intravenous fluids for the first 24 hours, to ensure good urine flow. Patients resting in bed for long periods are prone to blood clots in their legs (which can pass to the lungs and cause serious breathing problems). This can be prevented by elastic stockings and by periodically exercising the patient's legs. The patient remains in the hospital one to two days following surgery and can return to work in one to two weeks.

Risks

The complications and side effects that may occur during and after prostatectomy include:

- Excessive bleeding, which in rare cases may require blood transfusion.
- Incontinence when, during retropubic prostatectomy, the muscular valve (sphincter) that keeps urine in the bladder is damaged. Less common today, when care is taken not to injure the sphincter.
- Impotence, occurring when nerves to the penis are injured during the retropubic operation. Today's "nerve-sparing" technique has drastically cut down on this problem.
- Some patients who receive a large volume of irrigating fluid after TURP develop high blood pressure, vomiting, trouble with their vision, and mental confusion. This condition is caused by a low salt level in the blood, and is reversed by giving salt solution.
- A permanent narrowing of the urethra called a stricture occasionally develops when the urethra is damaged during TURP.

KEY TERMS

BPH—Benign prostatic hypertrophy, a very common noncancerous cause of prostatic enlargement in older men.

Catheter—A tube that is placed through the urethra into the bladder in order to provide free drainage of urine and blood following either TUR or open prostatectomy.

Cryosurgery—In prostatectomy, the use of a very low-temperature probe to freeze and thereby destroy prostatic tissue.

Impotence—The inability to achieve and sustain penile erections.

Incontinence—The inability to retain urine in the bladder until a person is ready to urinate voluntarily.

Prostate gland—The gland surrounding the male urethra just below the base of the bladder. It secretes a fluid that constitutes a major portion of the semen.

Urethra—The tube running from the bladder to the tip of the penis that provides a passage for eliminating urine from the body.

- There is about a 34% chance that the cancer will recur within 10 years of the procedure. In addition, about 25% of patients experience what is known as biochemical recurrence, which means that the level of prostate-specific antigen (PSA) in the patient's blood serum begins to rise rapidly. Recurrence of the tumor or biochemical recurrence can be treated with radiation therapy or androgen deprivation therapy.

Normal results

In patients with BPH who have the TURP operation, urination should become much easier and less frequent, and dribbling or incontinence should cease. In patients having radical prostatectomy for cancer, a successful operation will remove the tumor and prevent its spread to other areas of the body (**metastasis**). If examination of lymph nodes shows that cancer already had spread beyond the prostate at the time of surgery, other measures are available to control the tumor.

Technology

Responding to spoken instructions, a specially engineered robot has assisted in more than 500 operations to remove the prostate glands of cancer patients. Used by surgeons in the United States and Europe, the AESOP system is the first surgical robot approved by the Food and Drug Administration (FDA). By positioning a slender optical tube (endoscope) that is passed through the patient's body, the robotic arm allows the surgeon to view the minimally invasive surgery on a video monitor and use both hands to improve surgical precision and results while minimizing side effects. Patients spend about 12 hours in the hospital and return to work within two days.

Research

Early findings released by the Prostate Cancer Outcomes Study (PCOS) confirm that radical prostatectomy results in significant sexual dysfunction and some loss of urinary control. Initiated by the National Cancer Institute (NCI) in 1994, PCOS is the first systematic evaluation of how primary cancer treatments affect patients' quality of life.

Protein electrophoresis

Definition

Protein electrophoresis is a technique used to separate the different component proteins (fractions) in a mixture of proteins, such as a blood sample, on the basis of differences in how the components move through a fluid-filled matrix under the influence of an applied electric field.

Purpose

Protein electrophoresis is a **screening test** used to evaluate, diagnose, and monitor a variety of diseases and conditions through examination of the amounts and types of protein in a blood, urine, or cerebrospinal fluid (CSF) specimen.

Precautions

Certain other diagnostic tests or prescription medications can affect the protein electrophoresis results. The administration of a contrast dye used in some other tests may falsely elevate apparent protein levels. Drugs that can alter results include aspirin, bicarbonates, chlorpromazine (Thorazine), **corticosteroids**, isoniazid (INH), and neomycin (Mycifradin). The total serum protein concentration may also be affected by changes in the patient's posture or by the use of a tourniquet during the drawing of blood.

Because there is less protein in urine and CSF samples than in blood, these samples often must be concentrated before analysis. The added sample handling can lead to contamination and erroneous results. In collection of a CSF specimen, it is important that the sample not be contaminated with blood proteins that would invalidate the CSF protein measurements.

Description

Proteins—long chains of connected amino acids—are biologically important building-block chemicals that contain the elements carbon, hydrogen, nitrogen, and oxygen. Some proteins also contain sulfur, phosphorus, iron, iodine, selenium, or other trace elements. There are 22 amino acids commonly found in all proteins. The human body is capable of producing fourteen of these amino acids; the remaining eight are called essential amino acids, and must be obtained from food. Proteins are found in muscles, blood, skin, hair, nails, and the internal organs and tissues. Enzymes and antibodies are proteins, and many hormones are proteinlike. Electrophoresis is one of a variety of techniques that can be used to fractionate (separate) protein mixtures into individual component proteins.

The serum protein electrophoresis test requires a blood sample drawn by venipuncture (having blood drawn from a vein) performed in the doctor's office or on site at a medical laboratory. The urine protein electrophoresis test requires either an early morning urine sample or a 24-hour urine sample, according to the physician's request. A CSF specimen must be collected by **lumbar puncture** (spinal tap), generally performed by a physician as an outpatient procedure in a hospital. Because of risks associated with the lumbar-puncture procedure, the patient must sign a consent form, and should be prepared to remain for six to eight hours under observation.

Preparation

It is usually not necessary for the patient to restrict food or fluids before blood is drawn for a serum protein electrophoresis test; a four-hour fast is requested before drawing blood for lipoprotein testing. For protein electrophoresis on all types of samples, any factors that might affect test results, such as whether the patient is taking any medications, should be noted.

Aftercare

After a blood sample is drawn, a small bandage may be applied to the puncture site, and the patient may be cautioned about the possibility of fainting or of lightheadedness. Following lumbar puncture for the collection of CSF, the patient must be kept lying flat in the hospital under observation for at least six to eight hours.

Risks

Risks posed by the venipuncture are minimal but may include slight bleeding from the puncture site, the devel-

opment of a small bruise at the puncture site, or both. Other risks include fainting or lightheadedness after the sample is drawn. Lumbar puncture can lead to leakage of CSF from the puncture site, headache, infection, symptoms of meningitis, nausea, vomiting, or difficulty urinating. Rarely, pre-existing intracranial pressure can lead to brain herniation, resulting in brain damage or death.

Normal results

Blood proteins

Serum protein electrophoresis is used to determine the total serum protein concentration, which is an indication of the patient's hydration state: dehydration leads to high total serum protein concentration. Further, the levels of different blood proteins rise or fall in response to such disorders as cancer and associated protein-wasting syndromes, immune-system disorders, liver dysfunction, impaired nutrition, and chronic fluid-retaining conditions. The different types of blood proteins are separated into fractions of five distinct classes: albumin, alpha$_1$-globulins, alpha$_2$-globulins, beta-globulins, and gamma-globulins (immunoglobulins). In addition to standard protein electrophoresis, **immunoelectrophoresis** may be used to assess the blood levels of specific immunoglobulins. Immunoelectrophoresis is usually ordered when the serum protein electrophoresis test shows an unusually high amount of protein in the gamma-globulin fraction.

ALBUMIN Albumin, which is produced in the liver, is the most abundant blood protein. It makes a major contribution to the regulation of water movement between the tissues and the bloodstream. Albumin binds calcium, thyroid hormones, fatty acids, and many drugs, keeping them in the blood circulation and preventing them from being filtered out by the kidneys. Albumin levels can play a role in the effectiveness and toxicity of therapeutic drugs and in drug interactions.

GLOBULINS Serum globulins are separated in protein electrophoresis as four main fractions: alpha$_1$-, alpha$_2$-, beta-, and gamma-globulins.

- The major alpha$_1$-globulin is alpha$_1$-antitrypsin, produced by the lungs and liver. Alpha$_1$-antitrypsin deficiency is a marker of an inherited disorder characterized by an increased risk of emphysema.
- Alpha$_2$-globulins include serum haptoglobin, alpha$_2$-macroglobulin, and ceruloplasmin. Haptoglobin binds to hemoglobin, released from damaged red blood cells during hemolysis, to prevent its excretion by the kidneys. Alpha$_2$-macroglobulin accounts for about one third of the alpha$_2$-globulin fraction. Ceruloplasmin is involved in the storage and transport of copper and iron in the body.
- Beta-globulins include transferrin, low-density lipoproteins (LDL), and complement components. Transferrin transports dietary iron to the liver, spleen, and bone marrow. Low-density lipoprotein is the major carriers of cholesterol in the blood. Complement is a system of blood proteins involved in inflammatory response.
- The gamma-globulin fraction contains the immunoglobulins, a family of proteins that function as antibodies. Antibodies, in response to infection, allergic reactions, and organ transplants, recognize and bind foreign bodies, or antigens, to facilitate their destruction by the immune system. The **immune response** is regulated by a large number of antigen-specific gamma-globulins that fall into five main classes called IgG, IgA, IgM, IgB, and IgE. When the serum protein electrophoresis test demonstrates a significant deviation from the normal gamma-globulin levels, a supplemental test, immunoelectrophoresis, should be ordered to identify the specific globulin(s) involved.

The following serum protein electrophoresis reference values are representative; some variation among laboratories and specific methods is to be expected. (1 gm = approximately 0.02 pt and 1 dl = approximately 0.33 fluid oz.)

- Total protein: 6.4–8.3 g/dL
- Albumin: 3.5–5.0 g/dL
- Alpha$_1$-globulin: 0.1–0.3 g/dL
- Alpha$_2$ globulin: 0.6–1.0 g/dL
- Beta-globulin: 0.7–1.2 g/dL
- Gamma-globulin: 0.7–1.6 g/dL

Urinary proteins

Protein electrophoresis is performed on urine samples to classify disorders that cause protein loss via the kidneys. In urine, normally no globulins and less than 0.050 g/dL albumin are present.

Cerebrospinal fluid (CSF) proteins

In CSF, the total protein concentration is normally 0.015–0.045 g/dL, with gamma-globulin accounting for 3% to 12%. The main use of CSF protein electrophoresis testing is in the diagnosis of central nervous tumors and multiple sclerosis.

Abnormal results

Deviations in serum protein levels from reference levels are considered in conjunction with symptoms and results from other diagnostic procedures.

KEY TERMS

Acute-phase proteins—Proteins produced during the acute-phase response, a set of physiological changes that occur in response to biologic stress such as trauma or sepsis.

Albumin—A blood protein produced in the liver that helps to regulate water distribution in the body.

Antibodies—Immunoglobulin protein molecules produced by B cells during the immune response. Each antibody recognizes an individual antigen to trigger immune defenses.

Antigen—Foreign body that triggers immune response.

Bence-Jones protein—The Ig light chain, part of an immunoglobulin, that is detected by urine protein electrophoresis in the case of multiple myeloma.

Complement—A group of complex proteins of the beta-globulin type in the blood that bind to antibodies during anaphylaxis. In the complement cascade, each complement interacts with another in a pattern that causes fluid build-up in cells, leading to lysis (cell destruction).

Electrophoresis—A technique used to separate the proteins in a biological sample on the basis of differences in how the components move through a fluid-filled matrix under the influence of an applied electric field.

Globulins—A group of proteins in blood plasma whose levels can be measured by electrophoresis in order to diagnose or monitor a variety of serious illnesses.

Hemolysis—Also called hematolysis, the breakage of red blood cells and concomitant liberation of hemoglobin.

Lumbar puncture—Also called spinal tap, a procedure for the withdrawal of spinal fluid from the lumbar region of the spinal cord for diagnosis, or for injection of a dye for imaging, or for administering medication or an anesthetic.

Paraprotein—A paraprotein is an immunoglobulin produced by a clone of identical B cells.

Protein—Proteins, such as enzymes and antibodies, are biologically important molecules made of long chains of connected amino acids that contain the elements carbon, hydrogen, nitrogen, and oxygen. Certain proteins may also contain sulfur, phosphorus, iron, iodine, selenium, or other trace elements.

Albumin levels are increased in dehydration and decreased in malnutrition, pregnancy, liver disease, inflammatory diseases, and protein-losing states such as malabsorption syndrome and certain kidney disorders. Low serum albumin levels can indicate disease and can influence analysis of thyroid hormones and calcium.

Alpha$_1$-globulins are increased in inflammatory diseases and decreased or absent in juvenile pulmonary emphysema, a hereditary disease.

Alpha$_2$-globulins are increased in acute and chronic inflammation and nephrotic syndrome. Decreased values may indicate hemolysis (the release of hemoglobin from red blood cells). Low haptoglobin can indicate tumor **metastasis**, severe sepsis, or chronic liver disease. The concentration of macroglobulin is increased during nephrosis. Ceruloplasmin concentration is increased during pregnancy and decreased in Wilson's disease, a rare inherited condition that leads to accumulation of copper in the liver.

Beta-globulin levels are increased in **multiple myeloma** and also in conditions of high cholesterol (hypercholesterolemia), such as in atherosclerosis, and in iron deficiency **anemia**. Levels are decreased in coagulation disorders.

Gamma-globulin levels are increased in multiple myeloma. The levels are increased as well in chronic inflammatory disease and autoimmune conditions such as rheumatoid arthritis and systemic lupus erythematosus, cirrhosis, and acute and chronic infection. The gamma-globulins are decreased in leukemia, in a variety of genetic immune disorders, and in secondary immune deficiency related to steroid use or to severe infection. Immunoglobulin deficiency due to inherited disorders can range from partial or complete loss of a single immunoglobulin class to complete absence of all immunoglobulins.

Finding an individual (oligoclonal) band in the gamma fraction of the electrophoresis result indicates the presence of a paraprotein. Type IgG or IgA paraproteins associated with multiple myeloma may be found by serum protein electrophoresis testing; however, the tumor may also produce only Ig light chains that are removed from the blood by the kidneys. This Ig light chain (also known as the Bence-Jones protein) is

detected by urine protein electrophoresis and is found nearly exclusively in patients with multiple myeloma.

In urine samples, abnormal results other than the presence of the Bence-Jones protein indicate disruption of kidney function or acute inflammation. Hemoglobin and myoglobin are found in the urine of patients with infection or hemolysis.

An increase in total protein concentration in the CSF is often found with central nervous system (CNS) tumors and in meningitis.

Proteomics

Definition

Proteomics is the systematic study of all of the proteins in a cell, tissue, or organism.

Description

The term proteome was coined in 1994 to describe all of the proteins in a given cell, tissue, or organism. Proteomes are extremely complex and differ among individuals, cell types, and within the same cell depending on cell activity, stimuli, and disease. There are estimated to be between one and ten million different proteins in the human body. Relatively few of these proteins have been identified.

Proteomics is being developed for use in cancer diagnosis and treatment. A protein pattern or array from blood or a cancer cell eventually may be the primary means of diagnosing cancer. Although significant advances have been made in clinical studies, as of 2005, proteomics was not yet available in clinical settings.

Proteomics technology for cancer diagnosis and treatment identifies biomarkers—proteins and protein patterns in blood, urine, and tissue that can be used to detect:

- early cancers
- treatment response
- the likelihood of relapse after treatment

It is expected that proteomics will be used to:

- develop better cancer treatments
- predict the effects of various treatments
- develop individualized therapies for each patient

Proteomics has led to the identification of many biomarker proteins and the discovery of many new proteins in the blood. As of 2005, proteomics has been used to identify hundreds of proteins in the ovary, prostate, breast, and esophagus that increase or decrease as cells begin to grow abnormally.

Procedures

Progress in proteomics has been made possible by the development of new technologies including:

- high-resolution mass spectrometry (MS) that can sort out thousands of proteins and protein fragments on the basis of their molecular weight and electrical charge
- sophisticated artificial intelligence computer programs that can learn to identify the specific patterns of a few proteins present in a huge protein array
- laser capture microdissection microscopes that use low-energy laser beams and special transfer film to lift single cells from a tissue, to collect and analyze all of the proteins in the cell by (MS) and computer technology

A mass spectrometer consists of:

- an ionization source that removes electrons from (ionizes) the proteins and protein fragments in a sample so that they all have a positive charge
- a mass analyzer that measures the mass-to-charge ratio (m/z) of the ionized (charged) proteins and fragments, as gases under a vacuum
- a detector that determines the number of ions present at each m/z value

The result is a mass spectrum or chart with a series of spikes or peaks, each representing a charged protein fragment from the sample. The height of each peak represents the amount of that particular protein or fragment that is present in the sample. The size of the peaks and the distance between them is the protein pattern or array of the entire sample. Each spectrum may have more than 15,000 data points—one for every protein and protein fragment—with their molecular weight and intensity values reflecting their relative abundance in the sample.

Computers rapidly analyze the MS data searching for subtle differences among multiple protein patterns and for proteins that might serve as biomarkers. Once potential biomarkers are identified, the computer is trained to sort through the patterns of thousands of proteins for the few small protein biomarkers that can distinguish between cancer and control samples or between cancer protein patterns before and after treatment.

MS-based proteomic analysis is very fast. The entire process—from collecting a few drops of blood to the spectral analysis—can occur in less than one minute. Extremely small amounts of protein can be detected and hundreds of samples can be analyzed sequentially.

Laser capture microdissection microscopes enable scientists to use tissue removed from a patient by a **biopsy** to isolate pure samples of normal cells, precancerous cells, and tumor cells from a single tissue of a single patient. Analysis of the protein patterns from these cells enable researchers to study:

- patterns that may predict early-stage cancer
- how a particular treatment affects the network of proteins in a cell
- early signs of cancer drug toxicity
- mechanisms of drug resistance
- means for reducing side effects of treatment
- changes in protein patterns during tumor recurrenceIt may be possible to predict from the protein patterns which patients are likely to have an early toxic response to a treatment, so that doses can be lowered or a different treatment can be chosen.

Initially, researchers are concentrating on ovarian and prostate cancers, which usually are not detected in early stages when the cancer is progressing without symptoms. By using proteomics for early detection, tumors may be treated before they spread (metastasize) to other parts of the body. Scientists also are studying the most common, solid human tumors including breast, colon, lung, and pancreatic cancers.

Cancers

Ovarian cancer

More than 80% of ovarian cancers are not diagnosed until they have reached an advanced stage when the five-year-survival rate is 20% or less. However in the 20% of women whose **ovarian cancer** is diagnosed at an early stage, the prognosis is excellent, with a five-year-survival rate of over 95%.

In 2002 researchers used MS-based proteomics to examine the protein patterns in blood serum, obtained with a finger prick, from 50 patients with stage-I ovarian cancer and 66 controls who were either healthy or had a benign (non-cancerous) condition such as ovarian cysts, fibroids, endometriosis, or general inflammatory disease. Such conditions are much more common than ovarian cancer but may have symptoms that suggest the possibility of cancer. Out of the complex patterns of tens of thousands of serum proteins, the computer identified a specific combination of five proteins that could distinguish between the cancer patients and the controls. Using this identified sub-pattern, all of the cancer patients tested positive—a 100% sensitivity. Among the controls, 5% were false positives demonstrating a specificity of 95%.

In 2004, using higher-resolution MS, a different protein pattern, and a larger group of patients and controls, researchers were able to achieve 100% sensitivity and specificity for diagnosing ovarian cancer. However validation of the procedure on a large clinical sample is needed before a commercial test becomes available. These clinical studies are being carried out in high-risk clinics, in which many women are considering prophylactic oophorectomies—removal of the ovaries—to prevent ovarian cancer, because they have a family history of the disease or carry mutations in the BRCA genes that greatly increase their risk for breast and ovarian cancers.

As of 2005, a clinical trial also was underway comparing proteomics with standard CA-125 blood tests that use a single protein as a biomarker for ovarian cancer. The blood protein CA-125 may be elevated in women with benign conditions as well as ovarian cancer. Another ongoing clinical trial is attempting to use proteomics to predict the early recurrence of ovarian cancer.

The small low-level proteins that have proven useful for the proteomics of ovarian cancer have been found to accumulate on large carrier blood proteins such as albumin. Scientists have found that by extracting the carrier-protein fraction of the blood they can obtain much higher quantities of these biomarkers.

Prostate cancer

Prostate specific antigen (PSA) levels are used as a preliminary screen for **prostate cancer**. However 70–75% of men who undergo biopsies because of abnormal PSA levels do not have cancer. It has been difficult to rule-out cancer without a biopsy in patients with slightly elevated PSA levels (4–10 nanograms per ml). MS-based proteomics of the blood proteins in 167 patients with prostate cancer, 77 patients with benign prostate hyperplasia, and 82 healthy males correctly classified 96% of the samples as either prostate cancer or non-cancer including benign prostate hyperplasia. Most of the

cancers were correctly identified and the specificity was 71%, meaning that were a number of false positives. The test was effective in men with normal, slightly elevated, and high PSA levels. Thus proteomics may prove useful for choosing whether to perform a biopsy and may reduce the incidence of unnecessary biopsies.

Molecules called phosphates commonly are added to or removed from proteins to change their activity or function. Specific changes in phosphorylated proteins—those with attached phosphates—are believed to be important for prostate cancer progression. Researchers are studying whether changes in phosphorylation, as detected by MS-based proteomics, can be used as biomarkers for diagnosing the progression of prostate and other cancers.

Breast cancer

Proteomic studies on **breast cancer** have found a combination of three blood proteins that may be useful for discriminating between women with breast cancer, women with benign breast disease, and healthy women. About 70–80% of breast cancers originate in the mammary ducts—the thin tubes that lead to the nipples. Nipple aspirate fluid from these ducts has a higher concentration of breast-specific proteins than blood. Possible tumor-marker proteins from this fluid are being studied by proteomics.

A 2003 proteomics study successfully identified fluctuating levels of specific active proteins inside breast and ovarian tumor cells. This may help determine early in treatment whether a particular drug is effective in a given patient.

About 25–30% of women with breast cancer have high levels of the protein Her-2/neu on the surfaces of their cancer cells. The cancer drug **Herceptin** is an antibody that attaches to Her-2/neu and prevents the protein from promoting cancer cell growth. Ongoing proteomics studies are monitoring key signaling systems in cells that may be influenced by Herceptin and other cancer drugs that target specific molecules. Proteomics has been used to measure the levels of active and inactive signaling proteins in isolated cancer cells obtained from tumor biopsies before and at various times after drug treatment. It has been found that breast cancer patients with a poor prognosis have more of the active form of the protein AKT that promotes cell survival. Herceptin lowers this AKT levels, promoting tumor cell death.

Other cancers

A 2004 proteomics study found a protein pattern that may predict which people with familial adenomatous polyposis (FAP)—an inherited condition that often leads to colon cancer—will respond to the preventive drug celecoxib. Protein patterns from patients before and after drug treatment distinguished between those in which celecoxib decreased the number of colon polyps that are characteristic of FAB and those who did not respond to the drug. One particular protein peak appeared only in patterns from non-responsive patients. A few protein peaks changed significantly in all patients following treatment with celecoxib.

Scientists are searching for blood protein patterns that may predict a person's risk for prostate cancer, pancreatic cancer, and **melanoma**. Protein patterns have been found in tumor tissue from lung and bladder cancers that may be able to discriminate between cancerous and healthy tissues.

As of 2005 proteomics **clinical trials** were testing blood protein patterns to:

- determine the response to **radiation therapy** in patients with localized prostate cancer and identify patients who might benefit from aggressive treatment
- predict the development of **non-small cell lung cancer** in patients with suspicious lung abnormalities
- determine whether a patient has a type of **lymphoma** known as mycosis fungoides/cutaneous T-cell lymphoma

KEY TERMS

Biomarker—A distinctive biological indicator of a condition or process.

Biopsy—The removal of a small piece of tissue for examination.

Laser capture microdissection microscope—An instrument that uses low-energy laser beams and special transfer film to lift single cells from a tissue.

Mass spectroscopy, MS—A technique that separates mixtures of substances on the basis of molecular weight and electrical charge.

Mass-to-charge ratio, m/z—The ratio of the molecular mass of a substance to its electrical charge; used for protein separation by MS.

Phosphorylation—The enzymatic addition of a phosphate group to a protein.

Prostate specific antigen, PSA—A biomarker used as a preliminary screen for prostate cancer.

Protein array—The pattern of proteins in blood, tissue, or a cell as determined by MS.

Proteome—The collection of all of the proteins in a cell, tissue, or organism.

• predict whether patients with psoriasis or **cutaneous T-cell lymphoma** will remain in remission.

Psycho-oncology

Definition

Psycho-oncology is a broad-based approach to cancer therapy that treats the emotional, social, and spiritual distress which often accompanies cancer. According to Dr. Jimmie Holland, the founder of psycho-oncology, the field has two major emphases. The first is the study of cancer patients' psychological reactions to their illness at all stages of its course; the second is analysis of the emotional, spiritual, social, and behavioral factors that influence the risk of developing cancer and long-term survival following treatment. Some psycho-oncologists consider their field a subspecialty of psychiatry while others emphasize its multidisciplinary aspects. In addition to psychiatrists, departments of psycho-oncology in major cancer centers may include nurses, surgeons, bioethicists, social workers, psychologists, clergy, palliative care specialists, and volunteers.

Description

Psycho-oncology is a relatively new addition to the care of cancer patients. It began in the mid-1970s when Dr. Holland returned to the practice of psychiatry after her children were in school. Married to an oncologist,

she had noted that her husband's colleagues focused on the physical effects of the anticancer drugs they were giving their patients to the point of failing to take the patients' thoughts and emotions into account. To some extent this oversight was part of the medical culture of the 1950s and 1960s; at that time cancer carried a stigma because it had low rates of survival. Many doctors were taught in medical school to withhold a diagnosis of cancer from the patient on the grounds that the disease was virtually a death sentence and the truth would be unbearable. Such highly regarded newspapers as the *New York Times* even refused to print the words "breast cancer" when the founders of the Reach to Recovery program first wanted to insert notices of their meetings.

In the 1970s, however, this attitude of shame and secrecy was reversed, partly because of the patients' rights movement, but also because newer and more effective treatments for cancer came into use and the number of long-term survivors of cancer increased. In 1977 Dr. Holland started the first full-time psychiatric service in a cancer research center in order to study and treat the emotional and psychological crises experienced by cancer patients. She conducted some of the earliest research studies of the emotional impact of cancer on patients and their families.

In the early 2000s, psycho-oncology has become an accepted part of cancer treatment, with departments of psycho-oncology established in most major cancer centers in Canada and the United States. The field has its own journal, *Psycho-Oncology*, as well as national and international societies for interested professionals.

Special concerns

Special concerns in psycho-oncology include the feelings of guilt or anxiety expressed by many cancer patients that they cannot adopt or maintain the positive attitudes that some people believe are essential to fighting cancer. Such patients feel burdened by the notion—sometimes voiced by family members—that their literal survival depends on visualizations (usually visualizations of their immune system combating the cancer) or otherwise acting cheerful and upbeat. In addition, some extreme forms of New Age thought lead some people to "blame the victim" that is, to say such things to cancer patients as, "You must have subconsciously wanted to develop this cancer," or, "It's your bad karma—you must have done something bad in a previous existence to deserve this disease." Psycho-oncologists, however, do not regard mental attitudes toward cancer as the sole factor affecting long-term survival, and they do not insist that patients adopt a one-size-fits-all approach to coping with cancer. Dr. Holland's list of recommendations for coping with cancer emphasizes flexibility, as she urges patients to:

- Use coping techniques or patterns that have helped them in the past in dealing with the stresses of life. For example, someone who has been helped by talking through their problems with trusted friends or family members should not suddenly start to keep their problems to themselves in coping with cancer.
- Take the "one-day-at-a-time" approach in dealing with the symptoms and other problems that cancer brings with it. This approach, which is sometimes called "chunking it down," helps by keeping large-scale worries about the long-term future manageable.
- Seek out a doctor with whom they feel comfortable. A doctor/patient relationship based on trust and mutual respect makes it easier to ask appropriate questions and to be a full participant in treatment planning.
- Continue to draw on religious or spiritual beliefs and practices that have been helpful in the past. Patients who do not consider themselves religious or spiritual may still find comfort in activities that they found meaningful or inspiring, such as the performing arts or nature walks.
- Keep a notebook for recording dates of treatments, medication side effects, laboratory test results, x-ray findings, etc. This record can be valuable in monitoring or evaluating one's emotional ups and downs as well as changes in physical health.
- Keep a journal or diary for expressing feelings and emotional reactions. This record also may be useful in providing perspective.

Psycho-oncologists may also help patients deal with the increasing complexity of cancer therapy, as many patients have treatment teams consisting of several physicians in different subspecialties as well as social workers, nurses, clergy, and other professionals. Some patients experience the sheer number of caregivers involved in their treatment as an additional source of stress.

Treatments

Psycho-oncologists emphasize the importance of treating cancer patients as individuals with unique patterns of emotional responses to the disease as well as unique physical responses to medical and surgical treatments. Consequently, psycho-oncologists tailor their treatment to the needs and concerns of each patient. As of the early 2000s, psycho-oncologists may provide one or more of the following treatments for or services to cancer patients:

KEY TERMS

Bioethics—A field of study concerned with the moral and spiritual implications of medical research and treatments.

Distress—In general, any acute feeling of pain, anxiety, or sadness; in the context of psycho-oncology, any unpleasant emotion that interferes with a cancer patient's ability to cope with symptoms and treatment.

New Age thought—A general term for a set of beliefs that became popular in the 1970s but had been previously associated with the occult, secret doctrines and teachings, or paranormal phenomena. New Age writers commonly believe that the mind can control the body; some believe that this control includes disease processes.

Oncology—The medical specialty that deals with the development, diagnosis, and treatment of cancer.

Visualization—A technique for forming mental images or pictures of the healing process as a way of strengthening the immune system and/or fighting such disease agents as cancer cells or the AIDS virus.

QUESTIONS TO ASK YOUR DOCTOR

- How do you feel about my use of complementary or alternative therapies as part of my treatment program? Are there any that you would advise against?
- What reading materials or other resources would you recommend so that I can help myself cope with my symptoms and the side effects of cancer treatment?
- Where do you fit my emotional, psychological, and spiritual concerns into my treatment regimen?

- individual psychotherapy or counseling
- leading support groups for patients and family members
- crisis intervention
- medication management
- strategies for dealing with pain and other physical symptoms of cancer
- monitoring the patient's emotional distress level
- referrals to a pastoral counselor in the patient's faith tradition

Many psycho-oncologists use a pain scale, "distress thermometer," or self-administered questionnaires as a way of identifying the patient's specific areas of concern as well as monitoring his or her levels of distress at various points in the treatment process. Some commonly used questionnaires are the Mental Adjustment to Cancer (MAC) scale, first published in the United Kingdom in 1987; the Brief Symptom Inventory (BSI); and the Distress Management Screening Measure (DMSM), a newer scale that was tested in the United States in 2003–2004. Sample questions from these self-administered measures, as well as explanations of the treatments offered to cancer patients at different levels of emotional distress, can be found in *Distress*, a 32-page booklet available free of charge from the American Cancer Society and the National Comprehensive Cancer Network (NCCN).

Psycho-oncologists may also provide specialized counseling in the areas of death and bereavement or sex therapy if they have the appropriate training, or they may refer patients with these needs to qualified counselors in those fields.

Alternative and complementary therapies

Most psycho-oncologists support patients' use of complementary and alternative (CAM) therapies provided that they do not interfere with the patient's surgery, **chemotherapy**, or other mainstream treatments. Dr. Larry Dossey, a well-known expert in the field of alternative medicine, thinks that cancer patients are drawn to CAM treatments because they address questions about the larger meaning of illness that many patients have. He says, "The immense popularity of alternative therapies . . . may be due in large measure to the fact that they help people find meaning in their lives when they need it most." Significantly, several studies of cancer patients who have integrated CAM approaches into their treatment regimens have *not* found that these patients are more distressed or more likely to develop psychiatric disorders than patients who rely on conventional treatments alone.

As of 2005, the National Cancer Institute (NCI) and the National Center for Complementary and Alternative Medicine (NCCAM) are jointly funding **clinical trials** of several complementary and alternative treatments for cancer. Present trials include studies of yoga, Reiki, acupuncture, massage therapy (for cancer-related **fatigue**),

hyperbaric oxygen therapy, **mistletoe** extract, and pancreatic enzyme therapy (for pancreatic cancer). Details of these clinical trials are available on the NCCAM website.

New trends in research in psycho-oncology

Areas of particular concern to psycho-oncologists in the early 2000s include cultural differences that affect people's patterns of coping with cancer, and the long-term psychological effects of being a cancer survivor. With regard to the first, recent European studies suggest that English-speaking patients and patients from southern Europe have different styles of coping with cancer diagnosis and treatment even though both groups have similar percentages of highly distressed patients. With regard to survivorship, the Behavioral Research Center of the American Cancer Society is conducting a long-term study of cancer survivors' quality of life, with a special focus on their psychological adjustment and family relationships, to be completed in 2015.

Radiation therapy

Definition

Radiation therapy, sometimes called radiotherapy, x-ray therapy radiation treatment, cobalt therapy, electron beam therapy, or irradiation uses high energy, penetrating waves or particles such as x rays, gamma rays, proton rays, or neutron rays to destroy cancer cells or keep them from reproducing.

Purpose

The purpose of radiation therapy is to kill or damage cancer cells. Radiation therapy is a common form of cancer therapy. It is used in more than half of all cancer cases. Radiation therapy can be used:

- alone to kill cancer
- before surgery to shrink a tumor and make it easier to remove
- during surgery to kill cancer cells that may remain in surrounding tissue after the surgery (called intraoperative radiation)
- after surgery to kill cancer cells remaining in the body
- to shrink an inoperable tumor in order to reduce pain and improve quality of life
- in combination with **chemotherapy**

For some kinds of cancers such as early-stage **Hodgkin's disease**, **non-Hodgkin's lymphomas**, and certain types of prostate or brain cancer, radiation therapy alone may cure the disease. In other cases, radiation therapy used in conjunction with surgery, chemotherapy, or both, increases survival rates over any of these therapies used alone.

Precautions

Radiation therapy does not make the person having the treatments radioactive. In almost all cases, the benefits of this therapy outweigh the risks. However radiation therapy can have has serious consequences, so anyone contemplating it should be sure to understand why the treatment team believes it is the best possible treatment option for their cancer. Radiation therapy is often not appropriate for pregnant women, because the radiation can damage the cells of the developing baby. Women who think they might be pregnant should discuss this with their doctor.

Description

Radiation therapy is a local treatment. It is painless. The radiation only acts on the part of the body that is exposed to the radiation. This is very different from chemotherapy in which drugs circulate throughout the whole body. There are two main types of radiation therapy. In external radiation therapy a beam of radiation is directed from outside the body at the cancer. In internal radiation therapy, called brachytherapy or implant therapy, a source of radioactivity is surgically placed inside the body near the cancer.

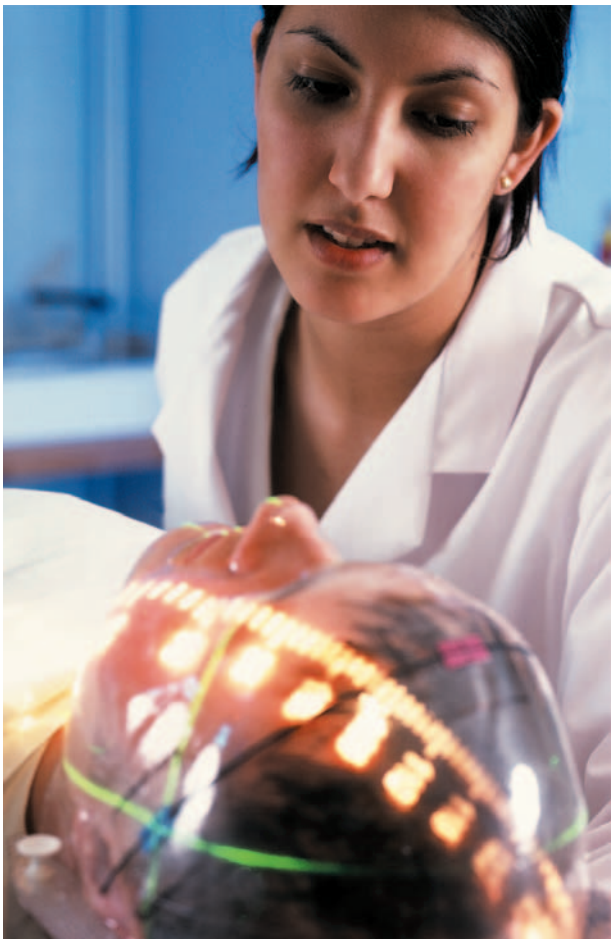
How radiation therapy works

The protein that carries the code controlling most activities in the cell is called deoxyribonucleic acid or DNA. When a cell divides, its DNA must also double and divide. High-energy radiation kills cells by damaging their DNA. This blocks their ability to grow and increase in number.

One of the characteristics of cancer cells is that they grow and divide faster than normal cells. This makes them particularly vulnerable to radiation. Radiation also damages normal cells, but because normal cells are growing more slowly, they are better able to repair radiation damage than are cancer cells. In order to give normal cells time to heal and reduce side effects, radiation treatments are often given in small doses over a six- or seven-week period.

External radiation therapy

External radiation therapy is the most common kind of radiation therapy. It is usually done during outpatient



Radiographer prepares a patient for radiation therapy. She is aiming laser cross-hairs onto the site of a brain tumor. The patient's head is protected and held in place by a plastic mask. *(Copyright Simon Fraser, Science Source/Photo Researchers, Inc. Photo reproduced by permission.)*

visits to a hospital clinic and is usually covered by insurance.

Once a doctor called a radiation oncologist determines the proper dose of radiation for a particular cancer, the dose is divided into smaller doses called fractions. One fraction is usually given each day, five days a week for six to seven weeks. However, each radiation plan is individualized depending on the type and location of the cancer and what other treatments are also being used. The actual administration of the therapy usually takes about half an hour daily, although radiation is only administered for one to five minutes at each session. It is important to attend every scheduled treatment to get the most benefit from radiation therapy.

Recently, trials have begun to determine if there are ways to deliver radiation fractions so that they kill more cancer cells or have fewer side effects. Some trials use smaller doses given more often. Up-to-date information on voluntary participation in **clinical trials** and where they are being held is available by entering the search term "radiation therapy" at the following web sites:

- National Cancer Institute. <http://cancer-trials.nci.nih.gov> or (800) 4-CANCER.
- National Institutes of Health Clinical Trials. <http://clinicaltrials.gov>
- Center Watch: A Clinical Trials Listing. <http://www.centerwatch.com>.

The type of machines used to administer external radiation therapy and the material that provides the radiation vary depending on the type and location of the cancer. Generally, the patient puts on a hospital gown and lies down or sits in a special chair. Parts of the body not receiving radiation are covered with special shields that block the rays. A technician then directs a beam of radiation to a pre-determined spot on the body where the cancer is located. The patient must stay still during the administration of the radiation so that no other parts of the body are affected. As an extra precaution in some treatments, special molds are made to make sure the body is in the same position for each treatment. However, the treatment itself is painless, like having a bone x-rayed.

Internal radiation therapy

Internal radiation therapy is called brachytherapy, implant therapy, interstitial radiation, or intracavitary radiation. With internal radiation therapy, a bit of radioactive material is sealed in an implant (sometimes called a seed or capsule). The implant is then placed very close to the cancer. The advantage of internal radiation therapy is that it concentrates the radiation near the cancer and lessens the chance of damage to normal cells. Many different types of radioactive materials can be used in the implant, including cesium, iridium, iodine, phosphorus, and palladium.

How the implant is put near the cancer depends on the size and location of the cancer. Internal radiation therapy is used for some cancers of the head, neck, thyroid, breast, female reproductive system, and prostate. Most people will have the radioactive capsule implanted by a surgeon while under either general or local anesthesia at a hospital or surgical clinic.

Patients receiving internal radiation therapy do become temporarily radioactive. They must remain in the hospital during the time that the implant stays in place. The length of time is determined by the type of cancer and the dose of radioactivity to be delivered. During the time the implant is in place, the patient will have to stay in bed and remain reasonably still.

While the implant is in place, the patient's contact with other people will be limited. Health care workers will make their visits as brief as possible to avoid exposure to radiation, and visitors, especially children and pregnant women, will be limited.

The implant usually can be removed in a simple procedure without an anesthetic. As soon as the implant is out of the body, the patient is no longer radioactive, and restrictions on being with other people are lifted. Generally people can return to a level of activity that feels comfortable to them as soon as the implant is removed. Occasionally the site of the implant is sore for some time afterwards. This discomfort may limit specific activities.

In some cases, an implant is left permanently inside the body. People who have permanent implants need to stay in the hospital and away from other people for the first few days. Gradually the radioactivity of the implant decreases, and it is safe to be around other people.

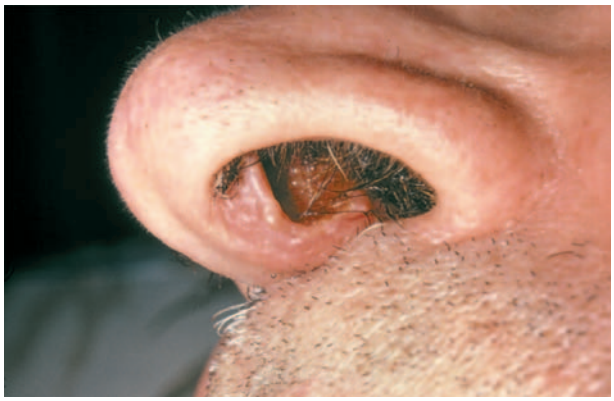
Radioimmunotherapy

Radioimmunotherapy is a promising way to treat cancer that has spread (metastasized) to multiple locations throughout the body. Antibodies are immune system proteins that specifically recognize and bind to only one type of cell. They can be designed to bind only with a certain type of cancer cell. To carry out radioimmunotherapy, antibodies with the ability to bind specifically to a patient's cancer cells are attached to radioactive material and injected into the patient's bloodstream. When these man-made antibodies find a cancer cell, they bind to it. Then the radiation kills the cancer cell. This process is still experimental, but because it can be used to selectively attack only cancer cells, it holds promise for eliminating cancers that have spread beyond the primary tumor.

Radiation used to treat cancer

PHOTON RADIATION Early radiation therapy used x rays like those used to take pictures of bones, or gamma rays. X rays and gamma rays are high-energy rays composed of massless particles of energy (like light) called photons. The distinction between the two is that gamma rays originate from the decay of radioactive substances (like radium and cobalt-60), while x rays are generated by devices that excite electrons (such as cathode ray tubes and linear accelerators). These high-energy rays act on cells by disrupting the electrons of atoms within the molecules inside cells, disrupting cell functions, and, most importantly, by stopping their ability to divide and make new cells.

PARTICLE RADIATION Particle radiation is radiation delivered by particles that have mass. Proton therapy has been used since the early 1990s. Proton rays consist of protons, a type of positively charged atomic particle, rather than photons, which have neither mass nor charge. Like x rays and gamma rays, proton rays disrupt cellular activity. The advantage of using proton rays is that they can be shaped to conform to the irregular shape of the tumor more precisely than x rays and gamma rays. They allow delivery of higher radiation doses to tumors without increasing damage to the surrounding tissue.



(Copyright Dr. P. Marazzi, Science Source/Photo Researchers, Inc. Reproduced by permission.)

Neutron therapy is another type of particle radiation. Neutron rays are very high-energy rays. They are composed of neutrons, which are particles with mass but no charge. The type of damage they cause to cells is much less likely to be repaired than that caused by x rays, gamma rays, or proton rays.

Neutron therapy can treat larger tumors than conventional radiation therapy. Conventional radiation therapy depends on the presence of oxygen to work. The center of large tumors lack sufficient oxygen to be susceptible to damage from conventional radiation. Neutron radiation works in the absence of oxygen, making it especially effective for the treatment of inoperable **salivary gland tumors**, bone cancers, and some kinds of advanced cancers of the pancreas, bladder, lung, prostate, and uterus.

Recent advances in radiation therapy

A newer mode of treating brain cancers with radiation therapy is known as stereotactic radiosurgery. As of the early 2000s, this approach is limited to treating cancers of the head and neck because only these parts of the body can be held completely still throughout the procedure. Stereotactic radiosurgery allows the doctor to deliver a single high-level dose of precisely directed radiation to the tumor without damaging nearby healthy brain tissue. The treatment is planned with the help of

Before, two weeks after, and six months after radiation therapy to treat squamous cell carcinoma inside the left nostril. *(Copyright Dr. P. Marazzi, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

three-dimensional computer-aided analysis of CT and MRI scans. The patient's head and neck are held steady in a skeletal fixation device during the actual treatment. Stereotactic radiosurgery can be used in addition to standard surgery to treat a recurrent brain tumor, or in place of surgery if the tumor cannot be reached by standard surgical techniques.

Two major forms of stereotactic radiosurgery are in use as of 2003. The gamma knife is a stationary machine that is most useful for small tumors, blood vessels, or similar targets. Because it does not move, it can deliver a small, highly localized and precise beam of radiation. Gamma knife treatment is done all at once in a single hospital stay. The second type of radiosurgery uses a movable linear accelerator-based machine that is preferred for larger tumors. This treatment is delivered in several small doses given over several weeks. Radiosurgery that is performed with divided doses is known as fractionated radiosurgery. The total dose of radiation is higher with a linear accelerator-based machine than with gamma knife treatment.

Another advance in intraoperative radiotherapy (IORT) is the introduction of mobile devices that allow the surgeon to use radiotherapy in early-stage disease and to operate in locations where it would be difficult to transport the patient during surgery for radiation treatment. Mobile IORT units have been used successfully as of 2003 in treating early-stage breast cancer and rectal cancer.

Radiation sensitizers are another recent innovation in radiation therapy. Sensitizers are medications that are given to make cancer cells easier to kill by radiation than normal calls. Gemcitabine (Gemzar) is one of the drugs most commonly used for this purpose.

Preparation

Before radiation therapy, the size and location of the patient's tumor are determined very precisely using **magnetic resonance imaging** (MRI) and/or **computed tomography** scans (CT scans). The correct radiation dose, the number of sessions, the interval between sessions, and the method of application are calculated by a radiation oncologist based on the tumor type, its size, and the sensitivity of the nearby tissues.

The patient's skin is marked with a semi-permanent ink to help the radiation technologist achieve correct positioning for each treatment. Molds may be built to hold tissues in exactly the right place each time.

Aftercare

Many patients experience skin burn, **fatigue**, nausea, and vomiting after radiation therapy regardless of where the radiation is applied. After treatment, the skin around the site of the treatment may also become sore. Affected skin should be kept clean and can be treated like sunburn, with skin lotion or vitamin A and D ointment. Patients should avoid perfume and scented skin products and protect affected areas from the sun.

Nausea and vomiting are most likely to occur when the radiation dose is high or if the abdomen or another part of the digestive tract is irradiated. Sometimes nausea and vomiting occur after radiation to other regions, but in these cases the symptoms usually disappear within a few hours after treatment. Nausea and vomiting can be treated with antacids, Compazine, Tigan, or Zofran.

KEY TERMS

Anemia—Insufficient red blood cells in the body.

Antibody—Protein molecule that recognizes and binds specifically to a foreign substance in the body in order to eliminate it.

Chemotherapy—Injecting drugs into the body where they circulate and kill cancer cells.

Computed tomography (CT or CAT) scan—Using X rays taken from many angles and computer modeling, CT scans help locate and size tumors and provide information on whether they can be surgically removed.

Fractionation—A procedure for dividing a dose of radiation into smaller treatment doses.

Gamma rays—Short wavelength, high energy electromagnetic radiation emitted by radioactive substances.

Hodgkin's disease—Cancer of the lymphatic system, characterized by lymph node enlargement and the presence of a large polyploid cells called Reed-Sternberg cells.

Magnetic resonance imaging (MRI)—MRI uses magnets and radio waves to create detailed cross-sectional pictures of the interior of the body.

Stereotactic—Characterized by precise positioning in space. When applied to radiosurgery, stereotactic refers to a system of three-dimensional coordinates for locating the target site.

Fatigue frequently starts after the second week of therapy and may continue until about two weeks after the therapy is finished. Patients may need to limit their activities, take naps, and get extra sleep at night.

Patients should see their oncologist (cancer doctor) at least once within the first few weeks after their final radiation treatment. They should also see an oncologist every six to twelve months for the rest of their lives so they can be checked to see if the tumor has reappeared or spread.

Risks

Radiation therapy can cause **anemia**, nausea, vomiting, **diarrhea**, hair loss (alopecia), skin burn, sterility, and rarely death. However, the benefits of radiation therapy almost always exceed the risks. Patients should discuss the risks with their doctor and get a second opinion about their treatment plan.

Normal results

The outcome of radiation treatment varies depending on the type, location, and stage of the cancer. For some cancers such as Hodgkin's disease, about 75% of the patients are cured. **Prostate cancer** also responds well to radiation therapy. Radiation to painful bony metastases is usually a dramatically effective form of pain control. Other cancers may be less sensitive to the benefits of radiation.

Radical neck dissection

Definition

Radical neck dissection is an operation used to remove cancerous tissue in the head and neck.

Purpose

The purpose of radical neck dissection is to remove lymph nodes and other structures in the head and neck that are likely or proven to be malignant. Variations on neck dissections exist depending on the extent of the cancer. A radical neck dissection removes the most tissue. It is done when the cancer has spread widely in the neck. A modified neck dissection removes less tissue, and a selective neck dissection even less.

Precautions

This operation should not be done if cancer has metastasized (spread) beyond the head and neck, or if the cancer has invaded the bones of the cervical vertebrae (the first seven vertebrae of the spinal column) or the skull. In these cases, the surgery will not effectively contain the cancer.

Description

Cancers of the head and neck (sometimes inaccurately called throat cancer) often spread to nearby tissues and into the lymph nodes. Removing these structures is one way of controlling the cancer.

Of the six hundred lymph nodes in the body, about 200 are in the neck. Only a small number of these are removed during a neck dissection. In addition, other structures such as muscles, veins, and nerves may be removed during a radical neck dissection. These include the sternocleidomastoid muscle (one of the muscles that functions to flex the head), internal jugular (neck) vein, submandibular gland (one of the salivary glands), and the spinal accessory nerve (a nerve that helps control speech, swallowing and certain movements of the head and neck). The goal is always to remove all the cancer but to save as many components surrounding the nodes as possible.

Radical neck dissections are done in a hospital under general anesthesia by a head and neck surgeon. An incision is made in the neck, and the skin is pulled back to reveal the muscles and lymph nodes. The surgeon is guided in what to remove by tests done prior to surgery and by examination of the size and texture of the lymph nodes.

A radical neck surgery in progress. *(Custom Medical Stock Photo. Reproduced by permission.)*

Preparation

Radical neck dissection is a major operation. Extensive tests are done before the operation to try to determine where and how far the cancer has spread. These may include lymph node biopsies, CT (**computed tomography**) scans, magnetic resonance imaging (MRI) scans, and barium swallows. In addition, standard pre-operative blood and liver function tests are performed, and the patient will meet with an anesthesiologist before the operation. The patient should tell the anesthesiologist about all drug allergies and all medication (prescription, non-prescription, or herbal) that he or she is taking.

Aftercare

A person who has had a radical neck dissection will stay in the hospital several days after the operation, and sometimes longer if surgery to remove the primary tumor was done at the same time. Drains are inserted under the skin to remove the fluid that accumulates in the neck area. Once the drains are removed and the incision appears to be healing well, patients are usually discharged from the hospital, but will require follow-up doctor visits. Depending on how many structures are removed, a person who has had a radical neck dissection may require physical therapy to regain use of the arm and shoulder.

Risks

The greatest risk in a radical neck dissection is damage to the nerves, muscles, and veins in the neck. Nerve damage can result in numbness (either temporary

KEY TERMS

Barium swallow—Barium is used to coat the throat in order to take x-ray pictures of the tissues lining the throat.

Computed tomography (CT or CAT) scan—Using x rays taken from many angles and computer modeling, CT scans help size and locate tumors and provide information on whether they can be surgically removed.

Lymphatic system—Primary defense against infection in the body. The tissues, organs, and channels (similar to veins) that produce, store, and transport lymph and white blood cells to fight infection.

Lymph nodes—Small, bean-shaped collections of tissue found in lymph vessels. They produce cells and proteins that fight infection and filter lymph. Nodes are sometimes called lymph glands.

Magnetic resonance imaging (MRI)—MRI uses magnets and radio waves to create detailed cross-sectional pictures of the interior of the body.

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Metastasize—Spread of cells from the original site of the cancer to other parts of the body where secondary tumors are formed.

or permanent) to different regions on the neck and loss of function (temporary or permanent) to parts of the neck, throat, and shoulder. The more extensive the neck dissection, the more function the patient is likely to lose. As a result, it is common following radical neck dissection for a person to have stooped shoulders, limited ability to lift the arm, and limited head and neck rotation and flexion due to the removal of nerves and muscles. Other risks are the same as for all major surgery: potential bleeding, infection, and allergic reaction to anesthesia.

Normal results

Normal lymph nodes are small and show no cancerous cells under the microscope.

Abnormal results

Abnormal lymph nodes may be enlarged and show malignant cells when examined under the microscope.

QUESTIONS TO ASK THE DOCTOR

- What tests will you do to determine if my cancer has spread?
- Which parts of my neck will be removed?
- How will a radical neck dissection affect my daily activities after recovery?
- What is the likelihood that all my cancer can be removed with a radical neck dissection?
- Are the lymph nodes on one or both sides of my neck involved?
- What will my appearance be like after surgery?
- How will my speech and breathing be affected?

Radiofrequency ablation

Definition

Radiofrequency ablation is a treatment that uses radio waves to create heat and directs the heat though a needle probe at cancer cells to destroy tumors.

Purpose

Radiofrequncy ablation (RFA) is minimally invasive, meaning it involves having to enter the body, but not as severely as major surgery. Because of this and its ability to create heat in a specific location, RFA is a good

treatment choice for patients with many types of cancer. RFA also has proven to be an excellent alternative for many patients who have not been able to receive surgery or other cancer therapy, or who have tried other cancer treatments that have failed. For example, some patients cannot have surgery because they have heart or lung conditions that make a long procedure under general anesthesia risky. In other cases, the type, characteristics, or location of the cancer make RFA a better option. The treatment is used not only to help treat cancer, but to ease pain in cancer patients, treat tumors that recur, and to treat some conditions other than cancer.

Liver tumors

One of the cancers treated most by RFA is cancer of the liver. In many cases, removing the tumor with surgery would not leave enough healthy tissue for the liver to still function. Liver tumors that spread (metastasize) from cancers that started somewhere else in the body also are good candidates for RFA. If a patient has several tumors spread out across the liver, surgeons cannot operate. RFA can eliminate the smaller tumors and a surgeon can follow up by operating on the larger tumor if necessary. In some cases, a previous attempt to treat the tumor, such as with **chemotherapy**, has failed and RFA is the next option. RFA also might be used to treat a tumor that has recurred.

Lung tumors

Some patients with lung cancer also are too ill to have conventional surgery or want to avoid the long recovery and possible complications of surgery. RFA once was thought useful only for early, small lung cancers. But research released in 2004 showed that it safely and effectively treated advanced lung cancer as well. The technique also may be used to treat cancer spread to the lung (lung metastases). Physicians also may use RFA to remove most of a tumor that is too large to remove with surgery. The process of making the tumor smaller is called debulking.

Kidney tumors

Many patients with kidney tumors have surgery, but some patients only have one kidney, making RFA the preferred treatment, since it helps spare the only kidney. As with other organs, RFA is an excellent alternative for patients who have conditions that might prevent them from having surgery or for whom recovery from surgery would be difficult. RFA for kidney (renal) cancer is an excellent choice for patients with more than one tumor, if the tumors are smaller than about 4 to 5 cm.

Bone cancer and pain

When cancer spreads to the bones, it can become very painful. Usually, RFA for bone cancer is not used to treat the cancer, but to relieve the pain associated with it. Physicians also may use RFA to relieve pain associated with other cancers by shrinking a tumor that is causing pain, particularly when the tumor has not responded to other treatments or cannot be reached or treated with surgery. This may be referred to as palliation or palliative care.

Other cancers

Researchers continue to find new uses for RFA to treat a number of cancers. For example, a 2004 report showed that RFA could assist with **lumpectomy** for **breast cancer** by giving the patient a cancer-free area around the site where the tumor is removed. RFA also improved cosmetic results. RFA is considered safe, predictable, and cheap when compared to many other treatments.

Precautions

RFA is safe for most patients, and generally can be used in place of surgery for patients who cannot withstand longer surgical procedures, complications, and recovery times. Still, physicians will discuss the benefits and risks of RFA with patients in advance. The procedure usually will require some anesthesia. A medical history and blood tests may rule out some patients or require them to adjust certain medications. Also, some tumors or cancers are not considered treatable with RFA. The number and size of tumors that can be treated in a particular organ may be limited.

Description

Radiofrequency refers to the radio waves, or form of electromagnetic energy, produced by an electrical generator used in the RFA. Electromagnetic energy already is present in the natural environment, as in visible light, microwaves, and radio waves. The energy from radiofrequency is safer than that from **x rays** because it is absorbed by living tissue as simple heat, which does not change the structure of the cells.

The patient lies on a table in an examination or surgical suite and becomes a sort of electrical circuit through which the radio waves pass. Grounding pads are placed on the patient's back or thighs. Most RFA procedures today are performed by an interventional radiologist. An interventional radiologist is a medical doctor who specializes in performing medical procedures that involved radiology to diagnose and treat disease. The radiologist usually uses ultrasound, but sometimes **computed tomography** (CT) or **magnetic**

KEY TERMS

Lumpectomy—Removal of a breast tumor (by surgery) with a limited amount of surrounding breast tissue.

Metastasize—To spread to distant sites. This is the term used when cancer from one organ or site moves to another area of the body and causes cancer in another area or organ.

Percutaneous—Through the skin.

Recur, recurrence—Cancer that happens again after time has passed.

resonance imaging (MRI) equipment and video monitors during the procedure to guide the way to the tumor.

Most interventional radiologists guide the small needle or probe that holds the current through the patient's skin and directly into the tumor. This is called the percutaneous method and will make for an easier recovery. Sometimes, a single needle electrode is used; at other times, one straight needle contains many curved needles that retract inside the main probe until its tip is positioned within the tumor. Once the physician has positioned the tumor, the electrodes can open up like an umbrella to deliver heat to a larger area.

The heat can be controlled by the physician. At temperatures above 113 degrees Fahrenheit, RFA "cooks" the tumor. During the procedure, the radiologist is using real-time imaging (ultrasound, CT, or MRI) to locate the cancerous tumor and guide the needle probe. A small needle can accurately heat a precise area. If a tumor is large, the radiologist may have to guide and reposition the probe several times to destroy the entire tumor. After destroying the tumor, the physician also will use the probe to heat and destroy a small margin or rim of healthy tissue around the cancerous tumor. This helps ensure that no single cancerous cell is left behind that can regrow. After the treatment is completed, a small bandage is placed over the probe insertion site. Each RFA treatment takes 15 to 30 minutes, but the entire procedure can take longer, depending on the number of tumors, tumor size, and location. For instance, the interventional radiologist may have to reposition the probe several times for one liver mass, then turn to a second smaller mass, for a total procedure time of 90 minutes. Some procedures can take up to three hours. RFA procedures are performed in hospitals, imaging centers, and physician offices. Most are done on an outpatient basis.

QUESTIONS TO ASK YOUR DOCTOR

- Why is radiofrequency ablation the best alternative for my cancer?
- What are the risks involved in the treatment?
- How many of these procedures have you performed?

Some pain can be associated with RFA, even with the percutaneous method. Most physicians will insert an intravenous (IV) line in the patient through which they will give anesthesia that makes the patient drowsy, but not completely out. This is often called "conscious sedation." In complex procedures, general anesthesia may be required with an anesthesiologist or nurse anesthetist present and monitoring the patient's vital signs. Sometimes, the physician uses a laparascope to introduce the probe. Although **laparoscopy** requires a tiny incision, it still is considered surgery. Some surgeons also use RFA on patients as part of general surgery. RFA sometimes is called radiofrequency thermal ablation.

Preparation

Before the RFA procedure, patients may have blood drawn for routine blood tests. The physician, nurse, or scheduler will provide preparation instructions that will include concerns about eating or drinking before the procedure. These instructions will depend on the type of anesthesia planned. Normally, patients will be told not to eat or drink eight hours (or after midnight) before the RFA procedure. Certain medications may need to be changed or stopped before the procedure. For example, blood thinners and aspirin may interfere with the procedure. A patient should reveal all current medications to the interventional radiologist or surgeon and follow preparation instructions.

Aftercare

The treatment team will move the patient to a recovery room following the procedure to allow anesthesia to wear off and to receive pain medication as needed. Some patients also have nausea and will receive medications and instructions for nausea and pain care before leaving the facility. Patients will have to remain in bed for the first few hours following the procedure, but seldom have to stay overnight from RFA. However, those having the procedure through surgery will require some hospital stay.

Once they return home, patients will be instructed to drink plenty of fluid and to take a prescription narcotic such as Percocet for the first day or two if pain continues. The physician likely will instruct patients not to drive a car or make important decisions for 24 hours after the procedure because of anesthesia effects. Excessive physical activity also is discouraged. However, most patients can resume normal diet, physical activity, and sexual activity within a few days of RFA.

Risks

The risks associated with radiofrequency ablation are relatively minor compared to those associated with many other cancer treatments, particularly surgery. However, no procedure is risk-free. Although rare, there is a risk of serious injury if the needle makes a hole (perforates) a nearby organ. If this happens, the patient may require surgery to repair the injury. There also is a minor risk of infection at the site where the probe is inserted. Patients may experience bruising or bleeding. Another possible complication from RFA to the lungs is air or gas in the chest cavity (pneumothorax), which may require a chest tube for a few days to drain the air. Finally, RFA is a complicated procedure and should be performed only by a physician trained specifically to do the procedure. Most interventional radiologists have extensive experience in these and similar procedures, but patients can check with accrediting societies, local medical societies and their primary care physicians and ask questions of the physician who will perform the procedure.

Normal results

Results vary, depending on the location, type, and size of tumor. Normally, scar tissue replaces the tumor cells destroyed by RFA and shrinks over a period of time. Patients should have no pain from the procedure after a few days.

Abnormal results

If pain continues for more than a few days, the patient should contact the physician. Some patients also develop flu-like symptoms and **fever** following RFA that can last for a few weeks. Bleeding after RFA has been reported. If it continues and is severe, the patient may have to return for an additional RFA procedure or surgery to control the bleeding. Sometimes, cancer recurs following RFA because tumors are so tiny they cannot be seen. Some patients will need another RFA procedure in the future.

Radiopharmaceuticals

Definition

Radiopharmaceuticals are radioactive substances that may be used to treat cancer.

Purpose

The common radiopharmaceuticals that are used in cancer treatment include:

- Chromic phosphate P 32 for the treatment of lung, ovarian, uterine, and prostate cancers
- Sodium iodide I 131 for treating certain types of **thyroid cancer**
- Strontium chloride Sr 89 for treating cancerous bone tissue
- Samarium Sm 153 lexidronam for treating cancerous bone tissue
- Sodium phosphate P 32 for treating cancerous bone tissue and other types of cancers.

Description

Radiopharmaceuticals used in cancer treatment are small, simple substances, containing a radioactive isotope or form of an element. They are targeted to specific areas of the body where cancer is present. Radiation emitted from the isotope kills cancer cells. These isotopes have short half-lives, meaning that most of the radiation is gone within a few days or weeks.

Chromic phosphate P 32 and sodium iodide I 131

Chromic phosphate P 32 is a salt of chromium and phosphoric acid, containing a radioactive form of the element phosphorous, ^{32}P. Its brand name is Phosphocol P 32. Chromic phosphate P 32 is used to treat fluid accumulations that can result from lung, ovarian, or uterine cancers. It is 50-80% effective in stopping fluid leakage from these organs. Chromic phosphate P 32 also is used to kill cancer cells that remain following surgery for uterine cancer. It may be used to treat ovarian or prostate cancers directly. The use of chromic phosphate P 32 is not combined with external beam radiation, but may be used in conjunction with **chemotherapy**.

Sodium iodide I 131, also called radioactive iodine or radioiodide, is a salt of sodium and a radioactive form of the element iodine, ^{131}I. Sodium iodide I 131 is taken up by the thyroid gland, which absorbs most of the iodine in the body. Sodium iodide I 131 can destroy the thyroid gland, with only minor effects on other parts of the body. It is used following surgery for thyroid cancer to destroy any remaining cancerous thyroid tissue, or to destroy thyroid cancer that has spread (metastasized) to lymph nodes or other tissues. Sodium iodide I 131 is a standard treatment for differentiated thyroid cancer that has spread to the neck and other parts of the body. Its use improves the survival rate for such patients. It is not clear whether radioiodide is beneficial for small cancers of the thyroid that have not metastasized to other tissues.

Bone metastasis

Several radiopharmaceuticals are used to treat cancerous tissue in the bone, particularly from **prostate cancer**. Most prostate cancer metastasizes to the bone and often this is the cause of death. When injected into a vein these radiopharmaceuticals accumulate in cancerous bone tissue and give off radiation that kills cancer cells and relieves pain in the majority of patients. These treatments are most effective for cancer that has metastasized to multiple bones. Sometimes these radiopharmaceuticals are used in conjunction with external beam radiation that is directed at the most painful areas.

Strontium chloride Sr 89 (strontium-89) is the most common radiopharmaceutical for treating bone cancer or prostate cancer that has metastasized to the bone. It is a salt of chlorine and a radioactive isotope of strontium, ^{89}Sr. Its brand name is Metastron. Men with advanced prostate cancer who are responding to chemotherapy appear to have a better chance of survival if bone metastases is treated with strontium-89 every six weeks in conjunction with a chemotherapy drug.

Samarium SM 153 lexidronam is a radioactive form of samarium, ^{153}Sm. The element is inside a small molecule called lexidronam. The brand name for samarium SM 153 lexidronam is Quadramet. It is used primarily to treat prostate cancer that has metastasized to the bone.

Sodium phosphate P 32 is a salt of sodium and phosphoric acid containing a radioactive form of the element phosphorous, ^{32}P. It is used primarily for breast and prostate cancers that have metastasized to the bone. It also may be used to treat other types of cancer.

Two other radioactive isotopes, rhenium 86 and rhenium 188, sometimes are used to treat bone **metastasis** from prostate cancer.

Recommended dosage

Dosages of radiopharmaceuticals vary with the individual and the type of treatment. Dosages of radioactive materials are expressed in units called millicuries.

Chromic phosphate P 32 is a suspension that is delivered through a catheter, or tube, inserted into the

sac surrounding the lungs, or into the abdominal or pelvic cavities. The usual dosage is 15-20 millicuries for abdominal administration and 10 millicuries for administration to the lung sac. Chromic phosphate P 32 also may be injected into the ovaries or prostate.

Sodium Iodide I 131 is taken by mouth as a capsule or a solution. The usual dose for treating thyroid cancer is 30-200 millicuries, depending on age and body size. Doses may be repeated. Treatment usually requires two to three days of hospitalization. For this therapy to be effective there must be high levels of thyroid-stimulating hormone (TSH, or thyrotropin) in the blood. This hormone can be injected prior to treatment.

Strontium-89 is injected into a vein. The usual dosage is 4 millicuries, depending on age, body size, and blood cell counts. Repeated doses may be required.

The usual dosage of samarium Sm 153 lexidronam is 1 millicurie per kg (0.45 millicurie per lb) of body weight, injected slowly into a vein. Repeated doses may be necessary. Because samarium Sm 153 lexidronam may accumulate in the bladder, it is important to drink plenty of liquid prior to treatment and to urinate often after treatment. This reduces the irradiation of the bladder.

The dosage of sodium phosphate P 32 depends on age, body size, blood cell counts, and the type of treatment. The usual dosages range from 1–5 millicuries. Repeated doses may be required.

Precautions

Some individuals may have an allergic reaction to strontium-89, samarium SM 153 lexidronam, or sodium phosphate P 32.

Radiopharmaceuticals usually are not recommended for use during pregnancy. It is recommended that women do not become pregnant for a year after treatment with sodium iodide I 131. Breast-feeding is not possible during treatment with radiopharmaceuticals.

Precautions before treatment with sodium iodide I 131

Foods containing iodine, such as iodized salt, seafoods, cabbage, kale, or turnips, should be avoided for several weeks prior to treatment with sodium iodide I 131. The iodine in these foods will be taken up by the thyroid, thereby reducing the amount of radioiodide that can be taken up. Radiopaque agents containing iodine sometimes are used to improve imaging on an **x ray**. A recent x-ray exam that included such an agent may interfere with the ability of the thyroid to take up radioiodide.

Diarrhea or vomiting may cause sodium iodide I 131 to be lost from the body, resulting in less effective treatment and the risk of outside contamination. Kidney disease may prevent the excretion of radioiodide, increasing the risk of side effects from the drug.

Precautions after treatment with radiopharmaceuticals

Strontium-89, samarium Sm 153 lexidronam, and large total doses of sodium iodide I 131 may temporarily lower the number of white blood cells, which are necessary for fighting infections. The number of blood platelets (important for blood clotting) also may be lowered. Precautions for reducing the risk of infection and bleeding include:

- avoiding people with infections
- seeking medical help at the first sign of infection or unusual bleeding
- using care when cleaning teeth
- avoiding touching the eyes or inside of the nose
- avoiding cuts and injuries

It is important to drink plenty of liquids and to urinate often after treatment with sodium iodide I 131. This flushes the radioiodide from the body. To reduce the risk of contaminating the environment or other people, the following procedures should be followed for 48–96 hours after treatment is sodium iodide I 131:

- avoiding kissing and sex
- avoiding the handling of another person's eating utensils, etc.
- avoiding close contact with others, especially pregnant women
- washing the tub and sink after each use
- washing hands after using or cleaning the toilet
- using separate washcloths and towels
- washing clothes, bed linens, and dishes separately
- flushing the toilet twice after each use

Strontium-89 and samarium Sm 153 lexidronam also are excreted in the urine. To prevent radioactive contamination, special measures should be followed for one week after receiving strontium-89 and for 12 hours after receiving samarium Sm 153 lexidronam:

- using a toilet rather than a urinal
- flushing the toilet several times after each use
- wiping up and flushing any spilled urine or blood
- washing hands after using or cleaning a toilet

KEY TERMS

Half-life—Length of time for the decay of one half of the radiation in a sample of a given radioactive isotope.

Isotopes—Forms of a chemical element that have the same number of protons (atomic number) but different numbers of neutrons and different atomic weights.

Lymph nodes—Small round glands, located throughout the body, that remove foreign organisms and debris from the lymphatic fluid.

Metastasis—Spread of cancer from its point of origin to other parts of the body, such as the bone.

Millicurie—Unit for measuring radioactivity; one millicurie is the quantity of a radioactive isotope that undergoes 3.7×10^{7} disintegrations per second.

Platelet—Blood component that aids in clotting.

Thyroid—Gland on each side of the trachea (windpipe) that secretes hormones to regulate metabolism and growth.

- washing soiled clothes and bed linens separately from other laundry.

Individuals with bladder control problems must take special measures following treatment to prevent contamination with radioactive urine.

Side effects

The more common side effects of chromic phosphate P 32 may include:

- loss of appetite (anorexia)
- abdominal cramps
- diarrhea
- nausea and vomiting
- weakness or fatigue

Less common but serious side effects of chromic phosphate P 32 may include:

- severe abdominal pain
- severe nausea and vomiting
- fever
- chills
- dry cough
- sore throat
- chest pain
- difficulty breathing
- bleeding or bruising

Side effects of treatment with sodium iodide I 131 are rare and temporary. However, they may include:

- loss of taste
- dry mouth (xerostomia)
- stomach irritation
- nausea and vomiting
- tenderness in the salivary glands or neck

Large total doses of radioiodine may cause infertility in men.

Flushing and transient increased **bone pain** are among the more common side effects of strontium-89.

Less common side effects of samarium Sm 153 lexidronam include:

- irregular heartbeat
- temporary increase in bone pain
- nausea and vomiting

Signs of infection due to low white blood cell counts after treatment with strontium-89, samarium Sm 153 lexidronam, or sodium iodide I 131 include:

- fever or chills
- cough or hoarseness
- lower back or side pain
- painful or difficult urination

Signs of low platelet count after treatment with strontium-89, samarium Sm 153 lexidronam, or sodium iodide I 131 include:

- bleeding or bruising
- black, tar-like stools
- blood in urine or stools
- tiny red spots on the skin

Side effects are rare with sodium phosphate P 32. However, for patients treated with sodium phosphate P 32 for bone pain, side effects may include:

- diarrhea
- fever
- nausea and vomiting

Anemia (low red blood cell count) or a decrease in the white blood cell count also are possible.

Since children and older adults are particularly sensitive to radiation, they may experience more side effects during and after treatment with radio- pharmaceuticals.

Interactions

Radiation therapy or anticancer drugs may increase the harmful effects of strontium-89 and samarium SM 153 lexidronam on the bone marrow. Medicines containing calcium may prevent strontium-89 from being taken up by bone tissue. Etidronate (Didronel, one of the so-called **bisphosphonates** that may be used to prevent or treat osteoporosis) may prevent samarium Sm 153 lexidronam from working effectively.

Margaret Alic, Ph.D.

Raloxifene

Definition

Raloxifene is a synthetic called an antiestrogen. It mimics the action of estrogen on the bones, but blocks the effects of estrogen on breast and uterine tissues.

Purpose

Raloxifene is a hormone therapy drug that protects against bone loss (osteoporosis) in postmenopausal women. During large studies of raloxifene's effectiveness against osteoporosis, researchers discovered that women taking the drug developed fewer breast cancers than women taking the placebo. Therefore, it is being considered as a drug used to fight **breast cancer**.

Description

In 1997 the United States Food and Drug Administration (FDA) approved raloxifene for use against bone loss (osteoporosis) in postmenopausal women. As of 2001, raloxifene (Evista) was being tested as a hormone therapy drug to reduce the risk and fight breast cancer in postmenopausal women. As of 2003, raloxifene was only approved for use in postmenopausal women. However, studies were looking at its effects in preventing cancer in all women and in lowering risk of fractures in women with osteopenia.

Raloxifene belongs to a family of compounds called **antiestrogens**. Antiestrogens are used in cancer therapy to inhibit the effects of estrogen on target tissues. Estrogen is a steroid hormone secreted by granulosa cells of a maturing follicle within the female ovary. Depending on the target tissue, estrogen can stimulate the growth of female reproductive organs and breast tissue, play a role in the female menstrual cycle, and protect against bone loss by binding to estrogen receptors on the outside of cells within the target tissue. Antiestrogens act selectively against the effects of estrogen on target cells in a variety of ways, thus they are called selective estrogen receptor modulators (SERMs).

Raloxifene selectively inhibits the effects of estrogen on breast tissue and uterine tissue, while selectively mimicking the effects of estrogen on bone (by increasing bone mineral density). Its effects on breast and uterine tissue are thought to make raloxifene an excellent therapeutic agent against breast cancer and uterine cancer. Although researchers are unclear on exactly how raloxifene kills cancer cells, it is known to compete with estrogen by binding to estrogen receptors, therefore limiting the effects of estrogen on breast and uterine tissue. Raloxifene also may be involved in other anti-tumor activities affecting oncogene expression, promotion of apoptosis, and growth factor secretion.

In 2000 the STAR (Study of **Tamoxifen** and Raloxifene) study began. The purpose of this double-blind study was to evaluate the use of tamoxifen (another type of SERM) and raloxifene over a five year period in 22,000 postmenopausal women 35 years or older who are at high risk for developing breast cancer. The study will evaluate both the effectiveness and degree of side effects to determine which drug is most beneficial.

Recommended dosage

Recommended dose for cancer treatment will emerge as clinical trials enter their final phases. Most studies, including the STAR trial, are using a total of 60 milligrams of raloxifene administered either once or twice (morning and night) each day with notable success. If a dosage is missed, patients should not double the next dosage. Instead, they should go back to their regular schedule and contact their doctor.

Precautions

Although raloxifene is only approved for use by women past the child bearing years, researchers emphasize that it is not recommended for women who are pregnant or breast feeding. In test animals, raloxifene caused birth defects and miscarriages. Although it is not known whether raloxifene is present in breast milk, it is possible that its presence may be toxic to infants. Further, this drug is not recommended for use in children.

KEY TERMS

Anticoagulant—An agent preventing the coagulation (clotting) of blood.

Apoptosis—A type of cell death where cells are induced to commit suicide.

Double-blind study—A study where neither the participant nor the physician know who has received the drug in question.

Granulosa cells—Cells that form the wall of the ovarian follicle.

Oncogene—A gene whose presence can cause cancer; these genes usually arise through mutation of a normal gene.

Ovarian follicle—Several layers of cells that surround a maturing egg in the ovary.

Thromboembolism—A blood clot that blocks a blood vessel in the cardiovascular system.

Patients at risk for the formation of thromboembolisms should use raloxifene with caution. Raloxifene can cause a higher risk of developing blood clots. Additionally, women experiencing liver disease will have a higher level of raloxifene in their blood system.

Side effects

Although raloxifene is usually well tolerated by patients, there are some side effects. Commonly reported side effects include mild nausea, vomiting, hot flashes, weight gain, **bone pain**, and hair thinning, which are not severe enough to stop therapy. Most of the side effect information regarding raloxifene comes from studies using it to counter osteoporosis where patients have not needed to take it over a long period of time. When studied for anticancer properties, raloxifene needs to be taken over a longer period of time. Since raloxifene's anticancer properties still are under investigation, researchers are not completely aware of all of the long term and potentially serious side effects. Researchers are aware that women taking raloxifene are three times more likely to develop thromboembolisms than women not taking raloxifene.

Interactions

The usefulness of raloxifene can be diminished if patients also are on estrogen supplements (such as Premarin, Estrace, Estratab, Climara, or Vivelle) and cholesterol-lowering cholestyramines (such as Questran). Cholestyramines decrease the absorption of raloxifene into the blood, while estrogen supplements increase the amount of estrogen competing with raloxifene for binding sites on target cells' estrogen receptors.

Raloxifene interferes with the anticoagulant effect of **warfarin** with severe consequences and even death. Patients using warfarin should make sure their physician is aware prior to commencing treatment with raloxifene.

Receptor analysis

Definition

Receptor analysis is a diagnostic test that determines an important biological characteristic of the cells in a tumor—their response to normal growth factors.

Purpose

The goal of receptor analysis is to reveal whether the cancer cells in a tumor have specific molecules, termed receptors, on the cell surface. This test is routinely performed for **breast cancer**, as well as other tumors. Information as to the presence of these specific receptors can play a role in deciding the best course of treatment for a particular patient.

Precautions

Because this test is performed on a piece of tissue that has already been removed during a surgical or diagnostic procedure, it does not require any precautionary measures on behalf of the patient.

KEY TERMS

Anti-estrogen —A drug, for example tamoxifen, that prevents the hormone estrogen from influencing the behavior of specific types of cells.

Biopsy—A piece of tissue removed for diagnostic examination.

Receptors—Molecules, usually found on the surface of a cell, that are required for cells to be influenced by hormones and other growth factors.

QUESTIONS TO ASK THE DOCTOR

- What fraction of the cells in my tumor has normal receptors?
- Do the results of the receptor assay on the biopsy of my tumor make me a candidate for anti-estrogen treatment?
- How do the results of the receptor assays on my tumor influence your decision as to my treatment and prognosis?

Description

The cancer cells found in tumors or in the blood of leukemia patients can differ in many ways, and to varying degrees from the corresponding cells in normal tissues and blood. In some respects, cancer treatment depends upon the differences in behavior between tumor and normal cells. For example, tumor cells often grow faster than normal (non-cancerous) cells. The changes that occur as normal cells become cancerous are progressive. As a tumor develops the cells generally become less similar to normal cells and behave in a biologically different way. Some cancer treatments make use of the ways that cancer cells in a tumor can be like cells in the normal surrounding tissue.

One the most fundamental ways in which the early stages of some cancers resemble healthy tissue is that the growth of the cells in the tumor responds to some of the same factors that control the growth of normal tissues. The most common example of this is the response of breast cancer cells to estrogen. During the normal menstrual cycle, the mammary glands respond to changes in the levels of two hormones, estrogen and progesterone. In many cases, the growth of breast cancer tumor cells also responds to the presence or absence of estrogen. The response of both normal and tumor cells to these hormones depends upon presence of molecules termed estrogen and progesterone receptors. If cells in a breast tumor have these receptors, it is possible to inhibit the growth of the cancer cells by preventing estrogen from stimulating their growth. This is generally accomplished through the use of anti-estrogen drugs such as **tamoxifen**.

Receptor analysis usually involves a special technique, called immunocytochemistry, to examine a small piece of the tumor tissue. A tissue section, a slice of the tumor, is placed on a glass microscope slide. These tissue sections, which are very similar to those used in the initial diagnosis of the patient's breast cancer, are incubated with antibody preparations that will react with estrogen and progesterone receptors. Special reagents that lead to a chemical reaction where these antibodies are bound produce a visible color in cells that have hormone receptors. A pathologist then looks at the section with a microscope to determine the percentage of tumor cells that are receptor-positive. This information can be used to decide whether a woman with breast cancer should be treated with anti-estrogens. In addition, the presence of estrogen receptors is itself an accepted prognostic indicator. Tumors that have high levels of estrogen receptors are generally less aggressive. Taken together with information as to the patient's age, the size and grade of the tumor, and whether or not there is lymph node involvement, it is possible for a doctor to have some idea as to the likelihood the patient will remain disease-free after initial treatment.

Estrogen receptor analysis is an important and generally accepted part of managing breast cancer. More recently, assays for other cell surface receptors have been explored and introduced for the management of breast and other cancers. Examples of these include androgen receptors in **prostate cancer** and epidermal growth factor receptor (EGFR) in a variety of cancers. In 2001 the most prominent example of a receptor assay, other than estrogen receptor analysis, was testing for a cell surface molecule designated HER2. Patients whose tumors express higher than normal amounts of HER2 are believed to have worse prognoses. However, these patients may be treated with a specific reagent, a monoclonal antibody, which is targeted toward the HER2 protein. Analysis for HER2 can be performed in a similar way to estrogen receptor immunocytochemical assays, currently marketed as the HercepTest, or by using a different type of test that directly examines the gene for HER2. Treatment with the monoclonal antibody to HER2 can improve the survival of patients who express higher-than-normal levels of HER2 in their tumor cells.

Risks

This test is performed on a piece of tissue that has been removed during the initial surgery or diagnostic procedure used to establish the nature of the tumor. It does not require any new surgery on the patient and, so, does not entail any risk to the patient.

Results

Receptor assays measure molecules that play normal and essential roles in the natural function of various tissues. Abnormal results depend upon the particular tissue and the type of cancer involved. The presence of the appropriate receptor, for example estrogen receptors in breast tumors, may be indicative that the cancer can be treated with compounds that can inhibit the growth of the cells that make up the tumor. In other cases, receptor assays may enable a doctor to know the origin of a tumor. That is, sometimes it is not possible for a pathologist to examine a **biopsy** and be certain what type of cancer a tumor represents. Knowing the identity of the receptors found on the tumor cells may then provide important information for establishing the diagnosis and best course of treatment for such patients.

Reconstructive surgery

Definition

Reconstructive surgery is a type of plastic surgery performed to reshape abnormal structures of the body to improve function and appearance. Reconstructive surgery is different from cosmetic surgery, which is performed to reshape normal structures of the body to improve a patient's appearance and self-esteem.

Purpose

The goals of reconstructive surgery are to reshape abnormal structures of the body, to improve function, and/or to allow a person to have a more normal appearance. Abnormal structures of the body that are corrected during reconstructive surgery may be the result of birth defects, developmental abnormalities, trauma or injury, infection, tumors, or disease. The three most commonly performed reconstructive surgeries in the United States are tumor ablation (removal) and reconstruction, hand surgery, and breast reconstruction.

Precautions

Reconstructive surgery should not be performed on patients who are not healthy enough to withstand a surgical procedure performed under general anesthetic. People with severe diabetes, an autoimmune disorder such as AIDS, or a suppressed immune system should not undergo reconstructive surgery. This type of surgery is also contraindicated in patients with a history of excessive smoking, obesity, poor wound healing, abnormal scarring and/or a bleeding disorder. Women who are pregnant should not undergo reconstructive surgeries.

Patients who have received recent irradiation treatments (generally within the last three to six months) should not undergo surgical procedures involving these tissues. Recently irradiated tissue is highly prone to infection and has poorer wound healing.

In some cases, after tumor removal surgeries, it is necessary to monitor the affected tissue for redevelopment of the tumor. Patients requiring this type of postoperative surveillance should not undergo further reconstructive surgeries since these surgeries could obscure the results of imaging techniques (**x ray**, **computed tomography**, or **magnetic resonance imaging**) used to monitor tumor recurrence.

Patients with an allergy to collagen, beef, or beef products should not receive collagen injections.

Description

The most commonly performed reconstructive surgeries of cancer patients are breast reconstruction, laceration repair, scar revision, and tumor removal.

Breast reconstruction

Breast reconstruction surgeries can be performed as part of the procedure to remove the breast (immediate **mastectomy**). They may also be performed as a separate procedure after recuperation from a mastectomy

(delayed). There are two types of breast reconstruction: autogenous free flap reconstruction and breast implants.

Autogenous free flap reconstructions use tissue from another part of the body to form the reconstructed breast. This category of breast reconstruction includes the techniques called TRAM (transverse rectus abdominis myocutaneous), LD (latissimus dorsi), VRAM (vertical rectus abdominis myocutaneous), and DIEP (deep inferior epigastric perforator) flaps. These names refer to the location from which the tissue for reconstruction is taken. As of 2001 TRAM, in which tissue is taken from the abdominal region, is the most common breast reconstruction procedure in the United States. As of 2004, DIEP is preferred when the reconstruction involves both breasts.

Breast implants involve the placement of an artificial object in the body to simulate the shape and size of the natural breast. The implant is most commonly a saline (salt water) or silicone-filled bag. Because of the health problems reported by many women after silicone breast implants, this technique is no longer as widespread as it once was, particularly for reconstructive surgeries.

A technique that is still in the experimental stage is breast tissue engineering, which seeks to use a relatively small amount of the patient's own adipose (fatty) tissue to create a larger volume of material that could be used to reconstruct the breast. As of 2004 one of the limitations on breast reconstruction is the need to use fairly large amounts of adipose tissue from the patient's body.

Breast reconstruction usually involves more than one operation; in fact the average number of secondary procedures required is four for reconstruction of one breast and 5.5 for reconstruction of both breasts. The factors that complicate breast reconstruction include delaying the reconstruction after the mastectomy; the need for radiation therapy; and the presence of other risk factors affecting the patient's health.

Laceration repair

Laceration repair includes the repair of large wounds caused by the removal of large tumors or tumors associated with the skin. It also includes the surgical repair of wounds that fail to heal or heal improperly. Laceration repair can be subdivided into four general categories: direct closure, skin grafts, tissue expansion, and flap surgery.

Direct closure (stitches) is usually only performed on wounds that are not very deep beneath the surface of the skin and that have straight edges of skin on either side of the wound. The primary goal in direct closure is to provide a permanent closure of the wound with a minimum of scarring.

Skin grafts are used for wounds that are wide and difficult or impossible to close directly. This technique involves removing healthy skin from a location on the patient (the donor site) and using it to cover the wound site. The skin will grow back at the donor site but often leaves a color mismatch. The donor site is chosen to best match the color of the skin needed in the graft area.

Tissue expansion is used to grow extra skin by stretching skin near the site that will require the skin. A small inflatable balloon is placed under the skin next to the area where the skin will be removed. Over time, this balloon is slowly filled with salt water until the skin has grown to the required size. The surgical procedure that involves the loss of skin is then performed and closed with the extra skin that was formed during the tissue expansion process. The major advantage associated with tissue expansion is that the skin grown in this way remains connected to its original blood and nerve supply, so the risk of loss of sensation in the area of the wound is greatly diminished. Also, the scars that result from tissue expansion are generally less noticeable than those from skin grafts or skin flaps. A final advantage of this method is the near perfect match in color provided by this skin.

Flap surgery involves taking a section of living tissue, with its blood supply, from one part of the patient and moving it to the area where it is needed. In most flap surgeries, one end of the flap remains attached to its original blood supply so that it continues to be nourished as it grows to heal the wound. In cases where the flap is completely removed and transplanted to another part of the body, the surgery involves the reconnection of all the tiny blood vessels of the flap tissue to the blood vessels of the new location (microsurgery). Flap surgery has the advantage of being able to restore both form and function to areas of the body that have lost skin, fat, muscle, and/or skeletal support. The most commonly performed flap surgeries are the autogenous breast reconstructions discussed above. But, this procedure is used throughout the body with a great amount of success.

Scar revisions

Many cancer patients have scarring that results from their particular form of cancer or from the number or severity of surgical procedures or radiation that they have undergone. In some of these cases, surgeries to minimize or reshape the scar, or scars, may be undertaken. Most physicians will recommend that a scar be allowed to heal for at least one year prior to a recommendation of scar revision. But, in extreme cases of loss of mobility, increased sensitivity, or inflamed and irritable scars that do not respond to topical steroid creams, this timetable may be shortened.

KEY TERMS

Cosmetic surgery—A form of plastic surgery that is performed to alter normal tissue to improve the appearance of that tissue.

Flap surgery—A procedure in which a portion of living tissue is moved from one part of a patient's body to another to restore shape and/or function to the targeted location.

Plastic surgery—A type of surgery that is performed to alter the physical characteristics of a patient. This medical discipline is subdivided into cosmetic surgery and reconstructive surgery.

Reconstructive surgery—A form of plastic surgery that is performed to repair or reshape abnormally formed tissue to improve the form and/or function of that tissue.

Scar revision—A surgical procedure that attempts to diminish the physical appearance of a scar. This procedure is also used to add flexibility and range of motion to joints and muscles that were previously hindered by a particular scar.

QUESTIONS TO ASK THE DOCTOR

- What are alternatives to this surgical procedure?
- What will the scars look like and can I expect them to decrease over time?
- How many reconstructions have you performed previously and may I see examples of the results or talk to former patients?
- Will this procedure be covered by my insurance?
- How long will the pre-operation waiting period, the hospital stay, and the recovery procedure be?

Unless proof of the scar contributing to a medical condition or a decrease in physical function can be shown, scar revision surgery is considered by most insurance companies to be a cosmetic surgery that is not covered as an insurance benefit. The most common reason for scar revision to be classified as a reconstructive rather than a cosmetic procedure is a loss of mobility of muscles or joints caused by the scar.

The most common procedure for scar revision is called Z-plasty. In this procedure, the old scar is removed and the two sides of the wound are cut into a z-shape that is designed to follow the natural lines and contours of the surrounding skin. This z-shaped wound is then closed with stitches. Other scar revision procedures include skin grafts and flap surgeries. Z-plasty is the least likely of these procedures to be covered by insurance.

Tumor removal

The surgical procedure used to remove a tumor will be chosen by the surgeon based on the type and size of the tumor. Other factors influencing the surgical technique chosen for tumor removal include: the location of the tumor within the body; the potential for recurrence of the tumor at this, or another, location in the body; and, the stage of development of both the tumor itself and the underlying cancer.

Skin cancers are generally removed by a cutting out (excision) of the cancerous portion of skin, with the wound closed by stitches or left to heal on its own. In cases of large or spreading skin cancers, major surgery involving skin grafts or flap surgeries may be required. For skin cancers in the facial area, **Moh's surgery** with primary or flap closure may be performed.

Preparation

The preparation for a reconstructive surgery depends on the type of surgery that is to be performed. Some reconstructive surgeries can be performed on an outpatient basis. These procedures require only a local anesthetic and very little patient preparation other than counseling about the risks, possible achievable outcomes, and alternatives to the surgery. Other reconstructive surgeries are considered major operations. These require hospitalization, a general anesthetic and much more extensive counseling and discussion of possible alternatives.

Prescription medications that may interfere with the performance of reconstructive surgery should be discontinued approximately two weeks prior to surgery, unless the surgeon advises otherwise. These medications include any medicines that may interfere with the anesthetic or that may increase bleeding. Over-the-counter medications, such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs), should not be taken for at least one week prior to surgery unless approved by the doctor who will be performing the surgery. Patients undergoing surgeries that require a general anesthetic will be asked not to eat after midnight prior to the surgery and not to drink at least eight hours prior to surgery. The purpose of this is to ensure that the stomach is empty while the patient is unconscious. Otherwise, the stomach

contents could end up in the lungs, causing complications with the surgery or the recovery.

For procedures involving skin flaps, the patient may be asked to donate blood for possible use in a later transfusion.

In the case of tissue expansion procedures, the amount of time that will be required for the expansion of the tissue depends on the amount of tissue that must be grown to ensure an adequate closure of the wound. This may take a matter of days or several weeks.

Psychological and emotional preparation is important in reconstructive surgery to manage patient expectations. The patient should not expect cosmetically perfect results. Complete understanding of the limitations, as well as the benefits, of this surgery is necessary for a successful outcome.

Aftercare

The aftercare of a patient who has undergone a reconstructive surgery depends on the surgery, the overall health of the patient, and the wound care process. Some outpatient procedures require little aftercare other than a follow-up examination to determine the success of the procedure. Other procedures may require an extended hospitalization followed by extensive physical therapy. Smoking should be avoided, as it may cause delayed wound healing and higher risk of complications, including infection.

Procedures involving skin flaps or grafts require careful monitoring in the first days after surgery to ensure that proper blood circulation is taking place. Bandages and drainage tubes will remain in place for at least a day.

Scars may remain reddened and raised for a month or longer and may cause **itching**. Many people find that inflammation or severe itching from post-surgical scars is lessened, or completely eliminated, by topical treatments with vitamin E or steroidal creams.

After tumor removal, many patients require follow-up treatments and medical imaging to ensure that the tumor is not redeveloping.

Risks

The risks associated with all reconstructive surgeries are infection, bleeding, an unsightly scar, improper wound closure, and adverse reactions to anesthesia. Complications associated with flap reconstruction of the breasts include unusual firmness of the fatty tissue (fat necrosis), partial flap loss, fluid collection beneath the flap site, and muscle weakness (including abdominal hernias) at the donor site. For breast implants, complications include the formation of fibrous tissue around an implant, rupture or leakage of the implant, or movement of the implant from its intended location.

Normal results

The normal result of a reconstructive surgery is a patient who has an improved ability to function and/or an improved **body image** as a result of the surgery. A normal result also depends on the patient's realistic goals and expectations. The patient should understand that the feeling and appearance of the reconstructed area will be improved, not fully restored to an unaffected state.

Abnormal results

An abnormal result of a reconstructive surgery is a patient who suffers long-lasting health complications as a result of the surgery. Another abnormal result is a patient who suffers a degradation in the ability to function and/or has a loss of self-confidence caused by the loss of sensation or scarring that may accompany such procedures.

Rectal cancer

Definition

The rectum is the portion of the large bowel that lies in the pelvis, terminating at the anus. Cancer of the rectum is the disease characterized by the development of malignant cells in the lining or epithelium of the rectum. Malignant cells have changed such that they lose normal control mechanisms governing growth. These cells may invade surrounding local tissue or they may spread throughout the body and invade other organ systems.

Description

The rectum is the continuation of the colon (part of the large bowel) after it leaves the abdomen and descends into the pelvis. It is divided into equal thirds: the upper, mid, and lower rectum.

The pelvis and other organs in the pelvis form boundaries to the rectum. Behind, or posterior to the rectum is the sacrum (the lowest portion of the spine, closest to the pelvis). Laterally, on the sides, the rectum is bounded by soft tissue and bone. In front, the rectum is bounded by different organs in the male and female. In the male, the bladder and prostate are present. In the female, the vagina, uterus, and ovaries are present.

The upper rectum receives its blood supply from branches of the inferior mesenteric artery from the abdomen. The lower rectum has blood vessels entering from the sides of the pelvis. Lymph, a protein-rich fluid that bathes the cells of the body, is transported in small channels known as lymphatics. These channels run with the blood supply of the rectum. Lymph nodes are small filters through which the lymph flows on its way back to the blood stream. Cancer spreads elsewhere in the body by invading the lymph and vascular systems.

When a cell or cells lining the rectum become malignant, they first grow locally and may invade partially or totally through the wall of the rectum. The tumor here may invade surrounding tissue or the organs that bound it, a process known as local invasion. In this process, the tumor penetrates and may invade the lymphatics or the capillaries locally and gain access to the circulation in this way. As the malignant cells work their way to other areas of the body, they again become locally invasive in the new area to which they have spread. These tumor deposits, originating in the primary tumor in the rectum, are then known as **metastasis**. If metastases are found in the regional lymph nodes, they are known as regional metastases. If they are distant from the primary tumor, they are known as distant metastases. The patient with distant metastases may have widespread disease, also referred to as systemic disease. Thus the cancer originating in the rectum begins locally and, given time, may become systemic.

By the time the primary tumor is originally detected, it is usually larger than one centimeter (about 3/8 inch) in size and has over one million cells. This amount of growth is estimated to take about three to seven years. Each time the cells double in number, the size of the tumor quadruples. Thus like most cancers, the part that is identified clinically is later in the progression than would be desired. Screening becomes a very important endeavor to aid in earlier detection of this disease.

Passage of red blood with the stool, (noticeable bleeding with defecation), is much more common in rectal cancer than that originating in the colon because the tumor is much closer to the anus. Other symptoms (constipation and/ or **diarrhea**) are caused by obstruction and, less often, by local invasion of the tumor into pelvic organs or the sacrum. When the tumor has spread to distant sites, these metastases may cause dysfunction of the organ they have spread to. Distant metastasis usually occurs in the liver, less often to the lung(s), and rarely to the brain.

Demographics

There are about 36,500 cases of rectal cancer diagnosed per year in the United States. Together, colon and rectal cancers account for 10% of cancers in men and 11% of cancers in women. It is the second most common site-specific cancer affecting both men and women. Nearly 57,000 people died from colon and rectal cancer in the United States in 2003. In recent years the incidence of this disease is decreasing very slightly, as has the mortality rate. It is difficult to tell if the decrease in mortality reflects earlier diagnosis, less death related to the actual treatment of the disease, or a combination of both factors.

Cancer of the rectum is felt to arise sporadically in about 80% of those who develop the disease. About 20% of cases probably arise from genetic predisposition; some people have a family history of rectal cancer occur-

ring in a first-degree relative. Development of rectal cancer at an early age suggests a genetically transmitted form of the disease as opposed to the sporadic form.

Causes and symptoms

Causes of rectal cancer are probably environmental in sporadic cases (80%), and genetic in the heredity-predisposed (20%) cases. Since malignant cells have a changed genetic makeup, this means that in 80% of cases, the environment spontaneously induces change. Those born with a genetic predisposition are either destined to get the cancer, or it will take less environmental exposure to induce the cancer. Exposure to agents in the environment that may induce mutation is the process of **carcinogenesis** and is caused by agents known as carcinogens. Specific carcinogens have been difficult to identify; dietary factors, however, seem to be involved.

Rectal cancer is more common in industrialized nations. Dietary factors may be the reason. Diets high in fat, red meat, total calories, and alcohol seem to add to increased risk. Diets high in fiber are associated with a decreased risk. High-fiber diets may be related to less exposure of the rectal epithelium to carcinogens from the environment as the transit time through the bowel is faster with a high-fiber diet than with a low-fiber diet.

Age plays a definite role in rectal cancer risk. Rectal cancer is rare before age 40. This incidence increases substantially after age 50 and doubles with each succeeding decade.

There also is a slight increase of risk for rectal cancer in the individual who smokes.

Patients who suffer from an inflammatory disease of the colon known as ulcerative colitis are also at increased risk.

On chromosome 5 is the APC gene associated with familial adenomatous polyposis (FAP) syndrome. There are multiple mutations that occur at this site, yet they all cause a defect in tumor suppression that results in early and frequent development of **colon cancer**. This is transmitted to 50% of offspring and each of those affected will develop colon or rectal cancer, usually at an early age. Another syndrome, hereditary non-polyposis colon cancer (HNPCC), is related to mutations in any of four genes responsible for DNA mismatch repair. In patients with colon or rectal cancer, the p53 gene is mutated 70% of the time. When the p53 gene is mutated and ineffective, cells with damaged DNA escape repair or destruction, allowing the damaged cell to multiply. Continued replication of the damaged DNA may lead to tumor development. Though these syndromes (FAP and HNPCC) have a very high incidence of colon or rectal cancer, family history without the syndromes is also a substantial risk factor. When considering first-degree relatives, history of one with colon or rectal cancer raises the baseline risk from 2% to 6%; the presence of a second raises the risk to 17%.

The development of polyps of the colon or rectum commonly precedes the development of rectal cancer. Polyps are growths of the rectal lining. They can be unrelated to cancer, pre-cancerous, or malignant. Polyps, when identified, are removed for diagnosis. If the polyp, or polyps, are benign, the patient should undergo careful surveillance for the development of more polyps or the development of colon or rectal cancer.

Symptoms of rectal cancer most often result from the local presence of the tumor and its capacity to invade surrounding pelvic structure:

- bright red blood present with stool
- abdominal distention (stretching from internal pressure) bloating, inability to have a bowel movement
- narrowing of the stool, so-called ribbon stools
- pelvic pain
- unexplained weight loss
- persistent chronic **fatigue**
- rarely, urinary infection or passage of air in urine in males (late symptom)
- rarely, passage of feces through vagina in females(late symptom)

If the tumor is large and obstructing the rectum, the patient will not be evacuating stool normally and will get bloated and have abdominal discomfort. The tumor itself may bleed and, since it is near the anus, the patient may see bright red blood on the surface of the stool. Blood alone (without stool) may also be passed. Thus, hemorrhoids are often incorrectly blamed for bleeding, delaying the diagnosis. If **anemia** develops, which is rare, the patient will experience chronic fatigue. If the tumor invades the bladder in the male or the vagina in the female, stool will get where it doesn't belong and cause infection or discharge. (This condition is also rare.) Patients with widespread disease lose weight secondary to the chronic illness.

Diagnosis

Screening evaluation of the colon and rectum are accomplished together. Screening involves physical exam, simple laboratory tests, and the visualization of the lining of the rectum and colon. X rays (indirect visualization) and endoscopy (direct visualization) are used to visualize the organs' lining.

The physical examination involves the performance of a digital rectal exam (DRE). At the time of this exam, the physician checks the stool on the examining glove with a chemical to see if any occult (invisible), blood is present. At home, after having a bowel movement, the patient is asked to swipe a sample of stool obtained with a small stick on a card. After three such specimens are on the card, the card is then easily chemically tested for occult blood. These exams are accomplished as an easy part of a routine yearly physical exam.

Proteins are sometimes produced by cancers and these may be elevated in the patient's blood. When this occurs the protein produced is known as a tumor marker. There is a tumor marker for cancer of the colon and rectum; it is known as carcinoembryonic antigen, (CEA). Unfortunately, this may be made by other **adenocarcinomas** as well, or it may not be produced by a particular colon or rectal cancer. Therefore, screening by chemical analysis for CEA has not been helpful. CEA has been helpful in patients treated for colon or rectal cancer if their tumor makes the protein. It is used in a follow-up role, not a screening role.

Direct visualization of the lining of the rectum is accomplished using a scope or endoscope. The physician introduces the instrument into the rectum and is able to see the epithelium of the rectum directly. A simple rigid tubular scope may be used to see the rectal epithelium; however, screening of the colon is done at the same time. The lower colon may be visualized using a fiberoptic flexible scope in a procedure known as flexible **sigmoidoscopy**. When the entire colon is visualized, the procedure is known as total **colonoscopy**. Each type of endoscopy requires pre-procedure preparation (evacuation) of the rectum and colon.

The American Cancer Society has recommended the following screening protocol for colon and rectal cancers those over age 50:

- yearly fecal occult blood test
- flexible sigmoidoscopy at age 50
- flexible sigmoidoscopy repeated every 5 years
- double contrast barium enema every five years
- colonoscopy every 10 years

If there are predisposing factors such as positive family history, history of polyps, or a familial syndrome, screening evaluations should start sooner.

Evaluation of patients with symptoms

When patients visit their physician because they are experiencing symptoms that could possibly be related to colon or rectal cancer, the entire colon and rectum must be visualized. Even if a rectal lesion is identified, the entire colon must be screened to rule out a syndromous polyp or cancer of the colon. The combination of a flexible sigmoidoscopy and double contrast **barium enema** may be performed, but the much-preferred evaluation of the entire colon and rectum is that of complete colonoscopy. Colonoscopy allows direct visualization, photography, as well as the opportunity to obtain a **biopsy**, (a sample of tissue), of any abnormality visualized. If, for technical reasons the entire colon is not visualized endoscopically, a double contrast barium enema should complement the colonoscopy. A patient who is identified to have a problem in one area of the colon or rectum is at greater risk to have a similar problem in another area of the colon or rectum. Therefore the entire colon and rectum need to be visualized during the evaluation.

The diagnosis of rectal cancer is actually made by the performance of a biopsy of any abnormal lesion in the rectum. Many rectal cancers are within reach of the examiner's finger. Identifying how close to the anus the cancer has developed is important in planning the treatment. Another characteristic ascertained by exam is whether the tumor is mobile or fixed to surrounding structure. Again, this will have implications related to primary treatment. As a general rule, it is easier to identify and adequately obtain tissue for evaluation in the rectum as opposed to the colon. This is because the lesion is closer to the anus.

If the patient has advanced disease, areas where the tumor has spread, such as the liver, may require biopsy. Such biopsies are usually obtained using a special needle under local anesthesia.

Once a diagnosis of rectal cancer has been established by biopsy, in addition to the physical exam, an **endorectal ultrasound** will be performed to assess the extent of the disease. For rectal cancer, endorectal ultrasound is the most preferred method for staging both depth of tumor penetration and local lymph node status. Endorectal ultrasound:

- differentiates areas of invasion within large rectal adenomas that may appear benign
- determines the depth of tumor penetration into the rectal wall
- determines the extent of regional lymph node invasion, thereby determining the metastatic status
- can be combined with other tests (chest x rays and **computed tomography** scans, or CT scans) to determine the extent of cancer spread to distant organs, such as the liver and/or the lungs

The resulting rectal cancer staging allows physicians to determine the need for—and order of—radiation, sur-

gery, and **chemotherapy**. In 2003, it was reported that magnetic resonance imaging (MRI) also may be useful in staging rectal cancer. MRI may help physicians determine if a tumor can be resected and what the risk of cancer recurrence will be.

Treatment team

Surgery, radiation treatment and chemotherapy are used in the therapy of cancer of the rectum. The extent of the primary tumor dictates whether surgery or radiation will be utilized first. When surgery is the primary local therapy, radiation often has an adjunctive role in helping to prevent local recurrence. Chemotherapy may be used as an adjunct also to decrease recurrence and improve overall survival. Thus, teamwork is required utilizing the skills of the surgeon and the radiation and medical oncologists.

Clinical staging, treatments, and prognosis

Once the diagnosis has been confirmed by biopsy and the endorectal ultrasound has been performed, the clinical stage of the cancer is assigned. The treating physicians use staging to plan the specific treatment protocol for the patient. In addition, the stage of the cancer at the time of presentation gives a statistical likelihood of the treatment outcome, (prognosis).

Clinical staging

Rectal cancer first invades locally and then progresses to spread to regional lymph nodes or to other organs. Stage is derived using the characteristics of the primary tumor, its depth of penetration through the rectum, local invasion into pelvic structure, and the presence or absence of regional or distant metastases. A CT scan of the pelvis is helpful in staging because tumor invasion into the sacrum or pelvic sidewalls may mean surgical therapy is not initially possible. On this basis, clinical staging is used to begin treatment. The pathologic stage is defined when the results of analyzing the surgical specimen are available. (typically stage I and II).

Rectal cancer is assigned stages I through IV, based on the following general criteria:

- Stage I: the tumor is confined to the epithelium (layer of cells covering the surface) or has not penetrated through the first layer of muscle in the rectal wall.
- Stage II: the tumor has penetrated through to the outer wall of the rectum or has gone through it, possibly invading other local tissue or organs.
- Stage III: Any depth or size of tumor associated with regional lymph node involvement.
- Stage IV: any of previous criteria associated with distant metastasis.

Treatments

SURGERY Surgical resection remains the mainstay of therapy in the treatment of rectal cancer. Stage I, II, and even suspected stage III disease are treated by surgical removal of the involved section of the rectum (resection) along with the complete vascular and lymphatic supply. However, because of the improvement in staging methods (principally endorectal ultrasound), many rectal cancers are now selected for pre-surgical treatment with radiation and, often, chemotherapy. The use of chemotherapy prior to surgery is known as neoadjuvant chemotherapy, and, in rectal cancer, neoadjuvant chemotherapy is used primarily for Stage II and Stage III rectal cancers. Following neoadjuvant treatment, the remaining tumor (often only a scar) is resected. In some cases, such neoadjuvant treatment avoids the need for permanent colostomy by major tumor shrinkage prior to surgery. Following surgery, chemotherapy is completed.

In other patients, surgical therapy alone (some small Stage I lesions) is followed by additional radiation and chemotherapy is selected. In a small group of patients with small, Stage I lesions, endoluminal radiation alone is performed as a curative treatment.

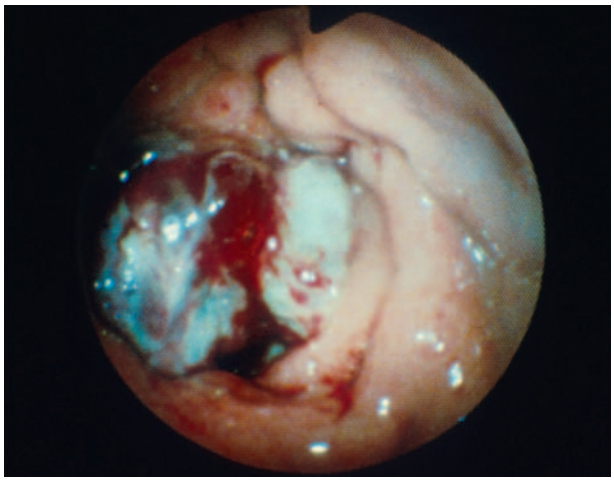
When determining primary treatment for rectal cancer, the surgeon's ability to reconnect the ends of the rectum must be considered. The pelvis is a confining space that makes surgical reconnection more difficult to do safely when the tumor is in the lower rectum. The upper rectum does not usually present a substantial problem to the surgeon restoring bowel continuity after the cancer has been removed. Mid-rectal tumors, especially in males where the pelvis is usually smaller than a woman's, may present technical difficulties in hooking the proximal bowel to the remaining rectum. Technical advances in stapling instrumentation have largely overcome these difficulties. If the anastomosis (hook-up) leaks postoperatively, infection can occur. In the past, this was a major cause of complications in resection of rectal cancers. Today, utilizing the stapling instrumentation, a hook-up at the time of original surgery is much safer. If the surgeon feels that the hook-up is compromised or may leak, a **colostomy** may be performed. A colostomy is performed by bringing the colon through the abdominal wall and sewing it to the skin. In these cases the stool is diverted away from the hook-up, allowing it to heal and preventing the infectious complications associated with leak. Later, when the hook-up has completely healed, the colostomy can be taken down and bowel continuity restored.

Stapling devices have allowed the surgeon to get closer to the anus and still allow the technical performance of a hook-up, but there are limits. It is generally felt that there should be at least three centimeters of normal rectum below the tumor or the risk of recurrence locally will be excessive. In addition, if there is no residual native rectum, the patient will not have normal sensation or control and will have problems with uncontrollable soilage, (**incontinence**). For these reasons, patients presenting with low rectal tumors may undergo total removal of the rectum and anus. This procedure is known as an abdominal-perineal resection. A permanent colostomy is performed in the lower left abdomen.

RADIATION As mentioned, for many late stage II or stage III tumors, **radiation therapy** can shrink the tumor prior to surgery. The other roles for radiation therapy are as an aid to surgical therapy in locally advanced disease that has been removed, and in the treatment of certain distant metastases. Especially when utilized in combination with chemotherapy, radiation used postoperatively has been shown to reduce the risk of local recurrence in the pelvis by 46% and death rates by 29%. Such combined therapy is recommended in patients with locally advanced primary tumors that have been removed surgically. Radiation has been helpful in treating effects of distant metastases, particularly in the brain. In very few cases, radiation alone may be the curative treatment for rectal cancer.

CHEMOTHERAPY Adjuvant chemotherapy, (treating the patient who has no evidence of residual disease but who is at high risk for recurrence), is considered in patients whose tumors deeply penetrate or locally invade (late stage II and stage III). If the tumor was not locally advanced, this form of chemotherapeutic adjuvant therapy may be recommended without radiation. This therapy is identical to that of colon cancer and leads to similar results. Standard therapy is treatment with 5-fluorouracil (5-FU, or fluorouracil) combined with **leucovorin** for a period of six to twelve months. 5-FU is an antimetabolite and leucovorin improves the response rate. Another agent, **levamisole** (which seems to stimulate the immune system) may be substituted for leucovorin. These protocols reduce the rate of recurrence by about 15% and reduce mortality by about 10%. The regimens have some toxicity but usually are tolerated fairly well.

Similar chemotherapy is administered for stage IV disease or if a cancer progresses and metastasis develops. Results show response rates of about 20%. A response is a temporary regression of the cancer in response to the chemotherapy. Unfortunately, these patients eventually succumb to the disease. **Clinical trials** have now shown that the results can be improved with the addition of another agent to this regimen. **Irinotecan** does not seem to increase toxicity but has improved response rates to 39%, added two to three months to disease-free survival, and prolonged overall survival by a little more than two months.



Rectal cancer seen through an endoscope. *(Custom Medical Stock Photo. Reproduced by permission.)*

Prognosis

Prognosis is the long-term outlook or survival after therapy. Overall, about 50% of patients treated for colon and rectal cancer survive the disease. As expected, the survival rates are dependent upon the stage of the cancer at the time of diagnosis, making early detection crucial.

About 15% of patients present with stage I disease, or are diagnosed with Stage I disease when they initially visit a doctor, and 85-90% survive. Stage II represents 20-30% of cases and 65-75% survive; 30-40% comprise the stage III presentation, of which 55% survive. The remaining 20-25% present with stage IV disease and are rarely cured.

Alternative and complementary therapies

Most alternative therapies have not been studied in clinical trials. Large doses of **vitamins**, fiber, and green tea are among therapies tried. A 2003 report on a large Harvard University study showed that people who took multivitamins for at least 15 years had a 34% reduction in risk of rectal cancer. Before initiating any alternative therapies, the patient should consult his or her physician to be sure that these therapies do

KEY TERMS

Adenocarcinoma—Cancer beginning in epithelial cells that line certain organs and have secretory properties.

Adjuvant therapy—Treatment involving radiation, chemotherapy (drug treatment), hormone therapy, or a combination of all three given after the primary treatment for the possibility of residual microscopic disease.

Anastomosis—Surgical re-connection of the ends of the bowel after removal of a portion of the bowel.

Anemia—The condition caused by too few circulating red blood cells, often manifest in part by fatigue.

Carcinogens—Substances in the environment that cause cancer, presumably by inducing mutations, with prolonged exposure.

Defecation—The act of having a bowel movement.

Epithelium—Cells composing the lining of an organ.

Lymphatics—Channels that are conduits for lymph.

Lymph nodes—Cellular filters through which lymphatics flow.

Malignant—Cells that have been altered such that they have lost normal control mechanisms and are capable of local invasion and spread to other areas of the body.

Metastasis—Site of invasive tumor growth that originated from a malignancy elsewhere in the body.

Mutation—A change in the genetic makeup of a cell that may occur spontaneously or be environmentally induced.

Occult blood—Presence of blood that cannot be appreciated visually.

Polyps—Localized growths of the epithelium that can be benign, pre-cancerous, or harbor malignancy.

Resect—To remove surgically.

Sacrum—Posterior bony wall of the pelvis.

Systemic—Referring to throughout the body.

not complicate or interfere with the recommended therapy.

Coping with cancer treatment

For those with familial syndromes causing colon cancer, genetic counseling may be appropriate. Psychological counseling may help anyone having trouble coping with a potentially fatal disease. Local cancer support groups are often identified by contacting local hospitals or the American Cancer Society.

The Colon Cancer Alliance offers online support at the following web page: <http://www.ccalliance.org/connect/support.html>.

Clinical trials

Clinical trials are scientific studies in which new therapies are compared to current standards in an effort to identify therapies that offer better results.

Agents being tested for efficacy in patients with advanced disease include **oxaliplatin** and CPT-11. Please see reference below for current information available from the National Cancer Institute regarding these clinical trials.

Prevention

There is not an absolute method for preventing colon or rectal cancer. An individual can lessen risk or identify the precursors of colon and rectal cancer. The patient with a familial history can enter screening and surveillance programs earlier than the general population. High-fiber diets and vitamins, avoiding obesity, and staying active lessen the risk. In fact, a 2003 report said that vigorous exercise (to the point of sweating or feeling out of breath) lowered risk of rectal cancer by nearly 40% compared to those who exercised less. Avoiding cigarettes and alcohol may be helpful. By controlling these environmental factors, an individual can lessen risk and to this degree prevent the disease.

By undergoing appropriate screening when uncontrollable genetic risk factors have been identified, an individual may be rewarded by the identification of benign polyps that can be treated as opposed to having these growths degenerate into a malignancy.

Special concerns

Polyps are growths of the epithelium of the colon. They may be completely benign, pre-malignant or cancerous. The association of colon and rectal cancers in patients with certain types of polyps is that many polyps begin as a benign growth and later acquire malignant characteristics. There are two types of polyps, pedunculated and sessile. This terminol-

ogy comes from their appearance; those that are pedunculated are on a stalk like a mushroom and the sessile polyps are broad based and have no stalk. Unless a pedunculated polyp gets large, malignant potential is very small. This type may also be easily removed at endoscopy. The sessile polyp is also known as a villous **adenoma**, as many as one-third of these harbor a malignancy. Therefore, the villous adenoma is considered premalignant. Sessile polyps may or may not be easily managed with the colonoscope and may need surgical removal because of their pre-malignant nature.

Polyps commonly present with occult blood in the stool. Since they are associated with the development of cancer, patients who have developed polyps need to enter a program of careful surveillance.

Elderly or debilitated patients with rectal cancers that seem localized may be treated by local destruction of the tumor through the anus. If the tumor is amenable to local resection or destruction by laser or cautery through the anus, the patient may be treated this way. This select group of patients may not be able to tolerate the standard therapy. Local control becomes the main issue while avoiding high-risk surgery and the inherent complications.

Renal pelvis tumors

Definition

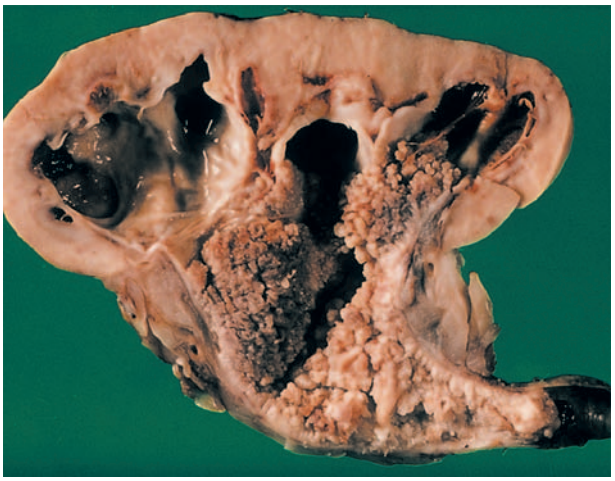
Renal pelvis tumors are rare kidney cancers appearing in a specific part of the kidney known as the pelvis of the kidney.

Description

The word "renal" means having to do with the kidneys. A part of each kidney in the human body is called the renal pelvis. The renal pelvis in each kidney is the portion of the collecting system that empties into the ureters (tubes that carry urine from the kidneys to the bladder).

Renal pelvis tumors usually appear after an earlier condition called renal papillary necrosis has already developed. The tumors may be composed of any one of several different types of cells. Most commonly, these tumors are of a type of cell known as a transitional cell carcinoma.

A transitional cell is intermediate between the flat squamous cell and the tall columnar cell. It is restricted to the epithelium (cellular lining) of the urinary bladder, ureters, and the renal pelvis. **Transitional cell carcinomas** have a wide range in their gross appearance depending on their locations. Some of these carcinomas are flat in appearance, some are papillary (small elevation), and others are in the shape of a node. Under the microscope, however, most of these carcinomas have a papillary-like look. There are three generally recognized grades of transitional cell carcinoma. The grade of the carcinoma is determined by particular characteristics found in the cells of the tumor. Transitional cell carcinoma typically affects the mucosa (the moist tis-



Transitional-cell carcinoma of the renal pelvis fills. *(Copyright Biophoto Associates, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

sue layer that lines hollow organs or the cavity of the body) in the areas where it originates— in this case, the kidney.

Demographics

Because statistics on these tumors are gathered with statistics on other kidney tumors, little information specific to tumors of the pelvic area of the kidney, as opposed to other areas of the kidney, is available. These tumors are relatively uncommon, however; they account for no more than 5% of cancers of the kidney and upper urinary tract. This percentage would indicate that 1785 Americans (1104 men and 684 women) were diagnosed with cancer of the renal pelvis in 2004 and 624 patients (394 men and 230 women) died of the disease. Renal pelvis cancers are more common in men than in women, as the statistics indicate, and appear most commonly in persons over the age of 65.

Causes and symptoms

The causes of renal cell cancer are not completely understood as of the early 2000s, but are thought to be related to the excretion of irritating substances in the urine. The appearance of renal pelvis tumors is often associated with a history of cigarette smoking and the overuse of certain pain medicines, as well as with a history of either kidney stones or **bladder cancer**. People who have worked in the rubber, paint, dye, printing, textile, and plastic industries and been exposed to certain chemicals are also at increased risk for this type of cancer. The risk is elevated, as well, for people with a rare kidney condition called Balkan nephropathy. This condition is more likely to affect people from Romania, Greece, Bulgaria, Serbia, Croatia, Bosnia-Herzegovina, and other countries included in the former Yugoslavia.

Approximately four out of five patients have symptoms of blood in the urine at the time of diagnosis. Approximately one out of three patients experiences pain in the side or lower back. Other frequent symptoms include urinary frequency or urgency, unintentional weight loss, brown or rusty-colored urine, and fatigue. Some patients may have no symptoms, while others may feel generally ill, visit the doctor for this general complaint, and have the cancer diagnosed at that time.

Diagnosis

Either urography or pyelography may be used to diagnose renal pelvis tumors. Both urography and pyelography are types of x-ray procedures that may be used to visualize portions of the urinary tract. The kidneys are part of the urinary tract. If urography is used, it is usually followed by **cystoscopy**. Cystoscopy involves the use of a medical instrument that permits the physician to look directly at portions of the urinary tract.

A newer technique is called ureteroscopy. Performing ureteroscopy increases the diagnostic accuracy doctors are able to attain. However, there is a risk that ureteroscopy may cause damage to some portion of the urinary tract. Therefore, ureteroscopy is usually reserved for those patients for whom unanswered questions remain after conventional diagnostic approaches have been completed.

The doctor may also order an **x ray** of the chest, a bone scan, and liver function tests to see whether the cancer has spread.

Clinical staging, treatments, and prognosis

Clinical staging

Tumor stage and grade provide important information on how an individual patient's renal pelvis tumor(s) will be treated and on the patient's prognosis. The primary tumor is staged on the basis of whether it remains superficial or has settled into the kidney. Patients with more superficial tumors have the best prognosis. However, even these patients may develop new tumors later.

Another factor important in determining treatment and prognosis is to determine the type and character of the individual cells that make up the tumor. Cells with a well-differentiated structure are associated with longer patient survival than cells with poorly differentiated structure.

Treatments

Surgery constitutes standard treatment for renal pelvis tumors. The surgical procedure is called a radical nephroureterectomy, and may involve the removal of a portion of the bladder as well. Some surgeons have attempted to perform part of the procedure through an endoscope rather than the standard open surgery, but early reports indicate that the rate of cancer recurrence is higher with endoscopic surgery.

Some patients should not receive surgical treatment for this cancer. Other patients should undergo a relatively more limited surgical procedure than the standard procedure—one in which less of the kidney is removed. Those who should be approached in the more limited way may include patients with only one single kidney, patients with cancer of both kidneys, and patients with Balkan nephropathy. In addition, patients who are in generally poor health may not be good candidates for surgery or may receive a limited surgical procedure.

Of course, patients with a single tumor comprised of well-differentiated cells are likely to have a better long-term outcome following a limited surgical procedure than are patients with several tumors comprised of poorly differentiated cells. It should be understood, however, that more limited procedures may involve a greater likelihood that the cancer will return.

Patients with Balkan nephropathy usually benefit from receiving the more limited procedure. These patients are at pre-existing risk of kidney failure because of the Balkan nephropathy; thus, the more of their kidneys preserved, the better for their future overall medical outcomes.

Some surgical procedures used for renal pelvis tumors are performed using a medical device that moves along the body channels used by urine. The use of this device in the treatment of renal pelvis tumors is, however, limited to extremely small tumors.

X-ray therapy may be used following a surgical procedure for renal pelvis tumors. In particular, it may be used if there is any evidence that tumor cells have affected any of the surrounding organs or if they are appearing in the lymph nodes. In addition, x-ray therapy may be recommended for patients who are at a higher-than-average risk for reappearance of cancer, for example, patients who are heavy smokers. Some authorities believe that additional studies are needed to clarify the effects of x-ray therapy for these patients.

Patients who experience pain related to renal pelvis tumors may receive x-ray treatment to control pain. Such treatment may be very effective. Patients with such pain may also benefit from **chemotherapy**.

KEY TERMS

Balkan nephropathy—A rare inherited kidney disorder that is associated with increased risk of developing renal pelvis tumors.

Cystoscopy—A medical procedure involving the use of a medical instrument that permits the physician to look directly at portions of the urinary tract.

Pyelography—A type of x-ray procedure applied to a portion of the urinary tract, of which the kidneys form part.

Renal—Having to do with the kidneys.

Renal papillary necrosis—A medical condition affecting the kidney and that increases a person's risk of developing a tumor of the renal pelvis.

Renal pelvis—That portion of the collecting system of the kidney that empties into the ureter.

Ureteroscopy—A diagnostic procedure that increases the diagnostic accuracy of the examination of possible renal pelvis tumors. Ureteroscopy may cause damage to some portion of the urinary tract. Therefore, ureteroscopy is usually reserved for those patients for whom unanswered questions remain after conventional diagnostic approaches have been completed.

Urography—A type of x-ray procedure applied to a portion of the urinary tract, of which the kidneys form part.

The patient with advanced renal pelvis cancer does not receive treatment that attempts to cure the disease. Rather, the treatment is palliative—it is used in an attempt to make the patient feel better and to improve the patient's quality of life. **Cisplatin** used alone has been shown to be an effective chemotherapy medicine in this situation.

It may, however, be preferable to use combination chemotherapy rather than cisplatin alone for patients with advanced disease, as a recent study demonstrated. The combination chemotherapy used in this study is the so-called M-VAC regimen, which consists of **methotrexate**, **vinblastine**, Adriamycin (**doxorubicin**), and cisplatin. This combination of medicines permitted patients both to live for a longer time without return of cancer and to live for a longer time overall.

Another combination of chemotherapy medicines studied for patients with advanced disease is the so-called CMV, which consists of cisplatin, methotrexate, and vinblastine.

QUESTIONS TO ASK THE DOCTOR

- How can I obtain supportive care so I come through this not only alive but with my family and emotional life intact?
- What sort of benefit and what sort of side effects might each of the available treatment options bring?
- Would you please inform me about treatment options and let me tell you about the priorities in my life so I can participate in forming a treatment plan?
- What is my prognosis?
- What are the chances, after I have completed treatment, that cancer may return? How frequently should I be checked so we can defeat any cancer that appears in the future?

It is important to examine the side effects that may accompany chemotherapy in these patients. Some of these side effects are severe, and a small percentage of patients treated using this modality die. Both the M-VAC and the CMV regimens help approximately half of patients and give some patients additional months of life.

Other newer medicines that have been tried as chemotherapy for patients with renal pelvis tumors and advanced disease are **paclitaxel** (Taxol) and **gemcitabine** (Gemzar). In 2005, it was questionable whether the use of either one of these medicines as single-drug chemotherapy produces superior results to the M-VAC or CMV regimens.

Prognosis

In terms of patient survival, almost all patients with superficial tumors composed of relatively well-differentiated cells live more than five years. In contrast, patients with poorly differentiated (abnormal in maturity and function) tumors that have invaded deep into the kidney and transplanted cells to other parts of the body may live only one year or less.

Approximately two out of five patients given limited surgical treatment for renal pelvis tumors will have new tumors develop. Therefore, it is important that these patients receive careful and regular follow-up. Some authorities recommend examinations for new tumors of and near the renal pelvis at three-, six-, nine-, twelve-, eighteen, and twenty-four months following surgery, and annually afterwards.

Coping with cancer treatment

Cancer patients need supportive care to help them come through the treatment period with physical and emotional strength in tact. Many patients experience feelings of **depression**, anxiety, and **fatigue**, and many experience nausea, vomiting, and other side effects during treatment. Studies have shown that these can be managed effectively if the patient discusses these issues with the treating physician.

Prevention

Smoking cessation is the most important step. In addition, persons working in the rubber, paint, dye, printing, textile, and plastic industries might speak with their doctor about whether they are at elevated risk of developing this cancer.

Retinoblastoma

Definition

Retinoblastoma is a malignant tumor of the retina that occurs predominantly in young children.

Description

The eye has three layers, the sclera, the choroid, and the retina. The sclera is the outer protective white coating of the eye. The choroid is the middle layer and contains blood vessels that nourish the eye. The front portion of the choroid is colored and is called the iris. The opening in the iris is called the pupil. The pupil is responsible for allowing light into the eye and usually appears black. When the pupil is exposed to bright light it contracts (closes), and when it is exposed to low light conditions it dilates (opens) so that the appropriate amount of light enters the eye. Light that enters through the pupil hits the lens of the eye. The lens then focuses the light onto the retina, the innermost of the three layers. The job of the retina is to transform the light into information that can be transmitted to the optic nerve, which will transmit this information to the brain. It is through this process that people are able to see the world around them.

Occasionally a tumor, called a retinoblastoma, will develop in the retina of the eye. Usually this tumor forms in young children but it can occasionally occur in adults. Most people with retinoblastoma develop only one tumor (unifocal) in only one eye (unilateral). Some, however, develop multiple tumors (multifocal) in one or both eyes. When retinoblastoma occurs independently in both eyes, it is then called bilateral retinoblastoma.

Occasionally, children with retinoblastoma develop trilateral retinoblastoma. Trilateral retinoblastoma results from the development of an independent brain tumor that often forms in a part of the brain called the pineal gland. In order for retinoblastoma to be classified as trilateral, the tumor must have developed independently and not as the result of the spread of the retinal cancer. The prognosis for trilateral retinoblastoma is quite poor.

The retinal tumor which characterizes retinoblastoma is malignant, meaning that it can metastasize (spread) to other parts of the eye and eventually other parts of the body. In most cases, however, retinoblastoma is diagnosed before it spreads past the eye to other parts of the body (intraocular) and the prognosis is quite good. The prognosis is poorer if the cancer has spread beyond the eye (extraocular).

Retinoblastoma can be inherited or can arise spontaneously. Approximately 40% of people with retinoblastoma have an inherited form of the condition and approximately 60% have a sporadic (not inherited) form. Individuals with multiple independent tumors, bilateral retinoblastoma, or trilateral retinoblastoma are more likely to be affected with the inherited form of retinoblastoma.

Demographics

Approximately 1 in 15,000 to 1 in 30,000 infants in Western countries are born with retinoblastoma, making it the most common childhood eye cancer. It is, however, a relatively rare childhood cancer and accounts for approximately 3% of **childhood cancers**. The American Academy of Ophthalmology estimates that 300–350 cases of retinoblastoma occur in the United States each year.

Retinoblastoma is found mainly in children under the age of five but can occasionally be seen in older children and adults. Retinoblastoma is found in individuals of all ethnic backgrounds and is found equally frequently in males and females. The incidence of bilaterial retinoblastoma in the United States is thought to be slightly higher among black children than among either Caucasian or Asian American children.

Causes and symptoms

Causes

Retinoblastoma is caused by changes in or absence of a gene called RB1. RB1 is located on chromosome 13q14. Cells of the body, with the exception of the egg and sperm cells, contain 23 pairs of chromosomes. All of the cells of the body excluding the egg and the sperm cells are called the somatic cells. The somatic cells contain two of each chromosome 13 and therefore two copies of the RB1 gene. Each egg and sperm cell contains only one copy of chromosome 13 and therefore only contains one copy of the RB1 gene.

RB1 produces a tumor suppressor protein that normally helps to regulate the cell cycle of cells such as those of the retina. A normal cell of the retina goes through a growth cycle during which it produces new cells. Genes such as tumor suppressor genes tightly regulate this growth cycle.

Cells that lose control of their cell cycle and replicate out of control are called cancer cells. These undergo many cell divisions, often at a quicker rate than normal cells, and do not have a limited lifespan. A group of adjacent cancer cells can form a mass called a tumor. Malignant (cancerous) tumors can spread to other parts of the body. A malignant tumor of the retina (retinoblastoma) can result when just one retinal cell loses control of it cell cycle and replicates out of control.

Normally the tumor suppressor protein produced by RB1 prevents a retinal cell from becoming cancerous. Each RB1 gene produces tumor suppressor protein. Only one functioning RB1 gene in a retinal cell is necessary to prevent the cell from becoming cancerous. If both RB1 genes in a retinal cell become non-functional, then a retinal cell can become cancerous and retinoblastoma can result. An RB1 gene is non-functional when it is changed or missing (deleted) and no longer produces normal tumor suppressor protein.

Approximately 40% of people with retinoblastoma have inherited a nonfunctional or deleted RB1 gene from either their mother or father. Therefore, they have a changed/deleted RB1 gene in every somatic cell. A person with an inherited missing or non-functional RB1 gene will develop a retinal tumor if the remaining RB1 gene becomes changed or deleted in a retinal cell. The remaining RB1 gene can become non-functional when exposed to environmental triggers such as chemicals and radiation. In most cases, however, the triggers are unknown. Approximately 90% of people who inherit a changed or missing RB1 gene will develop retinoblastoma.

People with an inherited form of retinoblastoma are more likely to have a tumor in both eyes (bilateral) and are more likely to have more than one independent tumor (multifocal) in one or both eyes. The average age of onset for the inherited form of retinoblastoma is one year, which is earlier than the sporadic form of retinoblastoma. Although most people with the inherited form of retinoblastoma develop bilateral tumors, approximately 15% of people with a tumor in only one eye (unilateral) are affected with an inherited form of retinoblastoma.

A person with an inherited missing or non-functional RB1 gene has a 50% chance of passing on this abnormal gene to his or her offspring. The chance that their children will inherit the changed/deleted gene and actually develop retinoblastoma is approximately 45%.

Some people with retinoblastoma have inherited a non-functioning or missing RB1 gene from either their mother or father even though their parents have never developed retinoblastoma. It is possible that one parent has a changed or missing RB1 gene in every somatic cell but has not developed retinoblastoma because their remaining RB1 gene has remained functional. It is also possible that the parent had developed a retinal tumor that was destroyed by the body. In other cases, one parent has two normal RB1 genes in every somatic cell, but some of their egg or sperm cells contain a changed or missing RB1 gene. This is called gonadal mosaicism.

Retinoblastoma can also result when both RB1 genes become spontaneously changed or deleted in a retinal cell but the RB1 genes are normal in all the other cells of the body. Approximately 60% of people with retinoblastoma have this type of disease, called sporadic retinoblastoma. A person with sporadic retinoblastoma does not have a higher chance of having children with the disease. Their relatives do not have a higher risk of developing retinoblastoma themselves or having children who develop retinoblastoma. Sporadic retinoblastoma is usually unifocal and has an average age of onset of approximately two years.

Symptoms

The most common symptom of retinoblastoma is leukocoria. Leukocoria results when the pupil reflects a white color rather than the normal black or red color that is seen on a flash photograph. It is often most obvious in flash photographs since the pupil is exposed to a lot of light and the duration of the exposure is so short that the pupil does not have time to constrict. Children with retinoblastoma can also have problems seeing and this can cause them to appear cross-eyed (strabismus). People with retinoblastoma may also experience red, painful, and irritated eyes, inflamed tissue around the eye, enlarged pupils, and possibly different-colored eyes.

Diagnosis

Children who have symptoms of retinoblastoma are usually first evaluated by their pediatrician. The pediatrician will often perform a red reflex test to diagnose or confirm leukocoria. Prior to this test the doctor inserts medicated eye drops into the child's eyes so that the pupils will remain dilated and not contract when exposed to bright light. The doctor then examines the eyes with an ophthalmoscope, which shines a bright light into the eyes and allows the doctor to check for leukocoria. Leukocoria can also be diagnosed by taking a flash Polaroid

photograph of a patient who has been in a dark room for three to five minutes.

If the pediatrician suspects retinoblastoma on the basis of these evaluations, he or she will most likely refer the patient to an ophthalmologist (eye doctor) who has experience with retinoblastoma. The ophthalmologist will examine the eye using an indirect ophthalmoscope. The opthalmoscope shines a bright light into the eye, which helps the doctor to visualize the retina. This evaluation is usually done under general anesthetic, although some very young or older patients may not require it. Prior to the examination, medicated drops are put into the eyes to dilate the pupils, and anesthetic drops may also be used. A metal clip is used to keep the eyes open during the evaluation. During the examination, a cotton swab or a metal instrument with a flattened tip is used to press on the outer lens of the eye so that a better view of the front areas of the retina can be obtained. Sketches or photographs of the tumor as seen through the ophthalmoscope are taken during the procedure.

An ultrasound evaluation is used to confirm the presence of the tumor and to evaluate its size. Computed tomography (CT, or CAT, scan) is used to determine whether the tumor has spread outside of the eye and to the brain. Sometimes **magnetic resonance imaging** (MRI) is also used to look at the eyes, eye sockets, and the brain to see if the cancer has spread.

In most cases the cancer has not spread beyond the eye, and other evaluations are unnecessary. If the cancer appears to have spread beyond the eye, then other assessments such as a blood test, spinal tap (**lumbar puncture**), and/or bone marrow **biopsy** may be recommended. During a spinal tap, a needle is inserted between the vertebrae of the spinal column and a small sample of the fluid surrounding the spinal cord is obtained. In a bone marrow biopsy, a small amount of tissue (bone marrow) is taken from inside the hip or breast bone for examination.

Genetic testing

Establishing whether someone is affected with an inherited or non-inherited form of retinoblastoma can help to ascertain whether other family members such as siblings, cousins, and offspring are at increased risk for developing retinoblastoma. It can also sometimes help guide treatment choices, since patients with an inherited form of retinoblastoma may be at increased risk for developing recurrent tumors or other types of cancers, particularly when treated with radiation. It is helpful for the families of a child diagnosed with retinoblastoma to meet with a genetic specialist such as a genetic counselor and/or geneticist. These specialists can help to ascertain the chances that the retinoblastoma is inherited and facilitate **genetic testing** if desired.

If a patient with unilateral or bilateral retinoblastoma has a relative or relatives with retinoblastoma, it can be assumed that they have an inherited form of retinoblastoma. However, it cannot be assumed that a patient without a family history of the disease has a sporadic form.

Even when there is no family history, most cases of bilateral and trilateral retinoblastoma are inherited, as are most cases of unilateral, multifocal retinoblastoma. However, only 15% of unilateral, unifocal retinoblastoma cases are inherited.

The only way to establish whether someone has an inherited form of retinoblastoma is to see if the retinoblastoma gene is changed or deleted in the blood cells obtained from a blood sample. Approximately 5% to 8% of individuals with retinoblastoma possess a chromosomal abnormality involving the RB1 gene that can be detected by looking at their chromosomes under the microscope. The chromosomes can be seen by obtaining a blood sample. If this type of chromosomal abnormality is detected in a child, then analysis of the parents' chromosomes should be performed. If one of the parents possesses a chromosomal abnormality, then they are at higher risk for having other offspring with retinoblastoma. Chromosome testing would be recommended for the blood relatives of the parent with the abnormality.

Usually, however, a chromosomal abnormality is not detected in a child with retinoblastoma. In this case, specialized DNA tests that look for small RB1 gene changes need to be performed on the blood cells. DNA testing can be difficult, time consuming, and expensive, since there are many possible RB1 gene changes that can cause the gene to become nonfunctional.

If a sample of tumor is available, then it is recommended that DNA testing be performed on the tumor cells prior to DNA testing of the blood cells. This testing can usually identify the gene changes/deletions in the RB1 genes that caused the tumor to develop. In some cases, RB1 gene changes/deletions are not found in the tumor cells (as of 2001, approximately 20% of RB1 gene changes or deletions are not detectable). In these cases, DNA testing of the blood cells will not be able to ascertain whether someone is affected with an inherited or non-inherited form of retinoblastoma.

If the changes in both RB1 genes are detected in the tumor cell, then these same changes can be looked for in the blood cells. If an RB1 gene is deleted or changed in all of the blood cells tested, the patient can be assumed to have been born with a changed/deleted RB1 gene in all of their cells. This person has a 50% chance of passing the RB1 gene change/deletion on to his or her children. Most of the time, this change/deletion has been inherited from a parent. Occasionally the gene change/deletion

occurred spontaneously in the original cell that was formed when the egg and sperm came together at conception (de novo).

If an RB1 gene change/deletion is found in all of the blood cells tested, both parents should undergo blood testing to check for the same RB1 gene change/deletion. If the RB1 gene change/deletion is identified in one of the parents, it can be assumed that the retinoblastoma was inherited and that siblings have a 50% chance of inheriting the altered gene. More distant blood relatives of the parent with the identified RB1 gene change/deletion may also be at risk for developing retinoblastoma. Siblings and other relatives could undergo DNA testing to see if they have inherited the RB1 gene change/deletion.

If the RB1 gene change/deletion is not identified in either parent, then the results can be more difficult to interpret. In this case, there is a 90-94% chance that the retinoblastoma was not inherited.

In some cases, a person with retinoblastoma will have an RB1 gene change/deletion detected in some of their blood cells and not others. It can be assumed that this person did not inherit the retinoblastoma from either parent. Siblings and other relatives would therefore not be at increased risk for developing retinoblastoma. Offspring would be at increased risk since some of the egg or sperm cells could have the changed/deleted RB1 gene. The risks to offspring would probably be less than 50%.

In families where there are multiple family members affected with retinoblastoma, blood samples from multiple family members are often analyzed and compared through DNA testing. Ninety-five percent of the time, this type of analysis is able to detect patterns in the DNA that are associated with a changed RB1 gene in that particular family. When a pattern is detected, at-risk relatives can be tested to establish whether they have inherited an RB1 gene change/deletion.

PRENATAL TESTING If chromosome or DNA testing identifies an RB1 gene/deletion in someone's blood cells, then prenatal testing can be performed on this person's offspring. An amniocentesis or chorionic villus sampling can be used to obtain fetal cells which can be analyzed for the RB1 gene change/deletion or chromosomal abnormality.

Treatment team

If possible, a person with retinoblastoma should be referred to a medical center with a team of cancer specialists. It is important that this team include specialists such as a primary care pediatrician, an ophthalmologist with extensive experience in treating retinoblastoma, pediatric surgeons, radiation oncologists, pediatric medical oncologists, rehabilitation specialists, pediatric nurse specialists, genetic specialists, and social workers.

Clinical staging, treatments, and prognosis

A number of different classification (staging) systems are used to establish the severity of retinoblastoma and aid in choosing an appropriate treatment plan. The most widely used staging system is the Reese-Ellsworth system. This system is used to classify intraocular tumors and predict which tumors are favorable enough that sight can be maintained. The Reese-Ellsworth classification system is divided into:

- Group I (very favorable for maintenance of sight): small solitary or multiple tumors, less than 6.4 mm in size (1 inch = 25.4 mm), located at or below the equator of the eye
- Group II (favorable for maintenance of sight): solitary or multiple tumors, 6.4mm-16mm in size, located at or behind the equator of the eye
- Group III (possible for maintenance of sight): any tumor located in front of the equator of the eye, or a solitary tumor larger than 16 mm in size and located behind the equator of the eye
- Group IV (unfavorable for maintenance of sight): multiple tumors, some larger than 16 mm in size, or any tumor extending in front of the outer rim of the retina (ora serrata)
- Group V (very unfavorable for maintenance of sight): large tumors involving more than half of the retina, or vitreous seeding, in which small pieces of tumor are broken off and floating around the inside of the eye

When choosing a treatment plan, the first important criteria to ascertain is whether the cancer is localized within the eye (intraocular) or has spread to other parts of the body (extraocular). An intraocular retinoblastoma may only involve the retina or could involve other parts of the eye. An extraocular retinoblastoma could involve only the tissues around the eye or could result from the spread of cancer to the brain or other parts of the body.

It is also important to establish whether the cancer is unilateral (one eye) or bilateral (both eyes), multifocal or unifocal. In order for the tumors to be considered multifocal, they must have arisen independently and not as the result of the spread of cancer cells. It is also important to check for trilateral retinoblastoma.

Treatments

The treatment chosen depends on the size and number of tumors, whether the cancer is unilateral or bilateral,

and whether the cancer has spread to other parts of the body. The goal of treatment is to cure the cancer and prevent as much loss of vision as possible. Since the late 1990s, doctors treating patients with retinoblastoma have tended to avoid enucleation and external beam radiation therapy whenever possible, in favor of chemotherapy to reduce the tumor in addition to focal therapies. Improved methods of chemoreduction have led to increasing success in saving patients' eyes, often with some visual function.

TREATMENT OF INTRAOCULAR TUMORS Surgical removal of the affected eye (enucleation) is used when the tumor(s) are so large and extensive that preservation of sight is not possible. This surgery is performed under general anesthetic and usually takes less than an hour. Most children who have undergone this surgery can leave the hospital on the same day. A temporary ball is placed in the eye socket after the surgery. Approximately three weeks after the operation, a plastic artificial eye (prosthesis) that looks like the normal eye is inserted into the eye socket.

Radiation therapy is often used for treatment of large tumors when preservation of sight is possible. External beam radiation therapy involves focusing a beam of radiation on the eye. If the tumor has not spread extensively, the radiation beam can be focused on the cancerous retinal cells. If the cancer is extensive, radiation treatment of the entire eye may be necessary. External beam radiation is performed on an outpatient basis and usually occurs over a period of three to four weeks. Some children may need sedatives prior to the treatment. This type of therapy can result in a temporary loss of a patch of hair on the back of the head and a small area of "sun-burned" skin. Long-term side effects of radiation treatment can include cataracts, vision problems, bleeding from the retina, and decreased growth of the bones on the side of the head. People with an inherited form of retinoblastoma have an increased risk of developing other cancers as a result of this therapy. Some consideration should therefore be given to alternative treatment therapies for those with an inherited form of retinoblastoma.

Photocoagulation therapy is often used in conjunction with radiation therapy but may be used alone to treat small tumors that are located on the back of the eye. Photocoagulation involves using a laser to destroy the cancer cells. This type of treatment is done under local or general anesthesia and is usually not associated with post-procedural pain.

Thermotherapy is also often used in conjunction with radiation therapy or drug therapy (**chemotherapy**). Thermotherapy involves the use of heat to help shrink tumor cells. The heat is either used on the whole eye or localized to the tumor area. It is done under local or general anesthesia and is usually not painful.

Cryotherapy is a treatment often used in conjunction with radiation therapy but can also be used alone on small tumors located on the front part of the retina. Cryotherapy involves the use of intense cold to destroy cancer cells and can result in harmless, temporary swelling of the external eye and eyelids that can last for up to five days. Eye drops or ointment are sometimes provided to reduce the swelling.

Brachytherapy involves the application of radioactive material to the outer surface of the eye at the base of the tumor. It is generally used for tumors of medium size. A patient undergoing this type of procedure is usually hospitalized for three to seven days. During that time, he or she undergoes one surgery to attach the radioactive material and one surgery to remove it. Eye drops are often administered for three to four weeks following the operation to prevent inflammation and infection. The long-term side effects of this treatment can include cataracts and damage to the retina, which can lead to impaired vision.

Intravenous treatment with one or more drugs (chemotherapy) is often used for treatment of both large and small tumors. Chemotherapy is sometimes used to shrink tumors prior to other treatments such as radiation therapy or brachytherapy. Occasionally, it is also used alone to treat very small tumors.

TREATMENT OF INTRAOCULAR AND UNILATERAL RETINOBLASTOMA Often, by the time that unilateral retinoblastoma is diagnosed, the tumor is so large that useful vision cannot be preserved. In these cases removal of the eye (enucleation) is the treatment of choice. Other therapies are unnecessary if enucleation is used to treat intraocular unilateral retinoblastoma. If the tumor is small enough, other therapies such as external beam radiation therapy, photocoagulation, cryotherapy, thermotherapy, chemotherapy, and brachytherapy may be considered.

TREATMENT OF INTRAOCULAR AND BILATERAL RETINOBLASTOMA If vision can be preserved in both eyes, radiation therapy of both eyes may be recommended. Smaller, more localized tumors can sometimes be treated by local therapies such as cryotherapy, photocoagulation therapy, thermotherapy or brachytherapy. Some centers may use chemotherapy in place of radiation therapy when the tumors are too large to be treated by local therapies or are found over the optic nerve of the eye. Many centers are moving away from radiation treatment and toward chemotherapy because it is less likely to induce future tumors. Enucleation is performed on the more severely affected eye if sight cannot be preserved in both.

This child's right eye is completely covered with a retinoblastoma tumor. *(Custom Medical Stock Photo. Reproduced by permission.)*

EXTRAOCULAR RETINOBLASTOMA There is no proven effective therapy for the treatment of extraocular retinoblastomas. Commonly, radiation treatment of the eyes and chemotherapy is provided.

Prognosis

Individuals with intraocular retinoblastoma who do not have trilateral retinoblastoma usually have a good survival rate with a 90% chance of disease-free survival for five years. Those with extraocular retinoblastoma have less than a 10% chance of disease-free survival for the same amount of time. Trilateral retinoblastoma generally has a very poor prognosis. Patients with trilateral retinoblastoma who receive treatment have an average survival rate of approximately eight months, while those who remain untreated have an average survival rate of approximately one month. Patients with trilateral retinoblastoma who are asymptomatic at the time of diagnosis may have a better prognosis than those who experience symptoms.

Patients with an inherited form of unilateral retinoblastoma have a 70% chance of developing retinoblastoma in the other eye. Retinoblastoma recurs in the other eye in approximately 5% of people with a non-inherited form of retinoblastoma, so it is advisable for even these patients to be closely monitored. People with an inherited form of retinoblastoma who have not undergone radiation treatment have approximately a 26% chance of developing cancer in another part of the body within 50 years of the initial diagnosis. Those with an inherited form who have undergone radiation treatment have a 58% chance of developing a secondary cancer by 50 years after the initial diagnosis. Most of the secondary cancers are skin cancers, bone tumors (osteosarcomas), and soft-tissue **sarcomas**. Soft-tissue sarcomas are malignant tumors of the muscle, nerves, joints, blood vessels, deep skin tissues, or fat. The prognosis for retinoblastoma patients who develop secondary cancers, however, is very poor as of the early 2000s.

Survivors of retinoblastoma are likely to have visual field defects after their cancer treatment is completed, most commonly scotomas, which are areas of lost or depressed vision within an area of normal vision. The size and type of these visual defects are determined by the size and type of the original tumor and the form of therapy used to treat it.

Alternative and complementary therapies

There are no alternative or complementary therapies specific to the treatment of retinoblastoma. Since most people diagnosed with retinoblastoma are small children, most drug-based alternative therapies designed to treat general cancer would not be recommended. Many specialists would, however, stress the importance of establishing a well-balanced diet, including certain fruits, vegetables, and vitamin supplements, to ensure that the body is strengthened in its fight against cancer. Some advocate the use of visualization strategies, in which patients would visualize the immune cells of their body attacking and destroying the cancer cells.

The most common side effects of chemotherapy include nausea and vomiting, and temporary hair loss (alopecia). This treatment can result in a temporary decrease in blood cells, including white blood cells, red blood cells, and platelets.

Coping with cancer treatment

Both retinoblastoma itself and treatments such as enucleation and radiation can result in vision impairment and cause some mild disfigurement around the eye. Children with resulting vision impairment can often be helped by centers and programs for the visually impaired. It is recommended that children who have undergone enucleation should wear protective glasses to protect the remaining eye. Special glasses may be recommended for those who are involved in contact sports. **Reconstructive surgery** following enucleation or radiation treatment may be recommended to improve the cosmetic appearance of the area around the eye. Eye drops and ointments may also be used to counteract side effects such as swelling and inflammation that can be associated with cancer treatments such as brachytherapy and cryotherapy.

KEY TERMS

Amniocentesis—Prenatal testing performed at 16 to 20 weeks of pregnancy that involves inserting a needle through the abdomen of a pregnant mother and obtaining a small sample of fluid from the amniotic sack, which contains the fetus. Often is used to obtain a sample of the fetus' cells for biochemical or DNA testing.

Benign tumor—An abnormal proliferation of cells that does not spread to other parts of the body.

Bilateral—Affecting both eyes.

Brachytherapy—Cancer treatment that involves the application of radioactive material to the site of the tumor.

Cryotherapy—Cancer treatment in which the tumor is destroyed by exposure to intense cold.

Chromosome—A microscopic structure found within each cell of the body, made of a complex of proteins and DNA.

Chorionic villus sampling (CVS)—Prenatal testing performed at 10 to 12 weeks of pregnancy, which involves inserting a catheter through the vagina of a pregnant mother or inserting a needle through the abdomen of the mother and obtaining a sample of placenta. Often is used to obtain a sample of the fetus' cells for biochemical or DNA testing.

DNA (deoxyribonucleic acid)—The hereditary material that makes up genes; influences the development and functioning of the body.

DNA testing—Testing for a change or changes in a gene or genes.

Enucleation—Surgical removal of the eye.

Equator—Imaginary line encircling the eyeball and dividing the eye into a front and back half.

Extraocular retinoblastoma—Cancer that has spread from the eye to other parts of the body.

Gene—A building block of inheritance, made up of a compound called DNA (deoxyribonucleic acid) and containing the instructions for the production of a particular protein. Each gene is found in a specific location on a chromosome.

Intraocular retinoblastoma—Cancer that is limited to the eye and has not spread to other parts of the body.

Malignant tumor—An abnormal proliferation of cells that can spread to other sites.

Multifocal—More than one tumor present.

Ophthalmologist—Physician specializing in the diseases of the eye.

Optic nerve—The part of the eye which contains nerve fibers that transmit signals from the eye to the brain.

Oncologist—A physician specializing in the diagnosis and treatment of cancer

Photocoagulation—Cancer treatment in which the tumor is destroyed by an intense beam of laser light.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

Protein—A substance produced by a gene that is involved in creating the traits of the human body, such as hair and eye color, or is involved in controlling the basic functions of the human body, such as control of the cell cycle.

Retina—The light-sensitive layer of the eye that receives images and sends them to the brain.

Scotoma—An area of lost or depressed vision within the visual field surrounded by an area of normal vision. Survivors of retinoblastoma frequently develop scotomas.

Somatic cells—All the cells of the body with the exception of the egg and sperm cells.

Tumor—A growth of tissue resulting from the uncontrolled proliferation of cells.

Tumor-suppressor gene—Gene involved in controlling normal cell growth and preventing cancer.

Unifocal—Only one tumor present in one eye.

Unilateral—Affecting only one eye.

Vitreous—The transparent gel that fills the back part of the eye.

Vitreous seeding—When small pieces of tumor have broken off and are floating around the vitreous.

If chemotherapy is used, the child may experience side effects such as nausea, vomiting, and hair loss. The patient may also experience a decreased level of: white blood cells, which can cause an increased susceptibility to infection; red blood cells, which can result in **fatigue** or shortness of breath; and platelets, which can cause an increased risk of bruising or prolonged bleeding after an injury. These symptoms are generally temporary and can often be treated. There are a number of drugs on the market that can decrease or

QUESTIONS TO ASK THE DOCTOR

- What form and stage of retinoblastoma does my child have? Has the cancer spread beyond the eye?
- Was this an inherited disease? Should other family members be tested?
- What are the chances of maintaining my child's sight? What treatment options are appropriate for this?
- Are there support groups in the area to help my family cope with this diagnosis?

even eliminate **nausea and vomiting**. Early recognition of infections and treatments with **antibiotics** are very important. All high fevers should be reported to a physician immediately, and may require hospitalization. Platelet transfusions are sometimes necessary for the replacement of platelets. Loss of hair can be very traumatic to an older child, but the use of a wig until the hair grows back may be helpful.

Clinical trials

As of 2004 the National Cancer Institute is conducting four clinical trials for the treatment of retinoblastoma and one intensive study of individuals and families at high risk for cancer. The treatment trials include two forms of combination chemotherapy; the use of arsenic trioxide; and combination chemotherapy followed by bone marrow transplantation.

Prevention

Although retinoblastoma cannot be prevented, appropriate screening and surveillance should be applied to all at-risk individuals to ensure that the tumor(s) are diagnosed at an early stage. The earlier the diagnosis, the more likely that an eye can be salvaged and vision maintained.

Screening of people diagnosed with retinoblastoma

Children who have been diagnosed with retinoblastoma should receive periodic dilated retinal examinations until the age of five. Young children will need to undergo these evaluations under anesthetic. After five years of age, periodic eye examinations are recommended. It may be advisable for patients with bilateral retinoblastoma or an inherited form of retinoblastoma to undergo periodic screening for the brain tumors found in trilateral retinoblastoma. There are no specific screening protocols designed to detect non-ocular tumors. All lumps and complaints of **bone pain**, however, should be thoroughly evaluated.

Screening of relatives

When a child is diagnosed with retinoblastoma, it is recommended that parents and siblings receive a dilated retinal examination by an ophthalmologist who is experienced in the diagnosis and treatment of the disease. It is also recommended that siblings continue to undergo periodic retinal examinations under anesthetic until they are three years of age. From three to seven years of age, periodic eye examinations are recommended. The retinal examinations can be avoided if DNA testing indicates that the patient has a non-inherited form of retinoblastoma or if the sibling has not inherited the RB1 gene change/deletion. Any relatives who are found through DNA testing to have inherited an RB1 gene change/deletion should undergo the same surveillance procedures as siblings.

The children of someone diagnosed with retinoblastoma should also undergo periodic retinal examinations under anesthetic. Retinal surveillance should be performed unless DNA testing proves that their child does not possess the RB1 gene change/deletion. If desired, prenatal detection of tumors using ultrasound may also be performed. During the ultrasound procedure, a handheld instrument is placed on the maternal abdomen or inserted vaginally. The ultrasound produces sound waves that are reflected back from the body structures of the fetus, producing a picture that can be seen on a video screen. If a tumor is detected through this evaluation, the affected baby may be delivered a couple of weeks earlier. This can allow for earlier intervention and treatment.

Special concerns

Since retinoblastoma most often affects children, parents have the difficult task of helping the doctor explain the condition and prognosis to their child. It is very important for parents to be open and honest about the disease, and some have found it helpful to read their child a story about another child who has faced the same condition.

Dealing with a diagnosis of retinoblastoma can be very stressful and frightening for children. Talking to other children with the same diagnosis can be helpful. Talking to a counselor or using relaxation therapies may also help a child deal with the emotions and fear associated with retinoblastoma.

Children with retinoblastoma may experience difficulties with their self image because of the temporary loss of hair or the loss of one or both eyes. It is important to remind these children of their many positive qualities. It is also important to teach children strategies for coping

with others who may tease them or ask them questions about their condition.

The diagnosis of retinoblastoma can greatly impact the whole family. For some, therapy may be necessary to ensure that the family can cope with the stresses associated with this diagnosis. Talking with other families who have children with retinoblastoma can also be of help.

In general, most children and families cope very well with the diagnosis of retinoblastoma. Since the prognosis is usually very good, it is important that parents strive to maintain a positive outlook.

Rhabdomyosarcoma

Definition

Rhabdomyosarcoma is a childhood cancer. It begins in cells that will become skeletal muscle cells. Skeletal muscle is attached to bones and is different from the smooth muscle that lines the intestinal tract (esophagus, stomach, small and large intestines). With rhabdomyosarcoma, these muscle cells grow uncontrollably and form masses or lumps called tumors. They can start almost anywhere in the body where there is skeletal muscle.

Description

Rhabdomyosarcomas can start in any organ that contains skeletal muscle cells, but most commonly tumors are found in the head and neck and in the prostate, bladder, and vagina. From 5–8% of all cancers diagnosed in children are rhabdomyosarcomas.

Demographics

Rhabdomyosarcoma occurs most frequently in children ages 2 to 6 and 15 to 19 years old. More males than females develop rhabdomyosarcomas. Among younger children, the tumor is usually in the head and neck and may involve the area surrounding the eye. Less often, young children develop rhabdomyosarcomas of the genitourinary tract (bladder, prostate, vagina).

In the older age group, the most likely site is the male genitourinary tract, especially the testes and surrounding area. Other body parts where rhabdomyosarcoma may begin are on the arms, legs, trunk, or deep inside the abdomen (retroperitoneum).

Some cases of rhabdomyosarcoma run in families and are linked to genetic syndromes. Immediate family members of children with rhabdomyosarcoma are at increased risk of developing certain cancers that are not rhabdomyosarcomas, such as breast and brain tumors.

Causes and symptoms

The causes of rhabdomyosarcoma are not known. Certain inherited conditions that run in families increase the risk of developing this cancer. Rhabdomyosarcoma has been linked to medical conditions such as fetal alcohol syndrome, neurofibromatosis, Gorlin's syndrome, and **Li-Fraumeni syndrome**.

The symptoms of rhabdomyosarcoma depend on the site of the tumor and whether it has spread. When rhabdomyosarcoma begins in the head, it may involve the area surrounding the eye, the nasal passages or the ear and throat. Tumors in these areas may cause swelling, especially around the eye; blocked nasal passages or sinuses; ear pain and bleeding; and difficulties swallowing. Rhabdomyosarcomas in the head and neck may also put pressure on the brain or nerves.

When rhabdomyosarcoma affects an arm, leg or other body part, the swelling may be mistaken for a bruise or other injury. When the genitals or urinary tract are involved, there may be symptoms such as recurring urinary tract infections, blood in the urine, **incontinence**, or blockage of the urinary tract or rectum.

Rhabdomyosarcoma affecting the testes may cause swelling of the scrotum. When the uterus or vagina is affected, there may be a mass or small tumor pushing into the vaginal canal.

Diagnosis

Some patients who have rhabdomyosarcomas go to the doctor because they have discovered a lump or mass or swelling on a body part. Others have symptoms related to the part of the body that is affected by the tumor. The patient's doctor will take a detailed medical history to find out about the symptoms. The history is followed by a complete physical examination with special attention to the suspicious symptom or body part.

Depending on the location of the tumor (mass or lump), the doctor will order **imaging studies** such as **x ray**, ultrasound, **computed tomography** (CT) scans and **magnetic resonance imaging** (MRI) to help determine the size, shape and exact location of the tumor. The doctor may also order bone scans to determine if the tumor has spread to bones. Blood tests will be done and an examination of the bone marrow also may be performed.

A **biopsy** of the tumor is necessary to make the diagnosis of rhabdomyosarcoma. During a biopsy, some tissue from the tumor is removed. The tissue sample is examined by a pathologist, a doctor who specializes in the study of diseased tissue.

Types of biopsy

The type of biopsy done depends on the location of the tumor. For some small tumors, such as those on the arm or leg, the doctor may perform an excisional biopsy, removing the entire tumor and a margin of surrounding normal tissue. Most often, the doctor will perform an incisional biopsy, a procedure that involves cutting out only a piece of the tumor. This biopsy provides a core of tissue from the tumor that is used to determine its type and grade.

Treatment team

Patients with rhabdomyosarcoma are usually cared for by a multidisciplinary team of health professionals. The patient's pediatrician, or primary care doctor may refer the patient to other physician specialists, such as surgeons and oncologists (doctors who specialize in cancer medicine). Radiologic technicians perform x ray, CT and MRI scans and nurses and laboratory technicians may obtain samples of blood, urine and other laboratory tests.

Before and after any surgical procedures, specially trained nurses may explain the procedures and help to prepare patients and families. Depending on the tumor location and treatment plan, patients may also benefit from rehabilitation therapy with physical therapists and nutritional counseling from dieticians.

Clinical staging, treatments, and prognosis

Staging

The purpose of staging a tumor is to determine how far it has advanced. This is important because treatment varies depending on the stage. Stage is determined by the size of the

tumor, whether the tumor has spread to nearby lymph nodes,and whether the tumor has spread elsewhere in the body.

Tumors are staged using numbers to designate Stages I through IV. The higher the number, the more the tumor has advanced. Stage I rhabdomyosarcomas have not extended beyond the site where they began; they are limited to a single muscle or organ. Stage II tumors show signs of spread beyond the muscle or organ where they began. Stage III rhabdomyosarcomas are tumors that could not be removed in their entirety by surgery. As a result, some tumor remains at the site where it began. Stage IV rhabdomyosarcomas have involved either lymph nodes or have spread to distant parts of the body.

Treatment

Treatment for rhabdomyosarcoma varies depending on the location of the tumor, its size and grade, and the extent of its spread. By the time most cases of rhabdomyosarcoma are diagnosed, there has already been some spread of the disease. For these patients, the goals of treatment are to remove or control the tumor and combat the spread of the cancer.

Generally, when completely removing the tumor will not sharply reduce function, rhabdomyosarcoma tumors are surgically removed. The site, size, and extent of the tumor determine the type of surgery performed. The goal of removing as much tumor as possible is to reduce the amount of radiation needed after surgery. The part of the body where the tumor was removed is treated with radiation to destroy remaining tumor cells. Many patients also receive **chemotherapy**.

When the disease has spread throughout the body, there may be no benefit from surgical removal of the tumor. These cases, usually patients with Group IV tumors, are treated with chemotherapy.

Side effects

The surgical treatment of rhabdomyosarcoma carries risks related to the surgical site, such as loss of function resulting from head and neck surgeries. Head and neck surgeries also may result in deformities that may be cosmetically unsatisfactory. There also are the medical risks associated with any surgical procedure, such as reactions to general anesthesia or infection after surgery.

The side effects of **radiation therapy** depend on the site being radiated. Radiation therapy can produce side effects such as **fatigue**, skin rashes, nausea, **diarrhea**, and secondary cancers. Most of the side effects lessen or disappear completely after the radiation therapy has been completed.

The side effects of chemotherapy vary depending on the medication, or combination of anticancer drugs, used.

Rhabdomyosarcoma, a malignant tumor affecting the inside of the mouth. *(Copyright Eamonn McNulty, Science Source/ Photo Researchers, Inc. Reproduced by permission.)*

Nausea, vomiting, **anemia**, lower resistance to infection and hair loss are common side effects. Medication may be given to reduce the unpleasant side effects of chemotherapy.

Alternative and complementary therapies

Many patients explore alternative and complementary therapies to help to reduce the stress associated with illness, improve immune function and feel better. While there is no evidence that these therapies specifically combat disease, activities such as biofeedback, relaxation, therapeutic touch, massage therapy and guided imagery have been reported to enhance well-being.

Prognosis

The outlook for patients with rhabdomyosarcoma varies. It depends on the site of the tumor, how the cancer cells look under the microscope, and extent of spread. For example, patients with tumors affecting the area around the eye and the bladder are more likely to do well than patients with tumors that begin deep within the chest or abdomen.

Rhabdomyosarcoma may spread to areas near the tumor and it can spread to nearby lymph glands. To spread to distant parts of the body, the cells travel in the blood or through the lymph glands. The most common sites for **metastasis** (spread) are the lymph glands near the tumor, the lung, liver, bone marrow, and brain. In general, tumors that have spread widely throughout the body are not associated with favorable survival rates.

Patients with Stage I tumors that are completely removed surgically have excellent prognoses; eight-year survival is nearly 75%. Sixty five percent of patients with

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of cancerous cells or by killing them.

Metastasize—The spread of cancer cells from a primary site to distant parts of the body.

Oncologist—A doctor who specializes in cancer medicine.

Pathologist—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

Radiation therapy—Treatment using high energy radiation from X-ray machines, cobalt, radium, or other sources.

Stage—A term used to describe the size and extent of spread of cancer.

QUESTIONS TO ASK THE DOCTOR

- What stage is the rhabdomyosarcoma?
- What are the recommended treatments?
- What are the side effects of the recommended treatment?
- Is treatment expected to cure the disease or only to prolong life?

Stage II tumors are disease free after 8 years. Stage I and II rhabdomyosarcomas account for about 40% of all cases.

About 40% of patients with Stage III and 15% of those with Stage IV rhabdomyosarcomas are disease free after 8 years. Patients with tumors that do not respond to treatment and those who suffer recurrences have poor outlooks for long-term survival.

Coping with cancer treatment

Toddlers, children and teens undergoing cancer treatment have special needs. The diagnosis of a life-threatening illness, surgery and radiation or chemotherapy may cause fear, anxiety, **depression** and loss of self-esteem. Toddlers may be especially fearful when they are separated from their parents for medical tests and hospital stays. Disruption of their normal routines and discomfort from diagnostic tests and treatment may also cause anxiety. Older children face additional social problems including making up missed school work, explaining the illness and treatment to friends, and coping with physical limitations or disability.

Teens with serious illnesses and disabilities face special conflicts and challenges. One conflict is between the teen's growing desire for independence and the reality of dependence on others for the activities of daily living. It is important for teens to be fully informed about their disease and treatment plan and involved in treatment decision making. Many teens benefit from continuing contact with friends, classmates, teachers, and family during hospital stays and recovery at home.

Depression, emotional distress, and anxiety associated with the disease and its treatment may respond to counseling from a mental health professional. Play therapy often helps toddlers and young children to reveal and express their feelings about illness and treatment. Many cancer patients and their families find participation in mutual aid and group support programs help to relieve feelings of isolation and loneliness. By sharing problems with others who have lived through similar difficulties patients and families can exchange ideas and coping strategies.

Clinical trials

About 30 clinical studies were underway during 2001. For example, in one clinical trial at John Hopkins Oncology Center, patients with recurring or widespread rhabdomyosarcoma were being treated with chemotherapy to stop tumor cells from dividing and simultaneously being given stem cells (bone marrow transplantation) to replace the immune cells killed by chemotherapy.

Other **clinical trials** compare different combinations of chemotherapy drugs to find out which combination is most effective. For example, in one study, patients with previously untreated rhabdomyosarcoma were randomly assigned to two different combinations of chemotherapy drugs. Along with radiation therapy, patients in one group received three drugs, **vincristine**, **dactinomycin**, and **cyclophosphamide** once a week. Patients in the other group were given vincristine, cyclophosphamide, and topotecan, instead of dactinomycin.

Other types of clinical research study individuals and families at high risk of cancer to help identify cancer genes. To learn more about clinical trials visit the National Cancer Institute (NCI) CancerNet web site at http://cancernet.nci.nih.gov/ or the Pediatric Oncology Branch of the National Cancer Institute web site at <http://www.dcs.nci.nih.gov/pedonc>.

Prevention

Since the causes of rhabdomyosarcoma are not known, there are no recommendations about how to prevent its development. Among families with an inherited tendency to develop soft tissue **sarcomas**, careful monitoring may help to ensure early diagnosis and treatment of the disease.

Special concerns

Rhabdomyosarcoma, like other cancer diagnoses, may produce a range of emotional reactions in patients and families. Education, counseling and participation in group support programs can help to reduce feelings of guilt, fear, anxiety and hopelessness. For many parents suffering from spiritual distress, visits with clergy members and participation in organized prayer may offer comfort.

Richter's syndrome

Definition

Richter's syndrome is a rare and aggressive type of acute adult leukemia that results from a transformation of **chronic lymphocytic leukemia** into diffuse large cell **lymphoma**.

Description

Leukemia is a group of cancers of the white blood cells. In adults, white blood cells are made in the bone marrow of the flat bones (skull, shoulder blades, ribs, hip bones). There are three main types of white blood cells: granulocytes, monocytes, and lymphocytes. Richter's syndrome concerns only the lymphocytes.

Lymphocytic leukemia develops from lymphocytes in the bone marrow. Unlike many other cancers in which a tumor starts growing in one particular location, lymphocytic leukemia is a disease of blood cells that travel throughout the body. In chronic (long-term) lymphocytic leukemia (CLL), lymphocytes do not follow a normal life cycle, and eventually, too many will exist in the blood. They are abnormal and do not fight infections well.

In a small percentage of people, CLL, even when it is treated, transforms into a new kind of aggressive blood cancer called diffuse large cell lymphoma. When this transformation occurs, it is called Richter's syndrome. The disease is named for the American pathologist Maurice Nathaniel Richter, who practiced medicine early in the twentieth century.

Demographics

Richter's syndrome is a disease of older adults. It is an extremely rare disease. The American Cancer Society estimates that in 2000, there were 8,100 new cases of chronic lymphocytic leukemia, and that 98% of these were in adults. Of these 8,100 new cases, only a handful will develop into Richter's syndrome. In general, people who are more likely to get CLL are those who smoke, have been exposed to high doses of radiation, or who have had long-term exposure to herbicides and pesticides. People who have close relatives (parent, siblings or children) with CLL are also more likely to develop the disease. However, none of these risk factors predict whether CLL will develop into Richter's syndrome.

Causes and symptoms

Scientists have yet to understand why some people develop Richter's syndrome and others do not. So far, no firm genetic or environmental links have been found.

When the transformation from CLL to Richter's syndrome occurs, a change occurs in the way the lymphocytes look under the microscope. In addition, lymph nodes swell, tumors grow rapidly in the lymph system, and the patient may experience **fever**, **night sweats**, and **weight loss**. The patient's health deteriorates rapidly and severely.

KEY TERMS

Lymph nodes—Small, bean-shaped collections of tissue found in lymph vessels. They produce cells and proteins that fight infection and filter lymph. Nodes are sometimes called lymph glands.

Lymph system—Primary defense against infection in the body. The tissues, organs, and channels (similar to veins) that produce, store, and transport lymph and white blood cells to fight infection.

Lymphoma—A cancer of the lymph system.

QUESTIONS TO ASK THE DOCTOR

- What kind of changes in my body can I expect to see from this cancer?
- What is the treatment plan?
- What are the likely side effects of the treatment plan?
- How long am I likely to survive?
- Since Richter's syndrome is rare, how much experience do you have with this disease?
- Are there hospitals that specialize in the treatment of Richter's syndrome where I might receive treatment unavailable here?

Diagnosis

Diagnosis is made by examining blood cells under microscope and by a bone marrow **biopsy**. This is the same test used to diagnose CLL. A small amount of bone marrow from one of the flat bones is drawn out with a needle for laboratory examination. In some cases, lymph nodes are also removed and examined in the laboratory.

Treatment team

Since a person who develops Richter's syndrome is already a cancer patient, a treatment team is already in place. This team usually includes an oncologist (cancer specialist), a hematologist (blood specialist) and possibly a radiation oncologist (specialist in **radiation therapy**), radiation or **chemotherapy** technicians, and nurses with special training in cancer care. With the development of Richter's syndrome, a social worker or counselor may be added to the team.

Clinical staging, treatments, and prognosis

Richter's syndrome is not staged. Chemotherapy is used to treat Richter's syndrome, although treatments are often unsuccessful. In addition, allogenic **bone marrow transplantation** is currently being tried in some patients. This treatment is not common and is not done at many cancer centers. For Richter's syndrome, the median survival rate (the time to which half the patients survive) is less than one year.

Alternative and complementary therapies

Alternative and complementary therapies range from herbal remedies, vitamin supplements, and special diets to spiritual practices, acupuncture, massage, and similar treatments. When these therapies are used in addition to conventional medicine, they are called complementary therapies. When they are used instead of conventional medicine, they are called alternative therapies.

There are no specific alternative therapies directed toward Richter's syndrome. However, good nutrition and activities that reduce stress and promote a positive view of life have no unwanted side effects and may help improve the quality of life.

Unlike traditional pharmaceuticals, complementary and alternative therapies are not evaluated by the United States Food and Drug Administration (FDA) for either safety or effectiveness. Patients should be wary of "miracle cures." In order to avoid any harmful side effects or interference with regular cancer treatment, patients should notify their doctors if they are using any herbal remedies, vitamin supplements, or other unprescribed treatments. Alternative and experimental treatments normally are not covered by insurance.

Coping with cancer treatment

Richter's syndrome is usually fatal within a short time. Coming to grips with this is tremendously stressful for both the patient and family members. In addition, chemotherapy treatments can cause **fatigue**, nausea, vomiting, and other uncomfortable side effects. Some patients decide to end treatment rather than undergo this discomfort when their chance of recovery is almost nonexistent. Others wish to continue full treatment.

This and many other personal decisions are issues to discuss with loved ones. It is often helpful for loved ones to have the support of a therapist, religious leader, or other counselor at this time when emotions are intense and often conflicting. Hospice staff members or hospital social workers or chaplains can direct patients and family members to resources that address their individual needs.

Clinical trials

As of 2001, many ongoing **clinical trials** related to chronic lymphocytic lymphoma may be appropriate for people with Richter's syndrome. Participation is always voluntary. The selection of clinical trials underway changes frequently. Current information on what clinical trials are available and where they are being held is available by entering the search term "chronic lymphocytic lymphoma" at the following web sites:

- National Cancer Institute. <http://cancertrials.nci.nih.gov> or (800) 4-CANCER.
- National Institutes of Health Clinical Trials. <http://clinicaltrials.gov>.
- Center Watch: A Clinical Trials Listing. <http://www.centerwatch.com>.

Prevention

There is no known way to prevent the transformation of CLL into Richter's syndrome.

Rituximab

Definition

Rituximab is a humanized monoclonal antibody that selectively binds to CD20, a protein found on the surface of normal and malignant B cells and is used to reduce the numbers of circulating B cells in patients who have B-cell non-Hodgkin's **lymphoma** (NHL). Rituximab is sold as Rituxan in the United States.

Purpose

Rituximab is a monoclonal antibody used to treat NHL characterized by overgrowth of B cells, the cell involved in about 85% of NHL malignancies. Of all the B-cell cancers more than 90% express the CD20 protein on the cell surface, a requirement for the proper function of rituximab. By binding the CD20 protein on the B cell, the antibody targets it for removal from the circulation. Based on data gathered in the laboratory developers believe that rituximab triggers both cell-mediated and complement-mediated means to kill the B cells, two different methods that the immune system uses to eliminate foreign cells. Binding of the antibody may also trigger apoptosis, or programmed cell death, of the B cells.

Rituximab has been most effective against low-grade (indolent) or follicular B-cell NHL. Low-grade (slow progression) NHL often responds well to initial treatment, but frequently relapses, making rituximab a welcome addition to the treatment options. Additionally, rituximab has been used for a second course of treatments after relapse with some success. As most patients with NHL are in stage III or IV by the time of diagnosis and treatment, experience with rituximab treatment are primarily with those stages of the disease.

As of spring 2001 **clinical trials** were being held testing the ability of this drug to work against several other types of cancers, including newly diagnosed NHL, intermediate- or high-grade (aggressive) NHL, AIDS-associated NHL, **Waldenström's macroglobulinemia**, **Hodgkin's disease**, **hairy cell leukemia** (HCL), **chronic lymphocytic leukemia** (CLL), **multiple myeloma**, **mantle cell lymphoma**, and large cell lymphoma.

Description

Rituximab is produced in the laboratory using genetically engineered single clones of B cells. Like all antibodies it is a Y-shaped molecule that can bind to one particular substance, the antigen for that monoclonal antibody. For rituximab that antigen is CD20, a protein found on the surface of B cells. Rituximab is a humanized antibody, meaning that the regions that bind CD20, located on the tips of the Y branches, are derived from mouse antibodies but the rest of the antibody is human sequence. The presence of the human sequences helps to reduce the **immune response** by the patient against the antibody itself—a problem seen when complete mouse antibodies were used for cancer therapies. The human

KEY TERMS

Antibody—A protective protein made by the immune system in response to an antigen, also called an immunoglobulin.

Apoptosis—Internal system for cell death, also called programmed cell death.

CD20—A protein found on the surface of normal and malignant B cells.

Humanization—Fusing the constant and variable framework region of one or more human immunoglobulins with the binding region of an animal immunoglobulin, done to reduce human reaction against the fusion antibody.

Monoclonal—Genetically engineered antibodies specific for one antigen.

sequences also help to ensure that the various cell-destroying mechanisms of the human immune system are properly triggered with binding of the antibody.

In 1997 Rituximab was the first unconjugated (not linked to a radioactive isotope or toxin) antibody approved for use by the FDA to treat cancer. It is specifically approved for treatment of low-grade or follicular B-cell NHL. Administration of the antibody resulted in either complete or partial responses in a little less than half of those patients.

Rituximab can be used alone or in combination with other chemotherapeutic drugs. Specifically, very good results have been seen when used in combination with the CHOP **chemotherapy** regimen (**cyclophosphamide**, **doxorubicin**, **vincristine**, and prednisone). When used in combination, dosages of the antibody given before beginning chemotherapy, alternating with the other drugs, then after the chemotherapy as a "mop-up" have proven effective.

There are a number of clinical trials in progress testing the ability of rituximab to work in combination with other chemotherapy drugs, treatments, and cytokines. Some substances and treatments being tested include interleukins 2 and 11, stem cell transplantation, radioimmunotherapy, vaccination, and a wide variety of other chemotherapy combinations.

Recommended dosage

The recommended dosage for patients with low-grade or follicular NHL is 375 mg/m2 infused intravenously. The infusion is given at weekly intervals for four total dosages. Acetominophen and **diphenhydramine** hydrochoride are given 30-60 minutes before the infusion to help reduce side effects. If given as a retreatment the dosage is the same. Clinical trials were ongoing in 2001 to help clarify the ideal dosage and treatment schedule for this drug. Generally, decrease in symptoms occurs at an average of 55 days after the last administration of the antibody.

Precautions

Serious (even fatal) infusion reactions, especially with the first infusion, have been known with this drug. There are a number of patient conditions that can make taking this drug more dangerous. Specifically, heart problems such as arrhythmias and high blood pressure, and the medications taken to treat those conditions, can be a problem with this treatment.

Side effects

The majority of side effects occur after or during the first infusion of the drug. Some common side effects include dizziness, feeling of swelling of tongue or throat, **fever** and chills, flushing of face, headache, **itching**, nausea and vomiting, runny nose, shortness of breath, skin rash, and unusual fatigue.

Less common side effects include black, tarry stools; blood in urine or stools; fever or chills with cough or hoarseness; lower back or side pain, or painful or difficult urination; pain at place of injection; pinpoint red spots on skin; red, itchy lining of eye; swelling of feet or lower legs; unusual bleeding or bruising; and unusual weakness.

Although they are very rare this drug does have serious side effects such as chest pain and irregular heartbeat, particularly in patients already having heart conditions. It can also cause serious effects on the blood cells such as low red blood cell count (**anemia**) and low white blood cell count (**neutropenia**). Additionally, this drug has caused low blood pressure (hypotension).

In patients with high tumor burden (a large number of circulating malignant B cells) this drug can cause a side effect called **tumor lysis syndrome**. Thought to be due to the release of the lysed cells' contents into the blood stream, it can cause a misbalance of urea, uric acid, phosphate, and calcium in the urine and blood. Patients at risk for this side effect must keep hydrated and can be given **allopurinol** (an anitgout medication) before infusion.

Interactions

There have been no formal drug interaction studies done with rituximab.

Rofecoxib *see* **Cyclooxygenase 2 inhibitors**

S

Salivary gland tumors

Definition

A salivary gland tumor is an uncontrolled growth of cells that originates in one of the many saliva-producing glands in the mouth.

Description

The tongue, cheeks, and palate (the hard and soft areas at the roof of the mouth) contain many glands that produce saliva. In saliva there are enzymes, or catalysts, that begin the breakdown (digestion) of food while it is still in the mouth. The glands are called salivary glands because of their function.

There are three big pairs of salivary glands in addition to many smaller ones. The parotid glands, submandibular glands and sublingual glands are the large, paired salivary glands. The parotids are located inside the cheeks, one below each ear. The submandibular glands are located on the floor of the mouth, with one on the inner side of each part of the lower jaw, or mandible. The sublingual glands are also in the floor of the mouth, but they are under the tongue.

The parotids are the salivary glands most often affected by tumors. Yet most of the tumors that grow in the parotid glands are benign, or not cancerous. Approximately 8 out of 10 salivary tumors diagnosed are in a parotid gland. One in 10 diagnosed is in a submandibular gland. The remaining 10% are diagnosed in other salivary glands.

In general, glands more likely to show tumor growth are also glands least likely to show malignant tumor growth. Thus, although tumors of the sublingual glands are rare, almost all of them are malignant. In contrast, about one in four tumors of the parotid glands is malignant.

Cancers of the salivary glands begin to grow in epithelial cells, or the flat cells that cover body surfaces. Thus, they are called carcinomas.

Demographics

Cancers in the mouth account for fewer than 2% of all cases of cancer and about 1.5% of cancer deaths. About 7% of all cancers diagnosed in the head and neck region are diagnosed in a salivary gland. Men and women are at equal risk.

Mortality from salivary gland tumors in the United States is higher among male African Americans below the age of 50 than among older workers of any race or either sex. The reasons for these findings are not clear as of early 2004.

Causes and symptoms

When survivors of the 1945 atomic bombings of Nagasaki and Hiroshima began to develop salivary gland tumors at a high rate, radiation was suspected as a cause. Ionizing radiation, particularly gamma radiation, is a factor that contributes to tumor development. So is **radiation therapy**. Adults who received radiation therapy for enlarged adenoids or tonsils when they were children are at greater risk for salivary gland tumors.

Another reported risk factor is an association between wood dust inhalation and adenocarcinoma of the minor salivary glands of the nose and paranasal sinuses. There is also evidence that people infected with herpes viruses may be at greater risk for salivary gland tumors. And individuals infected with human immunodeficiency virus (HIV) have more salivary gland disease in general, and may be at greater risk for salivary gland tumors.

Although there has been speculation that the electromagnetic fields generated by cell phones increase the risk of salivary gland tumors, a recent study done in Denmark has concluded that the use of cell phones, pagers, and similar devices is not a risk factor.

Symptoms are often absent until the tumor is large or has metastasized (spread to other sites). In many cases, the tumor is first discovered by the patient's dentist. During regular dental examinations, the dentist

looks for masses on the palate or under the tongue or in the cheeks, and such checkups are a good way to detect tumors early. Some symptoms are:

- lump or mass in the mouth
- swelling in the face
- pain in the jaw or the side of the face
- difficulty swallowing
- difficulty breathing
- difficulty speaking

Diagnosis

A tissue sample will be taken for study via a **biopsy**. Usually an incision is necessary to take the tissue sample. Sometimes it is possible to take a tissue sample with a needle.

Magnetic resonance imaging (MRI) and **computed tomography** (CT) scans are also used to evaluate the tumor. They help determine whether the cancer has spread to sites adjacent to the salivary gland where it is found. MRI offers a good way to examine the tonsils and the back of the tongue, which are soft tissues. CT is used as a way of studying the jaw, which is bone.

Treatment team

Generally, physicians with special training in the organs of the nose and throat take responsibility for the care of a patient with a salivary gland cancer. They are called otolaryngologists or occasionally by a longer name, otorhinolaryngologists.

For short, otolaryngologists are usually labeled ENT (for Ear, Nose and Throat) specialists. An ENT specializing in cancer will probably lead the team. An oncologist or radiation therapist may be involved, and nurses, as well as a nutritionist, speech therapist and social worker, will also be part of the team. Depending on the extent of the cancer when diagnosed, some surgery and treatments result in extensive changes in the throat, neck and jaw. The social worker, speech therapist and nutritionist are important in helping the patient cope with the changes caused by surgery and radiation treatment. If there is great alteration to the neck because of surgery, rehabilitation will also be part of the recovery process and a rehabilitation therapist will become a member of the team.

Clinical staging, treatments, and prognosis

To assess the stage of growth of a salivary gland tumor, many features are examined, including how big it is and the type of abnormal cell growth. Analysis of the types of abnormal cell growth in tissue is so specific that many salivary gland tumors are given unique names.

In stage I cancer the tumor is less than one inch in size and it has not spread. Stage II salivary gland cancers are larger than one inch and smaller than two and one-half inches, but they have not spread. Stage III cancers are smaller than one inch, but they have spread to a lymph node. Stage IV cancers have spread to adjacent sites in the head, which may include the base of the skull and nearby nerves, or they are larger than two and one-half inches and have invaded a lymph node.

Surgical removal (excision) of the tumor is the most common treatment. **Chemotherapy** and radiation therapy may be part of the treatment, particularly if the cancer has metastasized, or spread to other sites; chemotherapy of salivary gland cancers, however, does not appear to extend survival or improve the patient's quality of life. Because there are many nerves and blood vessels near the three major pairs of salivary glands, particularly the parotids, the surgery can be quite complicated. A complex surgery is especially true if the tumor has spread.

A promising form of treatment for patients at high risk of tumor recurrence in the salivary glands near the base of the skull is gamma knife surgery. Used as a booster treatment following standard neutron radiotherapy, gamma knife surgery appears to be well tolerated by the patients and to have minimal side effects.

Tumors in small salivary glands that are localized and can usually be removed without much difficulty.

KEY TERMS

Adenoids—Common name for the pharyngeal tonsils, which are lymph masses in the wall of the air passageway (pharynx) just behind the nose.

Biopsy—Tissue sample is taken from the body for examination.

Computed tomography (CT)—X rays are aimed at slices of the body (by rotating equipment) and results are assembled with a computer to give a three-dimensional picture of a structure.

Lymph—Tissue that is part of the lymphatic system, the system that collects and returns fluid to the blood vessels and produces substances that fight infection.

Magnetic resonance imaging (MRI)—Magnetic fields and radio frequency waves are used to take pictures of the inside of the body.

Tonsils—Common name for the palatine tonsils, which are lymph masses in the back of the mouth, on either side of the tongue.

The outlook for survival once the tumor is removed is very good if it has not metastasized.

For parotid cancers, the five-year survival rate is more than 85% whether or not a lymph node is involved at diagnosis. The ten-year survival rate is just under 50%.

Most early stage salivary gland tumors are removed, and they do not return. Those that do return, or recur, are the most troublesome and reduce the chance an individual will remain cancer-free.

Alternative and complementary therapies

Such techniques as yoga, meditation, or biofeedback can help a patient cope with anxiety over the condition and discomfort from treatment and should be explored as an option.

Coping with cancer treatment

A support group helps during the course of treatment and follow-up. Patients are encouraged to join one. They should also be encouraged to take an active role in following the recommendations and decisions made by the treatment team.

Clinical trials

There are a number of **clinical trials** in progress. For example, the more researchers understand the nature of cancer cells, the better they are able to design drugs that attack only cancer cells. Or, in some cases, drugs that make it easier to kill cancer cells have also been designed.

The Cancer Information Service at the National Institutes of Health offers information about clinical trials that are looking for participants. The service can be contacted at (800) 422-6237.

QUESTIONS TO ASK THE DOCTOR

- Which type of salivary gland tumor do I have?
- Is this the best place to have the salivary gland tumor treated?

Prevention

Minimizing intake of alcoholic beverages may be important. Avoiding unnecessary exposure of the head to radiation may also be considered preventative. Anything that reduces the risk of contracting a sexually transmitted disease, such as the use of condoms, also may lower the risk of salivary gland cancer.

Special concerns

Salivary gland tumors are considered rare. Because there are so many salivary glands, and so many types of salivary tumors, most physicians (even those who specialize in diseases of the ears, nose and throat) are challenged when they must interpret results of study of tumor tissue. For treatment of a salivary gland tumor, it is best to find a medical facility that specializes in diseases of the head and neck. Such a facility will be better able to match treatment to the specific characteristics of the tumor.

Sarcoma

Definition

A general term for any cancer of the bone, cartilage, fat, muscle, blood vessels, or other connective or supportive tissues. Sarcomas can be divided into soft tissue and bone (osteogenic) sarcomas. Liposarcomas (cancerous tumors of fat tissue) are an example of soft tissue sarcomas, while **Ewing's sarcoma** is considered an osteogenic sarcoma.

Kate Kretschmann

Sargramostim

Definition

Sargramostim is a medicine used to increase the blood cell counts after bone marrow transplants and **chemotherapy**. Sargramostim may be referred to as GM-CSF or granulocyte-macrophage colony stimulating factor.

Purpose

Sargramostim is a drug approved by the Food and Drug Administration (FDA) to decrease the time it takes for the bone marrow blood counts to recover after a bone marrow transplant. This decreases the risk of infection, the amount of time patients are treated with **antibiotics**, and the amount of time patients are in the hospital

Sargramostim is approved for use after chemotherapy to increase the recovery of the white cell counts and decrease the length of time a patient may have a **fever** and infection due to a low white count.

Sargramostim can be used after **bone marrow transplantation**. Once the new healthy bone marrow has been given back to a patient, sargramostim can be administered to help increase the blood cell counts and decrease the risk of fever and infection. Sargramostim can be used in patients when bone marrow is not recovering after a bone marrow transplant.

Sargramostim can be used for patients who will undergo a peripheral blood stem cell transplant. Patients will receive the sargramostim before the transplant. The sargramostim in these patients causes young, non-developed blood cells, known as stem or progenitor cells, to move from the bone marrow to the blood where they will then be removed from a patient by the process of apheresis. These blood cells are stored until after the patient receives larges doses of chemotherapy that destroy the bone marrow and the cancer. The patient then receives these stored cells back by an intravenous infusion. The stored cells repopulate the bone marrow and develop into the many types of functioning blood cells.

Description

Sargramostim is known as the brand name Leukine or Prokine. It has been available for use in bone marrow transplant patients for almost a decade. In cancer patients, chemotherapy destroys white blood cells temporarily. These white blood cells will grow again, but during the time that the levels are low patients are at an increased risk of developing fevers and infection. Sargramostim acts to stimulate the bone marrow to make more white blood cells which can either prevent the white count from dropping below normal or decrease the time

that the level is low. This helps the patient avoid fevers and infections and allows them to receive their next doses of chemotherapy without delay.

Recommended dosage

Sargramostim is a clear colorless liquid that is dosed based on a mathematical calculation that measures a person's body surface area (BSA). This number is dependent on a patient's height and weight. The larger the person the greater the body surface area. Body surface area is measured in the units known as square meter (m^2). The body surface area is calculated and then multiplied by the drug dosage in milligrams per square meter (mg/m^2). This calculates the actual dose a patient is to receive.

It is kept refrigerated until ready to use and it is administered to patients as an injection directly underneath the skin, subcutaneously. Subcutaneous is the preferred way to give the drug; it can be given in the back of the arms, upper legs, or stomach area. Sargramostim can also be administered to patients as a short intravenous infusion into a vein over 15 to 30 minutes.

To treat chemotherapy caused neutropenia in AML patients

The starting dose for AML patients who have just finished induction chemotherapy is 250 micrograms per square meter per day. This is given beginning four days after the chemotherapy has ended or approximately day number eleven of therapy. The dose is administered as intravenous infusion over a period of four hours. The doctor will inform the patient when it is time to stop the sargramostim based on blood count monitoring.

For patients receiving bone marrow transplant

The recommended dose is 250 micrograms per square meter per day administered as a two-hour infusion intravenously. This medication should begin within 2 to 4 hours of the patient receiving the bone marrow infusion.

If the patient's counts are not returning after the bone marrow has been received, sargramostim can be administered at a dose of 250 micrograms per square meter per day intravenously over a two hour time period for 14 consecutive days. This can be repeated after a seven-day rest for two more cycles. The doctor may increase the dose to 500 micrograms per square meter per day if the white count does not rise.

For patients prior to receiving a peripheral blood stem cell transplant

The recommended dose is 250 micrograms per square meter per day. This can be given either as a once daily dose administered under the skin, or intravenously administered as a continuous infusion over 24 hours. This dosing should continue until the last day of collection.

For patients after receiving a peripheral blood stem cell transplant

The recommended dose is 250 micrograms per square meter per day. This can be given either as a once daily dose administered under the skin, or intravenously administered as a continuous infusion over 24 hours. This dosing should begin right after the patient receives the stem cell infusion and continue until the white count rises to acceptable levels.

Precautions

Sargramostim should not be received by a patient in the 24-hour time frame before or after receiving chemotherapy.

Blood counts will be monitored frequently while on sargramostim. This allows the doctor to determine if the drug is working and when to stop treatment.

Sargramostim can affect patients who have kidney or liver problems before beginning treatment. These patients will be monitored by the doctor for any changes in kidney or liver function.

It is not recommended to give sargramostim to patients who have certain types of leukemias.

Sargramostim should be used with caution in patients who have fluid problems, including heart and lung problems.

Patients with a known previous allergic reaction to sargramostim or yeast-derived substances should tell their doctor before receiving this drug.

Patients who may be pregnant or trying to become pregnant should tell their doctor before receiving sargramostim.

Side effects

One of the most common side effects of sargramostim is **bone pain**. The sargramostim causes bone marrow to produce more white blood cells, and the process causes the patient to experience pain in their bones.

Other common side effects due to sargramostim administration are fever, muscle aches, chills, and weakness.

An uncommon, but serious side effect of sargramostim is increased fluid in patients. This swelling with fluid can occur in the body as a whole, legs, arms, around the heart, and in the lungs.

KEY TERMS

Antibiotics—Specific drugs used to treat infections.

Apheresis—The process of removing and collecting specific cells from the blood through a machine.

Bone marrow transplant—A procedure that destroys all of a patient's diseased bone marrow and replaces it with healthy bone marrow.

Chemotherapy—Specific drugs used to treat cancer.

Intravenous—Entering the body directly through a vein.

Food and Drug Administration (FDA)—A government agency that oversees public safety in relation to drugs and medical devices. The FDA gives the approval to pharmaceutical companies for commercial marketing of their products.

Neutropenia—A condition involving low levels of the white blood cells responsible for fighting infections.

Peripheral blood stem cell transplant—A procedure that collects and stores healthy young and non-developed blood stem cells. These are then given back to a patient to help them recover from high doses of chemotherapy.

Reinfusion—The transfer through a vein of healthy stem cells or bone marrow to a patient that has received large doses of chemotherapy.

Subcutaneous—Underneath the initial layer of skin.

Patients who have received sargramostim treatment have reported: **nausea and vomiting**, muscle pain, abdominal pain, rash, **diarrhea**, hair loss (alopecia), mouth sores, **fatigue**, allergic reactions and **itching**, shortness of breath, weakness, dizziness, heart problems, pain at the injection site, blood clots, headache, cough, rash, constipation, and change in kidney and/or liver function. These side effects may be due to the chemotherapy administration patients have received prior to the sargramostim.

Interactions

Sargramostim should not be given at the same time as chemotherapy or **radiation therapy**. Dosing should begin at least 24 hours after the last dose of treatment.

Patients on lithium or steroids should tell their doctor before starting sargramostim therapy, as these drugs can affect the white blood cell count.

Nancy J. Beaulieu, RPh.,BCOP

Saw palmetto

Definition

Saw palmetto is a natural plant remedy used to treat men who are experiencing difficulty when urinating. According to the American Dietetic Association, saw palmetto is one of the most commonly used dietary supplements among Americans between the ages of 50 and 76.

Purpose

Saw palmetto is not used to treat cancer. It is used to treat non-malignant enlargement of the prostate gland, also called benign prostatic hyperplasia (BPH).

Although saw palmetto has also been used to treat prostatitis and chronic pelvic pain syndrome (CPPS) in men, it does not appear to be useful for these conditions. A group of researchers at Columbia University reported in early 2004 that men given saw palmetto for CP/CPPS showed no appreciable improvement at the end of a year-long trial.

Description

The prostate gland is found only in men. It is located where the bladder drains into the urethra. The urethra is the tube that takes urine out of the body. The prostate gland contributes to the fluid in which sperm are ejaculated (semen).

It is common for the prostate to enlarge in men over age 50. This enlargement often is not malignant. It is thought to occur because of the action of **testosterone**, a male hormone, on the cells of the prostate. As the prostate grows, it can press on the urethra and narrow it. This causes men to have problems with urination that include the frequent urge to urinate (especially at night) and a week, dribbling, interrupted urine stream.

Saw palmetto is the bushy palm, *Serenoa repens* that grows to a height of about 18 feet (6 m) along the coast of the United States from South Carolina to Florida, and in Southern California. It is also found in Europe along the Mediterranean. Other names for this plant are American dwarf palm, cabbage palm, serenoa, or sable. The

medicinal part of the saw palmetto is an extract from the dark, olive-sized berries.

Saw palmetto has a long history of use by Native Americans in treating bladder inflammation, urinary difficulties, sexual difficulties, and respiratory tract infections. Of these uses, the only scientifically substantiated claim is that saw palmetto eases urinary difficulties and increases urine output. Although the exact mechanism of action of saw palmetto has not been determined, it is believed to interfere with the action of testosterone on the prostate gland. Finasteride (Proscar, also known as Permixon) is a prescription drug used to treat BPH that works in the same way. It is important to remember that BPH is not cancer, and saw palmetto is not a treatment for cancer.

Recommended dosage

Extract of saw palmetto is available in health food stores in capsules, liquid concentrate, tablets, and as dried, ground berries. An average daily dose of the drug is 1–2 grams of which 320 mg are the active ingredients. Dosage may vary from manufacturer to manufacturer.

Saw palmetto is classified as a dietary supplement. The United States Food and Drug Administration does not test or certify it. Unlike traditional pharmaceuticals, its manufacture is largely unregulated. Dietary supplements such as saw palmetto are not required to meet standards of purity or effectiveness in controlled **clinical trials**. Men interested in using saw palmetto should look for a reputable manufacturer of supplements who provides adequate testing and label information. The cost of dietary supplements is not covered by insurance.

Precautions

Men who are having trouble urinating should see a doctor before taking any remedies on their own. **Prostate cancer** is a serious, sometimes life-threatening disease, and its symptoms can be similar to BPH. A blood test and physical examination are used to diagnose prostate cancer. It is believed that saw palmetto may interfere with this blood test (called a prostate specific antigen or PSA test). Men should have this blood test done before they begin taking saw palmetto to make sure they get correct results.

Side effects

Saw palmetto has few side effects, and is generally regarded as safe. Medical authorities in Germany, France, and Italy all officially recognize it as a safe and generally effective treatment for symptoms of BPH. Side effects that have been reported are uncommon but include headache, upset stomach, and **diarrhea**.

KEY TERMS

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Testosterone—The main male hormone. It is produced in the testes and is responsible for the development of primary and secondary male sexual traits.

Interactions

Since saw palmetto is a natural remedy, few controlled studies have been done on how it interacts with other herbal remedies or traditional pharmaceuticals. In general, however, persons taking birth control pills, estrogen replacement therapy, or testosterone replacement therapy should consult their doctor before taking saw palmetto.Patients taking any supplements such as **vitamins** or herbs should tell their doctor.

Scopolamine

Definition

Scopolamine, also called hyoscine hydrobromide, is used in cancer treatment to prevent **nausea and vomiting** that results from movement of the head.

Purpose

Chemotherapy causes nausea and vomiting in many people. These conditions can occur for several different reasons. Scopolamine is used to treat nausea and vomiting that result from movement of the head. In many ways, this type of nausea is similar to motion sickness.

Other uses of scopolamine include pre-anesthesia sedation. In combination with morphine, scopolamine may be given to women in childbirth to induce "twilight sleep." Lastly, scopolamine is used in an ophthalmic solution to dilate the pupil of the eye before an eye examination.

Description

Scopolamine is a natural product and is familiar to many people as a motion sickness medicine. In its most common form, it comes as a patch that a person with motion sickness wears behind the ear. It is also known by the brand names Transderm-Scop and Transderm-V.

As a motion sickness drug, scopolamine has been used for many years with few side effects. It is approved by the United States Food and Drug Administration (FDA), and its cost is usually covered by insurance. In cancer treatment, scopolamine is used to treat a particular type of nausea and vomiting that occur as a result of chemotherapy.

Scopolamine is classified as an anticholinergic drug. This means it works by blocking the nerve impulses that send information from the part of the inner ear that controls the sense of balance. In motion sickness, a person vomits because conflicting information arrives in the brain from the inner ear and the eye. Some chemotherapy drugs also cause the brain to receive conflicting information, so that when patients move their head, they feel nauseated. People vary in their sensitivity to this condition. This drug is effective in helping most people control nausea and vomiting that arises from this source.

Recommended dosage

Scopolamine comes in a patch that the patient applies behind the ear. The patch stays in place for three days and releases a continuous supply of the drug. To be effective, the patch must be applied at least four hours before chemotherapy is begun. After three days, the patch is removed. Unused patches should be stored at room temperature.

KEY TERMS

Narrow-angle glaucoma—Glaucoma is a disease where increased pressure in the eye causes damage and changes to the field of vision. Narrow-angle refers to a specific type of damage.

Precautions

People applying or removing a scopolamine patch should wash their hands well immediately after handling the patch so that they do not accidentally transfer any of the drug to other parts of their body (for example, by rubbing their eyes). Scopolamine should not be used in children, should be kept away from pets, and should be used with caution in the elderly.

The patch should be used with caution in patients with a history of either seizures or psychosis, because scopolamine may make either of these disorders worse.

Side effects

About 65% of the people who use scopolamine get a dry mouth. About 17% of people report feeling drowsy from the drug. Other less common side effects include blurred vision, disorientation, restlessness, confusion, dizziness, difficulty urinating, constipation, skin rash, dry red itchy eyes, extreme sensitivity to light, and narrow-angle glaucoma.

Interactions

Many drugs interact with nonprescription (over-the-counter) drugs and herbal remedies. Patients should always tell their health care providers about these remedies, as well as prescription drugs they are taking. Patients should also mention if they are on a special diet such as low salt or high protein.

Scopolamine interferes with the absorption of ketoconazole (Nizoral), an antifungal drug, sometimes used to treat **prostate cancer**. It may also interact with other anticholinergic drugs (drugs that block nerve impulses), antidepressants, and antihistamines. Scopolamine decreases the absorption of phenothiazines (antipsychotic drugs), and interfers with the effectiveness of levodopa, a drug given to treat Parkinson's disease.

Screening test

Definition

A screening test is a procedure that is performed to detect the presence of a specific disease. The individual or group of individuals (as in mass screenings) does not present any symptoms of the disease.

Purpose

The purpose of a cancer screening test is to identify the presence of a specific cancer in an individual that does not demonstrate any symptoms. Screening allows for early detection of cancer and can save the life of the person who might have died if the cancer was not detected by screening. If cancers are detected early, the treatment can be more effective and often less costly than if the cancer had progressed and needed drastic treatment.

KEY TERMS

BRCA-1 and BRCA-2—These are tumor suppressor genes whose inherited mutations have been associated with hereditary forms of breast cancer.

Digital rectal exam—The physician will feel the prostate for irregular symmetry by going into the rectum.

Genetic test—This tests for the presence of specific genes or the presence of mutations on specific genes.

Prostate-specific antigen test—This test measures the level of prostate antigen in the blood to identify presence of prostate cancer.

Transrectal ultrasonography—This test uses a small rectal probe to create an image of the prostate gland.

Precautions

Most screening tests have been developed to be non-invasive or mildly invasive. For example breast self-exams, mammograms, and pelvic exams may be uncomfortable but are non-invasive. Therefore, most screening tests will not be affected by medications that a patient may be taking or other unrelated conditions a patient may be experiencing.

Description

Before developing or administering a screening test, the effectiveness of the test needs to be evaluated. There are several criteria to consider when deciding whether or not to screen. First, is the cancer highly fatal and common? If yes, then it is suitable for screening. Second, in order to screen a cancer, there must be detectable pre-symptomatic indicators. Finally, the reliability of results needs to be evaluated. A test can have one of the four following outcomes: true positive, false positive, true negative, and false negative. Randomized controlled trials also help to identify effective screening.

Screening tests exist for many of the more common cancers such as **prostate cancer**, **breast cancer**, **colon cancer**, lung cancer, and **cervical cancer**. Each screening test has an advisable age to begin screening and a recommended frequency at which the test should be performed. As people age, cancer becomes more prevalent; therefore, more screening tests are recommended.

Prostate cancer screening

Prostate cancer affects many men each year. Screening includes a digital rectal exam, tests for

prostate-specific antigen (PSA), and transrectal **ultrasonography** (TRUS). Each of these tests takes less than half an hour to perform. The PSA test is an excellent tool as it is highly sensitive, reasonably priced, and well-tolerated by patients. Men should be counseled about the benefits and risks of detecting and treating an indolent tumor (this cancer may not have caused symptoms). The treatment may cause urinary and sexual problems.

Breast cancer screening

After skin cancer, breast cancer is the most common malignancy that is diagnosed in women. There are several screening methods that can be performed, including **breast self-exam** (performed by the patient), clinical breast exam, **mammography**, and BRCA-1 and BRCA-2 **genetic testing**. Genetic testing is offered to patients who have a familial history of breast cancer. All of these tests can be performed in the doctor's office and take less than half an hour. Genetic testing requires a blood sample, and it takes a few days to receive the results. Counseling is strongly advised prior to genetic testing.

Colon cancer

Colon cancer (colorectal cancer) is the third leading cause of cancer death in the United States and is the third most diagnosed cancer among both men and women. Screening tests include **fecal occult blood test**, flexible **sigmoidoscopy**, **barium enema**, and **colonoscopy**. High-risk patients (significant familial history) should begin screening at puberty or 10 years prior to occurrence of family member's tumor. Sigmoidoscopy and colonoscopy are slightly invasive, completed under mild sedative in the hospital on an outpatient basis, and take about 15 and 30 minutes respectively. Screening with colonoscopy is unique and reliable, because it allows visualization of the entire colon.

Preparation

Most screening procedures are non-invasive in order to make them convenient for patients and cost effective. Screening such as breast exams, mammography, pelvic exams, digital rectal exams, and tests that require blood samples require no preparation by the patient. However, barium enema, sigmoidoscopy, and colonoscopy all require prior preparation of the bowel. Patients will be asked to consume a clear liquid diet 24 hours prior to the exams, followed by liquid laxative about 2 hours prior to the exam. An enema or two may be required until the stool is clear.

Aftercare

Since most of the exams are non-invasive, there is no required aftercare. However, patients are encouraged to monitor themselves for any related symptoms of the cancer in question.

QUESTIONS TO ASK THE DOCTOR

- What medications interfere with the results of this test?
- What tests can be performed to confirm that the results of this screening test are accurate?
- What is the most accurate and cost-effective screening test for the type of cancer in question?
- Can this test be performed anonymously?
- Will my insurance company pay for this test?

Risks

Since no medical tests are perfect, there are several negative consequences associated with screening. First, if a patient's prognosis would be the same with or without the screening, then the patient experiences a longer time of being sick. Second, if the results of the tests are a false negative, then the patient may be negligent in identifying symptoms and warning signals. Conversely if the results of the test are a false positive, then the patient may be subjected to unnecessary diagnostic procedures and psychological trauma. Finally, insurance companies or employers that possess results of a positive genetic test could use that information unethically, impacting coverage and employment advances.

Normal results

Normal results vary for each test and need to be analyzed for false negative results.

Abnormal results

Doctors schedule more diagnostic testing if abnormal results arise. Normally, a **biopsy** is administered on the tissue in question in order to view the cells for typical cancer traits.

BOOKS

Bast, Robert C. *Cancer Medicine*. Hamilton, Ontario: B.C. Decker Inc., 2000.

PERIODICALS

Ruffin, Mack T., M.D., et al. "Predictors of Screening for Breast, Cervical, Colorectal, and Prostatic Cancer Among Community-Based Primary Care Practices." *The Journal of the American Board of Family Practice* January/February 2000: 1–10.

Sally C. McFarlane-Parrott

KEY TERMS

Late effect—A consequence of illness or therapy that becomes evident only after long-term patient monitoring.

Neoplasm—A new, abnormal growth of tissue. A neoplasm may be benign or malignant.

Solid tumor—A cancer that originates in an organ or tissue rather than in bone marrow or the lymph system.

Second cancers

Definition

A second cancer is a malignancy that develops in someone who has survived an earlier cancer.

Description

Formally referred to as second primary neoplasms, second cancers are also described as late effects of the original disease or of the treatment used to cure it.

Blood-based malignancies usually occur within a few years of treatment. Solid tumors may not become evident until 20 years later. Most second cancers affect parts of the body that have been exposed to radiation and are near the site of the original tumor.

Demographics

Having once had cancer almost doubles an individual's risk of having cancer a second time. A child who develops cancer before the age of 15 is eight times more susceptible to a new cancer than a boy or girl the same age who has not had the disease. Age does not seem to decrease the likelihood that any cancer survivor will develop a second malignancy.

Each year, almost 100,000 new malignancies are diagnosed among the more than 8,000,000 children, teenagers, and adults who have previously been treated for cancer. Although still rare, the incidence of new cancers in patients cured of one or more malignancies more than doubled (from approximately 6.4% to 15.3%) between 1973 and 1997. The rate of second cancers will continue to rise as the number of long-term cancer survivors continues to grow.

Children who have been treated for **Hodgkin's disease** are most at risk for developing a second cancer within 20 years. The likelihood is lowest for individuals who survive five years or longer after being treated for non-Hodgkin's **lymphoma**.

Causes

Some second cancers result from the risk factors responsible for the original disease. Some are caused by radiation or **chemotherapy** treatments that damage normal cells or suppress the patient's immune system.

Chemotherapy generally increases the likelihood of leukemia. Radiation raises the risk of developing **breast cancer** or other solid tumors.

Scientists do not fully understand why chemotherapy causes some cancer survivors to develop new malignancies. They believe radiation's role in second cancers is influenced by:

- the kind of radiation exposure the patient receives
- how much radiation the patient receives
- how old the patient is at the time of treatment
- the patient's personal and family medical history

Research

Although second cancers can occur following treatment for any type of cancer, researchers are concentrating on lymphoma, leukemia, and testicular cancer because these are the diseases that most often affect children and young adults.

Researchers are also trying to determine which types of cell damage can be characterized as precancerous and how:

- the patient's gender
- the patient's age at the time of diagnosis
- the stage of the original cancer at the time of diagnosis
- the length of the patient's survival affect the risk of developing a second cancer.

Other studies focus on whether administering both radiation and chemotherapy raises or lowers a patient's risk of developing a second cancer and how specific chemotherapy drugs, the number of times a patient is exposed to radiation, and the total amount of radiation a

patient receives during a course of treatment affect the chances of developing a new malignancy.

In 1993, the National Cancer Institute (NCI) initiated the Childhood Cancer Survivor Study (CCSS). The most extensive study of its kind ever undertaken, the ongoing investigation involves more than 20,000 patients diagnosed with cancer before the age of 21. It is designed to:

- provide new information about long-term effects of cancer and cancer treatments
- enable doctors to design treatments that increase survival rates and reduce the incidence and severity of unpleasant or harmful side effects
- help survivors understand how diagnosis and treatment can continue to affect their health
- implement programs for the prevention and early detection of second cancers and other late effects

In 1996, NCI established an Office of Cancer Survivorship (OCS) to identify and provide education and support for the special physical and emotional needs of cancer survivors.

OCS's mission is improving cancer survivors' quality of life. Priority research focuses on increasing awareness of the challenges associated with cancer survivorship and developing programs to lessen the burdens of cancer survivors.

NCI's Pediatric Oncology Branch conducts **clinical trials** for children whose cancer has recurred or has not responded to treatment.

Prevention

Researchers are:

- investigating the process that transforms cancer treatments into sources of new tumors
- studying ways to maintain or improve survival rates while treating patients with gentler types of chemotherapy or doses of radiation too low to inflict the cell damage that causes second cancers
- confident that further research into causes of second cancers will enable them to develop strategies to prevent the development of new malignancies

Even though only a small percentage of cancer survivors develop second malignancies, everyone who has had cancer must:

- follow a healthy lifestyle
- avoid known causes of cancer, like smoking or prolonged exposure to the sun
- diligently follow their doctor's recommendations regarding cancer screenings and other forms of medical surveillance

QUESTIONS TO ASK THE DOCTOR

- Am I likely to develop a second cancer?
- How can I reduce my risk of developing a second cancer?
- What symptoms might mean that I have developed a new cancer?
- What should I do if any of these symptoms occur?

- see a doctor as soon as they develop new symptoms or notice any changes in the way they look or feel

Special concerns

Improved long-term cancer survival rates have increased concern about the physical and psychological effects of the disease and the treatments used to cure it.

Doctors must monitor cancer patients carefully to make sure radiation and chemotherapy dosages low enough to eliminate unwanted side effects are strong enough to eradicate all a patient's cancer cells.

A patient who has had cancer should be aware of the risk of developing a second cancer. However, patients should not refuse or discontinue treatment for fear of developing a second malignancy. The benefits of cancer treatment far outweigh the risk of developing a new cancer.

Segmentectomy

Definition

Segmentectomy is the excision (removal) of a portion of any organ or gland. The procedure has several variations and many names, including wide excision, **lumpectomy**, tumorectomy, quadrantectomy, and partial **mastectomy**.

Purpose

The purpose of this procedure is to surgically remove a portion (in this case, with a cancerous tumor) of an organ or gland as a treatment.

Precautions

Because of the need for radiotherapy after segmentectomy, some patients, such as pregnant women and those with syndromes not compatible with radiation treatment, may not be candidates for this procedure. As with any surgery, patients should alert their physician about all allergies and any medications they are taking.

Description

Common organs that have segments are the breasts, lungs, and liver. When cancer is confined to a segment, removal of that portion may offer cancer-control results equivalent to larger operations. This is especially true for breast and liver cancers. In cases of lung cancer, **lobectomy** (surgical removal of all or part of the lung) is preferable, but if the patient does not have sufficient pulmonary function to tolerate this larger operation, then a segmentectomy may be necessary. For breast and lung cancers, this procedure is often combined with removal of some or all regional lymph nodes.

Preparation

Routine preoperative preparations, such as having nothing to eat or drink the night before surgery, are typically ordered for a segmentectomy. Information about expected outcomes and potential complications is also part of the preparation for this surgery.

Aftercare

After a segmentectomy, patients are usually cautioned against any moderate lifting for several days. Other activities may be restricted (especially if lymph nodes were removed) according to individual needs. Pain is often enough to limit inappropriate motion. Women who undergo segmentectomy of the breast are often instructed to wear a well-fitting support bra both day and night for approximately one week after surgery. Pain is usually well-controlled with prescribed medication. If it is not, the patient should contact the surgeon, as severe pain may be a sign of a complication, which needs medical attention.

Radiation therapy is usually started four to six weeks after surgery and will continue for four to five weeks. The timing of additional therapy is specific to each individual patient.

KEY TERMS

Conservation surgery—Surgery that preserves the aesthetics of the area to be worked on.

Excision—To surgically remove.

Lymph nodes—Small, bean-shaped organs located throughout the lymphatic system. Lymph nodes store special cells that can trap cancer cells and bacteria that are traveling through the body.

Radiotherapy—The treatment of disease with high-energy radiation, such as x or gamma rays.

Risks

Risk of infection in the area affecting a segmentectomy only occurs in 3% to 4% of patients.

Normal results

Successful removal of the tumor.

Abnormal results

Major bleeding and/or infection at the wound after surgery.

Clinical Trials

Using a segmentectomy to remove breast cancers (as a technique that conserves the aesthetics of a breast) is being investigated for large tumors after several cycles of preoperative **chemotherapy**. Segmentectomy is also being investigated for treating small-cell lung cancers. Information about clinical trial options is available from the National Cancer Institute at <http://www.nci.nih.gov>.

Semustine

Definition

Semustine, also known as methyl-CCNU, is one of a group of antineoplastic (antitumor) drugs known as alkylating agents. As of mid-2001, it was an **investigational drug**.

Purpose

Semustine has been used in the treatment of brain tumors, lymphomas, colorectal cancer, and **stomach cancer**. It is not clearly superior to other treatments for these diseases. It has also been associated with an increased risk of secondary (that is, treatment-related) leukemia. Thus, semustine is not widely used in the U.S.

Description

Like many antineoplastic (antitumor) therapies, semustine acts by killing quickly growing cells. Since cancerous cells are generally growing faster than normal cells, drugs that kill quickly growing cells generally affect tumors more than normal cells. However, some normal cells, such as white blood cells and platelets, also grow quickly, and can be severely affected by antineoplastic drugs. Antitumor therapies create a situation where the drug is racing to kill the tumor before it causes irreparable damage to normal tissues. The ideal situation is one in which the growth of the tumor is severely affected, but the growth of normal cells is unaffected. However, not every situation is ideal. Some patients taking antitumor drugs may have to discontinue treatment or decrease the dose because of side effects.

Semustine is included in the group of anticancer drugs known as alkylating agents.

Semustine is an investigational drug in the United States. This means that the FDA has not approved this drug for marketing in the U.S. as of mid-2001. Generally, investigational drugs are made available through participation in research studies.

Many drugs have toxic side effects, some of which are difficult to detect. **Clinical trials** are used to determine the side effects, drug interactions, and precautions for medicines, as well as their efficacy. Successful completion of multi-step clinical trials results in FDA approval of a drug. Many drugs that are used in clinical trials never gain FDA approval, however, possibly because of severe side effects that outweigh the benefits of the medication, or because the medication does not perform the function for which it was tested. Final approval of a drug is also expensive. Some drugs may not receive the financial support necessary to achieve final approval.

Recommended dosage

Since semustine is investigational, there is no recommended dosage. Different dosing schedules have been reported in the literature for different cancers.

Precautions and side effects

In the published reports of semustine use, a common side effect is **myelosuppression**, the damage to white

KEY TERMS

Investigational drug—A drug that has not been approved for marketing by the FDA. These drugs are generally available to patients through participation in research studies.

blood cells and platelets. Such damage may result in infection and bleeding, respectively. The myelosuppression from semustine is prolonged, meaning that it takes longer for blood cells to recover than is seen with many other anticancer drugs. Therefore, the interval between courses of semustine is longer than with other agents. Semustine also causes **nausea and vomiting**. Sometimes **anorexia**, or loss of appetite, persists after nausea and vomiting. As noted above, semustine has also been associated with the development of secondary leukemia.

Interactions

As of mid-2001, information on the interactions of semustine is not available.

Sentinel lymph node mapping

Definition

Sentinel lymph node mapping is a method of determining whether cancer has metastasized (spread) beyond the primary tumor and into the lymph system. The mapping procedure is used in conjunction with sentinel **lymph node biopsy** or dissection.

Purpose

The lymph system is the body's primary defense against infection. Lymph vessels carry clear, slightly yellow fluid called lymph that contains and proteins to help rid the body of infection. Lymph nodes are small, bean-shaped collections of tissue found along the lymph vessels. Cancer cells can break off from the original tumor and spread through the lymph system to distant parts of the body where secondary tumors are formed. One job of the lymph nodes is to clean the lymph by trapping foreign cells, such as bacteria or cancer cells, and identifying foreign proteins for antibody response.

The sentinel lymph node is the first lymph node that filters the fluid draining away from the primary tumor. If cancer cells are breaking off and entering the lymph system, the first filtering node (not necessarily the closest to the tumor) will be most likely to contain the breakaway cancer cells.

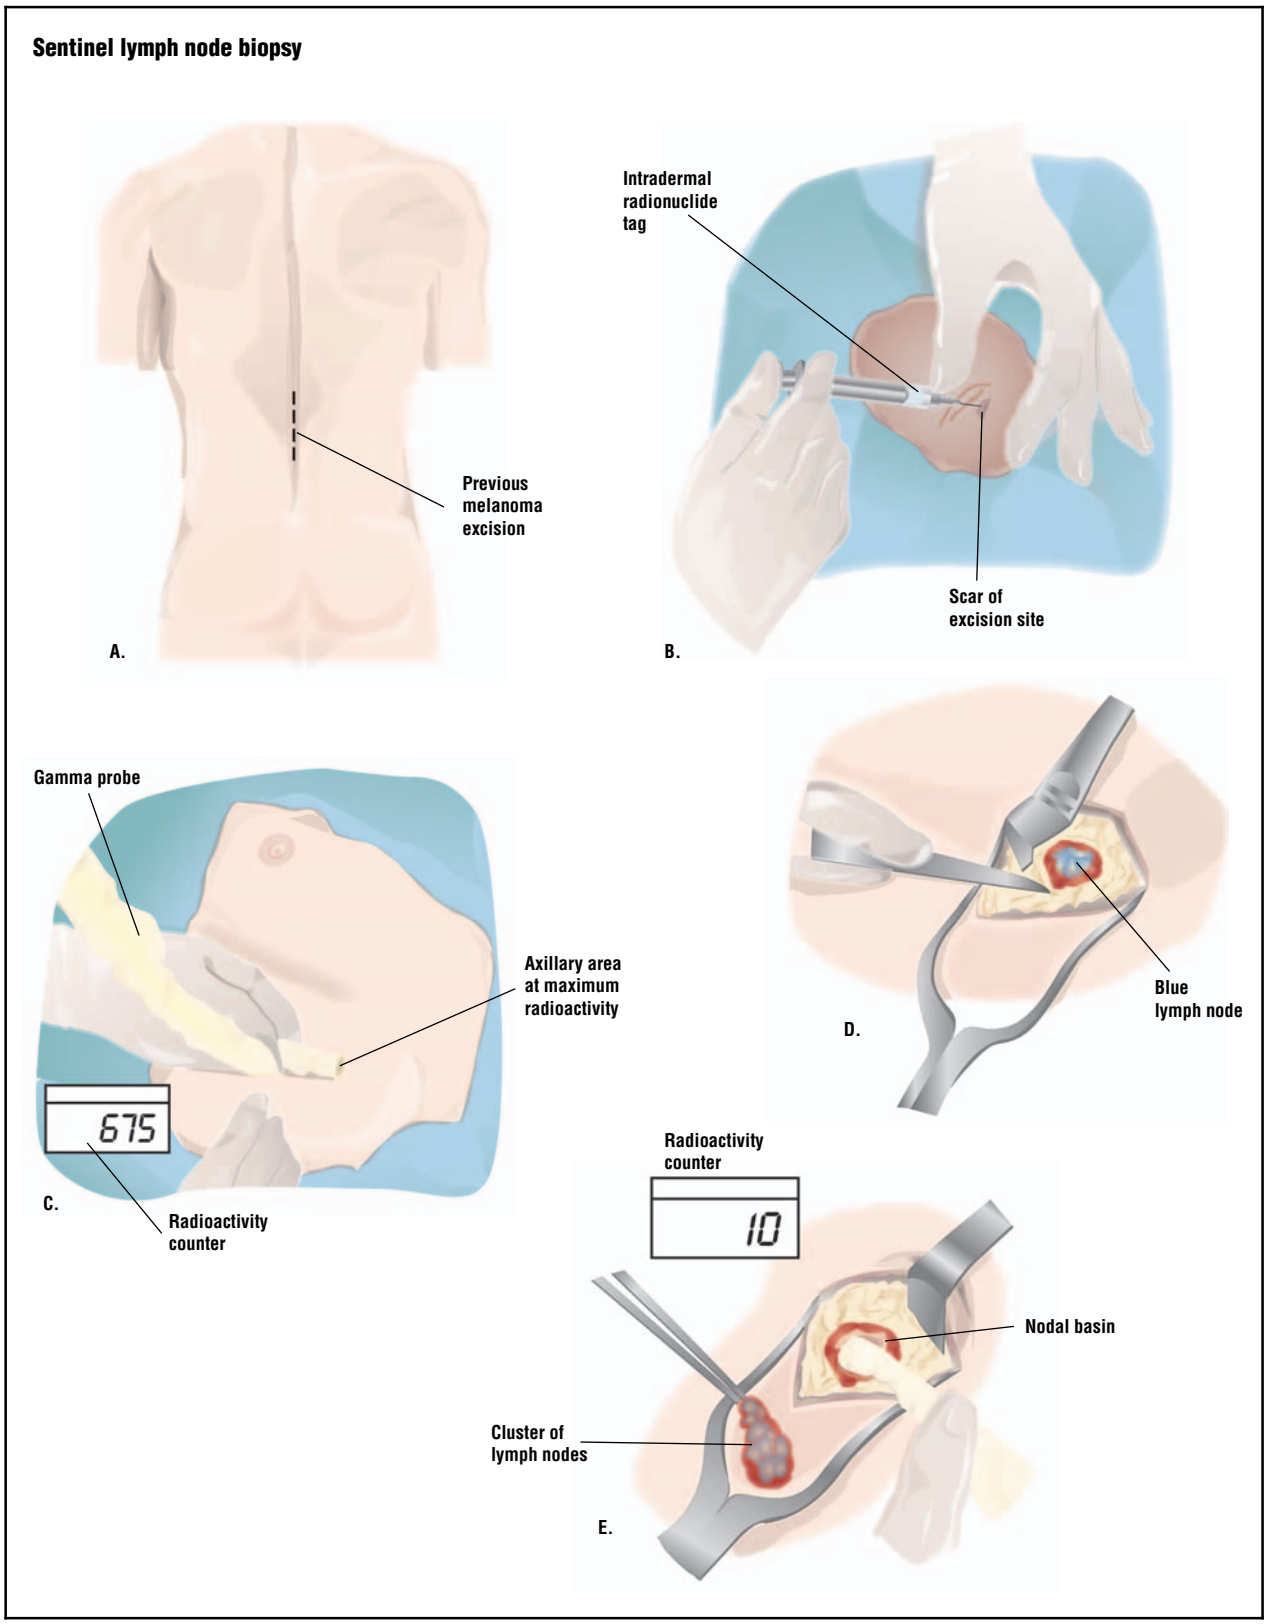
There are about 600 lymph nodes in the body. About 200 are in the head and neck and another 30–50 are in the armpit. Others are located in the groin. The sentinel node, or first filtering lymph node, will be different for each tumor and for each individual. Sentinel lymph node mapping is a technique for pinpointing which node is the most likely to receive the primary drainage from the tumor and therefore the most likely to contain cancer, so that it can be surgically removed and examined under the microscope for cancer.

If the sentinel node is cancer-free, there is a very high probability that cancer has not spread to any other node. If cancer cells are present in the sentinel node, it is likely that other nodes in the lymph system also contain cancer cells. This information is important in staging the cancer and individualizing cancer treatment for maximum benefit.

Sentinel lymph node mapping is a relatively new technique. It was first used in 1977 by researchers studying cancer of the penis. Later it was used successfully in staging **melanoma** (a type of skin cancer). In 1993, researchers first used the technique in **breast cancer** patients. Since then, **clinical trials** in breast cancer patients have demonstrated the accuracy and effectiveness of sentinel lymph node mapping and dissection in the staging of breast cancer. Researchers hope to be able to apply the sentinel node technique to other cancers in the future.

Advantages of sentinel lymph node mapping

Before sentinel node mapping was developed, there was no way of knowing whether and how far cancer had spread without removing and examining samples from many lymph nodes under the microscope. For example, in breast cancer patients, after a **lumpectomy** or **mastectomy** it was conventional treatment to remove most of the axillary nodes. These are the lymph nodes in the armpit. Removing axillary nodes causes frequent complications in as many as 80% of women. These complications include swelling (lymphedema), numbness, burning sensation in the armpit, reduction in arm and shoulder movement, and increased risk of infection.



(Illustration by Argosy Publishing. Reproduced by permission of the Gale Group.)

Sentinel **lymph node dissection** limits the extent of surgery. It provides the following advantages:

- Less surgical trauma because only one lymph node or a small cluster of nodes is removed. For example, in breast cancers, two or three nodes are generally removed.
- Fewer side effects from surgery.
- The lymph system is left intact and is better able to transport fluid and fight infection.
- Fewer risks of impairment of arm and shoulder movements.
- With only a small amount of tissue being removed, it can be studied much more exhaustively in the laboratory for the presence of cancer.
- Significant reduction in post-mastectomy pain.

How accurate are sentinel lymph node mapping and dissection?

In 2001, sentinel lymph node mapping is being used primarily in cases of melanoma and breast cancer. The technique is relatively new, and several breast cancer clinical trials are underway. One purpose is to determine the most accurate methods of finding the sentinel node. Another is to compare the control of cancer and survival rates of sentinel node **biopsy** with conventional axillary lymph node dissection in women whose sentinel nodes are both positive and negative for cancer. Up-to-date information about these clinical trials can be obtained from the National Cancer Institute at <http://www.cancertrials.nci.nih.gov> or (800) 4-CANCER.

Since sentinel lymph node mapping and dissection are relatively new, they are not done at every hospital. Doctors need special training in order to perform these procedures. Studies consistently have shown that the ability to locate the sentinel node increases the more experience doctors have with the procedure. Experienced physicians can pinpoint the sentinel node with about 95% to 98% accuracy. Similarly, studies have shown that there is a learning curve for surgeons and pathologists (doctors who examine the nodes in the laboratory) in sentinel lymph node dissection. The more experience they have, the more accurate they are.

Overall, accurate diagnoses from sentinel lymph node dissection are very high (92% or more). However, it is important that the patient find out how much training and experience the treatment team has with this procedure, and if necessary ask for a referral to another facility with more experienced staff. Some insurers may also consider the procedure experimental. Patients should check with their insurers about coverage, as the acceptance of this procedure is evolving.

KEY TERMS

Lumpectomy—Surgical removal of a tumor in the breast.

Lymph—Clear, slightly yellow fluid that carried by a network of thin tubes to every part of the body. Cells that fight infection are carried in the lymph

Lymph nodes—Small, bean-shaped collections of tissue found in lymph vessels. They produce cells and proteins that fight infection and filter lymph. Nodes are sometimes called lymph glands.

Lymph system—Primary defense against infection in the body. The tissues, organs, and channels (similar to veins) that produce, store, and transport lymph and white blood cells to fight infection.

Mastectomy—Surgical removal of the entire breast.

Metastasize—Spread of cells from the original site of the cancer to other parts of the body where secondary tumors are formed.

Precautions

Women with breast cancer who are the best candidates for sentinel node dissection are those with early stage breast cancer with low to moderate risk of lymph node involvement. Women who are not good candidates for sentinel node dissection are those who:

- Are believed to have cancer in the lymph nodes.
- Have had prior surgery (such as breast reduction surgery) that would change the normal pattern of lymph flow near the primary tumor.
- Have already received **chemotherapy**, because chemotherapy can create tissue changes that alter normal lymph flow.
- Are older, because lymph flow alters with age and the sentinel node may not be accurately detected. To get valid results, people with melanoma must have sentinel lymph node biopsy performed before wide excision of the original melanoma.

Description

Sentinel lymph node mapping and dissection is done in a hospital under general anesthesia. There are two methods of detecting the sentinel node. In the dye method, a vital blue tracer dye is injected near the tumor. The dye enters the lymph system and then collects in the sentinel or first filtering node. The surgeon looks for the accumulation of dye and removes the blue node.

In the radioactive technique, a low-level radioactive tracer is injected near the tumor. It is absorbed into the lymph system and travels to the sentinel node. A hand-held Geiger counter (a device that measures radioactivity) is passed over the area near the tumor until the spot with the most radioactivity is located. The radioactive ("hot") node is then removed. Because accuracy in locating the sentinel node is increased by 10% to 15% if both radioactive and dye tracers are used together, this is generally done.

Once the sentinel nodes are removed, they are sent to the laboratory to be examined for cancer. If no cancer cells are present, there is rarely a need to remove more lymph nodes. If cancer cells are present, it is likely that more lymph nodes will be removed. In any event, information from the sentinel node biopsy will be used to determine the best way to treat the cancer.

Preparation

Standard pre-operative blood and liver function tests are performed before sentinel node mapping and dissection. The patient will also meet with an anesthesiologist before the operation and should tell the anesthesiologist about all medication (prescription, non-prescription, or herbal) that he or she is taking and all drug allergies.

Aftercare

Since only a small amount of tissue is removed, patients generally recover quickly from sentinel node mapping and dissection. They may feel tired and from the anesthesia, and may experience minor burning, pain, and slight swelling at the site of the incision. If tracer dye is used, the dye stays in the body for up to nine months and may be visible under the skin.

Risks

The greatest risk associated with sentinel lymph node mapping is that the sentinel node cannot be identified and conventional removal of many lymph nodes will be necessary. Failure to locate the sentinel node happens in less than 5% of patients.

The second greatest risk is of a false-negative reading (approximately 5% to 8% for breast cancer), finding no cancer in the tissue sample when it is actually present. As discussed above, this test is extremely accurate when performed by an experienced treatment team.

Other risks associated with sentinel lymph node mapping are allergic reaction to the dye, infection at the incision site, and allergic reaction to anesthesia.

Normal results

If no cancer cells are found in the sentinel node, other lymph nodes do not need to be removed.

QUESTIONS TO ASK THE DOCTOR

- Am I a good candidate for sentinel lymph node mapping and biopsy?
- How much experience do you have with this procedure?
- If you have limited experience, can you refer me to a center where this operation is frequently performed?
- Where can I find out about clinical trials involving sentinel node mapping and biopsy?
- If I am not a good candidate for sentinel lymph node biopsy, why not, and what are my options?

Abnormal results

If cancer cells are found in the sentinel lymph node the treatment team may recommend an operation to remove more lymph nodes and/or radiation or chemotherapy to control the cancer.

Sexuality

Definition

Sexuality can be defined as the quality or state of being sexual. Quite often it is an aspect of one's need for closeness, caring, and touch.

Cancer and sexuality

Faced with a disease such as cancer most people initially lose interest in sex. Sexual desire is overshadowed by concern for one's health. Certain cancers directly affect sexual organs making sexual activity impossible or painful. **Chemotherapy**, radiation and surgical treatments of cancer can affect sexual activity making it difficult or undesirable. The side effects of cancer treatments such as nausea and pain can lessen sexual desire. Cancer treatments that disturb the normal hormone balance can also lessen desire. Many cancer patients are also worried that their partner may feel negatively about them because of the changes in their body and the fact that they have cancer.

Sexuality can be expressed in many different ways. It is possible to continue a healthy and satisfying relationship and maintain a healthy sexual image even after any changes brought about by cancer. Sexual intimacy can be a source of comfort during treatment and recovery from cancer. This may require some adaptation and change of the patient's current sexual patterns but with the right support groups and encouragement from the partner it should be possible to maintain healthy sexual activity.

Cancer and female sexuality

Women undergoing chemotherapy, **radiation therapy**, or pelvic surgery may experience pain during intercouse. This could be caused by changes in the size and moistness of the vagina, or infection of the bladder or vagina. Sometimes the pain is so severe that it sets off an involuntary contraction of the vagina called vaginismus. This contraction makes intercourse impossible. Extra lubrication is necessary to make intercourse comfortable. Vaginisimus can be treated by counseling and special relaxation training.

Radical surgery that will drastically change the physical aspects of the vagina and vulva pose an additional challenge for the affected woman and her partner. The woman may be affected psychologically by the change in appearance and also by the fear of pain or bleeding. The genitals may be physically altered so that sexual intercourse is difficult or impossible. Sex therapy, **reconstructive surgery**, or altering habits so that sexual needs are met without intercourse all may be options after surgery that radically affects the genitals.

Another common effect of cancer treatment is premature menopause. This may follow removal of ovaries by surgery, suppression of ovaries by chemotherapy or radiation therapy of the pelvis. The symptoms are much more severe than normal menopause causing vaginal dryness and tightness, hot flashes and sometimes low androgen levels which can also reduce sexual desire. Women who do not have hormone-sensitive tumors may want to consider hormone replacement therapy, after consultation with their doctor. Radiation treatment of the pelvis, cervix or vagina may cause scarring of the vagina. This makes it tighter and difficult to penetrate. Series of vaginal dilators of different sizes can help to relieve this problem. It is important to use these early to prevent vaginal shrinkage. Counseling may also be beneficial for the affected woman and her partner.

Cancer and male sexuality

Radiation therapy of the pelvis can impair sexual function. Circulating **testosterone** levels may come down temporarily and during this time men may have a loss of sexual desire. But this does not seem to be a permanent effect in all cases. It may be possible to get aroused by taking more time and experimenting with different kinds of caressing and love making. If erection does not occur after a significant period of time the doctor may suggest tests to check for sleep erections. Some are take-home tests and if they suggest that erection occurs normally during sleep, it is clear the physiological mechanism is intact and sexual counseling may relieve the problem. Sexual counseling may also be helpful to allow enjoyment with sexual caressing in the absence of erections. Men with medical impotence may also be helped by the use of Viagra. Men need replacement with hormones in only very rare cases. In fact, extra testosterone can cause undetected **prostate cancer** to grow.

Surgery for various cancers can cause sexual problems. Surgery for **bladder cancer** can lead to decreased sexual desire, lowered ability to obtain an erection, and less frequent or less intense orgasms. Surgery for **penile cancer** and **testicular cancer** can result in decreased fertility and desire, difficulties with erections and orgasms, and decreased volume of semen. In treating prostate cancer, the **biopsy** obtained to confirm diagnosis may decrease semen levels, and, after a man has had his prostate gland removed (**prostatectomy**), he may be unable to obtain an erection. However, new surgical advances and new chemotherapy options may help reduce these effects.

If, during surgery, the blood supply to the penis is affected, the surgeon may take an abdominal artery and try to connect it the penis. This operation is only successful in a quarter of the patients. Penile injection therapy and vacuum devices have been used to produce erections in the absence of sufficient blood flow. Medications that produce erections are risky and may lead to the formation of scar tissue. Vacuum erection devices are safer but intrude in the lovemaking. Medical erection problems

may also be treated by penile prosthesis. This is one of the best ways to treat a permanent erection problem.

Sexual problems of specific cancer treatments

Urostomy or colostomy

Before sexual activity one must ensure that the **urostomy** fits correctly. The appliance should be emptied to reduce the chance of a leak. A patterned pouch can be worn over it to cover it. Sexual activity with a **colostomy** can be performed with the same precautions. One can plan sexual activity at a time when the colostomy is not active and avoid gas-producing foods that day. Direct communication and reassurances from a loving partner can be extremely helpful.

Mastectomy

The breast symbolizes sexuality and when the treatment of **breast cancer** involves **mastectomy**, psychological counseling is helpful to regain desire and sexual enjoyment. There may be fewer problems when a **lumpectomy** is done. Women who feel awkward about the change after surgery may consider using a prosthesis covered with a nightgown or bra, or they may consider reconstruction either with or without implantation.

Limb amputation

Treatment mainly of primary tumors of bone often includes amputating a limb. If the partners can openly communicate they can decide whether the prosthesis needs to be worn during lovemaking. Prosthesis can help with movement and balance but the straps that attach it can get in the way. If the prosthesis is not used, pillows could be used instead for balance.

Treatment of facial cancer

Some cancers of the head and neck may be treated by partial removal of the facial bony structure. This can be psychologically very damaging as the scar is so public and affects the face, a vital part of the human personality. Following such surgery, speech may also be affected. Recent advances in facial prosthesis and plastic surgery may help regain a more natural appearance and speech.

Professional help for sexual problems

The first step is to discuss sexual problems with one's doctor. Sometimes doctors themselves may not be at ease discussing sexual issues. Cancer centers may have sexual rehabilitation centers with experts on staff comfortable dealing with these issues. Medical schools and some private practice groups run sexual dysfunction clinics that provide comprehensive care to treat sexual problems. Sex therapists can provide sexual counseling. It is important that the sex therapist be a psychiatrist, social worker or psychologist with special training in treating sexual problems. Professional societies such as American Association for Marriage and Family Therapy can give information about these specialists. It is important to avoid untrained people who provide useless and sometimes harmful therapy.

Sézary syndrome

Definition

Sézary syndrome is a type of **cutaneous T-cell lymphoma**, characterized by skin abnormalities, extreme **itching**, enlarged lymph glands, and abnormal blood cells.

Description

Sézary syndrome is a type of lymphoma, which is a disease where lymphocytes (a type of white blood cell) increase to very large numbers in a person's blood. Sézary syndrome is a type of lymphoma known as a cutaneous T-cell lymphoma, meaning that it is a disease where

the white blood cells known as T-lymphocytes increase to large numbers.

Sézary syndrome can affect many organs. In early stage disease, the skin is the only organ affected; however, later stage disease can affect other organ systems.

Demographics

Sézary syndrome is relatively rare, affecting about one in one million people. The incidence of the syndrome increases with age, with most cases appearing in people in their 50s or 60s. Men appear to be affected more often than women, and black males appear to be at higher risk of developing the syndrome than white males.

Causes and symptoms

There are no known causes of Sézary syndrome. Early in the course of study of the syndrome, it was thought that exposure to certain chemicals could trigger the disease. However, later studies have not shown any relation between industrial chemical exposure and Sézary syndrome

The symptoms of Sézary syndrome can be very subtle; because of this, it is often not diagnosed for many years. Early symptoms include skin lesions that can look like eczema and psoriasis. Later symptoms can include skin tumors, especially in body folds. Enlarged lymph glands in the neck, armpits, and groin can accompany the skin tumors. Later in the course of Sézary syndrome symptoms may relate to other areas of disease involvement.

Diagnosis

The diagnosis of Sézary syndrome is made by careful clinical evaluation. Generally, a patient with Sézary syndrome seeks treatment for skin lesions that are not responsive to ordinary medications. If the doctor suspects a cutaneous T-cell lymphoma, a blood test is ordered to see if there are any abnormalities, such as an increase or decrease in lymphocytes and the presence or absence of Sézary cells, which are certain white blood cells with a distinctive shape when viewed under a microscope. Finally, a sample (**biopsy**) of one the skin lesions is done to see if the lesion is part of Sézary syndrome or caused by some other disease.

Clinical staging, treatment, prognosis

Staging for cutaneous T-cell lymphoma, including Sézary syndrome, is based on the extent of skin involvement and the presence or absence of other manifestations of the syndrome. Stage I is characterized by mild skin involvement. In stage II there is extensive skin involvement, including skin tumors. Patients in stage III and IV have extensive skin involvement, blood abnormalities including Sézary cells, and swollen lymph nodes.

There are multiple therapies for Sézary syndrome. However, unless the disease is in an early stage, the chances for a complete cure are small. Nonspecific treatment includes skin lubricants and moisturizers to help treat the skin irritation and dryness that is common with the syndrome. Low potency steroid creams or ointments may be used to help treat itching and skin inflammation.

The first therapy used with some success against Sézary syndrome is mechlorethamine, or nitrogen mustard. It is applied daily to the entire skin surface (except for sensitive areas such as eyelids and genitalia) for six to twelve months, then three times a week for one to two years more. Several studies have investiagted the effectiveness of nitrogen mustard therapy, and have found that in stage I or II disease, the therapy causes complete remission in 60–80% of patients. Side effects are minimal, but dry skin, irritation, and change in skin pigmentation can occur.

Another treatment that has been used for many years, especially for stage II and III disease, is electron beam **radiation therapy**. Treatment with electron beam radiation therapy has been used since 1953, with good response rates seen in 50–70% of patients. Side effects can include excessive skin dryness, skin blistering, loss of hair on treated areas, and increased risk of skin cancer.

ECP, or photophoresis, has been approved by the FDA as a treatment for Sézary syndrome. In this mode of treatment, phototherapy with ultraviolet light is combined with leukapheresis. In leukapheresis, a person's blood is taken out and passed through special filters that remove circulating Sézary cells; the cells are treated with ultraviolet radiation, then reinfused into the patient. Response rates range from 55% to 75%, with some reports showing a 15–25% cure rate. Side effects can include nausea and **fever**.

Systemic **chemotherapy** is often used in patients who are in later stages of the disease. Using standard cancer chemotherapeutic agents such as **cyclophosphamide**, **vincristine**, and **doxorubicin**, response rates up to 19 months have been seen. No studies have shown an increased survival rate in patients getting aggressive, high-dose chemotherapy versus those getting more standard doses.

The prognosis for patients with Sézary syndrome is based on placing the patient in one of three categories:

KEY TERMS

Eczema—A superficial inflammation of the skin, generally with itching and a red rash.

Psoriasis—A chronic skin condition, causing red, scaling patches to appear to the skin.

Interferon —A substance produced by cells that can enhance the immune system.

Monoclonal antibodies —Antibodies made in the lab that can identify and target specific infectious agents and cancers.

good, intermediate, or poor. Patients with good prognosis have the condition limited to their skin. Their general survival time is more than 10 years. Patients in the intermediate category have skin lesions including tumors and plaques, but no blood involvement. Their survival time is five years. Patients in the poor risk category have extensive skin lesions along with blood abnormalities, including high levels of Sézary cells. Patients in this category, even with extensive treatment, generally have survival rates of only one year or less.

Coping with cancer treatment

There are multiple ways to help patients cope with side effects brought about by the treatment of Sézary syndrome. Lubricants can be used to help dryness, scaling, and itching of the skin caused by the use of topical treatments such as nitrogen mustard and electron beam therapy. Symptoms such as **nausea and vomiting**, caused by ECP and systemic chemotherapy, can be treated with standard anti-nausea and vomiting medication.

Clinical trials

In 2001, **clinical trials** are underway to investigate several forms of innovative treatment for cutaneous T-cell lymphoma and Sézary syndrome. Interferon has been used with some success in both early and late stage disease. Common side effects include a decrease in white blood cells and chronic **fatigue**. The use of **monoclonal antibodies** in treating late stage disease (III and IV) has been recently studied. Early studies have shown response rates of around 30%. Side effects include allergies to the monoclonal antibodies, fever, and fatigue.

Prevention

As of 2001, there are no known ways to prevent Sézary syndrome.

Sigmoidoscopy

Definition

Sigmoidoscopy is a procedure by which a doctor inserts either a short and rigid or slightly longer and flexible fiber-optic tube into the rectum to examine the lower portion of the large intestine (or bowel).

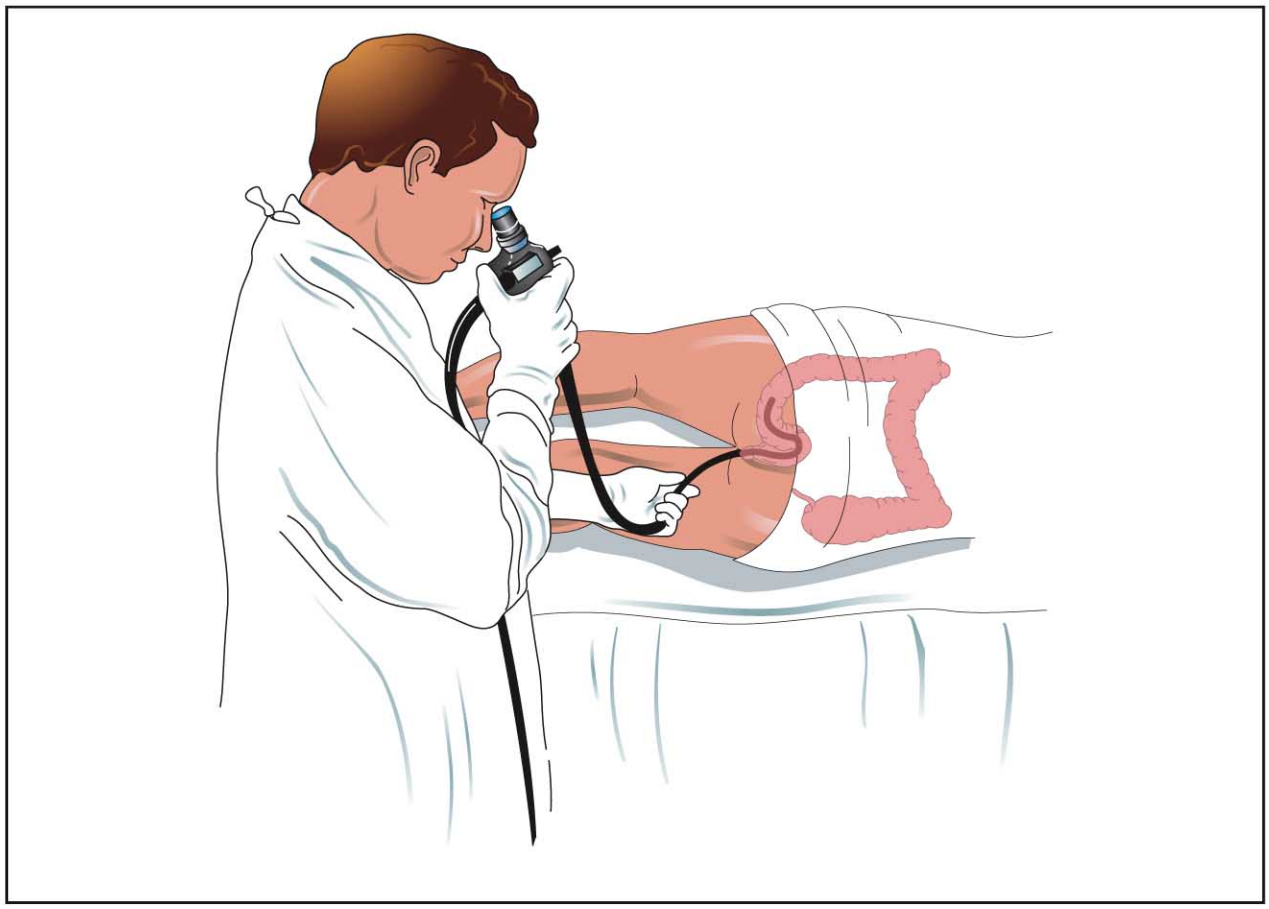
Purpose

Sigmoidoscopy is used most often in screening for colorectal cancer or to determine the cause of rectal bleeding. It is also used for the diagnosis of inflammatory bowel disease and other benign diseases of the lower intestine.

Cancer of the rectum and colon is the second most common cancer in the United States, claiming the lives of about 56,000 people annually. As a result, The American Cancer Society recommends that people age 50 and over be screened for colorectal cancer every five years. The screening includes a flexible sigmoidoscopy. Screening at an earlier age should be done on patients who have a family history of colon or **rectal cancer**, or small growths in the colon (polyps).

Individuals with inflammatory bowel disease (Crohn's colitis or ulcerative colitis) are at increased risk for colorectal cancer and should begin their screenings at a younger age, and be screened more frequently. Many doctors screen such patients more often than every three to five years. Those with ulcerative colitis should be screened beginning 10 years after the onset of disease; those with Crohn's colitis beginning 15 years after the onset of disease.

Some doctors prefer to do this screening with a colonoscope, which allows them to see the entire colon (cer-



Sigmoidoscopy is a procedure most often used in screening for colorectal cancer and as a test in diagnosis of possible inflammatory bowel disease. As illustrated above, the physician can view the rectum and colon through a sigmoidoscope, a flexible fiber-optic tube which contains a light source and a lens. *(Illustration by Electronic Illustrators Group.)*

tain patients, such as those with Crohn's colitis or ulcerative colitis, must be screened with a colonoscope). However, compared with sigmoidoscopy, **colonoscopy** is a longer process, causes more discomfort, and is more costly.

Studies have indicated that about one-fourth of all precancerous or small cancerous growths in the colorectal region can be seen with a rigid sigmoidoscope. The longer, flexible version, which is the primary type of sigmoidoscope used in the screening process, can detect more than one-half of all growths in this region. This examination is usually performed in combination with a **fecal occult blood test**, in an effort to increase detection of polyps and cancers that lie beyond the scope's reach.

Precautions

The exam is not always adequate. A 2004 study reported that among older patients and women, sigmoidoscopy is not always effective, particularly because insertion depth is not adequate. For unknown reasons, this is almost twice as true for women as for men.

Sigmoidoscopy can usually be conducted in a doctor's office or a health clinic. However, some individuals should have the procedure done in a hospital day surgery facility. These include patients with rectal bleeding, and patients whose blood does not clot well (possibly as a result of blood-thinning medications).

Description

Most sigmoidoscopy is done with a flexible fiber-optic tube. The tube contains a light source and a camera lens. The doctor moves the sigmoidoscope up beyond the rectum (the first 1 ft/30 cm of the colon), examining the interior walls of the rectum. If a 2 ft/60 cm scope is used, the next portion of the colon can also be examined for any irregularities.

The procedure takes 20 to 30 minutes, during which time the patient will remain awake. Light sedation may be given to some patients. There is some discomfort (usually bloating and cramping) because air is injected into the bowel to widen the passage for the sigmoidoscope. Pain is rare except in individuals with active inflammatory bowel disease.

In a colorectal cancer screening, the doctor is looking for polyps or tumors. Studies have shown that over time, many polyps develop into cancerous lesions and tumors. Using instruments threaded through the fiber-optic tube, cancerous or precancerous polyps can either be removed or biopsied during the sigmoidoscopy. People who have cancerous polyps removed can be referred for full colonoscopy, or more frequent sigmoidoscopy, as necessary.

The doctor may also look for signs of ulcerative colitis, which include a loss of blood flow to the lining of the bowel, a thickening of the lining, and sometimes a discharge of blood and pus mixed with stool. The doctor can also look for Crohn's disease, which often appears as shallow or deep ulcerations, or erosions and fissures in the lining of the colon. In many cases, these signs appear in the first few centimeters of the colon above the rectum, and it is not necessary to do a full colonoscopic exam.

Private insurance plans often cover the cost of sigmoidoscopy for screening in healthy individuals over 50, or for diagnostic purposes. Medicare covers the cost for diagnostic exams, and may cover the costs for screening exams.

Preparation

The purpose of preparation for sigmoidoscopy is to clean the lower bowel of stool so that the doctor can see the lining. Many patients are required to consume only clear liquids on the day before the test, and to take two enemas on the morning of the procedure. The bowel is cleaner, however, if patients also take an oral laxative preparation of 1.5 oz phospho-soda the evening before the sigmoidoscopy.

Certain medications should be avoided for a week before having a sigmoidoscopy. These include:

- apirin, or products containing aspirin
- ibuprofen products (Nuprin, Advil, or Motrin)
- iron or **vitamins** containing ironAlthough most prescription medication can be taken as usual, patients should check with their doctor in advance.

Aftercare

Patients may feel mild cramping after the procedure that will improve after passing gas. Patients can resume their normal activities almost immediately.

KEY TERMS

Biopsy—A procedure where a piece of tissue is removed from a patient for diagnostic testing.

Colorectal cancer—Cancer of the large intestine, or colon and rectum (the last 16 inches of the large intestine before the anus).

Inflammatory bowel disease—Ulcerative colitis or Crohn's colitis; chronic conditions characterized by periods of diarrhea, bloating, abdominal cramps, and pain, sometimes accompanied by weight loss and malnutrition because of the inability to absorb nutrients.

Polyp—A small growth that can be precancerous when it appears in the colon.

Risks

There is a slight risk of bleeding from the procedure. This risk is heightened in individuals whose blood does not clot well, either due to disease or medication, and in those with active inflammatory bowel disease. The most serious complication of sigmoidoscopy is bowel perforation (tear). This complication is very rare, however, occurring only about once in every 7,500 procedures.

Normal results

A normal exam shows a smooth bowel wall with no evidence of inflammation, polyps or tumors.

Abnormal results

For a cancer screening sigmoidoscopy, an abnormal result involves one or more noncancerous or precancerous polyps or tumors. Patients showing polyps have an increased risk of developing colorectal cancer in the future.

Small polyps can be completely removed. Larger polyps or tumors usually require the doctor to remove a portion of the growth for diagnostic testing. Depending on the test results, the patient is then scheduled to have the growth removed surgically, either as an urgent matter if it is cancerous, or as an elective surgery within a few months if it is noncancerous.

In a diagnostic sigmoidoscopy, an abnormal result shows signs of active inflammatory bowel disease, either a thickening of the intestinal lining consistent with ulcerative colitis, or ulcerations or fissures consistent with Crohn's disease.

QUESTIONS TO ASK THE DOCTOR

- Why do I need a sigmoidoscopy?
- Should I undergo a colonoscopy instead?
- If a biopsy is done, how long before I get the results?
- Will I need to have this test again in the future? When?

Sirolimus

Definition

Sirolimus is indicated by the Food and Drug Administration (FDA) to be used after a kidney transplant to prevent the body from rejecting the new kidney. Sirolimus may also have a role in prevention of organ rejection in heart or lung transplantation, and prevention of graft-versus-host disease in patients undergoing **bone marrow transplantation**. Sirolimus (formerly known as rapamycin) became available at the end of 1999 and is marketed under the brand name Rapamune by Wyeth-Ayerst Laboratories.

Description

Sirolimus belongs to a class of macrolide **antibiotics** and is isolated from an organism named *streptomyces hygriscopicus*.

Sirolimus prevents the immune system from attacking the transplanted organ by decreasing the growth of certain chemicals in the body responsible for the immune function (B and T lymphocytes). Sirolimus works differently from other immunosuppressants used to prevent organ rejection after transplantation (**azathioprine**, mycophenolate mofetil, **tacrolimus**, cyclosporine, and steroids). It should be given in combination with cyclosporine and steroids to prevent acute rejection of a transplanted kidney. This drug is available as a tablet and a liquid and can be used in children and adults.

Recommended dosage

Adults

KIDNEY TRANSPLANTATION The first dose of 3 tablets (2 mg each) or 6 milliliters of oral solution should be given as soon as possible after a kidney is transplanted. Then, a maintenance dose of 2 mg should be given once a day.

Children over 13 years of age and Adults less than 40 kg (88 lbs)

KIDNEY TRANSPLANTATION 3 mg of sirolimus per square meter of body surface area on day 1 after transplantation, followed by a maintenance dose of 1 mg per square meter per day.

Children less than 13 years of age

Check with a physician.

Administration

Sirolimus should be administered in combination with cyclosporine and steroids. To decrease the risk of side effects, sirolimus should be given four hours after cyclosporine. To avoid variations in blood levels, sirolimus should be taken consistently— either always with food or always without food. Sirolimus oral solution should only be mixed with water or orange juice and consumed immediately. Juices or liquids other than water or orange juice should not be used to mix sirolimus. Bottled sirolimus solution should be stored in the refrigerator, but not frozen. Refrigerated sirolimus solution may develop a slight haze. If haze is noticed, the drug should be left at room temperature and gently shaken until haze disappears. If a dose is missed, it should taken as soon as possible unless it is almost time for the next dose. Two doses at the same time should not be taken.

Precautions

Sirolimus may increase the risk of the following conditions:

KEY TERMS

Immune system—The body's mechanism to fight infections, toxic substances, and to recognize and neutralize or eliminate foreign material (for example, a body organ transplanted from another person).

Immunosuppressant—An agent that decreases activity of immune system (for example, radiation or drugs).

Lymphocele—A mass surrounded by an abnormal sac that contains lymph (fluid that is collected from tissues throughout the body) from diseased or injured lymphatic channels.

Lymphoma—Any malignant (cancerous) disorder of lymphoid tissue.

Steroids—Drugs such as prednisone or dexamethasone, which resemble body's natural hormones and are often used to decrease inflammation or to suppress activity of immune system.

Transplant—Tissue transferred from one part of the body to another or from one person to another.

- infections caused by viruses and bacteria
- lymphoma or skin cancer
- elevated blood lipids (cholesterol and triglycerides)
- decreased kidney function
- lymphocele formation after a kidney transplantation

Patients with the following conditions should use sirolimus with caution:

- an allergic reaction to tacrolimus (has a similar structure to sirolimus)
- liver disease (dose of sirolimus may need to be decreased)
- treatment with medications that are broken down in the liver and that may interact with sirolimus
- Pregnancy. These patients should use an effective method of birth control started before therapy with sirolimus and continued for 12 weeks after stopping this medication.

Patients should immediately alert their doctor if any of these symptoms develop:

- fever, chills, sore throat
- fast heartbeat
- trouble breathing
- unusual bleeding or bruising

Sirolimus should be taken consistently with regard to meals (either always taken with food or always taken on an empty stomach) and at least four hours after cyclosporine to decrease variability of blood sirolimus levels. Patients should avoid grapefruit or grapefruit juice because it may increase sirolimus levels in the blood. Those taking sirolimus will need to see a physician regularly to check blood and urine.

Side effects

The most common side effects include mild dose-related risk of bleeding, elevated blood cholesterol and triglyceride values, decreased kidney function, high blood pressure, **diarrhea** or constipation, rash, acne, joint pain, nausea, vomiting, stomachache, and decreased blood potassium and phosphate values. Sirolimus can decrease the number of red blood cells, which can cause a patient to look pale, feel tired, short of breath, and drowsy, and experience heart palpitations. People who are allergic to tacrolimus may develop an allergy when taking sirolimus.

Interactions

Sirolimus is broken down in the liver by the same enzyme system that also breaks down cyclosporine and tacrolimus. Because cyclosporine can increase sirolimus blood levels, sirolimus should be given four hours after the morning cyclosporine dose to decrease the risk of side effects. Diltiazem (Cardizem, Tiazac, Dilacor) and ketoconazole (Nizoral) can increase sirolimus blood levels. The use of ketoconazole should be avoided in patients taking sirolimus. Other drugs that are likely to increase sirolimus blood levels and increase its side effects include calcium channel blockers (used to treat high blood pressure), drugs that treat fungal infections (ketoconazole, itraconazole, fluconazole), macrolide antibiotics (erythromycin, clarithromycin), and anti-HIV drugs (ritonavir, nelfinavir, indinavir). Rifampin can greatly decrease sirolimus blood levels, potentially making it less effective. Other drugs that may decrease effectiveness of sirolimus include phenobarbital, **carbamazepine**, rifabutin, and **phenytoin**. Anyone who is taking these drugs should ask their physician if they could safely take sirolimus.

Olga Bessmertny, Pharm.D.

Sjögren's syndrome

Description

Sjögren's syndrome (SS) is an autoimmune disease, which means that the immune system has mounted an

attack against specific tissues of the body. For example, most patients with Sjögren's syndrome carry antibodies to molecules found in the nucleus of cells (antinuclear antibodies). Although Sjögren's syndrome can affect practically any organ in the body, it is characterized by dry mouth (**xerostomia**) and dry eyes (xerophthalmia). These hallmark symptoms are known as "sicca symptoms." Sjögren's syndrome goes by many names which include Sjögren's disease, dry-mouth and dry-eyes disease, sicca complex, and sicca syndrome. The disorder is named for Henrik Sjögren, a Swedish ophthalmologist.

Symptoms of Sjögren's syndrome include dry mouth, difficulty or inability to swallow (dysphagia), tooth decay (dental caries), impaired taste and smell, dry eyes, eye pain, eye redness, muscle pain (myalgia), and **fatigue**. Many patients develop a variety of skin problems that include dry patches, vasculitis, and cutaneous B-cell lymphoma. Other less common symptoms include **diarrhea**, headaches, joint pain (arthralgia), muscle weakness, hair loss (alopecia), and dry cough. About 33% of patients develop arthritis. Patients with cancer of lymphoid tissue (lymphoma) and Sjögren's syndrome have **fever**, nerve involvement, low numbers of red blood cells (**anemia**) and white blood cells (lymphopenia), inflammation of blood vessels of the skin (skin vasculitis), and disease of the lymph nodes (lymphadenopathy) much more frequently than patients with Sjögren's syndrome alone.

The symptoms of Sjögren's syndrome can have a pronounced effect on quality of life. Besides causing discomfort, the symptoms also disrupt sleep, which can have side effects such as fatigue, difficulty concentrating, and **depression**. Patients with Sjögren's syndrome are at risk for tooth decay and yeast infections in the mouth (erythematous candidiasis). Approximately 5% of the patients with Sjögren's syndrome develop malignant lymphoma.

SS is found in all races and ethnic groups. It is thought to affect between 0.1% and 3% of the population in the United States; this range reflects the lack of a uniform set of diagnostic criteria. According to the American College of Rheumatology, between 1 million and 4 million Americans have Sjögren's syndrome.

Causes

The cause of Sjögren's syndrome is unknown, although several viruses are suspected triggers of the autoimmune reaction. In 2004 a team of researchers in Greece presented evidence that a coxsackievirus may be the cause of SS. The sicca symptoms of Sjögren's syndrome are caused by the invasion and multiplication of white blood cells (lymphocytes) into the salivary glands and tear glands. The lymphocytes destroy the gland tissue and cause the glands to malfunction, reducing the production of tears and saliva. This invasion by lymphocytes, however, does not fully account for the sicca symptoms. Other, as yet unidentified, factors play a role in the development of the sicca symptoms.

Sjögren's syndrome can occur in combination with certain cancers. For more than half of the patients with non-Hodgkin lymphoma, the lymphoma is located in the salivary glands, causing them to malfunction. **Graft-vs.-host disease** in patients who have undergone **bone marrow transplantation** can cause eye problems similar to those seen in Sjögren's syndrome. Both **chemotherapy** and **radiation therapy** to the head and neck can cause xerostomia.

Treatments

There is no cure for Sjögren's syndrome. Therefore, treatment is aimed at relieving symptoms. Dry eyes may be treated with eye drops and avoidance of drying conditions such as wind, hair dryers, and medications that cause dry eyes (e.g. tricyclic antidepressants). Eyeglasses may protect the eyes from wind. The lower tear ducts may be blocked with silicone plugs (punctal occlusion) to conserve natural tears. Use of humidifiers, both at home and at work, can significantly reduce sicca symptoms. Saliva substitutes and sugar-free hard candies or chewing gum, which stimulate salivation, can reduce sicca symptoms. The drugs **pilocarpine** (Salagen) and cevimeline (Evoxac) can increase salivation. Cevimeline also has been found effective in relieving the symptom of dry eye in SS as well. Pain may be relieved by nonsteroidal anti- inflammatory drugs (e.g. Aleve) or other pain medications.

The patient with Sjögren's syndrome should faithfully conduct routine daily oral hygiene consisting of tooth brushing two to three times, flossing once, and utilizing medicated rinses as prescribed by the physician. Fluoride varnishes applied by a dentist and nightly fluoride treatments can help to prevent dental caries. Brushing and flossing should be performed carefully to prevent damage to the weakened oral mucosa.

Alternative and complementary therapies

In a controlled clinical study, the herbal vitamin supplement LongoVital was shown to increase the rate of salivation. Sicca symptoms may be reduced by acupuncture. Papayas contain papain, which is an enzyme that breaks up proteins. Eating papayas, drinking papaya juice, or drinking a solution of crushed papain tablets in water can liquefy thick saliva. Drinking a solution of meat tenderizer (which contains papain) in water is another alternative.

KEY TERMS

Autoimmune disease—A disease caused by the abnormal presence of antibodies against normal tissues of the body.

Coxsackievirus—Any of a group of enteroviruses that produce a disease in humans characterized by fever and rash. Coxsackieviruses are named for the town in upstate New York where they were first identified.

Lymphocytes—White blood cells. Lymphocytes play a vital role in the immune system.

Lymphoma—Any cancer of the tissues that make up the lymphatic system.

Sicca symptoms—Dry mouth and eyes.

Small intestine cancer

Definition

Cancer of the small intestine is a rare disease that results when abnormal, malignant cells divide out of control. Cancers in this location consist primarily of adenocarcinoma, **lymphoma**, sarcoma, and carcinoid tumors.

Description

The small intestine is a long tube inside the abdomen divided into three sections: the duodenum, jejunum, and ileum. The function of the small intestine is to break down food and to remove proteins, carbohydrates, fats, **vitamins**, and minerals. Obstruction of the small intestine by cancer may impair normal passage and digestion of food and nutrients.

Adenocarcinoma

These malignancies most often start in the lining of the small intestine, most frequently occurring in the duodenum and jejunum, the sections closest to the stomach. These tumors may obstruct the bowel, causing digestive problems. Adenocarcinoma is the most common cancer of the small intestine, but only accounts for 2% of all tumors in the gastrointestinal tract and 1% of all deaths related to cancer of the gastrointestinal tract. Carcinomas of the small intestine may appear at multiple sites.

Lymphoma

This fairly uncommon cancer is typically a non-Hodgkin's type that starts in the lymph tissue of the small intestine. (The body's immune system is comprised of lymph tissue, which assists in fighting infections.) Malignant lymphoma is not often found as a solitary lesion.

Sarcoma

Sarcoma malignancies of the small intestine are usually **leiomyosarcoma**. They most often occur in the smooth muscle lining of the ileum, the last section of the small intestine. Liposarcoma and angiosarcoma occur more rarely in the small intestine.

Carcinoid tumors

Carcinoid tumors are most often found in the ileum. In approximately 50% of cases, they appear in multiples.

Demographics

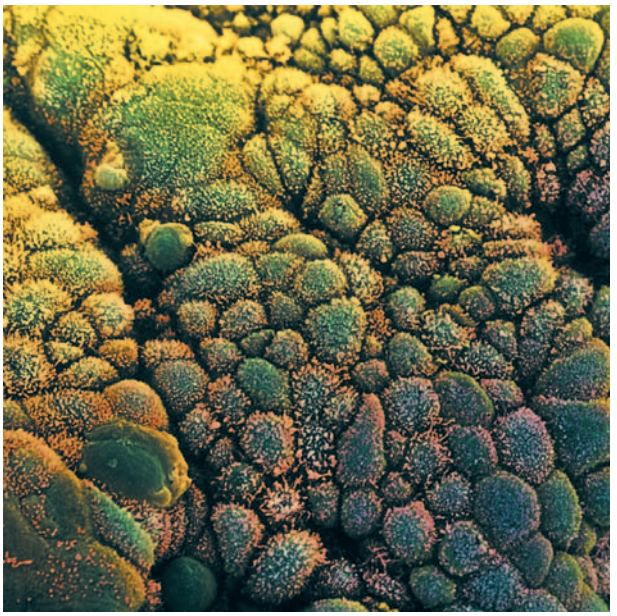
Approximately 50% of small intestine cancers are adneocarcinomas; 20% are lymphomas; 20% are carcinoid; and about 10% are **sarcomas**.

Causes and symptoms

The causes of this cancer are not known, but factors that contribute to its development include exposure to carcinogens such as chemicals, radiation, and viruses. In addition, smoking and a poor diet may contribute to the incidence of small intestine cancer. The incidence of cancer is higher in obese individuals.

Often cancer of the small intestine does not initially produce any symptoms. Gastrointestinal bleeding is perhaps the most common symptom. A doctor should be consulted if any of these symptoms are present:

- involuntary **weight loss**
- a lump in the abdominal region
- blood in the stool
- pain or cramping in the abdominal region



Colored scanning electron micrograph (SEM) of cancer cells in the intestine. *(Copyright Quest, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Diagnosis

Evaluation begins by taking a patient's medical history and conducting a physical examination. If a patient experiences symptoms, a doctor may suggest the following tests:

- Upper gastrointestinal x ray/upper GI series: To allow the stomach to be seen easier on an **x ray**, the patient drinks a liquid called barium. This test can be conducted in either a doctor's office or a radiology department at a hospital.
- CT scan (computed tomography): A computerized x ray that takes a picture of the abdomen.
- MRI scan (**magnetic resonance imaging**): A imaging technique that uses magnetic waves to take a picture of the abdomen.
- Ultrasound: An imaging technique that uses sound waves to locate tumors.
- Endoscopy: An endoscope is a thin, lighted tube which is placed down the throat to reach the first section of the small intestine (duodenum). During this procedure, the doctor may take a **biopsy**, in which a small piece of tissue is removed for examination of cancereous cells under a microscope.

If small intestine cancer is evident, more tests will be conducted to determine if cancer has spread to other parts of the body.

Treatment team

Cancer treatment often requires a team of specialists and may include a surgeon, medical oncologist, radiation oncologist, nurse, physical therapist, occupational therapist, dietitian, and or a social worker.

Clinical staging, treatments, and prognosis

As with many other types of cancer, malignancies of the small intestine can be classified as localized, regional spread, or distant spread.

- Localized: The cancer has not spread beyond the wall of the organ it developed in.
- Regional spread: The cancer has spread from the organ it started in to other tissues such as muscle, fat, ligaments, or lymph nodes.
- Distant spread: The cancer has spread to tissues or organs outside of where it originated such as the liver, bones, or lungs.

Treatment options for small intestine cancer most often include surgery, and possibly **radiation therapy**, **chemotherapy**, and/or biological therapy. Cancer of the small intestine is treatable and sometimes curable depending on the histology. Removing the cancer through surgery is the most common treatment. If the tumor is large, a small portion may be removed if resection of the small intestine is possible. For larger tumors, surgery requires removing a greater amount of the surrounding normal intestinal tissue, in addition to some surrounding blood vessels and lymph nodes.

Radiation therapy kills cancer cells and reduces the size of tumors through the use of high-energy x rays. Radiation therapy may come from an external source using a machine or an internal source. Internal-based therapy involves the use of radioisotopes to administer radiation through thin plastic tubes to the area of the body where cancer cells are found. Side effects of radiation therapy include:

- fatigue
- loss of appetite
- nausea and vomiting
- **diarrhea**
- gas
- bloating
- mild temporary, sunburn-like skin changes
- difficulty tolerating milk products

Chemotherapy kills cancer cells with drugs taken orally or by injection in a vein or muscle. It is referred to as a systemic treatment due to fact that it travels through the bloodstream and kills cancer cells outside the small intestine. Adjuvant chemotherapy may be given following surgery to ensure all cancer cells are killed. Some side effects of chemotherapy are:

- nausea and vomiting
- loss of appetite (anorexia)
- temporary hair loss (alopecia)
- mouth sores
- fatigue, as a result of a low red blood cell count
- higher likelihood of infection or bleeding due to low white blood cell counts and low blood platelets, respectively

Radiation and chemotherapy are seldom beneficial in small intestinal cancers.

Utilizing the body's immune system, biological therapy stimulates the body to combat cancer. Natural materials from the body or other laboratory-produced agents are designed to boost, guide, or restore the body's ability to fight disease.

Treatment options for small interstine cancers are based on the type of cells found—adenocarcinoma, lymphoma, sarcoma, or carcinoid tumor—rather than the clinical staging system.

Treatment of adenocarcinoma of the small intestine may consist of:

- surgical removal of the tumor
- If the cancer cannot be removed by resection of the small intestine, surgery may be performed to bypass the cancer to allow food to travel through the intestine.
- symptom relief with radiation therapy
- chemotherapy or biological therapy in a clinical trial setting
- a clinical trial involving radiation and drug therapy (with or without chemotherapy) to elicit greater sensitivity to radiation using radiosensitizers

Treatment of lymphoma of the small intestine may consist of:

- surgical removal of the cancer and lymph nodes in close proximity to it
- Surgery accompanied by radiation therapy or adjuvant chemotherapy. If the disease is localized to the bowel wall, then surgical resection alone or combined chemotherapy should be considered. If the disease has extended to the regional lymph nodes, then surgical resection and combination chemotherapy is suggested at the time of diagnosis.

- For extensive lymphoma or lymphoma that cannot be removed surgically, chemotherapy with or without additional radiation therapy is frequently used to reduce the risk of recurrence.

Treatment of leiomyosarcoma of the small intestine may consist of:

- surgical removal of the cancer
- When cancer cannot be removed by resection, surgical bypass of the tumor is recommended to allow food to pass.
- radiation therapy
- For unresectable metastatic disease, surgery, radiation therapy, or chemotherapy is suggested in order to alleviate symptoms.
- For unresectable primary or metastatic disease, a clinical trial evaluating the benefits of new anticancer drugs (chemotherapy) and biological therapy.

For recurrent small intestine cancer, treatment may consist of the following measures, if the cancer has returned to one area of the body only:

- surgical removal of the cancer
- symptom relief using chemotherapy or radiation therapy
- a clinical trial using radiation and drug therapy (with or without chemotherapy) to elicit greater sensitivity to radiation using radiosensitizers

For recurrent metastatic adenocarcinoma or leiomyosarcoma, there is no standard effective chemotherapy treatment. Patients should be regarded as candidates for clinical studies assessing new anticancer drugs or biological agents.

For carcinoid tumors at least than 1 cm in size, surgical removal of the tumor and surrounding tissue is possible. Carcinoid tumors often grow and spread slowly, therefore, approximately half are found at an early or localized stage. By the time of sugery, 80% of the tumors over 2 cm in diameter have metastasized locally or to the liver.

The prognosis or likelihood of recovery depends on the type of cancer, the overall health of the patient, and whether the cancer has spread to other regions or is only localized in the small intestine. A cure depends on the ability to remove the cancer completely with surgery. Adenocarcinoma is most common in the duodenum, however, patient survival is less likely for individuals with cancer is in this area compared with those patients with tumors in the jejunum or ileum due to reduced rates of surgery to remove cancer. Between 1985-1995, there were 4,995 cases of adenocarcinoma of the small intestine reported to the National Cancer Database. Of these malignancies, 55% occurred in the duodenum, 13% in the ileum, 18% in the jejunum, and 14% were in unspecified areas. The National Cancer Database reported a median survival of 19.7 months for these patients with an overall 5-year disease survival rate of 30.5%. For resectable adenocarcinoma, the National Cancer Institute reports an overall five-year survival rate of only 20%, whereas resectable leiomyosarcoma's survival rate is reported at approximately 50%. One study found the overall rate of metastatic spread of leiomyosarcoma ranged from 24–50%; this cancer most often spread to the liver. Five-year survival in 705 patients with leiomyosarcoma was reported at 28%. Surgery is the preferred treatment for smooth muscle tumors. Little benefit was found for irradiation or chemotherapy, or for these therapies combined. Patients over 75 years of age have a significantly poorer survival rate than younger people. In addition, patients with poorly differentiated tumors have a poorer prognosis than those with moderately or well-differentiated tumors. Survival rate decreases with progression of disease by stage: localized 47.6%; regional 31%; distant 5.2%.

Alternative and complementary therapies

Bovine and shark cartilage is currently being explored in **clinical trials** for antitumor properties, but as of mid-2001 there is not enough evidence to warrant its use. Some popular herbs that are purported to have therapeutic effects in cancer treatment include echinacea, garlic, ginseng, and ginger. Laboratory studies have shown that echinacea has the potential to control the growth of cancerous cells, but more studies are needed to confirm efficacy in humans. In addition, dosage and toxicity levels still need to be established. Some studies suggest that diets high in garlic reduce the risk of stomach, esophageal, and colon cancers. There is still debate regarding the best form of garlic to take—whole raw garlic or garlic in tablet form; aged or fresh garlic; garlic with odor or ''deodorized'' garlic. Ginger is often recommended for its beneficial effects on the digestive system, but evidence has not confirmed efficacy in cancer treatment. Ginseng in excessive amounts can be very toxic, causing vomiting, bleeding, and death. Patients should not take herbal remedies without consulting their physicians, particularly if they intend to combine the herbs with prescription drugs. Herb and drug combinations can sometimes result in toxic interactions.

Coping with cancer treatment

Pain is a common problem for people with some types of cancer, especially when the cancer grows and presses against other organs and nerves. Pain may also

be a side effect of treatment. However, pain can generally be relieved or reduced with prescription medicines or over-the-counter drugs as recommended by the doctor. Other ways to reduce pain, such as relaxation exercises, may also be useful. It is important for patients to report pain to their doctors, so that steps can be taken to help relieve it.

Depression may affect approximately 15–25% of cancer patients, particularly if the prognosis for recovery is poor. A number of antidepressant medications are available from physicians to alleviate feelings of depression. Counseling with a psychologist or psychiatrist also may help patients deal with depression.

Clinical trials

As of 2001, Glivec (STI-571, or imatinib mesylate) is in clinical trials for treatment of gastrointestinal stromal tumors, as well as for leukemia and glioblastoma, a type of brain tumor. An open trial (GIST trial SWOG-S0033) led by Southwest Oncology Group will test those individuals with metastatic or recurrent disease using two doses of the drug.

Clinical trials may be suitable for patients suffering from small intestine cancer. The principal investigator should be contacted regarding participation in appropriate trials. For information about cancer trials, patients can visit the National Cancer Institute web site at <http://cancertrials.nci.nih.gov>.

Prevention

Most people who develop cancer do not have inherited genetic abnormalities. Their genes have been damaged after birth by substances in their environment. A substance that damages deoxyribonucleic acid (DNA) in a way that can lead to cancer is called a carcinogen. Carcinogens include certain chemicals, certain types of radiation, and viruses. Asbestos is one substance that is suspected of contributing to the development of small intestinal cancer. Although the precise causes of cancer are not known, a variety of factors are known to contribute to the development of cancer including tobacco smoke, and poor dietary habits such as high-fat diet. Eating a diet rich in fruits and vegetables and low in fat may reduce the likelihood of cancer. Studies have demonstrated that individuals who were protected from cancer ate a greater variety of foods and nutrients compared to those with cancer. Several fruits, vitamins, and minerals were found particularly protective against intestinal cancer including vitamin B_6, folate, niacin, and iron. Some studies have linked eating large amounts of salt-cured, salt-pickled, and smoked foods to cancers of the digestive system. Other studies have linked stomach cancers, specifically intestinal cancer, to a lack of fruits, vegetables, and fiber in the diet. For prevention of cancer, it is important to avoid carcinogens (smoking, chemicals) and known risk factors, and to pursue a healthy lifestyle which includes moderate alcohol intake, regular exercise, a low-fat diet, and a diet rich in fruits and vegetables. Modifying genetic predispositions through risk factor reduction can also assist in prevention.

KEY TERMS

Adenocarcinoma—A cancer that starts in glandular tissue.

Angiosarcoma—A malignant tumor that develops either from blood vessels or from lymphatic vessels.

Carcinogen—A substance that causes cancer.

Carcinoid—A tumor that develops from neuroendocrine cells.

Leiomyosarcoma—A cancerous tumor of smooth (involuntary) muscle tissue.

Liposarcoma—A cancerous tumor of fat tissue.

Lymphoma—A cancer of the lymphatic tissue.

Malignant—Cancerous; a tumor or growth that often destroys surrounding tissue and spreads to other parts of the body.

Metastasis—The spread of cancer from the original site to other body parts.

Radiation therapy—Also called radiotherapy, it uses high-energy rays to kill cancer cells.

Sarcoma—A malignant tumor of the soft tissue including fat, muscle, nerve, joint, blood vessel, and deep skin tissues.

Staging—Performing exams and tests to learn the extent of the cancer within the body, especially whether the disease has spread from the original site to other parts of the body.

Special concerns

Due to the side effects of radiation and chemotherapy, individuals must make a deliberate effort to eat as nutritiously as possible. Those who experience pain, nausea, or diarrhea may want to discuss treatments options with their doctor to ease these side effects.

Eating well during cancer treatment means getting enough calories and protein to help prevent weight loss

QUESTIONS TO ASK THE DOCTOR

- What is my diagnosis?
- Is there any evidence the cancer has spread?
- What is the stage of the disease?
- What are my treatment choices?
- What new treatments are being studied?
- Would a clinical trial be appropriate for me?
- What are the expected benefits of each kind of treatment?
- What are the risks and possible side effects of each treatment?
- How often will I have treatments?
- How long will treatment last?
- Will I have to change my normal activities?
- What is the treatment likely to cost?
- Is infertility a side effect of cancer treatment? Can anything be done about it?
- What is my prognosis?

and maintain strength. Eating nutritiously may also help an individual feel better.

Smoking cessation

Definition

Smoking cessation is the medical term for quitting smoking. It is a vital part of **cancer prevention** because smoking is the single most preventable cause of death from cancer. As early as 1982, the Surgeon General reported that tobacco causes more cancer deaths in the United States than any other factor–30% of all cancer deaths, including 87% of deaths from lung cancer. Although people think of smoking most often in connection with lung cancer, smoking is also associated with cancers of the mouth, throat, voice box (larynx), esophagus, pancreas, kidney, and bladder. Women who smoke increase their risk of cancer of the cervix. Quitting smoking, however, significantly reduces the risk of cancer; 15 years after quitting, a former smoker's risk is almost as low as that of someone who has never smoked.

Description

Smoking cessation covers several different approaches, ranging from medications and psychotherapy to special classes and programs. Smoking is a habit difficult to break because it involves many different aspects of a person's emotions and social life as well as physical addiction to nicotine. Most people who quit smoking successfully use a combination of treatments or techniques for quitting.

Special concerns

People who are trying to quit smoking are often concerned about:

- Withdrawal symptoms. Nicotine, the substance in tobacco that gives smokers a pleasurable feeling, is as addictive as heroin or cocaine. Withdrawal from nicotine may produce **depression**, anger, fatigue, headaches, problems with sleep or concentration, or increased appetite for food. These symptoms usually start several hours after the last cigarette. They may last for several days or several weeks.
- Weight gain. Many people, particularly women, gain between two and 10 pounds after giving up smoking.

A man with a nicotine patch. *(Photo Researchers, Inc. Reproduced by permission.)*

This mild weight gain, however, is not nearly as great a danger to health as continuing to smoke. Getting more exercise can help.

- Stress. Many smokers started to smoke as a way to cope with stress and tension. Finding other methods—exercise, meditation, biofeedback, massage, and others, can reduce the temptation to smoke when stress arises.
- Side effects of nicotine replacement products. Smokers who are using these products to help them quit may experience headaches, nausea, sore throat, or long-term dependence. Side effects can often be reduced or eliminated by using a lower dosage of the product or switching to another form of nicotine replacement.

Treatments

Nicotine replacement therapy

Nicotine replacement therapy gives the smoker a measured supply of nicotine without the other harmful chemicals in tobacco. It reduces the physical craving for **cigarettes** so that the smoker can handle the psychological aspects of quitting more effectively.

As of 2001, the Food and Drug Administration (FDA) had approved four forms of nicotine replacement therapy:

- Transdermal patches. Patches, which are non-prescription items, supply measured doses of nicotine through the skin. The doses are lowered over a period of weeks, thus helping the smoker to reduce the need for nicotine gradually.
- Nicotine gum. Nicotine gum provides a fast-acting nicotine replacement that is absorbed through the mouth tissues. The smoker chews the gum slowly and then keeps it against the inside of the cheek for 20 to 30 minutes. The gum is also available without prescription.
- Nasal spray. Nicotine nasal spray provides nicotine through the tissues that line the nose. It acts much more

KEY TERMS

Bupropion—An antidepressant medication given to smokers for nicotine withdrawal symptoms. It is sold under the trade name Zyban.

Buspirone—An anti-anxiety medication that is also given for withdrawal symptoms. It is sold under the trade name BuSpar.

Nicotine—A colorless, oily chemical found in tobacco that makes people physically dependent on smoking. It is poisonous in large doses.

QUESTIONS TO ASK THE DOCTOR

- What methods would you recommend to help me quit smoking?
- How can I cope with withdrawal symptoms and other side effects of quitting?
- Are there any stop-smoking programs in this area that you would recommend?

rapidly than the patches or gum, but requires a doctor's prescription.

- Inhalers. Nicotine inhalers are plastic tubes containing nicotine plugs. The plug gives off nicotine vapor when the smoker puffs on the tube. Some smokers prefer inhalers because they look more like cigarettes than other types of nicotine replacement. They also require a doctor's prescription.

Other medications

Bupropion, which is sold under the trade name Zyban, is an antidepressant medication given to lower the symptoms of withdrawal from nicotine. Bupropion by itself can help people quit smoking, but its success rate is even higher when it is used together with nicotine replacement therapy. Another drug that is sometimes given for nicotine withdrawal is buspirone (BuSpar), which is an antianxiety medication.

Stop-smoking programs and groups

Stop-smoking programs help by reinforcing a smoker's decision to give up tobacco. They teach people to recognize common problems that occur during quitting and they offer emotional support and encouragement. While stop-smoking programs do not have as high a success rate by themselves as medications or nicotine replacement therapy, they are very helpful as part of an overall quitting plan. The most effective programs include either individual or group psychological counseling. Many state Medicaid plans now cover the costs of smoking cessation programs; further information is available from the American Association of Respiratory Care at <http://www.aarc.org/advocacy/state/smoking_treatment.html.>

The Great American Smokeout has been held annually since 1977 on the third Thursday in November to call attention to the high human costs of smoking. Smokers are asked to quit for the day and donate the money saved on cigarettes to high school scholarship funds.

Nicotine Anonymous is an organization that applies the Twelve Steps of Alcoholics Anonymous (AA) to tobacco addiction. Its group meetings are free of charge.

Alternative and complementary therapies

Some people find that hypnosis helps them to quit. Acupuncture has also been used, but there are no large-scale studies comparing it to other stop-smoking treatments. A list of physicians who are also licensed acupuncturists is available from the American Academy of Medical Acupuncture at (800) 521-2262.

Other complementary approaches that have been shown to be useful in quitting smoking include movement therapies like yoga, t'ai chi, and dance. Prayer and meditation have also helped many smokers learn to handle stress without using tobacco.

Soft tissue sarcoma

Definition

Soft tissue sarcomas are cancerous (malignant) tumors that develop in mesodermal tissues that surround, support, and connect the structures and organs of the body.

Description

Soft tissues include muscles, fibrous (connective) tissues, fat, blood and lymph vessels, synovial tissues surrounding the joints, peripheral nerve tissues, and deep skin tissues. As soft tissue sarcomas grow, they may invade surrounding tissue, or spread (metastasize) to distant sites in the body. Together they account for less than 1% of all newly diagnosed cancers.

About one-half of all soft tissue sarcomas develop in the arms, legs, hands, or feet. About 40% occur in the trunk, internal organs, or the retroperitoneum—the back of the abdominal cavity. The remaining 10% occur in the head and neck.

Muscle tissue sarcomas

Rhabdomyosarcoma (RMS)—a skeletal muscle tumor—is the most common soft tissue **sarcoma** in children. Embryonal rhabdomyosarcoma (ERMS) is more common than alveolar rhabdomyosarcoma (ARMS). ERMS commonly develops in the head, neck, or reproductive or urinary tract organs. ARMS develops in the large muscles of the arms, legs, or trunk. All other soft tissue sarcomas in children are classified as non-rhabdomyosarcoma or non-RMS.

Leiomyosarcomas are smooth muscle tumors that occur most often in the retroperitoneum or internal organs but also may occur in the deep soft tissues of the arms or legs.

Fibrous tissue sarcomas

Soft tissue sarcomas often occur in connective tissue:

- **Fibrosarcoma** is a cancer of the tendons and ligaments.
- Malignant fibrous histiocytoma (MFH) is the most common soft tissue tumor of the limbs, although it also occurs in the retroperitoneum. MFH accounts for 40% of all soft tissue sarcomas.
- Dermatofibrosarcoma protuberans (DFSP) is a low-grade cancer of fibrous tissue under the skin, usually in the limbs or trunk.
- Desmoid tumors may be low-grade fibrosarcomas or a unique type of fibrous tissue tumor.

Fat tissue sarcomas

Liposarcomas develop in fat tissue anywhere in the body but occur most often in the thigh or the retroperitoneum. They range from very slow to very fast growing and account for 25% of all soft tissue sarcomas.

Blood and lymph vessel sarcomas

- Angiosarcoma is called hemangiosarcoma if it occurs in a blood vessel and lymphangiosarcoma if it occurs in a lymph vessel.
- Hemangioendothelioma—usually called epithelioid hemangioendothelioma (EHE) in adults—is a low-grade cancer in the blood vessels of soft tissue or internal organs such as the lungs or liver.
- Hemangiopericytoma is a sarcoma of the perivascular tissue around blood vessels that help control blood

flow. It most often develops in the legs, pelvis, or retroperitoneum.

- Kaposi's sarcoma is a tumor formed by cells similar to those that line blood and lymph vessels.

Synovial sarcoma

Synovial sarcomas are tumors of the synovium—the tough tissue that surrounds the joints. They occur most often in leg and arm joints, especially the knee. They are the most common non-RMS in children. Approximately 30% of synovial sarcomas occur in those under age 20.

Peripheral nerve sarcomas

Malignant peripheral nerve sheath tumors—also called malignant schwannomas, neurofibrosarcomas, or neurogenic sarcomas—are tumors in cells surrounding the peripheral nerves that run throughout the body. Ewing's tumors are a group of related cancers that share characteristics with nerve tissue in a developing embryo. Ewing's tumors that occur in soft tissue are extraosseous (outside of the bone) Ewing's (EOE) and primitive neuroectodermal tumors (PNET).

Other soft tissue sarcomas

Some soft tissue sarcomas are of uncertain origin:

- Mesenchymonia is a combination of tissue types that resemble fibrosarcoma and others.
- Alveolar soft-part sarcoma most commonly develops in the legs.
- Epithelioid sarcoma usually develops under the skin of the hands, forearms, lower legs, or feet.
- Clear cell sarcoma—also called malignant **melanoma** of the soft parts (MMSP), clear cell sarcoma of tendons, aponeuroses—is a rare sarcoma of the tendons and related tissues. It has some characteristics of malignant melanoma or skin cancer.
- Desmoplastic small cell tumors usually occur in the abdomen, pelvis, or tissues around the testes, primarily in males.

Demographics

It is estimated that 9,420 new cases of soft tissue sarcomas will be diagnosed in the United States during 2005—5,530 in males and 3,890 in females. Every year in the United States 850–900 children under age 20 are diagnosed with soft tissue sarcoma, accounting for 7.4% of cancers in that age group. During 2005 an estimated 1,910 American males and 1,580 females will die of soft tissue sarcoma.

Childhood soft tissue sarcomas occur most frequently during infancy or after age 10. Male children have a slightly higher incidence than females and black children have a slightly higher incidence than white children, particularly among 15–19-year-olds.

More than 85% of RMS occur in infants, children, and teenagers. Almost 60% of soft tissue sarcomas in children up to age four are RMS. The prevalence of RMS declines steadily with increasing age, accounting for only 23% of soft tissue sarcomas in 16–19-year-olds. ERMS accounts for 75% of RMS in children aged 1–14. ARMS can affect children in all age groups but is more prevalent among older children.

Other soft tissue sarcomas also affect different age groups:

- Adolescents are more likely to develop **leiomyosarcoma** in the trunk, whereas in adults it is more common in the uterus or digestive tract.
- Infantile fibrosarcoma affects children up to age four.
- Adolescents are more likely to develop fibrosarcoma in the arms or legs and MFH in the legs.
- Adults are more likely to develop fibrosarcoma in the arms, legs, or trunk, or DFSP in the trunk; MFH is most common in older adults.
- Liposcarcoma can occur in the arms and legs of older teenagers and in the arms, legs, or trunk of adults; however it is most common in people aged 60–65.
- Adults are more likely to develop hemangiosarcoma in the arms, legs, or trunk, lymphangiosarcoma in the arms, or Kaposi's sarcoma in the legs or trunk.
- Hemangiopericytoma is more common in adults, although infantile hemangiopericytoma occurs in children up to age four.
- Synovial sarcomas usually occur in young adults.
- Teenagers and adults can develop malignant peripheral nerve sheath tumors in the arms, legs, or trunk.
- Soft tissue Ewing's tumors are relatively common in children and very rare in adults.
- Mesenchymonia is a rare sarcoma of children.
- Aveolar soft-part sarcoma is rare, usually affecting young adults.
- Alveolar soft-part sarcoma of the muscular nerves of the arms or legs can affect children in all age groups but is more prevalent in older children.
- Epithelioid sarcoma usually affects adolescents and young adults.
- Desmoplastic small cell tumors are rare and affect primarily male teenagers and young adults.

Causes & symptoms

Causes

Although most soft tissue sarcomas have no known cause, those in children generally are associated with chromosomal changes. Other soft tissue sarcomas are caused by changes in the DNA carried on the chromosomes. Some of these changes or mutations are inherited but most are acquired during a person's lifetime, possibly from exposure to radiation or cancer-causing chemicals.

In addition:

- Leiomyosarcoma and some other soft tissue sarcomas have been linked to the **Epstein-Barr virus** in people with AIDS.
- Some hormones, particularly estrogen, cause desmoid tumors to grow.
- Angiosarcomas sometimes develop in an area that has been exposed to radiation.
- Kaposi's sarcoma appears to be related to infection by human herpesvirus-8.

Symptoms

During their early stages most soft tissue sarcomas do not cause symptoms. However as they grow larger the tumors begin to press against normal tissue causing soreness or pain. Synovial sarcoma causes tenderness, pain, or swelling in a joint.

Symptoms of soft tissue sarcoma can include:

- a new or growing lump anywhere in the body
- a usually painless swelling or lump in an arm or leg that grows over weeks or months.

About one-third of abdominal sarcomas cause increasing pain. Although symptoms may be nonspecific, abdominal tumors can grow large enough to be felt or to cause blockage or bleeding in the stomach or bowels. This leads to blood in vomit or stools and may cause stools to be very black and tarry.

RMS often develops in easily detectable regions such as a lump just under the skin or around the testes:

- RMS in an eye muscle can cause bulging eye
- RMS in the nasal cavity may cause nosebleeds
- RMS often occurs in the bladder or genitourinary tract causing difficult urination or blood in the urine
- RMS in the abdomen or pelvis may cause vomiting, abdominal pain, or constipation

Diagnosis

Only about 50% of soft tissue sarcomas are diagnosed at early stages before the cancer has spread. Soft tissue sarcomas in children may be particularly difficult to diagnose.

Diagnosis may include:

- a medical history to uncover any risk factors
- a physical examination
- ultrasound imaging for visualizing internal organs and masses
- a **computed tomography** (CT) scan—sometimes in conjunction with a radiocontrast dye—to help determine whether a sarcoma has spread to the liver or other organs
- magnetic resonance imaging (MRI)—sometimes with radiocontrast dyes—to obtain detailed images of organs or masses
- chest **x rays** to determine whether a sarcoma has spread to the lungs
- positron emission tomography (PET) to scan the entire body for metastasized cancer

Biopsies

Unlike most cancers, the size of a soft tissue sarcoma may be less important than the appearance of the cancer cell. Cells that appear similar to normal cells of the same tissue are called well-differentiated or moderately differentiated. Sarcoma cells that appear very different from normal tissue are referred to as poorly differentiated or undifferentiated. For example, ERMS cells resemble developing skeletal muscle cells in a 6–8-week-old fetus and ARMS cells resemble the normal muscle cells of a 10-week-old fetus. Therefore microscopic examination of sarcoma cells obtained by a biopsy—the removal of sarcoma tissue—is very important for determining the clinical stage, the probable growth rate of the cancer, the likelihood of **metastasis**, and the prognosis.

A fine needle aspiration (FNA) **biopsy** uses a very thin needle and syringe to remove small fragments of a superficial (near the surface), easily accessed sarcoma. The needle may be guided by feeling a mass near the surface or using a CT scanner. Although much less invasive than other types of biopsies, FNA may not provide enough tissue to identify a sarcoma, determine its type, and grade it. However it is useful for determining whether a suspected sarcoma is a benign tumor, another type of cancer, an infection, or some other disease. FNA also is used to determine whether tumors in other organs are metastases of the sarcoma.

If FNA indicates a sarcoma, another type of biopsy is used to confirm the diagnosis:

- A core needle biopsy removes a cylindrical piece of tissue of about one-sixteenth in. (0.15 cm) diameter

and 0.5 in. (1.3 cm) long. A CT scanner may be used to guide the needle into tumors located in internal organs. Although a core biopsy avoids an incision and may not require general anesthesia, the small sample size may cause a cancer to be missed or misdiagnosed.

- If the sarcoma is small, near the surface, and away from vital tissues, an excisional biopsy may be used to remove the entire mass and surrounding normal tissue. This combines a diagnostic biopsy with surgical treatment.
- An incisional biopsy removes a small portion of a large sarcoma.
- An open surgical biopsy under general anesthesia is used to diagnose RMS in children. In addition to the tumor sample, nearby lymph nodes may be removed for testing.

Testing

In addition to histological examination under a microscope, biopsy samples may require special testing to identify a sarcoma and its type and grade:

- An immunohistochemical test treats the sample with antibodies that recognize cell proteins that are typical of some types of sarcomas. When an antibody binds such a cell protein, a color change is detected microscopically.
- For cytogenetic techniques biopsied cells are grown in the laboratory for about a week and examined microscopically to determine whether chromosomal changes have occurred.
- Fluorescent *in situ* hybridization (FISH) may be used to detect chromosome abnormalities without first growing the cells.

Treatment team

Soft tissue sarcomas are treated by a multidisciplinary team of cancer specialists including:

- pathologists
- hematologists
- oncologists
- surgeons
- radiation oncologists

Children and adolescents with soft tissue sarcomas are treated at medical centers specializing in **childhood cancers** with treatment teams that include:

- a primary care physician
- pediatric hematologists/oncologists
- pediatric surgeons
- radiation oncologists
- pediatric oncology nurses
- nurse practitioners
- rehabilitation and physical therapists
- psychologists
- child-life specialists
- nutritionists
- social workers
- educators

Clinical staging, treatments, and prognosis

Staging systems

TNM Soft tissue sarcomas often are staged according to the TNM system of the American Joint Committee on Cancer, in which T is the primary tumor size and location:

- TX—cannot be assessed
- T0—no evidence of a primary tumor
- T1—the sarcoma is 2 in. (5 cm) or less
- T2—the sarcoma is more than 2 in. (5 cm)
- a—the tumor is superficial
- b—the tumor is deep in a limb or the abdomen.

N represents lymph node involvement in the region of the sarcoma:

- NX—cannot be assessed
- NO—lymph nodes free of sarcoma cells
- N1—regional lymph nodes have sarcoma cells.

Although RMS and synovial and epithelioid sarcomas commonly spread to lymph nodes, overall lymph node involvement occurs with less than 3% of adult soft tissue sarcomas.

M represents metastasis to distant organs:

- MX—cannot be assessed
- MO—sarcoma has not spread
- M1—distant metastases

GRADING In addition to a standard staging system, soft tissue sarcomas are graded according to the microscopic appearance of the cells, where G is the histological grade:

- GX—cannot be assessed
- G1 or low grade—cells appear normal, well-differentiated, slow-growing; these rarely metastasize

- G2 or intermediate—cells are moderately differentiated and fast growing
- G3 or high grade—cells are poorly differentiated and faster growing
- G4—cells are abnormal, poorly or undifferentiated, and very fast growing.

Clinical staging

Stage I sarcomas are low-grade cancers:

- Stage IA—G1–2, T1a or b, N0, M0
- Stage IB—G1–2, T2a, N0, M0

Stage II, III, and IV sarcomas are high-grade cancers:

- Stage IIA—G1–2, T2b, N0, M0
- Stage IIB—G3–4, T1a–b, N0, M0
- Stage IIC—G3—4, T2a, N0, M0
- Stage III—G3–4, T2b, N0, M0
- Stage IVA—any G, any T, N1, M0
- Stage IVB—any G, any T, any N, M1.

Treatments

In addition to the stage, treatment depends on other factors including the location of the sarcoma. Treatment of children with non-RMS usually follows the standard treatment for adults. However potential long-term effects of treatment are a greater concern in children, who are much more susceptible to radiation and are expected to live much longer than adults.

SURGERY Most stage I, II, and III soft tissue sarcomas are surgically removed, with the goal of completely removing (resectioning) the tumor, as well as at least 0.8–1.2 in. (2–3 cm) of surrounding tissue. Many soft tissue sarcomas in infants and young children can be treated successfully by surgery alone. Only about 5% of arm or leg sarcomas require **amputation** of the limb. Most patients have limb-sparing surgery followed by **radiation therapy**, although these procedures are more difficult in children than in adults. Amputation may be necessary when invading sarcoma cells surround essential nerves, arteries, or muscles, or when limb-sparing surgery would result in a dysfunctional limb or chronic pain. Amputation is not recommended if the sarcoma has metastasized to the lungs or other organs. Abdominal sarcomas are difficult to remove because they can be quite large and adjacent to vital organs.

Stage IVA sarcomas and nearby lymph nodes are surgically removed. Sometimes the removal of stage IVB sarcomas and all of their metastases is attempted. Surgery may be preceded by high-dose radiation and/or **chemotherapy** to shrink the tumor or for high-grade sarcomas that are at risk of metastasizing. If the only metastasis is in the lungs, sometimes the lung tumor can be removed.

RADIATION THERAPY Radiation therapy uses high-energy rays such as x rays to kill cancer cells:

- External beam radiation—delivered from outside the body—is aimed directly into the sarcoma and is the most common radiation treatment for soft tissue sarcomas.
- Internal radiation therapy (brachytherapy) delivers small pellets of radioactive material directly into the sarcoma through thin plastic tubes. It may be used alone or in combination with external beam radiation.

Radiation may be used:

- before and/or after surgery for all sarcoma stages
- for inoperable stage I and II sarcomas
- as the primary treatment for patients with health conditions that preclude surgery
- to kill small clusters of cancer cells
- to relieve symptoms of stage IVB sarcoma
- as an adjunct treatment 6–9 weeks after chemotherapy
- for recurrent sarcomas that were not treated previously with radiation
- to treat pain accompanying recurrences

Tumors of the retroperitoneum, trunk, head, or neck may be treated with fast neutron therapy.

Short-term side effects of radiation therapy may include:

- fatigue
- mild skin conditions
- infections
- nausea, vomiting, and **diarrhea** after irradiation of the abdomen
- mouth sores and loss of appetite after head or neck irradiation
- swelling, weakness, or pain following irradiation of large portions of a limb

Longer-term radiation effects can include:

- worsening of chemotherapy side effects
- breathing difficulties and lung damage from chest irradiation
- bone fractures, sometimes occurring years later
- headaches and mental problems one to two years after radiation therapy for metastatic sarcoma in the brain

CHEMOTHERAPY Chemotherapy may be used:

- as primary therapy for some sarcomas
- to shrink a stage II tumor prior to surgery
- as postoperative treatment for stage II sarcomas
- before or after surgery for stage III sarcomas to reduce the risk of recurrence
- to treat metastasized sarcomas
- to reduce pain with stage IV sarcomas
- for recurrence at a distant site

Synovial sarcomas respond more readily to chemotherapy than other soft tissue sarcomas. Chemotherapy usually does not prevent metastasis and the benefits of postoperative chemotherapy in children have been questioned.

Ifosfamide and **doxorubicin** (Adriamycin) are the most common drugs for treating soft tissue sarcoma. They may be used alone, together, or in combination with other drugs including:

- **dacarbazine**
- methotrexate
- **vincristine**
- cisplatin
- paclitaxel
- mesna for protecting the bladder from severe irritation caused by ifosfamide

When used alone only doxorubicin and ifosfamide have response rates above 20%. Doxorubicin alone or in combination with dacarbazine is the most frequently used chemotherapy for advanced sarcomas. High-dose ifosfamide is used to relieve symptoms of inoperable sarcomas.

Postoperative chemotherapy for ERMS is usually vincristine and **dactinomycin** (actinomycin-D). For group II and III RMS, **cyclophosphamide** is added for a three-drug combination called VAC. **Topotecan** also may be included.

Temporary side effects of chemotherapy may include:

- nausea and vomiting
- loss of appetite
- hair loss
- mouth sores

Chemotherpy can damage blood-producing bone marrow cells, increasing the risk of:

- fatigue
- bruising or bleeding
- infection

Most side effects disappear when chemotherapy ends, although it sometimes causes infertility. Doxorubicin can weaken the heart and ifosfamide and cyclophosphamide can cause permanent kidney or bladder damage.

RECURRENCES Treatment of recurrent soft tissue sarcomas depends on the initial type and treatment. If the initial treatment was minimal, a local recurrence may be treated with surgery and radiation. If the original treatment was aggressive, limb amputation may be necessary. The lungs are the most common distant site of sarcoma recurrences, usually within two to three years after the initial diagnosis. These are treated as stage IV disease. In older patients symptoms of recurrence may be treated by the sequential use of single chemotherapy drugs. Synovial sarcomas tend to recur locally and involve regional lymph nodes; however distant metastasis occurs in about 50% of cases, sometimes many years later.

Prognosis

Stage I and II soft tissue sarcomas rarely metastasize although they may recur locally if inadequately treated:

- Stage I sarcomas have a five-year-survival rate of 99% and only a 20% chance of recurrence within five years.
- Stage II sarcomas have an 82%-five-year-survival rate and a five-year-recurrence risk of 35%.
- Stage III sarcomas have a five-year-survival rate of 50% and a five-year-recurrence risk of about 65%.
- Stage IV sarcomas are usually incurable with a five-year-survival rate of 10–15%.
- Surgery to remove metastatic lung sarcomas has a five-year-survival rate of 20–30% and occasionally a complete cure.
- Patients over age 60 have a poorer prognosis than younger adults.

In children:

- stage I: 90% never have a recurrence
- stage II: about 89% survive long term and about 50% of recurrences are cured in the second round of treatment
- stage III: about 70% survive long term
- stage IV: a five-year-survival rate of less than 30%, although children under age 10 with metastatic embryonal tumors have a 50% chance of survival.

Younger children with RMS have higher survival rates than older children and adolescents and ERMS has a more favorable prognosis than ARMS. More than 70% of children survive ERMS and second malignancies arise in less than 25% of survivors, usually in children with more advanced disease.

KEY TERMS

Alveolar rhabdomyosarcoma, ARMS—A type of soft tissue sarcoma in the large muscles of the arms, legs, or trunk that primarily affects older children.

Brachytherapy—Irradiation in direct contact with a sarcoma.

Cytogenetics—The combined study of heredity and the structure and function of cells.

Dermatofibrosarcoma protuberans, DFSP—A low-grade cancer of fibrous tissue under the skin, usually in the limbs or trunk.

Embryonal rhabdomyosarcoma, ERMS—The most common type of RMS in children, occurring in the head, neck, or genitourinary tract and resembling fetal skeletal muscle tissue.

Epithelioid hemangioendothelioma, EHE—Hemangioendothelioma in adults.

Extraosseous Ewing's tumor, EOE—A type of Ewing's tumor in soft tissue outside of the bone tissue with some characteristics of embryonic nerve tissue.

Hemangioendothelioma—A low-grade sarcoma of the blood vessels of soft tissues or internal organs such as the lungs or liver.

Fine needle aspiration, FNA—A type of biopsy that uses a very thin needle to remove small pieces of a superficial suspected sarcoma.

Lymph nodes—The filtering system for the lymph that carries white blood cells of the immune system throughout the body via lymph vessels.

Mesoderm—The middle layer of embryonic cells that gives rise to skin, connective tissue, blood and lymph vessels, the urogenital system, and most muscles.

Malignant fibrous histiocytoma, MFH—The most common soft tissue tumor of the limbs, occurring primarily in older adults and accounting for 40% of all soft tissue sarcomas.

Primitive neuroectodermal tumor, PNET—A type of Ewing's tumor in soft tissue with some characteristics of embryonic nerve tissue.

Non-RMS—All soft tissue sarcomas in children that are not RMS.

Retroperitoneum—The space between the lining of the abdominal and pelvic walls and the back wall of the body.

Rhabdomyosarcoma, RMS—A cancerous tumor of the skeletal muscle and the most common soft tissue sarcoma in children.

TNM—A cancer staging system in which T is the primary tumor size and location, N is lymph node involvement, and M is metastasis to distant parts of the body.

Children with non-RMS generally have a better prognosis than adults, although if the sarcoma is not removed completely, metastasizes, or recurs, the prognosis is poor:

- Leiomyosarcoma has a good prognosis unless it is within the gastrointestinal tract.
- Infantile fibrosarcoma—which occurs in children under five—has an excellent prognosis when treated with surgery alone.
- Adult-type fibrosarcomas have a survival rate of about 60% in both children and adults.
- MFH has a survival rate of about 50%.
- Desmoid tumors rarely metastasize and have an excellent prognosis.
- Liposarcomas have a good prognosis if completely removed.
- The prognosis for angiosarcomas and hemangioendotheliomas depends on their removal, the extent of the disease, and the grade of the malignancy.
- Hemangiopericytoma has an excellent prognosis in young children and an overall survival rate of 30–70%.
- Synovial sarcoma has a survival rate of 80%.
- Neurofibrosarcoma has a very good prognosis with complete removal; otherwise the prognosis is poor.
- Alveolar and clear cell soft-part sarcomas have a 50% survival rate and late relapses are common.

High-grade retroperitoneal sarcoma has a less favorable prognosis because of the difficulty of completely removing the tumor and the limitations on high-dose radiation therapy. Local recurrence is the most common cause of death in these patients.

Clinical trials

As of 2005 numerous **clinical trials** for treating soft tissue sarcomas in children and adults were underway, including trials to evaluate:

- chemotherapy prior to surgery

- regional chemotherapy in which drugs are injected directly into the artery that supplies an affected limb
- new drugs for reducing heart damage from doxorubicin, so that higher doses can be used
- the use of radiation therapy during surgery for abdominal and retroperitoneal sarcomas
- drugs such as interleukin-2 to boost the immune system
- vaccines that may cause the immune system to recognize abnormal chemicals in sarcomas and destroy the cells
- stem-cell transplantations that allow higher levels of chemotherapy for treating RMS.

Prevention

Most soft tissue sarcomas develop in people with no known risk factors. Since early detection is very important, a healthcare professional should be consulted about unexplained lumps, growths, or other symptoms. Less than 5% of soft tissue sarcomas are caused by radiation exposure. Lymphangiosarcomas can develop where lymph nodes have been damaged by radiation or surgically removed.

A high percentage of patients with angiosarcoma of the liver have been exposed to vinyl chloride. Although exposures to other chemicals—including dioxin, herbicides containing phenoxyacetic acid, and chlorophenols in wood preservations—have been suggested as risk factors for soft tissue sarcoma, there are no proven connections.

The only known risk factors in children are congenital (present at birth) abnormalities and genetic (inherited) conditions:

- Li-Fraumeni syndrome increases the risk of soft tissue sarcomas as well as other types of cancer and there is a high risk of developing soft tissue sarcoma in an area that was irradiated to treat another cancer.
- Children with inherited retinoblastoma—an eye cancer—are at increased risk for soft tissue sarcoma.
- Children with Beckwith-Wiedemann syndrome are at risk for developing RMS.
- Gardner's syndrome increases the risk of desmoid tumors in the abdomen.
- Neurofibromatosis or von Recklinghausen's disease is characterized by benign neurofibromas; in about 5% of cases these develop into malignant peripheral nerve sheath tumors.

Those with a family history of sarcomas or other cancers occurring at a young age may have **genetic testing** to assess their risk.

QUESTIONS TO ASK YOUR DOCTOR

- What type of sarcoma do I have?
- Has the cancer spread?
- What stage is the cancer and what does that mean for me?
- What are the treatment options?
- What treatment do you recommend and why?
- What are the risks and side effects of each treatment?
- What are the risks of recurrence after each treatment?
- How should I prepare for the treatment?
- How much work or school will be missed?
- What is the recovery time after treatment?
- What is my estimated survival time?

Special concerns

Since advanced soft tissue sarcoma has a high risk of metastasis and recurrence, following treatment a patient may have:

- frequent physical examinations
- chest x rays, ultrasound, or CT or MRI scans

Spinal axis tumors

Definition

Spinal axis tumors are tumors that affect the spinal cord—the bundle of nerves that lies inside the backbone. Another term for spinal axis tumors is spinal cord tumors.

Description

Spinal axis tumors form on or near the spinal cord and produce pressure on the associated nerves and blood vessels. There are three types of spinal axis tumors: extradural, extramedullary intradural, and intramedullary.

Extradural spinal axis tumors

Extradural tumors are found outside the dura mater, the membrane that encases the spinal cord. Extradural tumors are wedged between the dura mater and the bone of the spine. Types of extradural tumors include chordomas, osteoblastomas, osteomas, and hemangiomas.

Extramedullary intradural spinal axis tumors

Extramedullary intradural tumors are found inside the dura mater but outside the nerves of the spinal cord itself. Types of extramedullary tumors include meningiomas and neurofibromas.

Intramedullary spinal axis tumors

Intramedullary tumors are found inside the nerves of the spinal cord. Types of intramedullary tumors include astrocytomas, ependymomas, and hemangioblastomas.

Benign vs. malignant

Spinal axis tumors are classified as either benign or malignant. The cells of malignant tumors are very different from normal cells, grow quickly, and usually spread easily to other parts of the body. Benign tumors have cells that are similar to normal cells, grow slowly, and tend to be localized. However, even benign tumors can cause significant problems when they grow within the confined space inside the backbone.

Demographics

Primary spinal axis tumors, or tumors that originate in the spinal axis itself, are extremely rare and represent only 0.5% of all diagnosed tumors. Malignant primary spinal axis tumors comprise about 65% of all spinal axis tumors. However, most spinal axis tumors result from **metastasis**, or spreading, of other types of cancer to the

spinal axis. Other cancers that can spread to the spinal axis include head and neck cancer, **thyroid cancer**, skin cancer, **prostate cancer**, lung cancer, **breast cancer**, and others. The American Cancer Society estimates that brain and spinal cord cancers (primary only) represent approximately 1.4% of all cancers and 2.4% of all cancer-related deaths, but separate statistics for spinal cord cancers only are unavailable.

Half of all spinal axis tumors occur in the thoracic, or chest, region as opposed to the neck (cervical) or lower back (lumbar) region.

Spinal axis tumors occur with equal frequency in members of all races and ethnic groups. There does not appear to be any relationship between spinal axis tumors and any geographic region. Males and females are affected in equal numbers by spinal axis tumors.

Causes and symptoms

The cause, or causes, of primary spinal axis tumors are not known. The cause of metastatic spinal axis tumors is the originating cancer in another part of the body.

The symptoms of spinal axis tumors are the result of increased pressure on the nerves of the spine. These symptoms include:

- constant, severe, burning or aching pain
- numbness of the skin or decreased temperature sensation
- muscle weakness, wasting, or even paralysis
- problems with bladder and bowel control
- muscle spasticity or problems in walking normally

The location of the tumor determines where the symptoms are most noticeable. A tumor in the cervical region can cause symptoms in the neck or arms, while a tumor in the thoracic region may cause chest pain. A tumor in the lumbar region can result in observable symptoms in the back, bladder and bowel, and legs.

Diagnosis

The diagnosis of spinal axis tumors begins with a medical history and physical examination when the patient brings his or her symptoms to the doctor's attention. The diagnosis may be difficult to make due to the similarity of tumor symptoms to those caused by disc herniation or other spinal cord injuries.

If the doctor suspects a spinal axis tumor may be present, further diagnostic tests are ordered. These tests are performed by a neurological specialist. Imaging tests that may be ordered include:

- magnetic resonance imaging (MRI)
- computed tomography (CT)
- bone scan
- spinal tap and myelogram, a specialized x-ray technique

KEY TERMS

Astrocytoma—A tomor that begins in the brain or spinal cord in cells called astrocytes.

Chordoma—A type of bone cancer.

Dura mater—The tough membrane that encases the nerves of the spinal cord.

Ependymoma—A tumor that begins in the tissue that lines the central canal of the spinal cord and the ventricles of the brain. About 85% of these tumors are benign.

Hemangioblastoma—A tumor composed of capillaries and disorganized clumps of capillary cells or angioblasts.

Hemangioma—A benign tumor consisting of a mass of blood vessels.

Meningioma—A tumor that occurs in the meninges, the membranes that cover the brain and spinal cord. Meningiomas usually grow slowly and primarily affect adults.

Metastasic tumor—A tumor that results from the spreading of one type of cancer to other parts of the body.

Neurofibroma—A fibrous tumor of nerve tissue.

Osteoblastoma—A benign tumor that most frequently occurs in the vertebrae, leg bones, or arm bones of children and young adults.

Osteoma—A usually benign tumor of bone tissue.

Spinal cord—The bundle of nerves that runs inside the backbone.

Treatment team

Treatment of any primary central nervous system tumor, including spinal axis tumors, is different from treating tumors in other parts of the body. Spinal cord surgery requires much more precision than most other surgeries. Also, the thoracic area, where the majority of spinal axis tumors are located, is highly sensitive to radiation. The most up-to-date treatment opportunities are available from experienced, multi-disciplinary medical professional teams made up of doctors, nurses, and

technologists who specialize in cancer (oncology), neurosurgery, medical imaging, drug or **radiation therapy**, and anesthesiology.

Clinical staging, treatments, and prognosis

Malignant tumors of the spinal axis may spread (metastasize) to other parts of the central nervous system, but almost never spread to other parts of the body. As of mid-2001, there is no staging system for spinal axis tumors. The most important factors in determining prognosis for individuals with these tumors are the type of cell involved (eg. astrocyte, ependyma, etc.) and the grade of the tumor (an indicator of the aggressiveness of the tumor cells). Grade I tumors have cells that are not malignant and are nearly normal in appearance. Grade II tumors have cells that appear to be slightly abnormal. Grade III tumors have cells that are malignant and clearly abnormal. Grade IV tumors contain fast-spreading and abnormal cells. In general, the survival rate for some types of spinal cord tumors, such as extradural tumors and low-grade astrocytomas, is better than for other types, such as ependymomas.

The treatment of spinal axis tumors depends on the location of the tumor and the severity of the symptoms. Many spinal axis tumors can be treated by surgical removal of the tumor. Medical advances in surgical techniques, such as microsurgery and laser surgery, have greatly improved the success rate of spinal cord surgeries.

In some instances of spinal axis tumors, the tumor is inoperable. Patients with inoperable spinal axis tumors are generally treated with radiation therapies.

Other treatments may include the use of steroids to reduce swelling and pressure on the spinal cord, surgical decompression and fusion of the spine, and **chemotherapy** in selected cases. These may be the only treatments used if the spinal axis tumor is due to the metastasis of another primary cancer.

Prevention

Because the causes of spinal axis tumors are not known, there are no known preventative measures.

Special concerns

If left untreated, spinal axis tumors can cause loss of muscle function up to and including paralysis. This makes the proper diagnosis of spinal axis tumors important.

See also Astrocytoma; Brain and central nervous system tumors; Chordoma; Ependymoma.

QUESTIONS TO ASK THE DOCTOR

- Which type of spinal axis tumor do I have?
- Is my tumor operable?

Spinal cord compression

Description

In order to understand spinal cord compression, it is useful to understand the structure of the spinal cord and to understand the difference between the spinal cord and the vertebral column. The vertebral column includes the bony structure surrounding the spinal cord and the spinal cord itself. Also an important part of the vertebral column, the intervertebral disks, are found between vertebrae. They act as shock absorbers. The spinal cord, however, is the series of nerves that runs down the hollow part of the vertebrae. Thus, the bony vertebrae and shock-absorbing disks protect the spinal cord from physical damage and compression.

Spinal cord compression occurs when something presses down with sufficient force on the nerves within the spinal cord so that they lose their ability to function properly. Although trauma, degenerative back disease, and genetic disorders can cause pressure on the spinal

cord, the term spinal cord compression is usually reserved for cases in which the presence of a tumor results in pressure on the spinal cord. The tumor may originate in a number of areas and either directly or indirectly put pressure on the cord.

The spinal cord is a series of nerves bundled together that are responsible for most functions of the body, including, but not limited to, the "fight or flight" response, the movement of arms and legs, and feeling below the neck. Each nerve is responsible for different functions, such as movement, and each has a different position within the structure of the spinal cord. Thus, depending on which angle the spinal cord is compressed from, a person could experience numbness versus a loss of the ability to control muscles (often seen as an odd limp), depending on which area is compressed.

Not only do the different nerve clusters of the spinal cord have different functions, but each has nerves branching off from the spinal cord at many levels. Each of these branches controls different parts of the body. For example, nerves branching off the spinal cord in the low back control movement of the legs, and nerves branching off the spinal cord at the level of the neck are responsible for most of the movements of the arm. Thus, compression of the spinal cord at different levels can result in very different symptoms.

Vertebrae are, in order, divided into cervical, thoracic, lumbar, and sacral sections. The cervical vertebrae correspond to the neck, the thoracic vertebrae correspond to most of the torso, the lumbar vertebrae are found in the low back, and the sacral vertebrae correspond to the area of the buttocks. There are seven cervical, twelve thoracic, five lumbar, and five sacral vertebrae (although the sacrum is one bony structure and contains no intervertebral disks). The level of compression is indicated by using the first letter of the type of vertebra and then the number of the vertebra within the group. The topmost vertebrae are numbered lowest, so the first cervical vertebra is the vertebra closest to the head, and is known as C1. C7 is the cervical vertebra furthest down the spine. Compression of the spinal cord in this region would be known as compression at C7. The closer the compression is to the head, the more symptoms the patient is likely to have, since compression of the spinal cord affects all the levels of nerves below the area of compression that are part of the same nerve branch. For example, if movement were affected at C2 and below, a person would have difficulty using both arms and legs, whereas compression at T12 might result in just difficulty using the legs.

Importantly, the first symptom patients usually display prior to actual spinal cord compression is pain, especially pain that is not relieved by lying down, and which has lasted one month or more. This kind of pain should be sufficient to suspect imminent spinal cord compression due to cancerous causes. Also, there may be damage to nerve roots at the level of compression that can lead to symptoms in other parts of the body. For example, if the cord compression is in the lower part of the spine, then parts of the legs may be affected with numbness, tingling and loss of power and movement. Similarly, if the problem lies in the upper part of the spinal column, there may be a loss of power and sensation in parts of the arms or hands. If the cord compression becomes more severe, it can affect lower muscle functions such as bowel and bladder.

Causes

The most common cause of cancerous spinal cord compression is a vertebral **metastasis**. A metastasis is a cancerous lesion that arises from another tumor somewhere else in the body. Vertebral metastases account for 85% of cases of spinal cord compression, and 70% of those metastases occur in the thoracic vertebrae. About 5% to 10% of patients with cancer will develop metastases to the spinal cord. Tumors may also grow from the nerves themselves, from the connective tissue surrounding the nerves, or, rarely, from the bony vertebrae themselves. Tumors that grow from outside the vertebral column may cause pressure by either growing into the hollow space in the vertebral column or by pressuring the vertebrae into an abnormal conformation. More rarely, tumors in the vertebrae may cause compression indirectly by causing the vertebrae to collapse. Tumors that originate in the spinal cord or in the connective tissue overlying the spinal cord cause direct pressure because there is a limited area in which they can grow before impinging on the cord directly.

Treatments

If symptoms develop, prompt diagnosis and rapid treatment are crucial in order to avoid any permanent damage to the sensitive nerve tissue of the spinal cord. Usually, **magnetic resonance imaging** (MRI) or **computed tomography** (CT) scans will be performed to confirm cord compression and fully define the level and extent of the lesion. High-dose **corticosteroids** (oral or IV **dexamethasone**) may be promptly administered in order to reduce inflammation and pressure.

The goal of therapy for spinal cord compression includes pain control, avoidance of complications, preserving or improving neurologic functions, or reversing impaired neurologic functions. Treatment usually involves treatment of the underlying tumor. For most patients with cancer-induced compression, **radiation therapy** is the treatment of choice. However, if radiation

KEY TERMS

Neurologic—Pertaining to the nervous system.

Spinal cord—The name given to the series of nerves which travel down the vertebral column and govern most of the functions of the body, such as movement and sensation.

Vertebral column—The vertebral column is the bony structure made up of vertebra and intervertebral disks whose primary function is to protect the spinal cord.

therapy is unavailable or if neurologic signs worsen despite medical therapy, surgical decompression should be performed. Surgery is also indicated when a **biopsy** is needed, when the spine is unstable, when tumors have recurred after radiation therapy, or when any abscess is present. Finally, in some tumors known to be highly chemoresponsive, **chemotherapy** alone or in combination with other modalities may be used.

Splenectomy

Definition

Splenectomy is the surgical removal of the spleen, which is an organ that is part of the lymphatic system. The spleen is a dark purple, bean-shaped organ located in the upper left side of the abdomen, just behind the bottom of the rib cage. In adults, the spleen is about 4.8 × 2.8 × 1.6 in in size, and weighs about 4 or 5 oz. (It measures 12 × 7 × 4 cm, and weighs between 113 and 141 grams.) Its functions include: playing a role in the immune system, filtering foreign substances from the blood, removing worn-out blood cells from the blood, regulating blood flow to the liver, and sometimes storing blood cells. The storage of blood cells is called sequestration. In healthy adults, about 30% of blood platelets are sequestered in the spleen.

Purpose

Splenectomies are performed for a variety of different reasons and with different degrees of urgency. Most splenectomies are done after the patient has been diagnosed with hypersplenism. Hypersplenism is not a specific disease but a group of symptoms, or a syndrome, that can be produced by a number of different disorders. Hypersplenism is characterized by enlargement of the spleen (splenomegaly), defects in the blood cells, and an abnormally high turnover of blood cells. It is almost always associated with splenomegaly caused by specific disorders such as cirrhosis of the liver or certain cancers, such as leukemia or lymphomas (both Hodgkin's and non-Hodgkin's). Because serious consequences may result from removal of immune system organs such as the spleen, the decision to perform a splenectomy depends on the severity and prognosis of the disease or condition causing the hypersplenism.

Splenectomy always necessary

There are two diseases for which splenectomy is the only treatment—primary cancers of the spleen and a blood disorder called hereditary spherocytosis (HS). In HS, the absence of a specific protein in the red blood cell membrane leads to the formation of relatively fragile cells that are easily damaged when they pass through the spleen. The cell destruction does not occur elsewhere in the body and ends when the spleen is removed. HS can appear at any age, even in newborns, although doctors prefer to put off removing the spleen until the child is five or six years old.

Splenectomy usually necessary

There are some disorders in which splenectomy is usually recommended. They include:

- Immune (idiopathic) thrombocytopenic purpura (ITP). ITP is a disease involving platelet destruction. Splenectomy has been regarded as the definitive treatment for this disease and is effective in about 70% of chronic ITP cases. More recently, however, the introduction of new drugs in the treatment of ITP has reopened the question as to whether splenectomy is always the best treatment option.
- Trauma. The spleen can be ruptured by blunt as well as penetrating injuries to the chest or abdomen. Car accidents are the most common cause of blunt traumatic

injury to the spleen. Occasionally, the spleen is injured during an operation within the abdomen. Sometimes, the spleen can be repaired (splenorrhaphy) rather than removed.

- Abscesses in the spleen. These are relatively uncommon but have a high mortality rate.
- Rupture of the splenic artery. Rupture sometimes occurs as a complication of pregnancy.
- Hereditary elliptocytosis. This is a relatively rare disorder. It is similar to HS in that it is characterized by red blood cells with defective membranes that are destroyed by the spleen.

Due to more sophisticated imaging techniques, nonoperative splenic preservation is becoming more common for injuries due to splenic trauma. Splenectomy should be avoided whenever possible as the advantages of splenic preservation have been well established. Specifically, splenectomy increases the risks of postoperative and long-term infection, and the procedure is associated with excessive transfusion requirements.

Splenectomy sometimes necessary

In other disorders, the spleen may or may not be removed.

- Hodgkin's disease, a serious form of cancer that causes lymph nodes to enlarge and causes the immune system to malfunction. Treatments such as radiation, **chemotherapy**, and surgical removal of the spleen can exacerbate this malfunction, increasing the likelihood of infection. Splenectomy is sometimes performed in order to find out how far the disease has progressed. However, splenectomy has been shown to increase the risk of secondary **acute leukemia** in patients with Hodgkin's disease.
- Hairy cell leukemia. Patients may suffer discomfort due to a very enlarged spleen caused by leukemia cells growing in the spleen. Splenectomy was once the only treatment for this disease; but due to the complications associated with splenectomy (low blood cell counts, **fatigue**, frequent infections, and easy bleeding or bruising), physicians are now more often recommending chemotherapy.
- Chronic myeloid disorders. These disorders include chronic myelocytic leukemia, polycythemia vera, essential thrombocythemia, and agnogenic myeloid metaplasia (**myelofibrosis**); they enlarge the spleen to various degrees. In early stages of chronic myelocytic leukemia, splenectomy does not provide much benefit.
- Myelofibrosis. Myelofibrosis is a disorder in which bone marrow is replaced by fibrous tissue. It produces severe and painful splenomegaly. Splenectomy does not cure myelofibrosis but may be performed to relieve pain caused by the swollen spleen.
- Thrombotic thrombocytopenic purpura (TTP). TTP is a rare disorder marked by **fever**, kidney failure, and an abnormal decrease in the number of platelets. Splenectomy is one part of treatment for TTP.
- Autoimmune hemolytic disorders. These disorders may appear in patients of any age but are most common in patients over 50. The red blood cells are destroyed by antibodies produced by the patient's own body (autoantibodies).
- Thalassemia. Thalassemia is a hereditary form of **anemia** that is most common in people of Mediterranean origin. Splenectomy is sometimes performed if the patient's spleen has become painfully enlarged.

Precautions

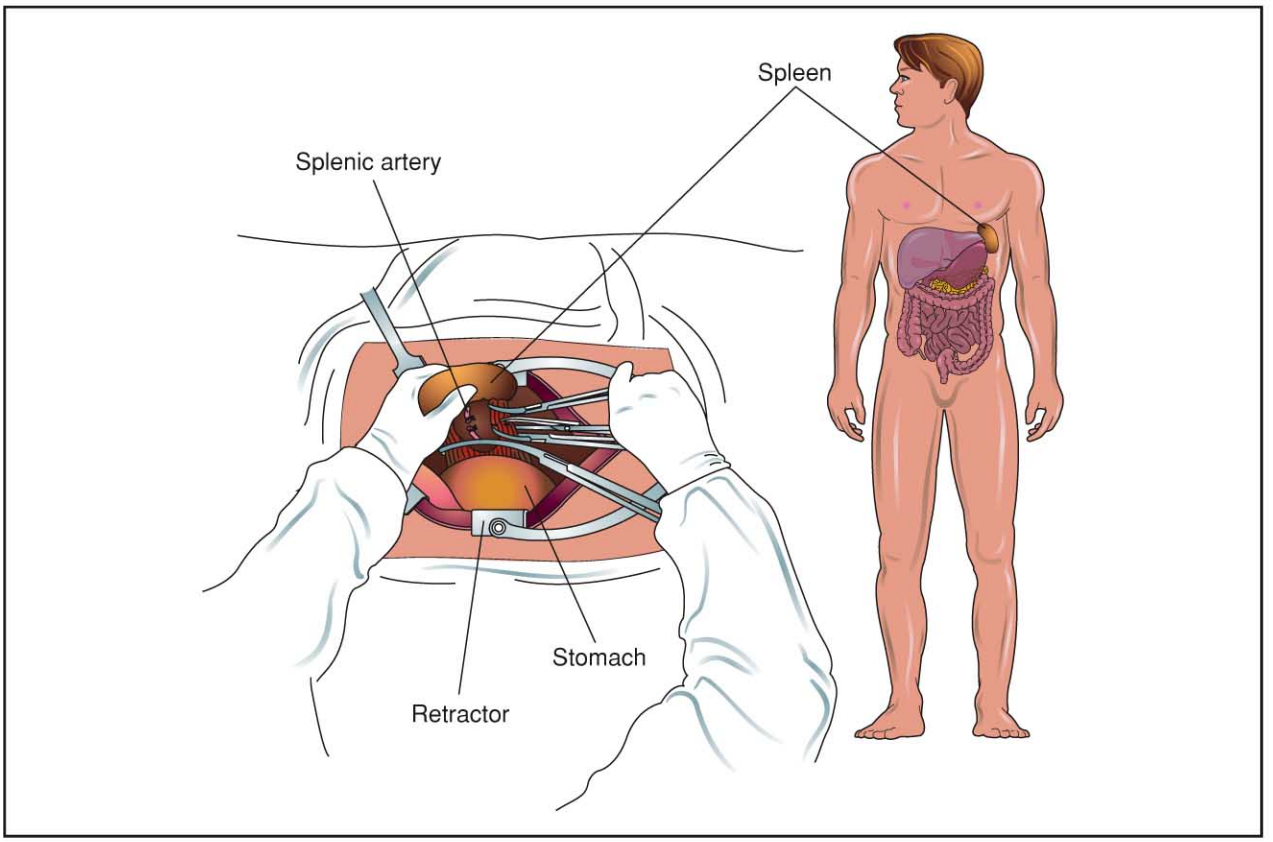
Patients should be carefully assessed regarding the need for a splenectomy. Because of the spleen's role in protecting against infection, it should not be removed unless necessary. The operation is relatively safe for young and middle-aged adults. Older adults, especially those with cardiac or pulmonary disease, are more vulnerable to post-surgical infections. Thromboembolism following splenectomy is another complication for this patient group, which has about 10% mortality following the surgery. Splenectomies are performed in children only when the benefits outweigh the risks.

The most important part of the assessment is the measurement of splenomegaly. The normal spleen cannot be felt when the doctor examines the patient's abdomen. A spleen that is large enough to be felt indicates splenomegaly. In some cases the doctor will hear a dull sound when he or she thumps (percusses) the patient's abdomen near the ribs on the left side. **Imaging studies** that can be used to demonstrate splenomegaly include ultrasound tests, technetium-99m sulfur colloid imaging, and **computed tomography** (CT) scans. The rate of platelet or red blood cell destruction by the spleen can be measured by tagging blood cells with radioactive chromium or platelets with radioactive indium.

Description

Complete splenectomy

REMOVAL OF ENLARGED SPLEEN Splenectomy is performed under general anesthesia. The most common technique is used to remove greatly enlarged spleens. After the surgeon makes a cut (incision) in the abdomen, the artery to the spleen is tied to prevent blood loss and reduce the spleen's size. It also helps prevent further sequestration



Splenectomy is the surgical removal of the spleen. This procedure is performed as a last resort in most diseases involving the spleen. In some cases, such as in many types of cancer, splenectomy does not cure the condition causing the splenomegaly—it only relieves the symptoms from the enlarged spleen. *(Illustration by Electronic Illustrators Group.)*

of blood cells. The surgeon detaches the ligaments holding the spleen in place and removes it. In many cases, tissue samples will be sent to a laboratory for analysis.

REMOVAL OF RUPTURED SPLEEN When the spleen has been ruptured by trauma, the surgeon approaches the organ from its underside and fastens the splenic artery.

In some cases, the doctor may prefer conservative (non-surgical) management of a ruptured spleen, most often when the patient's blood pressure is stable and there are no signs of other abdominal injuries. In the case of multiple abdominal trauma, however, the spleen is usually removed.

Partial splenectomy

In some cases the surgeon removes only part of the spleen. This procedure is considered by some to be a useful compromise that reduces pain from an enlarged spleen while leaving the patient less vulnerable to infection.

Laparoscopic splenectomy

Laparoscopic splenectomy, or removal of the spleen through several small incisions, has been more frequently used in recent years. Laparoscopic surgery involves the use of surgical instruments, with the assistance of a tiny camera and video monitor. Laparoscopic procedures reduce the length of hospital stay, the level of post-operative pain, and the risk of infection. They also leave smaller scars. Laparoscopic splenectomy is not, however, the best option for many patients.

A laparoscopic splenectomy using a hanger wall-lifting procedure may provide a better technique and can avoid the usual complications associated with pneumoperitoneum. The patient's left lower chest and left abdominal wall are lifted by three wires in two directions, left laterally and vertical to the abdominal wall.

Laparoscopic splenectomy is gaining increased acceptance in the early 2000s as an alternative to open splenectomy for a wide variety of disorders, although splenomegaly still presents an obstacle to laparoscopic splenectomy; massive splenomegaly has been considered a contraindication. In patients with enlarged spleens, however, laparoscopic splenectomy is associated with less morbidity, decreased transfusion rates, and shorter hospital stays than when the open approach is

used. Patients with enlarged spleens usually have more severe hematologic diseases related to greater morbidity; therefore, laparoscopic splenectomy has potential advantages.

The most frequent serious complication following laparoscopic splenectomy is damage to the pancreas. Application of a hydrogel sealant to the pancreas during surgery, however, appears to significantly reduce the risk of leakage from the pancreas.

Splenic embolization

Splenic embolization is an alternative to splenectomy that is used in some patients who are poor surgical risks. Embolization involves plugging or blocking the splenic artery to shrink the size of the spleen. The substances that are injected during this procedure include polyvinyl alcohol foam, polystyrene, and silicone. Embolization is a technique that needs further study and refinement.

Preparation

Preoperative preparation for nonemergency splenectomy includes:

- correction of abnormalities of blood clotting and the number of red blood cells and/or platelets
- treatment of any infections
- Control of immune reactions. Patients are usually given protective vaccinations about a month before surgery. The most common **vaccines** used are Pneumovax or Pnu-Imune 23 (against Pneumococcal infections) and Menomune-A/C/Y/W-135 (against meningococcal infections).

Aftercare

Immediately following surgery, patients should follow instructions and take all medications intended to prevent infection. Blood transfusions may be indicated for some patients to replace defective blood cells. The most important part of aftercare, however, is long-term caution regarding vulnerability to infection. Patients should see their doctor at once if they have a fever or any other sign of infection, and avoid travel to areas where exposure to malaria or similar diseases is likely. Children with splenectomies may be kept on antibiotic therapy until they are 16 years old. All patients can be given a booster dose of pneumococcal vaccine five to ten years after splenectomy.

Risks

The chief risk following splenectomy is overwhelmingly bacterial infection, or postsplenectomy sepsis. This vulnerability results from the body's decreased ability to clear bacteria from the blood, and lowered levels of a protein in blood plasma that helps to fight viruses (immunoglobulin M). The risk of dying from infection after splenectomy is highest in children, especially in the first two years after surgery. The risk of postsplenectomy sepsis can be reduced by vaccinations before the operation. Some doctors also recommend a two-year course of penicillin following splenectomy or long-term treatment with ampicillin.

KEY TERMS

Embolization—An alternative to splenectomy that involves injecting silicone or similar substances into the splenic artery to shrink the size of the spleen.

Hereditary spherocytosis (HS)—A blood disorder in which the red blood cells are relatively fragile and are damaged or destroyed when they pass through the spleen. Splenectomy is the only treatment for HS.

Hypersplenism—A syndrome marked by enlargement of the spleen, defects in one or more types of blood cells, and a high turnover of blood cells.

Immune or idiopathic thrombocytopenic purpura (ITP)—A blood disease that results in destruction of platelets, which are blood cells involved in clotting.

Laparoscope—An instrument used to view the abdominal cavity through a small incision and perform surgery on a small area, such as the spleen.

Pneumovax—A vaccine that is given to splenectomy patients to protect them against bacterial infections. Other vaccines include Pnu-Imune and Menomune.

Sepsis—A generalized infection of the body, most often caused by bacteria.

Sequestration—A process in which the spleen withdraws some normal blood cells from circulation and holds them in case the body needs extra blood in an emergency. In hypersplenism, the spleen sequesters too many blood cells.

Splenomegaly—Abnormal enlargement of the spleen.

Thromboembolism—A clot in the blood that forms and blocks a blood vessel. It can lead to infarction, or death of the surrounding tissue due to lack of blood supply.

Other risks following splenectomy include inflammation of the pancreas and collapse of the lungs. In some cases, splenectomy does not address the underlying causes of splenomegaly or other conditions. Excessive bleeding after the operation is an additional possible complication, particularly for ITP patients. Infection immediately following surgery may also occur.

Normal results

Results depend on the reason for the operation. In blood disorders, the splenectomy will remove the cause of the blood cell destruction. Normal results for patients with an enlarged spleen are relief of pain and of the complications of splenomegaly. It is not always possible, however, to predict which patients will respond well or to what degree.

See also Infection and sepsis.

Squamous cell carcinoma of the skin

Definition

A squamous cell carcinoma is a skin cancer that originates from squamous keratinocytes in the epidermis, the top layer of the skin. *Squamous* is a term that indicates a surface with a scaly nature.

Description

Squamous keratinocytes are flattened unpigmented skin cells in the middle of the epidermis. When they become cancerous, these cells invade the dermis (the layer of skin just below the epidermis) and spread out into the normal skin. They become visible as a small growth or area of change in the skin's appearance.

Most squamous cell carcinomas appear on areas that have been exposed to the sun: the head and neck, forearms, backs of the hands, upper part of the torso, and lower legs. Many develop in precancerous patches called actinic keratoses. Actinic keratoses are rough, scaly patches on the skin that usually start to show up in middle age. They are associated with a lifetime's exposure to the sun. Estimates of the chance that an actinic keratosis will turn into a squamous cell carcinoma vary from 0.24% to 20%.

Squamous cell carcinomas can also originate in old scars and burns, long-standing sores, and other areas of chronic skin irritation. These tumors tend to be more dangerous than those that arise in actinic keratoses.

The least dangerous type of squamous cell carcinoma is called **Bowen's disease**, intraepithelial squamous cell carcinoma, or squamous cell carcinoma *in situ*. Bowen's disease can show up anywhere on the skin, but it is especially common on the head and neck. This cancer usually grows slowly; but may evolve into a more serious, spreading form if it is not removed.

Other types of squamous cell carcinomas grow fairly quickly and can develop within a few months. These tumors may spread in the skin along the blood vessels, nerves, and muscles. They can also metastasize, or spread to other areas. On the average, 2–6% of squamous cell carcinomas metastasize, but the rate varies with the tumor site. At least 95% of the tumors that originate in actinic keratoses remain in the skin; but up to 38% of the cancers from scars are metastatic. **Metastasis** is also more likely when the cancer originates on the ear, lip, or genitalia, is large or deep, or develops in someone with a severely suppressed immune system. Cancers that regrow after treatment, and tumors that spread along the nerves are particularly dangerous.

Demographics

Squamous cell carcinoma is the second most common type of skin cancer in North America. There are between 80,000 and 100,000 cases diagnosed each year in the United States.

Squamous cell carcinomas are more common in the older adult population rather than the young. Overall, the chance of developing one is about 7%–11%. The likelihood increases with exposure to the sun, and is greatest for fair-skinned individuals who tan poorly. Living near the equator, where ultraviolet light is more intense, also increases the risk. A weakened immune system— for instance, from an organ transplant, or AIDS—can also increase the risk of developing a squamous cell carcinoma by a factor of 5 to 250.

Squamous cell carcinomas tend to be most dangerous in individuals with dark skin. The mortality rate for African-Americans with squamous cell carcinomas is 17–24%, much higher than the 2% death rate for white males with nonmelanoma skin cancer. One reason for this disparity is that the cancers that develop in dark skin are more likely to come from old scars and burns than from actinic keratoses.

Causes and symptoms

Squamous cell carcinoma is caused by genetic damage to a skin cell. A number of factors can increase the risk that this will happen, but the exact cause is rarely known.

Any of the following changes may be a warning sign that an actinic keratosis is developing into a squamous cell carcinoma:

- pain
- increased redness
- sores or bleeding
- hardening or thickening
- increased size

Most squamous cell carcinomas begin as a small red bump on the skin. More advanced squamous cell carcinomas have the following characteristics:

- a few millimeters to a few centimeters in diameter
- reddish-brown, flesh-colored, pink, or red
- bumpy or flat
- sharp, irregular edges in Bowen's disease; others may have no definite edge
- may be crusted or scaly
- may contain bleeding sores

Diagnosis

Squamous cell carcinomas are usually diagnosed with a skin **biopsy** taken in the doctor's office. This is generally a brief, simple procedure. After numbing the skin with an injection of local anesthetic, the doctor snips out the tumor or a piece of it. This skin sample is sent to a pathologist to be read. It can take up to a week for the biopsy results to come back. Squamous cell carcinomas are graded into categories of one through four. The grading is based on how deeply the tumor penetrates in the skin and how abnormal its cells are. Higher grades are more serious.

Treatment team

Primary care physicians remove some squamous cell carcinomas; other cancers, including larger or more complicated tumors, may be referred to a dermatologist. The services of a plastic surgeon are occasionally necessary. Metastatic tumors are often treated by an oncologist, surgeons, specially trained nurses, and specialists in radiation treatment.

Clinical staging, treatments, and prognosis

Staging

In stage 0 (Bowen's disease), the cancer is very small and has not yet spread from the epidermis to the dermis.

In stage I, the cancer is less than 2 cm (0.8 inches) in diameter. No cancer cells can be found in lymph nodes or other internal organs.

In stage II, the cancer is more than 2 cm (0.8 inches) in diameter. No cancer cells can be found in lymph nodes or other internal organs.

In stage III, cancer cells have been found in nearby lymph nodes or in the bone, muscle, or cartilage beneath the skin.

A stage IV cancer can be any size. In this stage, cancer cells have been discovered in internal organs that are distant from the skin. Squamous cell carcinomas tend to spread to nearby lymph nodes, the liver, and the lungs.

Treatment

The treatment options for a squamous cell carcinoma depend on the size of the tumor, its location, and the likelihood that it will spread aggressively or metastasize. All of the treatments described below generally have cure rates of approximately 90% to 99% for small, localized cancers. The five-year cure rates are highest with Moh's surgery, also called Mohs micrographic surgery.

One option is conventional surgery. The doctor numbs the area with an injection of local anesthetic, then cuts out the tumor and a small margin of normal skin around it. The wound is closed with a few stitches. One advantage of conventional surgery is that the wound usually heals quickly. Another benefit is that the complete cancer can be sent to a pathologist for evaluation. If cancer cells are found in the skin around the tumor, additional treatments can be done.

Laser surgery may be an alternative. A disadvantage to laser surgery is that the wounds from some lasers heal more slowly than cuts from a scalpel. The advantage is that bleeding is minimal.

Another option is Moh's micrographic surgery. This technique is a variation of conventional surgery. In this procedure, the surgeon examines each piece of skin under the microscope as it is removed. If any cancer cells remain, another slice is taken from that area and checked. These steps are repeated until the edges of the wound are clear of tumor cells, then the wound is closed. The advantage to this technique is that all of the visible cancer cells are removed but as much normal skin as possible is spared. Mohs surgery is often used for larger or higher risk tumors and when cosmetic considerations are important. The main disadvantage is that it takes much longer than conventional surgery and requires a specially trained surgeon.

In cryosurgery, liquid nitrogen is used to freeze the tumor and destroy it. This treatment is another type of blind destruction; there is no skin sample to make sure the cancer cells have all been killed. Patients report swelling and pain after cryosurgery, and a wound appears a few days later where the cells were destroyed. Healing takes about four to six weeks. When the site heals, it has usually lost its normal pigment. There is a risk of nerve damage with this technique. Cryosurgery is generally used only for small cancers in stage 0 and stage I.

In electro dessication and curettage, the physician scoops out the cancer cells with a spoon-shaped instrument called a curette. After most of the tumor is gone, the rest is destroyed with heat from an electrical current. The wound is left open to heal like an abrasion. It leaks fluid, crusts over, and heals during the next two to six weeks. This method is generally used only for the smallest squamous cell carcinomas (stage 0 and stage I). One disadvantage is that there is no skin sample to confirm that the tumor is completely gone. The electrical current used during this surgery can interfere with some pacemakers.

Some cases of Bowen's disease can be treated by applying a lotion containing 5-fluorouracil (fluorouracil or 5-FU) for several weeks. This treatment usually gives good cosmetic results. The side effects from 5-fluorouracil include allergies to the ingredients, infections, redness, peeling, and crusting, sensitivity to the sun, and changes in skin color. The main disadvantage to this treatment is that the drug cannot penetrate very far and cancer cells in the deeper parts of the tumor may not be destroyed.

Radiation therapy is sometimes used for squamous cell carcinomas, especially when the tumor is at a site where surgery would be difficult or remove a sizeable amount of tissue. This treatment is sometimes combined with surgery for cancers that have metastasized or are likely to. One disadvantage is that tumors returning after radiation tend to grow more quickly than the original cancer. In addition, x rays may promote new skin cancers. The cosmetic results are usually good. In some cases the skin may lose a little pigment, or develop spider veins. Some doctors reserve radiation treatment for those over 60. One drawback of radiation therapy for squamous cell carcinomas in or near the mouth is that the radiation may cause the tissues inside the mouth to break down.

Chemotherapy is often added to surgery or radiation for stage IV cancers. Retinoids and interferon are experimental treatments that may be helpful.

Prognosis

Because many squamous cell carcinomas are not staged, precise five-year survival rates for each stage are not available. In general, the prognosis is very good for small squamous cell carcinomas that originate in actinic

KEY TERMS

Actinic keratosis (plural actinic keratoses)—A rough, dry, scaly patch on the skin associated with sun exposure.

Albinism—A genetic disease characterized by the absence of the normal skin pigment, melanin.

Antioxidant—A substance that can neutralize free radicals. Free radicals are damaging molecules formed from oxygen. Antioxidant vitamins include vitamin E, C, and beta-carotene, a form of vitamin A.

Biopsy—A sample of an organ taken to look for abnormalities. Also, the technique used to take such samples.

Chronic—Long-standing.

Dermis—A layer of skin sandwiched between the epidermis and the fat under the skin. It contains the blood vessels, nerves, sweat glands, and hair follicles.

Epidermis—The thin layer of skin cells at the surface of the skin.

Fluorouracil—A cancer drug.

Interferon alpha—A chemical made naturally by the immune system and also manufactured as a drug.

Local anesthetic—A liquid used to numb a small area of the skin.

Lymph node—A small organ full of immune cells, found in clusters throughout the body. Lymph nodes are where reactions to infections usually begin.

Nonmelanoma skin cancer—A squamous cell carcinoma or basal cell carcinoma.

Nonsteroidal anti-inflammatory drugs (NSAIDS)—A class of drugs that suppresses inflammation. Includes a wide variety of drugs, including aspirin.

Papillomavirus—A member of a group of viruses associated with warts and cervical cancer.

Pathologist—A doctor who specializes in examining cells and other parts of the body for abnormalities.

Precancerous—Abnormal and with a high probability of turning into cancer, but not yet a cancer.

Oncologist—A doctor who specializes in the treatment of cancer.

Retinoids—A class of drugs related to vitamin A.

Selenium—A mineral needed in extremely small quantities by the body. Large amounts can be very toxic.

Xeroderma pigmentosum—A genetic disease characterized by the inability to repair damaged DNA. Individuals with this disease develop an excessive number of skin cancers.

keratoses. However, cancers that were not completely destroyed may regrow. Tumors can redevelop in the scar from the surgery, on the edges of the surgery site, or deep in the skin. Larger or higher-risk tumors, cancers that regrow after treatment, and tumors that have invaded local tissues or metastasized are more difficult to cure. Most metastases show up within the first two years after a skin tumor has been removed. The five-year survival rate for metastatic cancers is 34%.

Alternative and complementary therapies

Alternative treatments for squamous cell carcinoma usually attempt to prevent rather than treat this cancer. Options being tested include antioxidant **vitamins**, minerals, and green tea extracts.

Coping with cancer treatment

Most squamous cell carcinomas are removed with techniques that cause few, if any, lasting side effects. Patients who have cosmetic concerns may wish to discuss them with their doctors.

Clinical trials

The medical community considers the following treatments to be experimental.

Clinical trials are testing whether interferon alpha, injected into the tumor, can destroy some squamous cell carcinomas. An early report from a combination of interferon alpha and retinoids is promising.

Ongoing trials are also evaluating whether small squamous cell carcinomas can be cured with photodynamic laser therapy. In this technique, a dye activated by laser light destroys the cancer. This dye is spread onto the skin, injected, or drunk. During a waiting period, normal cells clear the dye, then a laser activates the remainder. As of 2001, this technique was only useful for cancers very near the surface of the skin. One side effect after treatment is a period of excessive sun-sensitivity.

Other clinical trials are testing whether retinoids spread onto the skin can prevent or treat squamous cell carcinoma.

Another new experimental approach to squamous cell carcinoma is gene therapy. Researchers in Texas

reported in 2003 on a Phase III investigation that uses an adenovirus as a vector to carry an altered p53 gene into the cancerous squamous cells. The function of the p53 gene is to maintain the structure of the cell's DNA and to induce the cell to die if its DNA is damaged beyond repair. Phase I and phase II trials have indicated that this approach to treatment has lengthened the survival time in patients with recurrent squamous cell carcinoma.

Prevention

The most important risk factor for squamous cell carcinoma is exposure to the sun (or other source of ultraviolet light) combined with a lighter complexion and inability to tan. Other risk factors include:

- increasing age
- actinic keratoses
- a previous skin cancer
- exposure to arsenic or the chemicals in coal tars
- radiation treatments
- treatment with psoralen and ultraviolet light for psoriasis
- chronic skin damage such as burn scars and ulcers
- infection with some varieties of human papillomavirus
- genetic disorders such as xeroderma pigmentosum and albinism
- a weakened immune system

Most people will receive 80% of their lifetime exposure to the sun before they reach the age of 20. For this reason, prevention should start during childhood and adolescence. Some important steps to prevent squamous cell carcinoma, as well as other skin cancers include:

- Wear protective clothing and a wide-brimmed hat in the sun.
- Stay out of the sun from 10 A.M. to 4 P.M..
- Use a sunscreen that has a sun protection factor (SPF) of at least 15.
- Avoid suntanning booths.

Drugs related to vitamin A (including beta-carotene and retinoids), vitamin E, nonsteroidal anti-inflammatory drugs (NSAIDS), and selenium might be able to prevent some skin cancers. In 2001, their effectiveness was still in question.

Special concerns

Because many squamous cell carcinomas are found on the face and neck, cosmetic concerns are a priority for many patients. If there is a risk of noticeable scarring or damage, a patient may wish to ask about alternative types of removal or inquire about the services of a plastic surgeon.

QUESTIONS TO ASK THE DOCTOR

- What treatment(s) would you recommend for my tumor?
- How effective would you expect each of them to be, for a tumor of this size and in this location?
- How much cosmetic damage am I likely to see with each?
- Are there any alternatives?
- How should I prepare for the procedure?
- What is the risk that my tumor in particular will grow again?

After treatment, it is important to return to the doctor periodically to check for regrowth or new skin cancers. Approximately a third to a half of all patients with non-melanoma skin cancers find a new skin cancer within the next five years. Having a squamous cell carcinoma before the age of 60 may also increase the chance of developing other cancers in internal organs; however, this idea is still very controversial.

Stenting

Definition

Stenting is a procedure in which a cylindrical structure (stent) is placed into a hollow tubular organ to provide artificial support and maintain the patency of the opening. Although it is most often used for cardiovascular functioning, it is also utilized to manage obstructions in cancer patients.

Purpose

Stents are used in cancer patients to relieve obstructions due to:

- direct blockages within the tube (or lumen) due to cancer growth
- narrowing of the lumen from tumor growth outside pressing on the tube and narrowing the lumen
- occasionally from the build up of scar tissue (fibrosis) from radiation therapy

Tumors most likely to cause obstruction requiring stent placement include **esophageal cancer**, bronchogenic **carcinoma**, pancreatic cancer, cancers of the bile duct, and occasionally colorectal carcinomas.

Precautions

Every patient should be viewed individually with special consideration given to the patient's present status. Generally, surgical procedures are for the correction of a problem; but in many cancer cases, relief of symptoms is the only therapeutic option. Since it is extremely difficult to remove or reposition these stents after they are placed, the degree of relief to be offered by its insertion should be significant. The physician and the patient should discuss all alternatives and come to a mutual decision.

KEY TERMS

Endoscope—An instrument used for direct visual inspection of hollow organs or body cavities.

Esophagus—The muscular, membranous structure that extends from the throat to the stomach.

Lumen—The cavity or channel within a tube or tubular organ, such as a blood vessel or the intestine.

QUESTIONS TO ASK THE DOCTOR

- Am I a good candidate for this procedure?
- Do I have any contraindications that should be considered before having the procedure?
- Will I experience any improvement in my quality of life?
- What are the advantages and disadvantages of the procedure?
- Does the physician performing the procedure do this often or only occasionally?

Description

Endoscopic retrograde cholangiopancreatography (ERCP) is the name of the procedure utilized to place most stents for pancreatic and biliary tumors. The ERCP is a flexible endoscope, which can be directed and moved around the many bends in the upper gastrointestinal tract. The newer video endoscopes have a tiny, optically sensitive computer chip at the end which transmits electronic signals up the scope to a computer that displays an image on a large video screen. The scope has an open channel that permits other instruments to be passed through it to perform biopsies, inject solutions, or place stents. Since ERCP uses x-ray films, the procedure takes place in an x-ray area. Initially the throat is anesthetized with a spray solution and the patient is also usually mildly sedated. The endoscope is inserted into the upper esophagus and a thin tube is inserted through it to the main bile duct entering the intestinal area. Dye is injected into the bile duct and/or the pancreatic duct and x-ray films are taken. The patient usually lies on the left side and then turns onto the stomach to allow complete visualization of the ducts. The patient is able to breathe easily throughout the exam and rarely gags. Any gallstones found may be removed or if the duct has become narrowed, an incision can be made using electrocautery (electrical heat) to relieve the blockage. It is also possible to widen narrowed ducts by placing stents in these areas to keep them open. The patient is taken to recovery following the procedure, which takes 20–40 minutes.

Other endoscopes are used to place stents elsewhere in the body. For example, an esophagoscope is used to place stents in cases of esophageal cancer, a bronchoscope is used for procedures involving endobronchial obstructions, and a colonoscope is used in cases of colorectal obstructions.

Preparation

The patient is instructed not to eat or drink anything for eight hours prior to the procedure. Some physicians may request that no asprin be taken for a certain time period prior to the procedure to prevent excessive bleeding.

Aftercare

The patient may go home after the procedure or may spend one or two nights in the hospital. **Antibiotics** may be given especially if there has been long-standing biliary obstruction. Dietary restrictions are common after esophageal and colorectal stenting.

Risks

The most serious risk associated with the placement of a stent is the risk of perforation. If a tear is made, leakage with life-threatening infection may occur. Migration or recurrent obstruction may necessitate repeat stenting if possible. Occasionally bleeding may occur.

Normal results

Relief of the obstruction with resumption of the ability to eat, breathe, normally clear fluids from the liver or pancreas, or allow normal passage of stool is the desired result of this procedure.

Abnormal results

A sudden change in the degree of pain and/or **fever** that persists as well as any unusual changes should be communicated immediately to a physician.

Stereotactic needle biopsy

Definition

Stereotactic needle **biopsy** (SNB) is an ultrasound-guided and mammogram-directed needle aspiration biopsy of breast tissue. It is a diagnostic procedure used to determine the cause of radiographic abnormalities in breast tissue.

Purpose

Stereotactic needle biopsy is performed when nonpalpable (unable to be felt) abnormalities are identified by mammogram. The abnormality is generally located on a routine screening mammogram. This biopsy procedure uses a large (core) or small (fine) needle that withdraws samples of the abnormal breast tissue. The doctor uses either the mammogram or an ultrasound image of the abnormal tissue to guide the needle to the biopsy site. The needle is used to remove tissue samples of the site for laboratory analysis.

Description

The patient is made comfortable with a local anesthesia injection prior to the start of the procedure. Special imaging techniques are used to localize (easily see) the abnormal spot. First, the patient lies face down on a table with breasts suspended through an opening. Then mammograms are taken of the suspicious site from several different angles. This technique creates a virtual three-dimensional (stereotactic) picture of the abnormal area. A computer is used to guide the needle to the site for sample removal. If the abnormality can be seen easily on ultrasound, the biopsy may be performed with the patient lying on her back while ultrasound imaging localizes the abnormality. The samples are examined in the laboratory by a pathologist (a physician trained in identification of pathological or abnormal findings) to determine if cancer cells are present.

There are two different types of needles used for stereotactic needle biopsy. The procedures are similar, but the size of the needle varies. A fine-needle biopsy is most often used, in conjunction with ultrasound imaging, when a cyst is suspected. The doctor is able to suction a sample of fluid or tissue through the needle and send it for analysis. The needle is smaller and so is the sample of fluid or tissue extracted. In a core needle biopsy, the needle is larger, has a cutting edge, and enables the physician to extract a larger tissue sample from the suspicious area. A larger tissue sample can enhance laboratory accuracy in identifying the presence of cancer cells.

Preparation

Prior to ordering a breast biopsy, the physician gathers as much information from the patient as possible by asking questions that provide a medical history. The physician will perform a clinical breast examination through palpation to determine any changes from previous exams or to determine a baseline exam. The physician orders a routine screening mammogram (**x ray**) and interprets the results. If something abnormal is revealed on mammogram, further radiologic exams are requested. After confirming the presence of a radiographic abnormality, the physician will order a biopsy. A patient's written informed consent is necessary before any invasive procedure. The document should explain, in understandable language, the patient's treatment options, risks and benefits of the procedure, and potential complications.

General anesthesia is not used for the stereotactic needle biopsy procedure. Usually the physician will use a local injectable anesthetic agent at the needle insertion site to numb the area. When the anesthetic is injected at the biopsy site, the patient will feel a stinging sensation. The physician will wait until the numbing agent takes effect, then proceed with the biopsy. At this point, the patient should only feel a pressure sensation as the needle is guided to the biopsy site.

Precautions

Patients should discuss the indications (reasons for) and contraindications (reasons why not) of having a stereotactic needle biopsy performed with their doctor. While the procedure has been studied extensively with positive outcomes for accuracy of results, it is most indicated in cases where there is a non-palpable area of abnormal tissue identified by mammogram. However, vaguely palpable abnormalities can also be managed in this way. Physicians divide "abnormal findings" into several categories. A probable benign finding is a category 3, a suspicious abnormal finding is a category 4, and a highly suggestive of malignancy finding is a category 5.

When there is a probable benign finding (category 3), frequently there is no previous mammogram for comparison study. A stereotactic needle biopsy is done on a category 3 finding when there is a strong family history of **breast cancer**. Usually, a category 3 finding requires only a six month follow-up with **mammography**.

When there is a suspicious abnormality (category 4), a sterotactic needle biopsy is most useful, as well as indicated. In this category, stereotactic needle biopsy is used to differentiate those patients requiring surgical intervention from those needing clinical and mammographic (x-ray) follow-up.

In a category 5 finding, highly suggestive of malignancy, the physician can use information from a stereotactic needle biopsy to confirm a diagnosis and expedite surgical intervention in this category.

Stereotactic needle biopsy is not indicated in all cases where there is nonpalpable breast tissue abnormality. The size of the patient and size of the breast must be considered because a certain breast thickness is necessary for mammogram-guided biopsy. There is no such requirement for ultrasound-guided procedures. Abnormalities just under the skin are technically difficult for the placement of the biopsy needle and are best excised (removed) in an open surgical procedure. Also, areas of breast tissue micro-calcification (tiny areas of thickened breast tissue) that are not closely clustered together can be difficult to visualize in a stereotactic system and therefore difficult to retrieve during biopsy. Finally, the patient must be able to remain still and lie face down for the duration of the biopsy procedure (20 to 40 minutes). Any movement by the patient can render the localization of the abnormal site invalid.

Aftercare

After the procedure, the patient may experience pain or discomfort at the biopsy site. Mild bruising can also occur at the site. For these reasons, the physician may suggest that activities be limited for 24 to 48 hours post-procedure. The physician will suggest or prescribe a medication for discomfort relief. Often, a sport bra or other firm support garment will minimize breast movement and increase post-procedure comfort. Icing the area may also be reccommended. The physician will inform the patient of further follow-up care needed to monitor the patient's ongoing breast health and the subsequent intervals for follow-up imaging.

Risks

It is very important for the patient who is facing a stereotactic needle biopsy procedure to know that there is the possibility of needing a repeat biopsy procedure. A repeat biopsy is necessary if there is a discrepancy between the radiology reports and the pathologist's findings from laboratory analysis of the sample (concordance). As with any procedure, there is a slight risk of allergic reaction to anesthesia. To be well informed, patients should consult with their physician about the risks prior to undergoing SNB.

QUESTIONS TO ASK THE DOCTOR

- What type of physician performs a stereotactic needle biopsy?
- How long will it take to interpret the biopsy results?
- What type of pain management will be used during the procedure?
- Can the biopsy give false negative results?
- Will I have a fine needle biopsy or core biopsy? Why?

Results

Stereotactic needle biopsy is a diagnostic tool used to determine the presence of cancer cells. It is not a therapy used to obliterate an area of abnormal tissue. The results of the biopsy help the physician to determine the best medical or surgical options available to the patient. The biopsy results are reviewed by the physician performing the SNB and by the pathologist who analizes the sample. Results are reviewed and discussed with the patient and options for further treatment or follow up are presented. The patient, with the guidance and expertise of the physician, selects a course of therapy.

Stereotactic surgery

Definition

Stereotactic surgery is an approach to cancer diagnosis and treatment that makes use of a system of three-dimensional coordinates to locate a site (most commonly within the brain) as precisely as possible for **biopsy** or surgery. The English word *stereotactic* is a combination of a Greek root, *stereo-*, which means "solid" or "having three dimensions," and the Latin word *tactus*, which means "touch." Stereotactic neurosurgery may make use of a conventional incision and drill to enter the patient's skull or precisely focused beams of radiation to destroy cancerous tissue. This second method, which is called stereotactic radiosurgery, is not surgery in the usual sense of the word because no incision is involved.

Purpose

Stereotactic surgery may be performed either to obtain a tissue sample for biopsy or to remove or destroy the tumor itself. As of the early 2000s, stereotactic biopsies are the preferred method of confirming a diagnosis of a brain tumor, because of their precision and because they may offer the only method of obtaining a tissue sample if the tumor is located deep within the brain or close to structures that control vital functions. Stereotactic surgery may also be used in the diagnosis of epilepsy; since the areas of abnormal brain activity in epilepsy cannot always be identified by **imaging studies**, a neurosurgeon can use a stereotactic system to place electrodes for recording brain waves in the areas suspected of being the focus of seizures.

Stereotactic surgery can be used to treat movement disorders as well as brain tumors. In fact, the first clinical application of stereotactic systems in human medicine was in the treatment of schizophrenia in the late 1940s, followed by the use of stereotactic surgery to treat Parkinson's disease and chronic pain in the 1950s. As of the early 2000s, stereotactic surgery is used to treat such other movement disorders as Huntington's chorea and essential tremor, and to insert catheters into the brain to drain abnormal collections of fluid resulting from head injuries, hydrocephalus, or cysts.

Stereotactic radiosurgery can be used to treat movement disorders, malformations of blood vessels, and benign tumors (acoustic neuromas, pituitary adenomas, and meningiomas) as well as malignant tumors of the brain and spinal cord. It may also be used to treat cancers in the nose or other small and well-defined parts of the body, or as a follow-up "booster" treatment for patients with recurrent tumors who have already received the maximum safe dose of conventional **radiation therapy**.

Precautions

Stereotactic surgery or radiosurgery should be done only by qualified specialists who are experienced in these techniques, and performed only in treatment centers with the necessary high-level equipment.

Stereotactic radiosurgery with a gamma knife is most effective in treating relatively small tumors (an inch or less in diameter) with well-defined borders that have not invaded the brain; in addition, it is usually reserved for patients with a life expectancy of six months or longer. Large brain tumors may require partial removal by conventional open surgery prior to treatment with radiosurgery.

Description

Stereotactic surgery

The earliest forms of stereotactic surgery in humans developed out of an apparatus that was designed by Victor Horsley and Henry Clarke in 1906 to study brain functions in monkeys. It was not until 1946, however, that two American researchers designed a stereotactic frame to guide brain surgery in humans. There were two difficulties in transferring a stereotactic system from other mammals to humans, however; one problem was the much greater degree of variation among humans in the location of various bony landmarks on the skull that were used to identify the approximate location of various parts of the brain. The other problem was the lack of a reliable imaging method for visualizing internal brain structures.

By the 1940s, a method known as positive contrast ventriculography, in which some of the cerebral fluid in the ventricles of the brain was withdrawn and replaced with air or another contrast medium that would show up on an x-ray, allowed surgeons to identify structures within the brain in relation to one another. Ventriculography made it possible to use such internal structures as the posterior commissure or pineal gland rather than various points on the outside of the skull as landmarks for brain surgery. Researchers compiled stereotactic atlases, or collections of photographs of cross-sections of brain tissue, with reference grids around the borders of each photograph. A surgeon could consult one of these atlases in order to calculate the exact location of a targeted brain

structure with reference to the posterior commissure. Present-day stereotactic surgery still makes use of atlases, although they are now compiled from computer images rather than photographs.

The first frame that was used in stereotactic surgery in the 1940s consisted of a plaster cap fitted to the individual patient with a head ring and electrode carrier mounted to it. In the early 2000s, however, stereotactic surgery makes use of a base ring attached to the patient's skull, a CT or MRI scan, and an arc ring to guide the surgeon in drilling a hole through the skull. After the base ring is attached to the patient's scalp, he or she is taken to the operating room, where the base ring is attached to the operating table in order to hold the patient's head steady. The entry site for the surgeon's drill is selected, and the entry site and area of the tumor are located on a phantom image that relates these points to the patient's head. Coordinates derived from the phantom image are entered into a computer that determines the final path of the surgeon's instruments. An arc ring is then attached to the base ring to guide the surgeon's movements. This stereotactic s! ystem allows the surgeon to make only a very small incision (less than in long) in the scalp, and drill a hole smaller in diameter than a pencil in order to insert a biopsy needle or electrode.

Some medical centers use a frameless method for stereotactic brain surgery. In this method, images of the patient's head from CT or MRI scans are uploaded into a computer for display on a monitor. Markers on the patient's skin are registered by a probe linked to the computer by a camera, which joins the position of the patient's head on the operating table to the images on the computer monitor. In addition, the surgeon's instruments contain light-emitting diodes (LEDs) that are tracked by the computer during the operation.

Stereotactic radiosurgery and radiotherapy

Stereotactic radiosurgery (SRS) can be performed with three different types of machines to provide the radiation used to kill the tumor cells. The gamma knife is a stationary unit that contains 201 sources of gamma rays derived from cobalt-60 that can be focused by a computer on a single small area of the brain. The radiation can be directed very precisely to the tumor without destroying nearby healthy tissue. The patient lies on a couch with a large helmet attached to his or her headframe. The helmet contains holes that allow beams of radiation to enter. The couch is then slid into a gantry containing the cobalt-60. Treatment time varies from several minutes to over an hour, depending on the size, shape, and location of the tumor. Gamma knife radiosurgery is usually a single-dose treatment.

Radiosurgery can also be performed with a linear accelerator (also called a LINAC), which is a device that produces high-energy photons that can be used to treat larger tumors, metastatic tumors, or arteriovenous malformations. Linear accelerators are preferred for multisession treatments using smaller doses of radiation. Radiosurgery performed with divided doses is known as fractionated radiosurgery; some doctors prefer to call it fractionated stereotactic radiotherapy, or FSR. The advantage of fractionated treatment is that it allows a higher total dose of radiation to be delivered to the tumor without harming nearby normal tissues. The beams of radiation from a LINAC are shaped to a very high degree of accuracy by metal tubes known as collimators. Unlike the gamma knife unit, the LINAC moves around the patient during treatment, delivering arcs of radiation matched by computer to the shape of the tumor.

The third type of machine that can be used for radiosurgery is a cyclotron, which is a nuclear reactor used to accelerate charged particles (usually protons or ions) to high levels of energy that can be used for radiosurgery. Cyclotrons are available in very few locations as of 2005, however, and there have been few **clinical trials** comparing radiosurgery performed with a cyclotron to radiosurgery using a gamma knife or LINAC.

Preparation

Some cancer centers use an invasive form of preparation for stereotactic surgery or radiosurgery. In this method, the patient is not allowed food or drink after midnight the night before the procedure. He or she is given an intravenous sedative in the morning; local anesthetic is then applied at four points on the scalp. It is not necessary to shave the head. After the skin has been numbed, the surgeon fastens the base ring to the patient's skull with four pins, the insertion points of the pins determined by the location of the brain tumor. The patient is then given a CT or MRI scan. The resultant image allows the surgeon to calculate the exact area of the tumor in three dimensions. The planning and procedure may take anywhere from three to 12 hours.

Other cancer centers use a less invasive form of patient preparation that consists of an individualized mouthpiece used to attach a headframe (or ''halo'' to the patient's head. The headframe is used to prevent the head from moving during treatment as well as to position the head precisely.

Stereotactic radiosurgery is always preceded by a careful review of the patient's records to make sure that this type of treatment is appropriate for the tumor. The patient may be given steroid medications to control swelling of brain tissue or antiepileptic drugs to prevent seizures prior to radiosurgery.

If the patient is to receive fractionated radiosurgery or FSR, he or she will be given a simulation scan prior to treatment. The simulation scan allows the neurosurgeon to plan the treatment by making a set of images that show the exact location of the tumor in relation to normal brain tissue. The first step is the creation of a thermoplastic mask that will allow the doctor to position the patient's head precisely each time the patient receives a treatment. Next, the patient is positioned in a scanner while wearing the mask. The simulation scan takes about two and a half hours. When the patient returns for a treatment session about a week later, the molded thermoplastic mask is used to reposition the patient's head in the exact location that was used for the simulation scan. Fractionated treatments usually take between 30 and 90 minutes to complete.

A preparatory scan is not needed with some newer lightweight linear accelerators, which make use of a robot to position the dose of radiation rather than a frame to hold the patient's head in place. If the patient moves during treatment, the robot detects the movement and repositions the linear accelerator before delivering the radiation beam.

Aftercare

Stereotactic surgery

After the surgeon has completed the procedure, he or she closes the scalp incision—usually with only one stitch—and removes the base ring from its attachment points on the scalp by unscrewing the pins. These holes are small and do not require stitches, although an antibiotic medication is applied to prevent infection. The patient is taken to a recovery room, remains in the hospital overnight for observation, and goes home the next day. Patients must arrange for a friend or relative to drive them home. A follow-up visit with the neurosurgeon is scheduled for six to 12 weeks after treatment.

Stereotactic radiosurgery and radiotherapy

Patients receiving gamma knife treatment can be treated as outpatients, returning home after the procedure. If pins were used to attach a headframe to the patient's scalp, the head will be wrapped with gauze for about two hours before the patient is discharged.

Risks

Stereotactic surgery

The risks of stereotactic surgery are similar to those of other surgical procedures involving open incisions in the head or neck:

- infection
- scarring
- pain
- incomplete removal of the tumor
- swelling of brain tissue
- worsening of neurologic symptoms
- anesthesia reaction

KEY TERMS

Atlas—In anatomy, a collection of medical illustrations of one specific subject, such as the brain or heart. Detailed atlases of the brain are important guides for surgeons performing stereotactic neurosurgery.

Collimator—A metal tube designed to control the size and direction of a beam of radiation.

Cyclotron—A machine that accelerates charged atomic particles within a constant magnetic field.

Fractionated—In radiotherapy, treatment that is divided into several sessions of smaller doses of radiation rather than one large dose delivered in a single session.

Gamma knife—The name for a specific type of radiosurgery that uses highly focused cobalt-60 radiation to destroy cancerous tissue in the brain. It is not a knife in the conventional sense.

Hydrocephalus—A condition marked by the buildup of cerebrospinal fluid within the skull, causing increased pressure on the brain and a variety of neurologic symptoms. Stereotactic surgery may be used to place a catheter within the brain in order to drain the excess fluid.

Landmark—An anatomical structure that is easy to recognize and suitable as a reference point in locating other structures or making measurements.

Photon—A quantum of electromagnetic radiation with no mass and no charge.

Posterior commissure—A bundle of fibers that connects the two cerebral hemispheres near the third ventricle of the brain.

Radiosurgery—A form of cancer treatment in which tissue is destroyed by radiation from an external source or an implant rather than by manual removal. In spite of its name, radiosurgery is not surgery in the usual sense of making an incision, removing tissue, and then closing the incision.

Ventricles—Small cavities within the brain filled with cerebrospinal fluid.

QUESTIONS TO ASK YOUR DOCTOR

- Is stereotactic radiosurgery an option for treatment of my tumor?
- How much experience have you had with this form of treatment?
- What do you consider the advantages and drawbacks of gamma knife and linear accelerator radiosurgery?
- What are the risks of this treatment in my particular case?

Stereotactic radiosurgery

The risks of stereotactic radiosurgery are similar to those for other forms of radiation treatment of the brain or spinal cord:

- nausea and vomiting
- headaches
- dizziness
- fatigue
- hair loss
- radiation necrosis (a group or collection of dead brain cells)
- leukoencephalopathy (damage to the white matter of the brain)
- swelling of brain tissue

Normal results

Normal results of stereotactic surgery include the obtaining of an appropriate tissue sample for biopsy or the removal of cancerous tissue. Normal results of stereotactic radiosurgery include the shrinkage or death of cancer cells in the brain or spinal cord, the drainage of excess cerebrospinal fluid, or improvement in tremor and other symptoms of Parkinson's disease or Huntington's chorea.

Abnormal results

Abnormal results for stereotactic radiosurgery would include the failure of the tumor to respond to treatment.

Stomach cancer

Definition

Stomach cancer (also known as gastric cancer) is a disease in which the cells forming the inner lining of the stomach become abnormal and start to divide uncontrollably, forming a mass called a tumor.

Description

The stomach is a J-shaped organ that lies in the left and central portion of the abdomen. The stomach produces many digestive juices and acids that mix with the

food and aid in the process of digestion. There are five regions of the stomach that doctors refer to when determining the origin of stomach cancer. These are:

- the cardia, area surrounding the cardiac sphincter which controls movement of food from the esophagus into the stomach;
- the fundus, upper expanded area adjacent to the cardiac region;
- the antrum, lower region of the stomach where it begins to narrow;
- the prepyloric, region just before or nearest the pylorus;
- and the pylorus, the terminal region where the stomach joins the small intestine. Cancer can develop in any of the five sections of the stomach. Symptoms and outcomes of the disease will vary depending on the location of the cancer.

Demographics

Based on previous data from the National Cancer Institute and the United States Census, the American Cancer Society estimates that 21,700 Americans will be diagnosed with stomach cancer during 2001 and approximately 13,000 deaths will result from the disease. In most areas, men are affected by stomach cancer nearly twice as often as women. Most cases of stomach cancer are diagnosed between the ages of 50 and 70 but in families with a hereditary risk of stomach cancer, younger cases are more frequently seen.

Stomach cancer is one of the leading causes of cancer deaths in several areas of the world, most notably Japan and other Asian countries. In Japan it appears almost ten times as frequently as in the United States. The number of new stomach cancer cases is decreasing in some areas, however, especially in developed countries. In the United States, incidence rates have dropped from 30 individuals per 100,000 in the 1930s, to only 8 in 100,000 individuals developing stomach cancer by the 1980s. The use of refrigerated foods and increased consumption of fresh fruits and vegetables, instead of preserved foods with high salt content, may be a reason for the decline.

Causes and symptoms

While the exact cause for stomach cancer has not been identified, several potential factors have lead to increased numbers of individuals developing the disease and therefore, significant risk has been associated. Diet, work environment, exposure to the bacterium *Helicobacter pylori*, and a history of stomach disorders such as ulcers or polyps are some of these believed causes.

Studies have shown that eating foods with high quantities of salt and nitrites increases the risk of stomach cancer. The diet in a specific region can have a great impact on its residents. Making changes to the types of foods consumed has been shown to decrease likelihood of disease, even for individuals from countries with higher risk. For example, Japanese people who move to the United States or Europe and change the types of foods they eat have a far lower chance of developing the disease than do Japanese people who remain in Japan and do not change their dietary habits. Eating recommended amounts of fruit and vegetables may lower a person's chances of developing this cancer.

A high risk for developing stomach cancers has been linked to certain industries as well. The best proven association is between stomach cancer and persons who work in coal mining and those who work processing timber, nickel, and rubber. An unusually large number of these workers have been diagnosed with this form of cancer.

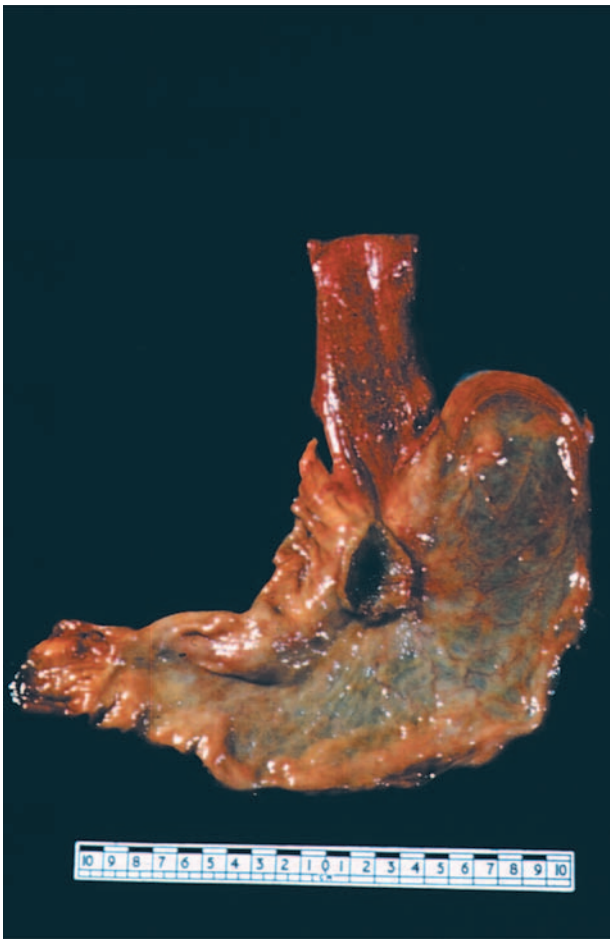
Several studies have identified a bacterium (*Helicobacter pylori*) that causes stomach ulcers (inflammation in the inner lining of the stomach). Chronic (long-term) infection of the stomach with these bacteria may lead to a particular type of cancer (lymphomas or mucosa-associated lymphoid tissue [MALT]) in the stomach.

Another risk factor is the development of polyps, benign growths in the lining of the stomach. Although polyps are not cancerous, some may have the potential to turn cancerous. People in blood group A are also at elevated risk for this cancer for unknown reasons. Other speculative causes of stomach cancer include previous stomach surgery for ulcers or other conditions, or a form of **anemia** known as pernicious anemia.

Stomach cancer is a slow-growing cancer. It may be years before the tumor grows very large and produces distinct symptoms. In the early stages of the disease, the patient may only have mild discomfort, indigestion, heartburn, a bloated feeling after eating, and mild nausea. In the advanced stages, a patient will have loss of appetite and resultant **weight loss**, stomach pains, vomiting, difficulty in swallowing, and blood in the stool. Stomach cancer often spreads (metastasizes) to adjoining organs such as the esophagus, adjacent lymph nodes, liver, or colon.

Diagnosis

Unfortunately, many patients diagnosed with stomach cancer experience pain for two or three years before informing a doctor of their symptoms. When a doctor suspects stomach cancer from the symptoms described



An excised section of a human stomach showing a cancerous tumor (center, triangular shape). *(Custom Medical Stock Photo. Reproduced by permission.)*

by the patient, a complete medical history will be taken to check for any risk factors. A thorough physical examination will be conducted to assess all the symptoms. Laboratory tests may be ordered to check for blood in the stool (**fecal occult blood test**) and anemia (low red blood cell count), which often accompany gastric cancer.

In some countries, such as Japan, it is appropriate for patients to be given routine screening examinations for stomach cancer, as the risk of developing cancer in that society is very high. Such screening might be useful for all high-risk populations. Due to the low prevalence of stomach cancer in the United States, routine screening is usually not recommended unless a family history of the disease exists.

Whether as a **screening test** or because a doctor suspects a patient may have symptoms of stomach cancer, endoscopy or barium x rays are used in diagnosing stomach cancer. For a barium **x ray** of the upper gastrointestinal tract, the patient is given a chalky, white solution of barium sulfate to drink. This solution coats the esophagus, the stomach, and the small intestine. Air may be pumped into the stomach after the barium solution in order to get a clearer picture. Multiple x rays are then taken. The barium coating helps to identify any abnormalities in the lining of the stomach.

In another more frequently used test, known as **upper gastrointestinal endoscopy**, a thin, flexible, lighted tube (endoscope) is passed down the patient's throat and into the stomach. The doctor can view the lining of the esophagus and the stomach through the tube. Sometimes, a small ultrasound probe is attached at the end of the endoscope. This probe sends high frequency sound waves that bounce off the stomach wall. A computer creates an image of the stomach wall by translating the pattern of echoes generated by the reflected sound waves. This procedure is known as an endoscopic ultrasound or EUS.

Endoscopy has several advantages, in that the physician is able to see any abnormalities directly. In addition, if any suspicious-looking patches are seen, **biopsy** forceps can be passed painlessly through the tube to collect some tissue for microscopic examination. This is known as a biopsy. EUS is beneficial because it can provide valuable information on depth of tumor invasion.

After stomach cancer has been diagnosed and before treatment starts, another type of x-ray scan is taken. **Computed tomography** (CT) is an imaging procedure that produces a three-dimensional picture of organs or structures inside the body. CT scans are used to obtain additional information in regard to how large the tumor is and what parts of the stomach it borders; whether the cancer has spread to the lymph nodes; and whether it has spread to distant parts of the body (metastasized), such as the liver, lung, or bone. A CT scan of the chest, abdomen, and pelvis is taken. If the tumor has gone through the wall of the stomach and extends to the liver, pancreas, or spleen, the CT will often show this. Although a CT scan is an effective way of evaluating whether cancer has spread to some of the lymph nodes, it is less effective than EUS in evaluating whether the nodes closest to the stomach are free of cancer. However, CT scans, like barium x-rays, have the advantage of being less invasive than upper endoscopy.

Laparoscopy is another procedure used to stage some patients with stomach cancer. This involves a medical device similar to an endoscope. A laparoscopy is a minimally invasive surgery technique with one or a few small incisions, which can be performed on an outpatient basis, followed by rapid recovery. Patients who may receive **radiation therapy** or **chemotherapy** before surgery may undergo a laparoscopic procedure to determine the precise stage of cancer. The patient with **bone pain**

or with certain laboratory results should be given a bone scan.

Benign gastric neoplasms are tumors of the stomach that cause no major harm. One of the most common is called a submucosal leiomyoma. If a leiomyoma starts to bleed, surgery should be performed to remove it. However, many leiomyomas require no treatment. Diagnosis of stomach cancers should be conducted carefully so that if the tumor does not require treatment the patient is not subjected to a surgical operation.

Clinical staging and prognosis

More than 95% of stomach cancers are caused by adenocarcinomas, malignant cancers that originate in glandular tissues. The remaining 5% of stomach cancers include lymphomas and other types of cancers. It is important that gastric lymphomas be accurately diagnosed because these cancers have a much better prognosis than stomach adenocarcinomas. Approximately half of the people with gastric lymphomas survive five years after diagnosis. Treatment for gastric **lymphoma** involves surgery combined with chemotherapy and radiation therapy.

Staging of stomach cancer is based on how deep the growth has penetrated the stomach lining; to what extent (if any) it has invaded surrounding lymph nodes; and to what extent (if any) it has spread to distant parts of the body (metastasized). The more confined the cancer, the better the chance for a cure.

One important factor in the staging of adenocarcinoma of the stomach is whether or not the tumor has invaded the surrounding tissue and, if it has, how deep it has penetrated. If invasion is limited, prognosis is favorable. Diseased tissue that is more localized improves the outcome of surgical procedures performed to remove the diseased area of the stomach. This is called a resection of the stomach.

Several distinct ways of classifying stomach cancer according to cell type have been proposed. The Lauren classification is encountered most frequently. According to this classification system, gastric adenocarcinomas are either called intestinal or diffuse. Intestinal cancers are much like a type of intestinal cancer called intestinal **carcinoma**. Intestinal tumors are more frequently found in males and in older patients. The prognosis for these tumors is better than that for diffuse tumors. Diffuse tumors are more likely to infiltrate, that is, to move into another organ of the body.

Treatment

Because symptoms of stomach cancer are so mild, treatment often does not commence until the disease is well advanced. The three standard modes of treatment for stomach cancer include surgery, radiation therapy, and chemotherapy. While deciding on the patient's treatment plan, the doctor takes into account many factors. The location of the cancer and its stage are important considerations. In addition, the patient's age, general health status, and personal preferences are also taken into account.

Surgery

In the early stages of stomach cancer, surgery may be used to remove the cancer. Surgical removal of adenocarcinoma is the only treatment capable of eliminating the disease. Laparoscopy is often used before surgery to investigate whether or not the tumor can be removed surgically. If the cancer is widespread and cannot be removed with surgery, an attempt will be made to remove blockage and control symptoms such as pain or bleeding. Depending on the location of the cancer, a portion of the stomach may be removed, a procedure called a partial gastrectomy. In a surgical procedure known as total gastrectomy, the entire stomach may be removed. However, doctors prefer to leave at least part of the stomach if possible. Patients who have been given a partial gastrectomy achieve a better quality of life than those having a total gastrectomy and typically lead normal lives. Even when the entire stomach is removed, the patients quickly adjust to a different eating schedule. This involves eating small quantities of food more frequently. High protein foods are generally recommended.

Partial or total gastrectomy is often accompanied by other surgical procedures. Lymph nodes are frequently removed and nearby organs, or parts of these organs, may be removed if cancer has spread to them. Such organs may include the pancreas, colon, or spleen.

Preliminary studies suggest that patients who have tumors that cannot be removed by surgery at the start of therapy may become candidates for surgery later. Combinations of chemotherapy and radiation therapy are sometimes able to reduce disease for which surgery is not initially appropriate. Preliminary studies are being performed to determine if some of these patients can become candidates for surgical procedures after such therapies are applied.

Chemotherapy

Whether or not patients undergoing surgery for stomach cancer should receive chemotherapy is a controversial issue. Chemotherapy involves administering anticancer drugs either intravenously (through a vein in the arm) or orally (in the form of pills). This can either be used as the primary mode of treatment or after surgery to destroy any cancerous cells that may have migrated to distant sites. Most cancers of the gastrointestinal tract do

not respond well to chemotherapy, however, adenocarcinoma of the stomach and advanced stages of cancer are exceptions.

Chemotherapy medicines such as **doxorubicin**, mitomycin C, and 5-fluorouracil (5-FU or fluorouracil), used alone, provide benefit to at least one in five patients. Combinations of agents may provide even more benefit, although it is not certain that this includes longer survival. For example, some doctors use what is called the FAM regimen, which combines 5-fluorouacil, doxorubicin, and mitomycin. Some doctors prefer using 5-fluorouracil alone to FAM since side effects are more moderate. Another combination some doctors are using involve high doses of the medications **methotrexate**, 5- **fluorouracil**, and doxorubicin. Other combinations that have shown benefit include the ELF regimen, a combination of **leucovorin**, 5- fluorouracil, and **etoposide**. The EAP regimen, a combination of etoposide, doxorubicin, and **cisplatin** is also used.

Although chemotherapy using a single medicine is sometimes used, the best response rates are often achieved with combinations of medicines. Therefore, in addition to studies exploring the effectiveness of new medicines there are other studies attempting to evaluate how to best combine existing forms of chemotherapy to bring the greatest degree of help to patients.

Radiation therapy

Radiation therapy is often used after surgery to destroy the cancer cells that may not have been completely removed during surgery. To treat stomach cancer, external beam radiation therapy is generally used. In this procedure, high-energy rays from a machine that is outside of the body are concentrated on the area of the tumor. In the advanced stages of stomach cancer, radiation therapy is used to ease the symptoms such as pain and bleeding. However, studies of radiation treatment for stomach cancer have shown that the way it has been used it has been ineffective for many patients.

Researchers are actively assessing the role of chemotherapy and radiation therapy used before a surgical procedure is conducted. They are searching for ways to use both chemotherapy and radiation therapy so that they increase the length of survival of patients more effectively than current methods are able to do.

Prognosis

Overall, approximately 20% of patients with stomach cancer live at least five years following diagnosis. Patients diagnosed with stomach cancer in its early stages have a far better prognosis than those for whom it is in the later stages. In the early stages, the tumor is small, lymph nodes are unaffected, and the cancer has not migrated to the lungs or the liver. Unfortunately,

KEY TERMS

Adenocarcinoma—Malignant cancers that originate in the tissues of glands or that form glandular structures.

Anemia—A condition in which iron levels in the blood are low.

Barium x ray (upper GI)—An x-ray test of the upper part of the gastrointestinal (GI) tract (including the esophagus, stomach, and a small portion of the small intestine) after the patient is given a white, chalky barium sulfate solution to drink. This substance coats the upper GI and the x rays reveal any abnormality in the lining of the stomach and the upper GI.

Biopsy—Removal of a tissue sample for examination under the microscope to check for cancer cells.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Endoscopic ultrasound (EUS)—A medical procedure in which sound waves are sent to the stomach wall by an ultrasound probe attached to the end of an endoscope. The pattern of echoes generated by the reflected sound waves are translated into an image of the stomach wall by a computer.

External radiation therapy—Radiation therapy that focuses high-energy rays from a machine on the area of the tumor.

Infiltrate—A tumor that moves into another organ of the body.

Polyp—An abnormal growth that develops on the inside of a hollow organ such as the colon, stomach, or nose.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Total gastrectomy—Surgical removal (excision) of the entire stomach.

Upper endoscopy—A medical procedure in which a thin, lighted, flexible tube (endoscope) is inserted down the patient's throat. Through this tube the doctor can view the lining of the esophagus, stomach, and the upper part of the small intestine.

only about 20% of patients with stomach cancer are diagnosed before the cancer had spread to the lymph nodes or formed a distant **metastasis**.

It is important to remember that statistics on prognosis may be misleading. Newer therapies are being developed rapidly and five-year survival has not yet been measured with these. Also, the largest group of people diagnosed with stomach cancer are between 60 and 70 years of age, suggesting that some of these patients die not from cancer but from other age-related diseases. As a result, some patients with stomach cancer may be expected to have longer survival than did patients just ten years ago.

Coping with cancer treatment

Many patients experience feelings of **depression**, anxiety, and **fatigue** when dealing with the knowledge and treatments associated with stomach cancer. Side effects such as **nausea and vomiting** may also present during treatment. Understanding what to expect as a result of the various treatments and learning about alternative methods for reducing these symptoms may improve the effectiveness of treatments and provide a more positive outlook in regard to the individual's situation. A doctor or other health professional should be consulted to develop strategies for managing any negative symptoms or feelings.

Prevention

Avoiding many of the risk factors associated with stomach cancer may prevent its development. Excessive amounts of salted, smoked, and pickled foods should be avoided, as should foods high in nitrates. A diet that includes recommended amounts of fruits and vegetables is believed to lower the risk of several cancers, including stomach cancer. The American Cancer Society recommends eating at least five servings of fruits and vegetables daily and choosing six servings of food from other plant sources, such as grains, pasta, beans, cereals, and whole grain bread.

Abstaining from tobacco and excessive amounts of alcohol will reduce the risk for many cancers. In countries where stomach cancer is common, such as Japan, early detection is important for successful treatment.

Special concerns

Following gastrectomy or partial gastrectomy it is important for the patient to carefully follow doctor's orders about what foods are eaten and when they should be eaten. In particular, the patient may be asked to have small, frequent meals.

QUESTIONS TO ASK THE DOCTOR

- Has the cancer spread to the lymph nodes?
- Has the cancer spread to the lungs, liver, or spleen?
- (After endoscopy or barium x-rays and CT scan have been completed)Would I benefit from endoscopic ultrasound or laparoscopy?
- (If surgery is recommended) Do recent studies show that it might be a good idea to also use chemotherapy or radiation therapy?
- (If gastrectomy or partial gastrectomy was performed) How should I alter my diet and eating patterns?
- (Following surgery) What foods should I be eating? Is there a registered dietitian I can speak with on a regular basis about what I should eat?

Stomatitis

Description

Stomatitis describes an inflammation of the mucous membranes of the mouth. This condition, frequently referred to as **mucositis**, can result from cancer treatments such as **chemotherapy** and **radiation therapy**. It is characterized by mouth ulcers or sores, and pain in the mouth. The first symptoms may be sensitivity to spicy foods and reddened mucous membranes. The patient with stomatitis may also experience a dry or swollen tongue, difficulty swallowing, and an inability to eat or drink. It is usually a short-term condition, lasting from just a few days to a few weeks. Reddened areas in the mouth may appear as early as three days after receiving chemotherapy, but normally it is within five to seven days. As time goes on, ulceration occurs. The inflammation can range from mild to severe. If such complications as infection do not occur, stomatitis usually heals completely within two to four weeks.

Although stomatitis is often a short-term problem, it is of concern to cancer patients and health care professionals because it can interfere with the patient's receiving adequate nutrition as well as cause pain and discomfort.

Causes

Stomatitis is most often caused by such cancer treatments as chemotherapy and radiation therapy. Chemotherapy medications work because they are attracted to rapidly growing cells like cancer cells. However, many of the body's normal cells also grow rapidly, and chemotherapy kills them as well. The mouth includes several structures that together are referred to as the oral cavity: the lips, teeth, gums, tongue, pharynx, and the salivary glands. Most of these structures are covered by mucous membranes, the shiny, pink moist lining of the mouth. The outer layer of mucous membranes grows very rapidly, and because of this characteristic they can easily be damaged by chemotherapy and radiation therapy. When these cells are damaged, they slough off, and the lining of the mouth is left vulnerable and without protection. This exposed lining may become inflamed, swollen, and dry, and will often develop ulcers or sores.

Stomatitis caused by radiation therapy normally develops in the area where the radiation is given. It generally begins seven to fourteen days after starting radiation. It will usually exhibit improvement about two to three weeks after the treatment stops.

Stomatitis may also develop as an indirect result of cancer treatment or the cancer itself. Chemotherapy can frequently cause the patient's infection-fighting white blood cells to drop down below normal levels. When this happens, the body may be unable to keep the normal organisms in the oral cavity in balance and stomatitis, as well as such infections as thrush (oral candidiasis), may result. The severity of the stomatitis is dependent on various factors, including the diagnosis, the patient's age, the patient's oral condition before cancer treatment, and the level of oral care during therapy. The duration and severity of the low white blood count is another factor.

Stomatitis may also be caused or worsened by wearing dentures, braces, or other dental appliances that irritate the tissues of the mouth. According to the American Dental Association, about 8.4% of all Americans over the age of 17 have denture stomatitis.

Treatments

Various measures can be taken by the cancer patient to help prevent the occurrence or severity of stomatitis. A carefully followed program of good oral care started before cancer treatment can reduce the severity of stomatitis. The primary preventative measures include good nutritional intake, good oral hygiene practices, and early detection of any oral lesions by either the patient or a health care professional.

Once cancer treatment has started, the patient should carefully observe the mouth daily. The patient should inform their health care professional if any symptoms such as reddened areas, swelling, blisters, sores, white patches, or bleeding are noted. Meticulous oral hygiene and comfort measures are the focus of care. Sometimes, no matter what the patient does, stomatitis occurs. However, if good oral care is performed, the severity of symptoms is usually lessened. The following measures may be recommended to treat stomatitis:

- Rinsing the oral cavity after meals and before bedtime with a mild salt-water or baking soda and water solution will help keep the mouth clean and free of debris.
- A soft-bristled toothbrush or soft foam tooth-cleaning device should be used to keep the mouth and teeth very clean.
- Maintaining a good nutritional intake and drinking adequate amounts of fluids helps the body heal the stomatitis.
- The use of any tobacco products and alcohol should be avoided, as they can irritate the lining of the mouth.
- Avoid spicy or acidic foods, or very hot foods.
- Patients who wear dentures should remove them at night rather than leaving them in the mouth overnight, and should clean them carefully with an antiseptic solution.

Sometimes stomatitis develops in spite of the patient's best efforts. If the mouth sores are painful

A close-up view of patient's mouth with gingivostomatitis cold sores. *(Custom Medical Stock Photo. Reproduced by permission.)*

KEY TERMS

Mucositis—Inflammation of the mucous membranes of the gastrointestinal tract. It is often used interchangeably with stomatitis.

Mucous membranes—The pink, moist, shiny lining of the mouth.

Oral cavity—The collective term for several structures in the mouth: the lips, teeth, gums, tongue, pharynx, and the salivary glands.

Thrush—An infection of the oral mucosa caused by fungi of the genus *Candida*. It is characterized by patches of a whitish curd-like material that can be scraped off, leaving raw and bleeding tissue underneath. Thrush is also known as oral candidiasis.

enough to prohibit eating and drinking, pain medications, including numbing medicines and both non-narcotic and narcotic pain medicines, may be prescribed.

Alternative and complementary therapies

Some preliminary studies have shown glutamine, an amino acid, to be effective in shortening the duration of stomatitis. Topical Vitamin E has also been studied and it shows some suggestions of being an effective therapy in patients with stomatitis. Other small studies suggest that using ice chips or a chamomile mouthwash will decrease the severity of symptoms. However, most of these studies have been small in scope, and cannot definitively claim the effectiveness of the varying treatments. As with anyone undergoing cancer treatment, the patient with stomatitis should consult with their physician or other health care professional regarding the usage of these alternative approaches.

More recently, a group of researchers in Brazil have reported that an extract made from the leaves of *Trichilia glabra*, a plant found in South America, is effective in killing several viruses that cause stomatitis.

Streptozocin

Definition

Streptozocin is one of the anticancer (antineoplastic) drugs called alkylating agents. It is available in the U.S. under the brand name Zanosar.

Purpose

Streptozocin is primarily used to treat cancer of the pancreas, specifically advanced islet-cell **carcinoma**.

Description

Streptozocin chemically interferes with the synthesis of the genetic material (DNA) of cancer cells, which prevents these cells from being able to reproduce.

Recommended dosage

Streptozocin is given by injection. The dosage prescribed varies widely depending on the patient, the cancer being treated, and whether or not other medications are also being taken.

Precautions

Streptozocin carries a risk of renal (kidney) toxicity. While receiving streptozocin, patients are encouraged to drink extra fluids, since this can increase the amount of urine passed and help prevent kidney problems.

Streptozocin may cause an allergic reaction in some people. Patients with a prior allergic reaction to streptozocin should not take this medication.

Streptozocin also may cause serious birth defects if either the man or the woman is taking this drug at the time of conception or if the woman takes this drug during pregnancy. Streptozocin also may cause miscarriage.

It is not known whether streptozocin is passed from mother to child through breast milk. However, since many drugs are excreted in breast milk and since streptozocin has the potential to adversely affect an infant, breast feeding is not recommended while this medication is being taken.

Streptozocin suppresses the immune system (by damaging white blood cells) and interferes with the normal functioning of certain organs and tissues. For these reasons, it is important that the prescribing physician is aware of any of the following pre-existing medical conditions:

- a current case of, or recent exposure to, chicken pox
- diabetes mellitus
- herpes zoster (shingles)
- a current case, or history of, gout or kidney stones
- all current infections
- kidney disease
- liver disease

Also, because streptozocin damages white blood cells and platelets, patients taking this drug must exercise extreme caution to avoid contracting any new infections or sustaining any injuries that result in bruising or bleeding.

Side effects

The common side effects of streptozocin include:

- fatigue
- loss of appetite (anorexia)
- nausea and vomiting
- increased susceptibility to infection and bleeding
- swelling of the feet or lower legs
- unusual decrease in urination
- temporary hair loss (alopecia)

Diarrhea is a less common side effect that may also occur.

Because streptozocin can damage the kidneys, liver, white blood cells, and platelets, patients taking this medication should be closely monitored for evidence of these adverse side effects. Laboratory tests, including renal function, urinalysis, complete blood count, and liver function, should be done at frequent intervals (approximately weekly) during drug therapy. If evidence of these adverse side effects is found, treatment with streptozocin may be discontinued or the dose may be decreased.

Interactions

Streptozocin should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician. It is particularly important that the prescribing physician be aware of the use of any of the following drugs:

- anti-infection drugs
- carmustine (an anticancer drug)
- cisplatin (an anticancer drug)
- cyclosporine (an immunosuppressive drug)
- deferoxamine (used to remove excess iron from the body)
- gold salts (used for arthritis)
- inflammation or pain medication other than narcotics
- narcotic pain medication containing acetaminophen (Tylenol) or aspirin
- lithium (used to treat bipolar disorder)
- methotrexate (an anticancer drug also used for rheumatoid arthritis and psoriasis)
- penicillamine (used to treat Wilson's disease and rheumatoid arthritis)

KEY TERMS

Antineoplastic—A drug that prevents the growth of a neoplasm by interfering with the maturation or proliferation of the cells of the neoplasm.

Neoplasm—New abnormal growth of tissue.

- phenytoin (an anticonvulsant)
- plicamycin (an anticancer drug)
- tiopronin (used to prevent kidney stones)

Sun's soup

Definition

A combination of vegetables and herbs, Sun's soup is a complementary therapy and dietary supplement used for its apparent anticancer properties and as a stimulant for the immune system.

Selected Vegetables and *Sun's Soup* are names of various mixtures of vegetables and herbs. These mixtures were developed by Alexander Sun, a Taiwanese biochemist. As of 2005, two formulations of these products are marketed in the United States as dietary supplements.

Purpose

As a complementary therapy, these products are believed to lengthened the survival of patients with advanced **non-small cell lung cancer** or other types of malignant tumors. In general, Sun's soup is used in conjunction with traditional cancer-fighting therapies, such as surgery, radiation, and **chemotherapy**.

Description

Also known as Selected vegetables, Sun's soup was developed by Alexander Sun, a biochemist, in the mid-1980s. Initially, the mixture contained shitake mushroom, mung bean, Hedyotis diffusa, and Scutellaria barbata, all of which are thought to fight cancer and stimulate the immune system. A 1999 study published in *Hepatogastroenterology* by Nakano and colleagues, lentinan, a beta-glucan found in shitake mushrooms, was used as adjunctive therapy with positive results. The authors reported that not only was the survival of the patients with gastric cancer prolonged, but their quality of life was improved. However, the National Cancer Institute asserted that lentinan may not be active when consumed as an ingredient in the soup. But the National Cancer Institute did other substances in shitake mushrooms may offer health benefits.

Sun began to treat other patients with a variant of the original mixture that excluded Hedyotis diffusa and Scutellaria barbata. This second formulation, a freeze-dried powder, was named Selected Vegetables (SV) or Dried Selected Vegetables (DSV). In 1992, Sun began a phase I/II clinical trial to evaluate DSV as a treatment for patients diagnosed with non-small cell lung cancer. By 1999, Sun and colleagues reported their results in an article published in *Nutrition and Cancer*. Knowing that DSV contained anti-tumor components, Sun and colleagues designed their study to measure how well patients tolerated using it on a long-term basis and its influence on the survival of patients with advanced non-small cell lung cancer. Therefore, there were two parts to the study: the toxicity arm and the survival arm. The toxicity arm was comprised of five patients with stage I non-small cell lung cancer, all of whom were asked to add DSV to their daily diet. Sun and colleagues refer to this group as the "toxicity study group (TG)." The survival arm was comprised of 19 patients with stage III or IV non-small cell lung cancer. Six of the 19 patients added DSV to their daily diet; Sun and colleagues referred to these patients as the "treatment group (SVG)." The remaining 13 patients who did not add DSV to their daily diet served as the "control group (CG)."

It is important to note that all the patients were treated with conventional therapies as deemed appropriate for them. TG patients had surgery plus **radiation therapy** or radiation therapy alone. SVG patients had radiation therapy alone or chemotherapy alone. CG patients had radiation therapy alone, chemotherapy alone, surgery plus radiation therapy, or chemotherapy plus radiation therapy with the exception of one patient who received palliative care, which is care that focuses on symptom management and quality of life issues.

With regard to the toxicity arm of the study, Sun and colleagues reported that "no clinical signs of toxicity were found in the TG patients in the 24-month study period." In fact, all five patients had either gained weight or maintained their weight. Another way the researchers measured how well the patients were tolerating the use of DSV was by recording changes in Karnofsky Perform-

ance Status (KPS), which is a common way of assessing a cancer patient's ability to perform routine tasks. A scoring system of 0 to 100 is used with a greater ability to handle everyday tasks associated with higher scores. Four out of the five TG patients had improved scores, which were measured at the time they entered the study and three months later. One TG patient's score remained the same. Two years after diagnosis, all five TG patients had survived and no recurrent tumors were found during follow-up. Furthermore, Sun and colleagues reported that the TG patients used DSV from 17 months to longer than 24 months. This led Sun and his team to conclude that DSV was "safe, nontoxic, and well tolerated."

With regard to the survival arm of the study, Sun and his team stated that "age, KPS, and body mass index of the SVG and CG patients were comparable" when the study began. Almost five months later a second weight measurement was taken that included 9 of the 13 CG patients and all six of the SVG patients. The average **weight loss** for the SVG group was 2.1%, whereas the average weight loss for the CG group was 11.6%. Reported as statistically significant, the group that added DSV to their daily diet clearly retained more body weight than the group that did not. A statistically significant difference was also noted with regard to the KPS scores between the CG group and the SVG group. One to three months after entering the trial, the KPS scores were improved for the SVG group, whereas the scores for the CG group declined. In other words, adding DSV to the daily diet of the patients in the SVG group not only appeared to help them avoid a decline in condition, but it was also associated with an actual improvement in condition. Furthermore, the median survival time of the CG patients was four months, whereas the median survival time of the SVG patients was 15.5 months. This statistically significant difference reported by Sun and his team supports the notion that adding DSV to the daily diet of a stage III or IV non-small cell lung cancer patient helps to prolong his or her life.

Encouraged by these results, Sun and his team reformulated the mixture and embarked on a pilot study to investigate its anticancer components, which was published in 2001 in *Nutrition and Cancer*. This third formulation was referred to as frozen selected vegetables (FSV). Through the use of a lung tumor model, tumor growth was assessed in mice. According to Sun and his team, a daily portion of FSV was "found to contain 63 mg of inositol hexaphosphate [found in legumes], 4.4 mg of daidzein [found in soy products], 2.6 mg of genistein [found in soy products], and 16 mg of coumestrol [estrogen-like substance found in plants]." Sun et al reported that mouse food containing 5% of FSV "was associated with a 53% to 74% inhibition of tumor growth rate." Fourteen patients with stage IIIB and stage IV non-small cell lung cancer who added FSV to their daily diet for 2 to 46 months were also evaluated. According to Sun et al, "the lead case remained tumor free for more than 133 months; the second case showed complete regression of multiple brain lesions after using FSV and radiotherapy. The median survival time of the remaining 12 patients was 33.5 months and one-year survival was greater than 70%." Ultimately, Sun et al concluded that not only was ingesting FSV nontoxic, but its ingestion was also "associated with objective responses, prolonged survival, and attenuation of the normal pattern of the progression of stage IIIB and stage IV of non-small cell lung cancer."

Though these results appear promising (as do the results of the previous 1999 clinical trial by Sun et al), the results should be viewed with some degree of caution, because more research is needed. For example, in order to confirm the results of the 2001 study, a large randomized controlled clinical trial should be conducted. Furthermore, as the National Cancer Institute points out, "all of the patients [in the 2001 study] were aware of the reported benefits of Sun's soup and had actively sought treatment." Therefore, the National Cancer Institute states cautions that "the results obtained with such highly motivated, self-selected patients might not be typical of those obtained with most patients diagnosed with advanced non-small cell lung cancer." In addition, both the 1999 and 2001 Sun et al studies share a weakness: the small number of patients involved. Another problem is that the formulations in both studies differ, making a comparison between the two difficult. Therefore, more studies testing both formulations on larger samples sizes are needed to confirm the results.

Recommended dosage

Patients should consult their physicians for dosage clarification, including how much and how often any dietary supplement should be taken, as well as the best formulation to use. For example, in the study conducted by Sun et al that was published in *Nutrition and Cancer* in 1999, the mixture tested was in the freeze-dried powder form and the participants orally consumed 30 grams of it a day, which they mixed with water or soup. In the subsequent study conducted by Sun et al that was published in *Nutrition and Cancer* in 2001, the participants orally consumed 10 ounces a day, which is approximately 283 grams, of the reformulated, frozen mixture. Both forms are available in the United States, but consumers should be aware that dietary supplements are not regulated by the United States Food and Drug Administration. Therefore, Sun's soup should be purchased only from a reputable supplier, preferably one who is recommended by a physician.

QUESTIONS TO ASK THE DOCTOR

- What is the most likely cause of my SVC syndrome?
- What tests will be done to determine the cause of my SVC syndrome?
- What are my treatment options for SVC syndrome?
- Am I a candidate for a stent?
- If I am a candidate for thrombolytic therapy, will ongoing anticoagulation be used? Will it interfere with my cancer therapy?
- If I choose to do nothing (opt for no therapy), what may be the consequence?
- Is my SVC syndrome presenting an oncologic medical emergency?

Precautions

Patients should consult with their physician regarding all food or over-the-counter medications before they are consumed.

The National Cancer Institute indicates that there is no information on the safety or the efficacy of this treatment.

Side effects

No toxic side effects are known to be associated with the use of Sun's soup. A bloated sensation was reported by participants in the 1999 study conducted by Sun and colleagues. Participants in the 2001 study did not experience any negative side effects. However, an important distinction between the two studies should be noted. In the 1999 study, the mixture of Sun's soup was in a freeze-dried powder form and was mixed with water or soup. In the 2001 study, a reformulated, frozen mixture of Sun's soup was used. This difference could explain why the participants reported different responses.

Interactions

Although Sun's soup is not known to interact with other medications, it is best for patients to consult a pharmacist and/or physician regarding the safety of its use.

Superior vena cava syndrome

Definition

The superior vena cava is a large vein in the chest that drains the blood from the upper body back to the heart. Compression or occlusion (blocking off) of this vein creates superior vena cava syndrome.

Description

When the superior vena cava (SVC) becomes compressed or occluded, the blood from the upper body cannot drain back to the heart properly. This creates suffusion (the spreading of bodily fluids into surrounding tissue) which causes varying degrees of airway obstruction, swelling and cyanosis (purple discoloration due to lack of oxygenation) of the face, neck, arms and chest area.

Causes

Cancer is the most common cause of superior vena cava Syndrome. Lung cancer, **lymphoma**, **breast cancer**, and **germ cell tumors** of the chest are commonly associated with SVC syndrome. Any cancer that invades or constricts the blood vessels in the chest can cause SVC syndrome. Other non-cancer causes of SVC

Syndrome are thyroid goiter, fungal infections, pericardial constriction, aortic aneurysm, and any other disease that creates swelling in the mediastinum (organs and vessels of the chest). Occasionally, SVC syndrome can be caused by a central vein catheter (an IV catheter that is placed into central circulation with its tip in the superior vena cava), which may cause a thrombosis (blockage) of the SVC.

Symptoms

Patients with superior vena cava syndrome (SVC syndrome) might experience facial swelling causing the shirt collar to feel tight, shortness of breath, coughing, a change of voice, or confusion. A patient might also notice distention or enlargement of veins near the surface of the skin. The development of these signs and symptoms is usually a gradual process taking up to four weeks from onset of symptoms to diagnosis.

Diagnosis

The physician diagnoses SVC syndrome by starting with a complete patient history and physical examination. The physician will ask about onset of symptoms and timeframes of symptom development. The physician will recommend a chest x ray and a computed tomography scan to visualize the chest area in order to confirm the presence of SVC syndrome. The physician may also order venous patency (flow of blood through the vein) studies using contrast dye and scanning techniques. The physician may order a scan done in a **Magnetic resonance imaging** (MRI) lab, ultrasound lab, or in nuclear medicine to help assess the cause of the superior vena cava syndrome. These tests help the physician identify the site and nature of the obstruction. If cancer of the bronchi is suspected, the patient should also anticipate other testing such as sputum collection, **bronchoscopy**, and **biopsy** of the suspected cancer site. These tests are very important to the oncologist (a physician who specializes in the treatment of cancer), because they will help to identify the disease, determine the stage, and hence the appropriate course of treatment.

Risks

Many patients have the symptoms of superior vena cava syndrome for more than a week before seeing their doctor. Sometimes the diagnosis of SVC syndrome is the first sign that there is cancer present in the body (only 3% to 5% of patients with SVC syndrome do not have cancer). Most patients with SVC syndrome do not die from the syndrome itself, but from the underlying disease, and the extent of the cancer invasion causing the syndrome. Physicians consider the presence of superior vena cava syndrome a life-threatening oncologic medical emergency when there is tracheal (airway) obstruction present. Further, if there is extensive suffusion causing swelling in the vessels in the brain, the patient's condition can rapidly deteriorate. Once the diagnosis of SVC syndrome is made, the physician will immediately commence determining the cause of the syndrome to avoid or minimize these risks.

KEY TERMS

Adjunctive therapy—Sometimes referred to as "secondary therapy," adjunctive therapy is used in conjunction with the primary therapy.

Beta-glucan—Found in a variety of mushrooms, beta-glucan is a type of polysaccharide believed by some researchers to contain anti-tumor properties and the ability to boost the immune system.

Bioavailability—The ability of a drug to be absorbed and used by the body.

Hedyotis diffusa—In ancient Chinese medicine, this herb has been used to boost the immune system.

Median survival time—The National Cancer Institute defines median survival time as "the time from either diagnosis or treatment at which half the patients with a disease are found to be, or expected to be, still alive." With regard to a clinical trial, median survival time is a common measurement used to determine the effectiveness of a treatment.

Non-small cell cancer—The National Cancer Institute defines non-small cell cancer as "a group of lung cancers, which includes squamous cell carcinoma, adenocarcinoma, and large cell carcinoma."

Scutellaria barbata—Commonly used in traditional Chinese medicine to treat lung cancer, Scutellaria barbata is an herb that belongs to the skullcap family.

Stage I non-small cell cancer—The National Cancer Institute defines this stage as "cancer [that] is present in the lung only. Stage I is also divided into stages IA and IB based on the size and location of the tumor."

Stage III non-small cell cancer—The National Cancer Institute defines this stage "as cancer that has spread to structures near the lung; to the lymph nodes in the area that separates the two lungs (mediastinum); or to the lymph nodes on the other side of the chest or in the lower neck." Stage III is also divided into stage IIIA (resection likely) and stage IIIB (resection unlikely).

QUESTIONS TO ASK YOUR DOCTOR

- Which risk group has my child been assigned to?
- What treatments would you recommend for a child in that group, and why would you recommend them?
- Is my child eligible for any current clinical trials for children with SPNETs?
- Would you recommend any of the treatments currently considered experimental?
- If the tumor recurs, what is my child's life expectancy? What can I do to make the remaining time as pain-free and enjoyable as possible?

Treatment

There are several treatment options to alleviate the symptoms of SVC syndrome. The feasibility of these options depends on the primary cause of the obstruction, the severity of the symptoms, the prognosis of the patient, and the patient's preferences and ultimate goals for therapy. The physician will need to determine the histology (cellular origin) of the obstructing cancer before proceeding with SVC syndrome treatment. Unless there is airway obstruction or swelling in the brain, treatment of SVC syndrome can be delayed to determine the stage of the underlying disease.

Medical management of SVC syndrome includes elevating the head, using steroids to minimize swelling, and diuretics to remove fluid from circulation. Some patient may develop collateral circulation (development of smaller vessel branches to assist with the excess fluid load on the SVC) and not need further treatment.

Chemotherapy is used on lymphomas or small cell lung cancers because they are sensitive to the drugs. Rapid initiation of chemotherapy in these situations can dramatically reduce the unpleasant symptoms of SVC syndrome in most patients. When chemotherapy is not the best choice for the cancer type, **radiation therapy** can provide some relief from symptoms.

Other treatment options include thrombolysis where a fibrolytic agent (agent that breaks down a thrombus or clot) is injected into the obstructed SVC. This option is used when it is determined that the obstruction is inside the vein. Stent placement (placing a sterile mesh tube inside the SVC to keep the vessel open) has been used successfully in some patients, but may require ongoing anticoagulation therapy after placement. Finally, surgical bypass of the obstructed SVC is a possible option for some patients, however the procedure is extensive and the patient must have appropriate healthy veins to graft to the affected area.

Supratentorial primitive neuroectodermal tumors

Definition

Supratentorial primitive neuroectodermal tumors, or SPNETs, are primary brain tumors found mostly in children. The word *supratentorial* refers to the location of these tumors in the part of the brain called the cerebrum, above the tentorium (the tentlike membrane that covers the cerebellum). This term is used to differentiate these tumors from medulloblastomas, which are sometimes called infratentorial primitive neuroectodermal tumors (IPNETs) because they are located beneath the tentorium. *Primitive* refers to the fact that SPNETs arise from cells that have not yet separated into more specialized types of cells. The word *neuroectodermal* means that these tumors develop out of a layer of cells in the embryo that eventually gives rise to the baby's nervous system. Supratentorial primitive neuroectodermal tumors are also called cerebral neuroblastomas.

Description

SPNETs are rapidly growing tumors that are considered highly malignant. While they resemble medullo-

blastomas in terms of the type of cells that give rise to them, they are far less common; the ratio of medulloblastomas to SPNETs is thought to be about 25: 1.

The location of SPNETs in the cerebrum means that they occur in the largest part of the brain—the portion that governs speech, emotions, voluntary muscular movements, and the ability to think, reason, and solve problems. These tumors may metastasize, or spread, to other parts of the central nervous system (CNS) via the cerebrospinal fluid. A doctor looking at a CT scan of one of these tumors will usually see a large mass with clear margins that contains cysts, calcifications (deposits of calcium within the brain cells), and patches of dead tumor cells. In some cases the doctor will also see evidence of bleeding into nearby tissue.

Demographics

These tumors are extremely rare, accounting for only 0.5–2 percent of childhood tumors of the central nervous system (CNS). About 2200 children below the age of 15 are diagnosed with malignant tumors of the brain and spinal cord each year in the United States; between 10 and 40 of these children will be diagnosed with SPNETs.

It is difficult to evaluate the statistical significance of racial or gender differences in such a small group; however, the available evidence from American cancer registries suggests that these cancers occur more frequently in Caucasian children than in African Americans, and more frequently in males than in females. The male: female ratio is thought to be about 1.8: 1.

SPNETs occur almost exclusively in younger children, with very few cases reported in adolescents or adults. About 75% of these tumors occur in children below the age of 15, with 50% diagnosed in children below the age of 10. Most SPNETs diagnosed in adults occur in young adults between the ages of 21 and 40.

Causes and symptoms

The causes of SPNETs are not well understood as of early 2005. They do not run in families and are not known to be associated with carcinogens in the environment. It is thought that they result from sporadic (random) gene mutations, possibly associated with abnormalities in the short arm of chromosome 17.

The symptoms of a supratentorial primitive neuroectodermal tumor are often insidious, which means that they are gradual in onset. They are caused by the increased pressure of cerebrospinal fluid inside the skull. Depending on the size of the tumor and the child's age, symptoms may include the following:

- headache, usually worse in the morning, sometimes relieved by vomiting
- blurred vision
- nausea and intermittent vomiting
- weakness or loss of sensation on one side of the body
- difficulty with balance
- frequent crying (in children below the age of three)
- decreased interaction with other people
- lowered energy level or unusual need for sleep
- irritability and other personality changes
- unexplained changes in weight or appetite

Parents should note, however, that none of these symptoms are unique to SPNETs; they may be produced by other types of brain tumors, head trauma, meningitis, migraine headaches, or several other medical conditions. In any event, a child with these symptoms should be seen by a doctor at once.

Diagnosis

The diagnosis of a supratentorial primitive neuroectodermal tumor begins with a review of the child's medical history and a thorough physical examination. The child may be given several vision tests if he or she is seeing double or having other visual disturbances. The doctor may notice one or more of the following signs, although none of them are distinctive features of SPNETs:

- Papilledema. Papilledema refers to swelling of the optic disk, usually caused by increased fluid pressure behind the eye.
- Ataxia. This term refers to loss of muscular coordination.
- Nystagmus. This refers to rapid involuntary movement of the eyeball. The doctor may be able to detect it by having the child look to the right or the left.
- Palsy of the lower cranial nerve.
- Dysmetria. This term refers to the loss of ability to estimate distance when using the muscles; an example would be overreaching when trying to pick up a small object.

The child's doctor will then order both laboratory tests and **imaging studies**. The laboratory tests are done to rule out such diseases as meningitis and to see whether the child's liver and other organs are functioning normally. The imaging studies are performed to determine the extent of the cancer and to assign the child to a risk group.

The diagnosis of SPNET cannot be confirmed, however, on the basis of a clinical examination. Instead, a neurosurgeon will perform what is known as an open **biopsy**. He or she will drill a small hole in the child's skull and remove a small piece of the tumor for examination by a pathologist.

Imaging tests

Imaging tests for SPNETs include the following:

- Magnetic resonance imaging (MRIs).
- Computed tomography (CT) scan.
- Chest x-ray.
- Bone scan. This test is necessary to determine whether the tumor has spread beyond the central nervous system.

Laboratory tests

Standard laboratory tests for children with brain tumors include a complete blood count (CBC), electrolyte analysis, tests of kidney, liver, and thyroid function, and tests that determine whether the child has been recently exposed to certain viruses. In addition, a **lumbar puncture** will usually be performed to look for cancer cells in the child's spinal fluid.

Treatment team

Since the 1960s, most children diagnosed with brain tumors have been treated in specialized children's cancer centers. A child with a SPNET will usually have a pediatric oncologist as his or her primary doctor, along with one or more specialists. These specialists may include a neurosurgeon, pathologist, neuroradiologist, radiation oncologist, medical oncologist, endocrinologist, nutritionist, physical therapist or rehabilitation specialist, and psychologist or psychiatrist. The team will also include social workers, clergy, and other professionals to help the parents cope with the stresses of their child's illness and treatments.

Clinical staging, treatments, and prognosis

Staging

Supratentorial primitive neuroectodermal tumors are not staged in the same way as cancers elsewhere in the body. Instead, children with these tumors are divided as of the early 2000s into two risk groups, average risk and poor risk. Assignment to these groups is based on the following factors:

- child's age
- size and location of the tumor
- whether the tumor has spread to other parts of the central nervous system
- whether the tumor has spread beyond the CNS to other parts of the body

Average-risk children are those older than three years, with most or all of the tumor removed by surgery and no evidence that the cancer has spread beyond the cerebrum. Poor-risk children are those who are younger than three years, whose cancer was located near the center of the brain or could not be removed completely by surgery, and whose cancer has spread to or beyond other parts of the CNS. The risk of recurrence is higher for children in the poor risk group.

Treatments

Treatments for SPNETs depend on the child's age and his or her risk group. Children younger than three years are not usually given **radiation therapy** because it can affect growth and normal brain development. They are usually treated with surgery first to remove as much of the tumor as possible, followed by **chemotherapy** if they are considered poor-risk patients. The drugs most commonly used to treat SPNETs include **lomustine**, **cisplatin**, **carboplatin**, and **vincristine**.

In addition to removing the tumor, the surgeon may also place a shunt to reduce pressure on the child's brain if the tumor is blocking the flow of cerebrospinal fluid. A shunt is a plastic tube with one end placed within the third ventricle of the brain. The rest of the shunt is routed under the skin of the head, neck, and chest with the other end placed in the abdomen or near the heart. About 30 percent of children treated for SPNETs require shunt placement.

Children three years and older are treated with surgery first, followed by radiation treatment of the entire brain and spinal cord. Those considered poor risks may also be given chemotherapy. Recurrent SPNETs are treated with further surgery and an additional course of chemotherapy.

Treatments for supratentorial primitive neuroectodermal tumors that are considered experimental as of 2005 include the following:

- Gamma knife surgery (GKS).
- Gene therapy.
- High-dose chemotherapy. Chemotherapy with **topotecan** has been reported to give promising results in treating SPNETs, as does high-dose chemotherapy combined with stem cell transplantation.
- **Photodynamic therapy**.
- **Bone marrow transplantation**.

- Newer drugs: **Irinotecan**, tipifarnib, lapatinib, ixabepilone, cilengitide, and tariquidar.

Prognosis

The prognosis for children with SPNETs depends largely on their risk group. In general, however, these tumors have a poorer prognosis than other types of brain tumors in children, in part because of the difficulty of removing the complete tumor due to its large size, its extensive blood supply, and its location within the cerebrum. The overall five-year survival rate of children with supratentorial primitive neuroectodermal tumors is reported to be 50–60 percent, but is much lower in children younger than three years and in older children who do not respond to radiation therapy.

Recurrent tumors of this type are almost always fatal; there are no effective therapies for recurrent SPNETs as of the early 2000s.

Alternative and complementary therapies

Some complementary therapies that are reported to help children with SPNETs include pet therapy, humor therapy, art therapy, and music therapy. All of these can be pleasurable for the child as well as relaxing. Ginger or peppermint may help to relieve the **nausea and vomiting** associated with chemotherapy.

Coping with cancer treatment

Children being treated for SPNETs can be given additional medications to treat nausea and other side effects of chemotherapy. With regard to homesickness and other emotional reactions to being away from home, childrens cancer centers have social workers and child psychologists who can educate the childs family about the cancer as well as help the child deal with separation issues.

The side effects of radiation therapy in children with brain tumors may include the formation of dead tissue at the site of the tumor. This formation is known as radiation necrosis. It occurs in about 5 percent of children who receive radiation therapy and may require surgical removal. Radiation necrosis, however, is not as serious as recurrence of the tumor.

Children who have difficulty speaking after brain surgery, or who experience physical weakness, difficulty walking, visual impairment, or other sensory problems, are given physical therapy and/or speech therapy on either an inpatient or outpatient basis.

Clinical trials

Because SPNETs are so rare, the American Cancer Society recommends that children diagnosed with these tumors be enrolled in an appropriate clinical trial. As of early 2005, there are about 30 **clinical trials** in the United States for children with various types of PNETs. Some of these trials involve gene testing to improve diagnosis of children with brain tumors, while others are exploring various combinations of chemotherapy (including new agents), photodynamic therapy, stem cell transplantation, and bone marrow transplantation as treatments for primitive neuroectodermal tumors.

KEY TERMS

Blastoma—An abnormal growth of embryonic cells. Supratentorial primitive neuroectodermal tumors are sometimes called cerebral neuroblastomas.

Calcification—A deposit of calcium within cells or tissues. Calcifications in the brain are often visible on imaging studies of SPNETs.

Cerebellum—The part of the brain that lies within the lower back portion of the skull behind the brain stem. The cerebellum helps to coordinate voluntary movements.

Cerebrum—The largest part of the brain in humans, occupying the upper part of the skull cavity. Supratentorial primitive neuroectodermal tumors are located in the cerebrum.

Medulloblastoma—A malignant tumor of the cerebellum that occurs mostly in children and is considered a type of primitive neuroectodermal tumor. Medulloblastomas are sometimes classified as infratentorial primitive neuroectodermal tumors because they develop underneath the tentorium.

Primary brain tumor—A tumor that starts in the brain, as distinct from a metastatic tumor that begins elsewhere in the body and spreads to the brain.

Primitive—Simple or undifferentiated. SPNETs are classified as primitive tumors because they arise from cells that have not yet separated into groups of more specialized cells.

Shunt—A tube inserted by a surgeon to relieve pressure on the brain from blocked cerebrospinal fluid. The tube allows the fluid to bypass the tumor that is blocking its flow.

Supratentorial—Located above the tentorium, which is the tentlike membrane that covers the cerebellum.

Ventricle—One of the small cavities located within the brain.

Prevention

There is no way to prevent SPNETs as of the early 2000s because their cause is still unknown.

Special concerns

Children with SPNETs are like children with other long-term illnesses in that they may develop emotional problems in reaction to restrictions on their activities, uncomfortable treatments, or being treated in a cancer center away from home. These children may withdraw from others, become angry or bitter, or feel inappropriately guilty about their illness. It is important for parents to reassure the child that he or she did not cause the cancer or deserve it as a punishment for being "bad." Parents may benefit from consulting a child psychiatrist about these and other emotional problems.

Another special concern is the task of explaining the childs illness and treatments to other family members and friends in ways that they can understand. Members of the childs treatment team can be helpful in providing simplified descriptions for siblings or schoolmates.

A third area of concern with **childhood cancers** is the parents' relationships with their other children and with each other. Siblings may resent the amount of time and attention given to the child with cancer, or they may fear that they too will develop a brain tumor. Support groups for families of children with cancer can help by sharing strategies for coping with these problems as well as allowing members to express anxiety and other painful feelings in a safe setting.

Suramin

Definition

Suramin (suramin hexasodium; CI-1003) is a polysulfonated naphthylurea. It is a growth factor antagonist for palliative treatment in hormone-refractory **prostate**

cancer and hormone-responsive metastatic prostate cancer.

Purpose

Suramin has been used for years to combat African sleeping sickness and river blindness but it has also been found beneficial in slowing the progression of prostate cancer. This drug is classified as an antiprotozoal or anthelminitic. In addition to combating prostate cancer, suramin has demonstrated anti-tumor activity against many types of tumors including endometrial, breast, ovarian, and lung cancer. It has a number of important biological functions for cancer treatment; it inhibits a number of growth factors and receptors needed for tumor growth including epidermal growth factor (EGF), platelet-derived growth factor (PDGF), fibroblast growth factor, and vascular endothelial growth factor. Suramin decreases blood plasma levels of insulin-like growth factors 1 and 2. Suramin also inhibits tumor antigen, DNA synthesis, cell motility, and urokinase activity. It has also demonstrated significant improvements in pain response. In one of the most recent clinical studies, published in 2001, suramin delayed disease progression, by inhibition of prostate-specific antigen levels, thus prolonging survival in prostate cancer patients. This study also demonstrated suramin delayed two other clinical study endpoints: progression-free survival (i.e. delaying disease progression) and time to pain progression.

Description

While conducting research into suramin as a potential anti-HIV agent, it was found that tumors regressed in HIV-associated cancers. This discovery led investigators to evaluate the antineoplastic effects of suramin. Unfortunately, suramin did not prove effective as an anti-HIV agent.

Suramin, under the brand name Metaret, was submitted for Food and Drug Administration (FDA) approval for treatment of hormone-refractory prostate cancer in 1997 by Warner-Lambert. However, a review by the Oncologic Drugs Advisory Committee in 1998 did not support FDA approval. It was given approval for the "List of Orphan Designations and Approvals." It has been reported to be under development by the Cooperative Research and Development Agreement (CRADA) with the National Cancer Institute (NCI) and the National Institute of Health (NIH). This drug was withdrawn in 2000 and will not be pursued for FDA approval by Pfizer, who merged with Warner-Lambert.

Recommended dosage

Since this drug is not FDA approved for cancer treatment, dosing information is not readily obtainable. Original research on suramin with continuous infusions was associated with severe toxicities. Due to these toxicities, a long half-life, and a narrow therapeutic range, there was a desire to avoid prolonged continuous infusions. During **clinical trials**, outpatient doses of suramin were aimed at maintaining plasma concentrations at 150 to 250 mcg/mL for three months' duration to minimize treatment exposure.

Precautions

The majority of the precautions listed below are based on suramin's use as an antiprotozoal agent. The following precautions should be considered:

- Allergies. Alert the doctor if any unusual or allergic reaction to suramin occurs or to any other substances, such as foods, preservatives, or dyes.
- Pregnancy. Suramin has not been studied in pregnant women, but animal studies in animals have shown that suramin may cause birth defects or death of the fetus. Before receiving this medicine, alert the doctor if you are pregnant or if you may become pregnant.
- Breast-feeding. It is not known whether suramin passes into breast milk. This issue should be discussed with a doctor for a mother who wishes to breast-feed.
- Children. Suramin can cause serious side effects in any patient, so prior to adminstration to children, discuss the risks with a doctor.
- Older adults. Elderly people are especially sensitive to the effects of suramin. This may increase the chance of side effects during treatment.
- Other medical problems. The presence of other medical problems may affect the use of suramin. Make sure to tell the doctor about any other medical problems, especially kidney or liver disease. Patients with kidney or liver disease may have an increased chance of side effects

Due to a risk of adrenal insufficiency (which results from the inadequate production of adrenal hormones) and coagulopathy (a defect that interferes with the blood clotting mechanism), patients receiving suramin should be administered hydrocortisone and vitamin K.

Significant toxicities are associated the use of suramin. However, with careful monitoring of serum concentrations, these toxicities are manageable.

Side effects

Rash, edema, and asthenia are commonly reported, but generally mild to moderate. Malaise and

KEY TERMS

Antagonist—A drug that binds to a cellular receptor for a hormone, neurotransmitter, or another drug. Antagonists block the action of the substance without producing any physiologic effect itself.

Antineoplastic—Antineoplastic therapy is a regimen of chemotherapy aimed at destroying malignant cells using a variety of agents that directly affect cellular growth and development.

Antiprotozoal—An agent destructive to protozoa.

Anthelmintic—An agent destructive to worms. Many anthelmintic drugs are toxic and should be given with care; the patient should be observed carefully for toxic effects after the drug is given.

Clinical trials—Highly regulated and carefully controlled patient studies, where either new drugs to treat cancer or novel methods of treatment are investigated.

DNA—Deoxyribonucleic acid. Genetic information carried in chromosomes.

Growth factors—Growth factors or human growth factors are compounds made by the body that function to regulate cell division and cell survival. Some growth factors are also produced in the laboratory by genetic engineering and are used in biological therapy. Growth factors are significant because they can induce angiogenesis, the formation of blood vessels around a tumor. These growth factors also encourage cell proliferation, differentiation, and migration on the surfaces of the endothelial cells.

Metastatic—The term used to describe a secondary cancer, or one that has spread from one area of the body to another.

Palliative—To alleviate disease without curing it.

Tumor—An abnormal mass of tissue that serves no purpose. Tumors may be either benign (non-cancerous) or malignant (cancerous).

fatigue are the most common dose-limiting toxicities, affecting 41% of patients in clinical trials for prostate cancer. The majority of the side effects listed below are based on suramin's use as an antiprotozoal agent. Different doses used for cancer treatment may effect the side effect profile. Abdominal pain, **fever**, metallic taste, and a general feeling of discomfort may be bothersome but do not usually require medical attention. These effects may disappear during treatment as the body adjusts to the medicine. Other common side effects are: cloudy urine; crawling or tingling sensation of the skin; **diarrhea**; faintness (particularly after missing meals); headache; increased skin color; irritability; **itching**; joint pain; loss of appetite (anorexia); nausea and vomiting; numbness or weakness in arms, hands, legs, or feet; stinging sensation on skin; swelling on skin; tenderness of the palms and the soles; and becoming easily tired.

Less common side effects may include: extreme fatigue or weakness; increased sensitivity of eyes to light; changes in or loss of vision; watery eyes; swelling around eyes; ulcers or sores in mouth; as well as painful and tender glands in the neck, armpits, or groin.

Side effects that may occur rarely include:

- cold and clammy skin
- convulsions
- decreased blood pressure
- difficulty breathing
- fever and sore throat
- fever with or without chills
- increased heartbeat
- loss of consciousness
- pale skin
- pinpoint red spots on skin
- red, thickened, or scaly skin
- swelling and/or tenderness in upper abdominal or stomach area
- swollen and/or painful glands
- unusual bleeding or bruising
- unusual fatigue or weakness
- yellow discoloration of the eyes or skin

Some patients may experience other side effects not listed above. Patients experiencing any other side effects should check with the attending physician.

Interactions

Drug interaction information is not readily available for suramin. However, as with any treatment, patients should alert their doctor to any prescription, over-the-counter, or herbal remedies they are taking in order to avoid possible drug interactions.

Crystal Heather Kaczkowski, MSc.

Syndrome of inappropriate antidiuretic hormone

Description

The syndrome of inappropriate antidiuretic hormone production (SIADH) is a condition in which the body develops an excess of water and a decrease in sodium (salt) concentration, as a result of improper chemical signals. Patients with SIADH may become severely ill, or may have no symptoms at all.

A syndrome is a collection of symptoms and physical signs that together follow a pattern. SIADH is one of the **paraneoplastic syndromes**, in which a cancer leads to widespread ill effects due to more than just the direct presence of tumor.

Normal physiology

The body normally maintains very tight control over its total amount of water and its concentration of sodium. Many organs including the kidneys, heart, and the adrenal, thyroid, and pituitary glands participate in this regulation. One important contribution is the release of a chemical substance, or hormone, by the pituitary gland into the bloodstream. This chemical substance, called antidiuretic hormone (ADH), is also known as arginine vasopressin, or AVP.

The pituitary releases ADH into the bloodstream when receptors in various organs detect that the body has too little water or too high a concentration of salt. ADH then affects the way the kidneys control water and salt balance. ADH causes the kidneys to decrease their output of urine. The body thus saves water by undergoing antidiuresis, that is, not excreting urine.

Simultaneously, the concentration of sodium in the body serum decreases. This decrease results from a second effect of ADH on the kidneys. When the kidneys retain extra water, the existing concentration of sodium in the body decreases slightly as a result of dilution. These functions are all part of the body's extremely precise control over water and salt balance in health.

Abnormal physiology in SIADH

Certain disease states can upset the delicate balance of water and salt in the body. If there is too much ADH in the body, or if the kidneys overreact to the ADH they receive, the body retains excess water and the serum sodium concentration becomes diluted and falls to abnormal levels. The patient with SIADH develops symptoms based on the degree of abnormality in the serum sodium concentration and the speed with which this concentration falls.

Normal serum sodium concentration is 135-145 mEq/L (milliEquivalents of sodium per liter of body fluid). When the sodium concentration is 125–135 mEq/L the patient may have mild nausea, loss of appetite, **fatigue**, headache, or still remain free of symptoms. As the sodium level drops below 120 mEq/L, the patient experiences greater weakness, confusion, sleepiness, vomiting, and weight gain. As the sodium concentration approaches 110 mEq/L, the patient may suffer seizures, coma, and death.

Causes

SIADH has many known causes, some of which particularly relate to cancer or its treatment. These causes include specific types of cancer, drugs used to treat cancer itself, drugs used to treat the effects of cancer, and conditions that arise as a consequence of cancer or its treatment.

Specific types of cancer

SIADH results from numerous different types of cancer. The malignancies known to cause SIADH include:

- **Lung cancer, small cell** type
- Gastrointestinal cancers (**pancreatic cancer, exocrine**; duodenal or stomach cancer)
- Genitourinary cancer (**bladder cancer**, **prostate cancer**, ovarian cancer)
- Lymphoma, including Hodgkin's disease
- Head and neck cancers (**oral cancers**, **laryngeal cancer**, nasopharyngeal cancer)
- Thymoma
- Brain and central nervous system tumors
- Breast cancer
- Melanoma

Certain cancers produce and secrete ADH themselves. This production occurs without regard for the needs of the body. Thus, the kidneys receive repeated signals to save water, even when the body already has a marked excess of fluid. Of all the types of cancer that produce ADH themselves, small-cell lung cancer is by far the most common. Small-cell cancer of the lung is the cause in 75% of cases of SIADH caused directly by a tumor. In some cases, the appearance of SIADH may be the first indication that a cancer exists.

Also, primary or metastatic tumors in the brain may lead to SIADH. SIADH here results from an increase in intracranial pressure (pressure within the head), or from other effects of intracranial disease on the brain. Increased intracranial pressure commonly causes various parts of the brain to work improperly.

Drugs used to treat cancer itself

A variety of drugs used in cancer treatment may lead to SIADH. The mechanism of this effect may be that the

drug causes the abnormal release of ADH, or that the drug makes existing ADH work in a stronger fashion than usual. **Chemotherapy** drugs that cause SIADH include:

- Vincristine, **vinblastine**, **vinorelbine** and other vinca alkaloids (Oncovin, Velban, Navelbine)
- Cyclophosphamide, **ifosfamide**, **melphalan** and other nitrogen mustards (Cytoxan, Ifex, Alkeran)
- Cisplatin (Platinol-AQ)
- Levamisole (Ergamisol)

Drugs used to treat the effects of cancer

SIADH may occur as a reaction to drugs used to treat effects of cancer such as pain, **depression**, or seizures. SIADH also may result from general anesthesia.

- Narcotic pain medications (morphine, Oramorph SR, fentanyl, Duragesic)
- Tricyclic antidepressants (**amitriptyline**, Elavil)
- Carbamazepine (Tegretol)
- General anesthetics

Conditions that arise as a consequence of cancer

SIADH may result from some of the debilitating consequences of cancer. For example, a person with cancer who is weak or unsteady will have a tendency to fall and hit the head. Skull fracture and other types of head injury may damage the brain or increase the intracranial pressure, and thus lead to SIADH.

Also, cancer patients who are weak, malnourished, receiving chemotherapy, or spending excessive time in bed have an increased risk of **pneumonia** and other infections. Infections including pneumonia, meningitis, and tuberculosis can cause SIADH.

Treatments

The treatment of SIADH involves relief of the urgent symptoms and correction of the underlying problem. For immediate improvement, all patients with SIADH require sharp restriction of their daily water intake. As little as two cups of liquid, about 500 ml, may be the daily limit for some patients. In cases where the sodium concentration is already dangerously low, doctors may cautiously give an intravenous infusion of fluid with a high concentration of sodium (hypertonic saline solution). However, this treatment carries some risk of damaging the brain. Physicians may also use a medicine such as furosemide (Lasix) that promotes water excretion (diuresis). Another drug, **demeclocycline**, blocks the action of ADH in the kidney.

The most definitive way to relieve SIADH is to address the underlying problem itself. Thus, if a tumor produces abnormal ADH, then surgery, **radiation therapy**, or chemotherapy may help by reducing tumor size. If SIADH results from use of a drug, then the patient must discontinue the medicine. Finally, doctors try to identify and treat any other correctable cause, such as an infection.

KEY TERMS

Antidiuretic hormone (ADH)—A chemical hormonal signal sent by the pituitary gland to the kidneys through the bloodstream, telling the kidneys to conserve water in the body.

Diuresis—The excretion of urine.

Hormone—A chemical signal released into the bloodstream that affects one or more other organs.

Hypertonic saline solution—Fluid that contains salt in a concentration higher than that of healthy blood.

Intracranial—Within the head.

Pituitary gland—A small organ, located at the base of the brain, that regulates many body functions.

SIADH—Syndrome of inappropriate antidiuretic hormone production

Serum—The clear yellowish liquid part of whole blood, after it is separated into solid and liquid components. It may be found within the vascular system or in body tissue itself.

Syndrome—A collection of symptoms and physical signs that together follow a pattern.

Prognosis

The prognosis of SIADH depends largely on its cause. Until recently, many physicians believed that the appearance of SIADH indicated a poor prognosis for cancer. However, more recent reports contradict this idea. The patient's ability to observe severe restriction of fluid intake may determine the degree of ongoing symptoms. SIADH usually improves after stopping a drug or curing an infection when that is the cause. When cancer is the direct cause of SIADH, one hopes for similar improvement of SIADH from treatments that reduce the amount of cancer in the body.

T

Tacrolimus

Definition

Tacrolimus belongs to a group of medicines known as immunosuppressive agents. It is used primarily to lower the body's natural immunity in order to prevent the rejection of organ transplants and to prevent graft-versus-host disease. Tacrolimus is also known as Prograf and FK506.

Purpose

Tacrolimus first saw use in transplant patients. By suppressing the activity of the immune system, tacrolimus makes it more likely that the recipient of a transplanted organ will accept that organ. It is especially used for kidney transplants.

In the fight against leukemia, grafts of stem cells from donors are sometimes given to the patient to encourage the blood of a recipient to begin production of normal cells. Tacrolimus may be given during the graft process because it seems to make the patient more receptive to the donated stem cells.

Description

Tacrolimus somehow suppresses, or prevents activity of, the cells in the lymphatic system, which are known as T cells. Under normal circumstances T cells mount an **immune response** to foreign materials in the body. However, during a transplant, T cells can cause the reaction that can lead to the rejection of a donor organ. The exact reason for the activity of tacrolimus is not understood.

Recommended dosage

Given by mouth, in a capsule, or by intravenous line, tacrolimus doses range from about 0.03 milligrams to 0.05 milligrams per kilogram (1 kilogram equals approximately 2.2 pounds) of body weight per day. Individuals with liver or kidney problems must be given a lower dose.

KEY TERMS

Intravenous line—A tube that is inserted directly into a vein to carry medicine directly to the blood stream bypassing the stomach and other digestive organs that might alter the medicine.

Lymphatic system—The system that collects and returns fluid in tissues to the blood vessels and produces defensive agents for fighting infection and invasion by foreign bodies.

Stem cell—Cell that gives rise to a lineage of cells. Particularly used to describe the most primitive cells in the bone marrow from which all the various types of blood cell are derived.

Precautions

Tacrolimus should be taken without food and long after a meal. If there is food in the stomach it will interfere with the way the drug makes its way into the body. Grapefruit juice can increase the activity of tacrolimus and should be avoided.

Side effects

Many serious side effects are associated with tacrolimus. Conditions affecting the brain brought on by the use of tacrolimus include coma (unconscious state) and delirium (uncontrolled and erratic conscious state). Most times the brain conditions are reversible. Headache, skin rashes, hair loss (**alopecia**), pain, sensitivity to light and shock (anaphylaxis) are all side effects. Kidney damage, which cannot be reversed, is also a danger.

Use of tacrolimus greatly increases the likelihood a person will get skin cancer and **lymphoma**. Anyone

using the drug should be monitored closely for changes in the skin, and all normal precautions for avoiding skin cancer, such as avoiding direct exposure to ultraviolet light, should be taken.

Interactions

This drug interacts with a long list of other drugs. It is important to tell the physician in charge of the care plan, each and every drug being taken, so that interactions can be avoided. Tacrolimus prevents effective vaccination, and vaccinations should not be given while the drug is in use.

Diane M. Calabrese

Tamoxifen

Definition

Tamoxifen (also known as Nolvadex) is a synthetic compound similar to estrogen. It mimics the action of estrogen on the bones and uterus, but blocks the effects of estrogen on breast tissue.

Purpose

Tamoxifen is used as adjuvant hormonal therapy immediately after surgery in early stages of **breast cancer** and in advanced metastatic breast cancer (stages III and above) in women and men. Adjuvant therapy is treatment added to curative procedures (such as surgery) to prevent the recurrence of cancer. Although tamoxifen is also used to treat malignant **melanoma**, brain tumors and uterine cancer, these uses are not indicated on the product label. According to U.S. Food and Drug Administration (FDA) guidelines, women who are at high risk of developing breast cancer may take tamoxifen to reduce their risk; however, prolonged use may increase the risk of developing **endometrial cancer** (also called uterine cancer).

In 2003, researchers described the use of high-dose tamoxifen, along with follicle-stimulating hormone (FSH) in stimulating ovary production for women who have had breast cancer who want to undergo in vitro fertilization. Standard in vitro therapies can increase estrogen and risk of breast cancer recurrence. The combination of tamoxifene and FSH may offer some breast cancer protection and hope for pregnancy.

Description

First synthesized in 1966 in Great Britain as an antifertility drug, tamoxifen was evaluated to treat cancer in 1970. In 1998, the FDA approved tamoxifen to reduce the risk of breast cancer. While tamoxifen can be given to patients alone, it is often given in combination with other chemotherapeutic drugs such as 5-fluorouracil (5-FU, or fluorouracil).

Tamoxifen belongs to a family of compounds called **antiestrogens**. Antiestrogens are used in cancer therapy to inhibit the effects of estrogen on target tissues. Estrogen is a steroid hormone secreted by the female ovary. Depending on the target tissue, estrogen can stimulate the growth of female reproductive organs and breast tissue, play a role in the female menstrual cycle, and protect against bone loss by binding to estrogen receptors on the outside of cells within the target tissue. Antiestrogens act selectively against the effects of estrogen on target cells in a variety of ways, thus they are called selective estrogen receptor modulators (SERMs).

Tamoxifen selectively inhibits the effects of estrogen on breast tissue, while selectively mimicking the effects of estrogen on bone (by increasing bone mineral density) and uterine tissues. These qualities make tamoxifen an excellent therapeutic agent against breast cancer. Although researchers are unclear about precisely how tamoxifen kills breast cancer cells, it is known to compete with estrogen by binding to estrogen receptors on the membrane of target cells. This limits the effects of estrogen on breast tissue. Tamoxifen also may be involved in other anti-tumor activities affecting oncogene expression, promotion of apoptosis (cancer cell death) and growth factor secretion. (Growth factors are hormones that influence cell division and proliferation, and these hormones can encourage cancers to grow.)

In 2000, the STAR (Study of Tamoxifen and **Raloxifene**) study began. The purpose of this double-blind study is to evaluate the use of tamoxifen and raloxifene (another type of SERM) over a five-year period in 22,000 postmenopausal women 35 years or older who are at high risk for developing breast cancer. The study will evaluate both the effectiveness and degree of side effects to determine which drug is most beneficial.

Another National Cancer Institute study that is relevant to the discussion of tamoxifen is the Breast **Cancer Prevention** Trial. This trial began in 1992 and was designed to see if tamoxifen was effective as a preventive against breast cancer. The study also was a double-blind study, and participants were receiving either tamoxifen or a placebo (an inactive pill that looks like tamoxifen). About four years into the study, in 1998, researchers reported that the women receiving tamoxifen:

- had 49% fewer diagnoses of invasive breast cancer
- had 50% fewer diagnoses of noninvasive breast cancer (such as ductal **carcinoma** in situ)

- had fewer fractures of the hip, wrist, and spine
- had more than twice the chance of developing endometrial cancer, and
- had increased chance of developing blood clots, both in the lung and in major veins when compared to the women receiving the placebo. Because of these findings, in 1998, the FDA approved the use of tamoxifen as a breast cancer preventive for high-risk women, as mentioned above.

Recommended dosage

Tamoxifen is taken orally and is available in 10- and 20-milligram (mg) tablets. Although it can be given within the range of 10 mg to 80 mg, the typical dosage is 20 to 40 mg daily for both adult females and males using tamoxifen for treatment of advanced breast cancer. At this dosage, there is an observed 30% response rate with complete remission in 10% of patients. It appears that patients 60 years and older have higher response rates. For patients using tamoxifen for adjuvant therapy after surgery, the typical dosage is 20 mg once daily for two to five years following surgery. Women at high risk for developing breast cancer usually take 20 mg daily for five years. If a dosage is missed, patients should not double the next dosage. Instead, they should go back to their regular schedule and contact their doctor.

Tamoxifen doesn't work for everyone. In 2003, scientists announced development of a new test that may predict whether patients' tumors are responding to tamoxifen treatment and warn clinicians if the tumor becomes resistant to the drugs.

Precautions

Tamoxifen is not recommended for use in children. Women who are pregnant or nursing should not use this drug since it has several side effects that, although rare, can be severe. It is known to cause miscarriages and birth defects. Women are encouraged to use birth control while taking tamoxifen. However, oral contraceptives can negatively alter the effects of tamoxifen. Therefore, patients should explore other, nonhormonal birth control options.

Great care should be exercised when tamoxifen is used with **warfarin**, an anticoagulant, because tamoxifen can interfere with the effects of warfarin, and dose adjustments may be necessary. Patients who are predisposed to the formation of thromboembolisms, or blood clots, should use tamoxifen with caution. It should be noted that smokers are at a higher risk for thromboembolism than nonsmokers.

KEY TERMS

Anticoagulant—An agent preventing the coagulation (clotting) of blood.

Apoptosis—A type of cell death where cells are induced to commit suicide.

Double-blind study—A study where neither the participant nor the physician know who has received the drug in question.

Oncogene—A gene whose presence can cause cancer; usually arising through mutation of a normal gene.

Thromboembolism—A blood clot that blocks a blood vessel in the cardiovascular system.

In late 2003, cancer experts were beginning to recommend a new group of drugs called aromatase inhibitors (Arimidex, common name anastrozole or Femara and Novartis, common name letrozole) as an alternative to tamoxifen or following tamoxifen therapy. These drugs fight breast cancer differently, but early research shows they fight it as effectively and with fewer side effects. However, these drugs also may be added after a course of tamoxifen to improve overall treatment results.

Side effects

Although tamoxifen is usually well tolerated by patients, there are some side effects. About 25% of patients experience side effects such as mild nausea, vomiting, hot flashes, weight gain, **bone pain**, and hair thinning. These side effects are usually not severe enough to stop therapy. Patients using tamoxifen for long periods of adjuvant therapy may face unwanted effects years into therapy, which warrant discontinued use of the drug. Some of these effects include possible increased risk of developing liver **adenoma** as well as increased risk of uterine (endometrial) cancer; eye problems such as retinal lesions, macular edema and corneal changes (most resolve after use is discontinued); neurological problems such as **depression**, dizziness, confusion, and **fatigue**; and genital problems such as vaginal bleeding, vaginal discharge, and endometriosis.

Interactions

Tamoxifen can interfere with the anticoagulant drug warfarin, and if these two drugs are used together, patients will need to be monitored very closely. Oral contraceptives can also interfere with the action of

tamoxifen. In 2003, researchers discovered that paroxetine, an antidepressant used to ease hot flashes that accompany treatment with tamoxifene, was interfering with tamoxifene's effectiveness.

Taste alteration

Description

Taste alteration refers to a decrease in the ability to taste foods (hypogeusia), changes in how food tastes (dysgeusia), or the complete loss of the ability to taste foods (ageusia). It also refers to the presence of a metallic or medicine-like taste in the mouth. Taste alterations may occur as a result of cancer treatment, infection within the mouth, or the cancer itself.

Taste alteration can have a significant effect on the nutritional status of a cancer patient. Patients with taste alteration may avoid certain foods, lose their appetite (**anorexia**), and lose weight. Eating can be a chore when the patient also has a dry mouth (**xerostomia**) or a mouth infection, such as **thrush**.

Causes

Humans have the ability to taste bitter, salty, sour, and sweet flavors with the taste buds. Taste buds are on the tongue, back portion of the roof of the mouth (soft palate), and the back of the throat. The taste buds are composed of taste cells. Taste cells have tiny hairs (microvilli) which take up microscopic particles of food in the mouth. Taste alteration occurs when the taste buds are damaged by cancer therapy or as a symptom of xerostomia or infection.

Taste alteration may be caused by the cancer itself. Invasion of the mouth by the tumor can alter taste. Between 88% and 93% of the patients with head and neck tumors have taste alterations. Cancer can cause the patient to become deficient in nutrients such as copper, niacin, nickel, vitamin A, and zinc, which can lead to taste alterations. In addition, it is believed that cancer-related chemicals in the bloodstream may affect taste.

Taste alteration can occur in patients who are receiving **radiation therapy** to the head, neck, or chest. The taste buds are very sensitive to radiation and taste alteration can occur within the first two weeks of radiation therapy. Also, radiation therapy can cause decreases in the production of saliva, which can alter taste. Reduced amounts of saliva can change the taste of salty and bitter foods.

Patients undergoing **chemotherapy** may experience taste alterations. Chemotherapy drugs damage the taste cells. The resulting alterations in taste are varied but the most common complaints include: a metallic taste, enhanced taste of bitter flavors (such as beef, pork, coffee, chocolate), and reduced taste of sweet flavors. Between 36% and 71% of the patients undergoing chemotherapy experience taste changes. **Antibiotics**, pain relievers (analgesics), antidepressants, and many other drugs can also affect taste. Chemotherapy drugs that are frequently associated with taste changes include:

- carboplatin
- cisplatin
- cyclophosphamide
- dacarbazine
- doxorubicin
- 5-fluorouracil (5-FU, or fluorouracil)
- levamisole
- methotrexate
- nitrogen mustard
- vincristine

Surgery to the head or neck can also cause taste alteration. Metallic or medicine-like tastes can be caused by a zinc deficiency or by increased levels of calcium or lactate.

Taste alteration is usually a temporary condition, although it may take a few months for taste to return to

KEY TERMS

Ageusia—The complete loss of the ability to taste foods.

Dysgeusia—Changes in what food normally tastes like.

Hypogeusia—The decreased ability to taste foods.

Taste buds—Tiny bumps located in several parts of the mouth that enable one to taste foods.

Taste cells—The cells that make up taste buds.

normal. However, surgery of the roof of the mouth (hard palate), tongue, or throat or high-dose radiation therapy can cause permanent taste alteration.

Treatments

There is no cure or treatment for taste alteration. Patients with this condition are counseled on methods to overcome the affect of taste alteration on eating. However, some studies have shown that zinc supplements, given at the first sign of taste alteration, can reduce radiation-induced taste changes.

The patient's teeth should be brushed and flossed before eating to remove old tastes and refresh the mouth. Rinsing the mouth with salted water, water containing baking soda, tea, or ginger ale before eating may be helpful. Brushing and flossing should be performed carefully to prevent damage to the weakened mouth tissues.

There are a variety of measures that can be taken to make food more tasteful and less offensive. Dietary recommendations include:

- eating foods that are cool or at room temperature
- adding tart flavors to foods such as lemon, citrus, and vinegar, unless mouth sores are present
- using mints, gum, or lemon drops to remove bad tastes after eating
- adding more sugar to foods to reduce salty, acid, or bitter tastes
- using barbecue sauce, basil, catsup, chili powder, garlic, mint, mustard, onion, oregano, rosemary, or tarragon to add flavor to foods
- eating frozen fruits such as grapes, melons, or oranges
- eating fresh vegetables, which may taste better than frozen or canned ones

Alternative and complementary therapies

Taste alteration related to a zinc deficiency can be treated by the addition of zinc to the diet. Zinc deficiency can be relieved by taking zinc picolinate supplements. Foods that are rich sources of zinc include oysters, crab, beef, pork, eggs, nuts, yogurt, and whole grains.

See also Sjögren's syndrome.

Belinda Rowland, Ph.D.

Temozolomide

Definition

A **chemotherapy** medicine used to reduce the size of a cancerous tumor and prevent the growth of new cancer cells. In the United States, temozolomide is known by the brand name Temodar and in the European Union as Temodal.

Purpose

Temozolomide is used as a treatment for a type of brain tumor called an anaplastic **astrocytoma**. Specifically, it is a treatment for patients who have experienced a relapse (or recurrence) of this disease while being treated with the drug **procarbazine**, one of a group of anticancer drugs known as nitrosoureas, which include **carmustine** and **lomustine**. As of 2001, it is being investigated as a treatment of newly diagnosed and advanced stages of other brain/central nervous system tumors, such as **oligodendrogliomas** and ependymomas, and for an advanced malignant **melanoma** that has spread to the central nervous system.

Description

Temozolomide was first made in a British laboratory in the early 1980s and was approved for use in the United States in 1999.

It is included in the cancer drug category termed **antineoplastic agents**. These drugs slow or prevent the growth of cancerous tumors. Temozolomide is among a subset of antineoplastic agents that were designed to target rapidly dividing cells in the body, such as the cancerous cells that form tumors. These drugs work by altering the structure of the DNA in fast-growing cells, causing a cell to die or to fail to replicate itself.

The use of temozolomide as a treatment for cancers other than brain cancer and in combination with different

cancer therapies is still experimental. Many ongoing **clinical trials** focus on the use of temozolomide as a cancer treatment not only for newly diagnosed and recurrent brain/central nervous system tumors, but also for advanced stages of **germ cell tumors**, lung cancer (non-small cell), **mycosis fungoides**, **Sézary syndrome**, and **gastrointestinal cancers**. Some clinical trials also involve experimental treatment of advanced brain cancer or malignant melanomas using a combination of temozolomide and other cancer drugs or therapies, such as **radiation therapy** and the drugs interleukin-12, **aldesleukin**, **thalidomide**, carmustine, **interferons**, and lomustine.

It is not yet known if temozolomide is more effective than other treatments, but it has been shown to stop or slow disease progression in patients with recurrent brain tumors who have not responded to other treatments, including other chemotherapy drugs, radiation therapy, or surgery. However, the duration of the response varies.

For the treatment of a malignant melanoma, temozolomide is as equally effective as **dacarbazine**, the drug most frequently used for this cancer. If the cancer spreads to the central nervous system, temozolomide may be more effective than dacarbazine, because it, unlike dacarbazine, is able to move from the blood into the central nervous system.

A possible advantage to the use of temozolomide over other therapy options is that a patient may be able to continue the treatment over a longer period of time. Decreased bone marrow activity (myelosuppression) is a common reaction to many chemotherapy drugs, including temozolomide. But unlike other drugs, this condition is temporary in temozolomide patients; therefore, patients can physically tolerate a more extended treatment. Also, the side effects experienced with temozolomide are usually less severe compared to other drug treatment options, resulting in patients with a better quality of life.

Recommended dosage

Temozolomide is available in capsules and is taken orally. Dosage is determined based on a patient's body height and weight. The typical dose for the first treatment cycle is 150 mg per day taken for five consecutive days, with each treatment cycle lasting 28 days. The number of treatment cycles depends on how well a patient tolerates the treatment and its effectiveness in treating the cancer. The optimal number of treatment cycles is not known.

Because myelosuppression is a common reaction to this drug treatment, white blood cell and platelet counts are carefully monitored, particularly in the first few treatment cycles. A complete blood count is made on day 22 and day 29 of a treatment cycle. If blood counts are below a certain level, treatment is either postponed or the dosage is decreased in the next treatment cycle. The minimum recommended dosage is 100 mg. Blood counts within an acceptable range can result in an increased dosage for the next cycle.

Precautions

Food decreases the rate at which temozolomide is absorbed into the bloodstream. Although there are no foods that should be avoided while taking this drug, it should be taken on an empty stomach and swallowed whole with a glass of water.

Side effects

The most common side effects for patients treated with temozolomide are nausea and vomiting, headache, **fatigue**, and constipation. In a study of 158 brain tumor patients, 53% experienced nausea and 42% experienced vomiting, and most of these cases were moderate, with only about 10% of the patients experiencing severe forms of either condition. Avoiding food prior to taking temozolomide can decrease the occurrence of these effects, or they can be controlled with medication. In the same study, 41% of the patients reported headaches, 34% reported feeling fatigued, and 33% experienced constipation.

Between 10% and 20% of the patients in the study experienced convulsions, partial paralysis, **diarrhea**, **fever**, feeling weak, a infection, dizziness, coordination problems, a **memory change**, or insomnia. Less than 10% of the 158 patients experienced **anorexia**, rash or **itching**, inflammation in the throat region, **incontinence**, back pain, an overactive adrenal gland, anxiety, comprehension problems, coughing, muscle pain, weight gain, **depression**, sinus problems, or abnormal vision.

Myelosuppression is experienced by 4% to 19% of patients. **Neutropenia** and **thrombocytopenia** are the most common forms, and the more severe cases of both are higher in women and in the elderly (patients older than age 70) than in men. When myelosuppression occurs, it usually appears late in the first few treatment cycles and does not worsen over time. On average, blood count levels return to normal 14 days after the lowest blood count is recorded.

Coping with side effects may require making some lifestyle changes or, in some cases, taking medication. For example, to treat constipation, patients may be told to increase the amount of fluid they drink, perform regular exercise, and eat more dietary fiber, while any infection will require medication. Treatment options for side effects should be discussed with a doctor.

KEY TERMS

Anaplasia—Characteristics of a cell, such as shape and orientation, that make it identifiable as a cancer cell.

Anaplastic astrocytoma—The advanced stage of a rapidly growing brain tumor. This type of tumor originates in the brain, unlike other brain tumors that may occur due to the spreading of cancer from another part of the body.

DNA (Deoxyribonucleic acid)—The genetic material found in each cell in the body that plays an important role in controlling many cell functions. When a cell divides to create two new cells, an identical copy of its DNA is found in each. If there is an error in a cell's DNA, division may not occur.

Drug clearance—The amount of a drug that is removed from the body through urination.

Interactions

Valproic acid, a drug used to treat seizures, decreases the clearance of temozolomide from the body by about 5%. No other negative drug interaction has been reported, although its interaction with many conventional and alternative drugs has yet to be studied.

Monica McGee, M.S.

Teniposide

Definition

Teniposide is a **chemotherapy** medicine used to treat cancer by destroying cancerous cells. Teniposide is also known as the brand name Vumon and may also be referred to as VM-26.

Purpose

Teniposide is approved by the Food and Drug Administration (FDA) as induction therapy (an initial, intensive course of chemotherapy) for refractory childhood acute lymphoblastic leukemia. Teniposide is used in combination with other chemotherapy drugs. It has also been used in some adult leukemias and lung cancers.

Description

Teniposide is a clear liquid for infusion into a vein. Teniposide is a semisynthetic derivative of podophyllotoxin found in extracts of the mandrake plant. It is a member of the group of chemotherapy drugs known as topoisomerase II inhibitors. Topoisomerase II is one of the enzymes involved in rearrangement of DNA structures, such as temporarily breaking DNA strands and resealing them. This process is necessary for cell replication, and topoisomerase II inhibitors interfere with this important process as it prevents the cells from further dividing and multiplying and the cells subsequently die.

Recommended dosage

A teniposide dose can be determined using a mathematical calculation that measures a person's body surface area (BSA). This number is dependent upon a patient's height and weight. The larger the person the greater the body surface area. Body surface area is measured in the units known as square meter (m^2). The body surface area is calculated and then multiplied by the drug dosage in milligrams per square meter (mg/m^2). This calculates the actual dose a patient is to receive.

To treat refractory childhood leukemia

Teniposide is dosed at 165 mg per square meter as an infusion into a vein over 30-60 minutes and is given with the chemotherapy drug **cytarabine** at a dose of 300 mg per square meter. This combination is given twice a week for eight to nine doses.

Other leukemia dosing includes teniposide 100 mg per square meter once or twice weekly, and teniposide 250 mg per square meter with the chemotherapy drug **vincristine** 1.5 mg per square meter given into a vein each week for four to eight weeks.

Patients with significant kidney and liver problems may need to receive a smaller dose of teniposide than patients with normal kidney and liver function.

Patiets with Down syndrome should receive a smaller dose with the initial treatment.

Precautions

Blood counts will be monitored regularly while on teniposide therapy. During a certain time period after receiving this drug, there is an increased risk of getting infections. Caution should be taken to avoid unnecessary exposure to germs. Patients with a known previous allergic reaction to chemotherapy drugs should tell their doctor before treatment. Patients who may be pregnant or trying to become pregnant should tell their doctor before

KEY TERMS

Anemia—Red blood cell count that is lower than normal.

Chemotherapy—Specific drugs used to treat cancer

Refractory cancer—Cancer that is not responding to treatment

DNA—Deoxyribonucleic acid, the genetic material inside cells that allows cells to function, separate, into two cells, and make more cells

Food and Drug Administration—A government agency that oversees public safety in relation to drugs and medical devices. The FDA gives the approval to pharmaceutical companies for commercial marketing of their products

Induction therapy—Initial intensive course of chemotherapy designed to wipe out abnormal cells and allow regrowth of normal cells.

Intravenous—Administered into the body through a vein.

Neutropenia—White blood cell count that is lower than normal.

receiving teniposide. Chemotherapy can cause men and women to be sterile (unable to have children). Patients should check with their doctors before receiving live virus **vaccines** while on chemotherapy.

Side effects

The most common side effect of teniposide is low blood counts, referred to as **myelosuppression**. When the white blood cell count is lower than normal, known as **neutropenia**, patients are at an increased risk of developing a **fever** and infections. Teniposide also causes the platelet count to fall. Platelets are blood cells in the body that allow for the formation of clots. When the platelet count is low patients are at an increased risk for bruising and bleeding. If the platelet count remains too low, a platelet blood transfusion is an option. Low red blood cell counts, referred to as **anemia**, may make patients feel tired, dizzy and lacking energy. A drug known as **erythropoietin** may be given to increase a patient's red blood cell count.

Teniposide infusions given too quickly into the vein can cause a significant drop in blood pressure. This can usually be avoided by administering the drug over a time period of at least 30-60 minutes. Teniposide can also cause mild to moderate **nausea and vomiting**. Patients will be given medicines known as **antiemetics** before receiving teniposide to help prevent or decrease this side effect. **Diarrhea**, loss of appetite (anorexia), and mouth sores and inflammation are also common. Rarely, allergic or anaphylactic-type reactions that include fever, sweating, tongue swelling, chest tightness, **itching**, shortness of breath, low blood pressure and increase heart rate, have occurred.

Other less common side effects caused by teniposide include rash, itching, hair loss (alopecia), liver and kidney problems, fatigue, seizures, tingling, fever, development of another type of cancer or leukemia due to taking the drug, and redness and pain at the site of injection into the vein. All side effects a patient experiences should be reported to their doctor.

Interactions

There is an increase risk of worsening some of the side effects of teniposide when it is administered with the medicines sodium salicylate, tolbutamide (a drug to lower blood sugar levels), or sulfamethizole (an antibiotic).

Nancy J. Beaulieu, R.Ph., B.C.O.P.

Testicular cancer

Definition

Testicular cancer is a disease in which cancer cells are discovered in one or both testicles. The testicles, also known as testes or gonads, are located in a pouch beneath the penis called the scrotum.

Description

The testicles make up one portion of the male reproductive system. Normally, they are each somewhat smaller than a golf ball in size and are contained within the scrotum. The testicles are a man's primary source of male hormones, particularly **testosterone**. They also produce sperm.

There are several types of cells contained in the testicles, and any of these may develop into one or more types of cancer. Over 90% of all testicular cancers begin in cells called germ cells. There are two main types of **germ cell tumors** in men: seminomas and nonseminomas. Seminomas make up about 40% of all testicular germ cell tumors. Nonseminomas make up a group of cancers, which include choriocarcinoma, yolk sac tumors, embryonal **carcinoma**, and teratoma.

Although testicular cancer accounts for less then 2% of all cancers in men, it is the most commonly seen cancer in young men aged 15 to 35. It is also one of the most curable.

Demographics

The American Cancer Society estimates that approximately 8, 980 new cases of testicular cancer will be diagnosed in American men in 2004. In addition, about 360 men will die of the disease during that year. Although the incidence of testicular cancer is rising, having doubled since 1975, it is still rare. Scandinavian countries have the highest rate in the world. Germany and New Zealand also have high rates. The lowest incidences of testicular cancer are in Asia and Africa.

Causes and symptoms

The exact causes of testicular cancer are unknown. However, there is research showing that some men are more likely to acquire it than others. The risk for testicular cancer is much higher for boys born with one or both of their testicles located in the lower abdomen rather than in the scrotum. This condition is called cryptorchidism or undescended testicles. The lifetime risk of getting testicular cancer is four times higher for boys with cryptorchidism than the risk in the general population. This risk factor remains even if surgery is done to place the testicle back into the scrotum.

Boys born with Down syndrome are also at higher risk of developing testicular cancer, although the reasons for this increased risk are not yet fully understood as of 2004.

There are other risk factors as well. Men who have had abnormal development of their testicles are at increased risk, as are men with Klinefelter's syndrome (a disorder of the sex chromosomes). A family history of testicular cancer increases the possibility of getting the disease. Men infected with the human immunodeficiency virus (HIV), especially those with AIDS, have a higher incidence, as do infertile men. Certain testicular tumors appear more frequently among men who work in certain occupations, like miners, oil workers, and utility workers. There is no conclusive evidence that injuries to the testicles, or environmental exposure to various chemicals causes the disease.

Testicular cancer usually shows no early symptoms. It is suspected when a mass or lump is felt in the testes, although a testicular mass does not always indicate cancer and is usually painless.

Symptoms of testicular cancer include:

- a lump in either testicle (usually pea-sized, but may be as large as a marble or an egg)
- any enlargement or significant shrinking of a testicle
- a sensation of heaviness in the scrotum
- a dull ache in the groin or lower abdomen
- any sudden collection of fluid in the scrotum
- tenderness or enlargement of the breasts
- pain or discomfort in a testicle or in the scrotum

Diagnosis

When a man exhibits symptoms that suggest a possibility of testicular cancer, several diagnostic steps will occur before a definitive diagnosis is made.

History and physical

The physician takes a personal and family medical history and a complete physical examination is performed. The doctor will examine the scrotum as well as the abdomen and other areas to check for additional masses.

Imaging studies

If a mass is found, the physician will likely have an ultrasound performed. Through the use of sound waves, ultrasounds can help visualize internal organs and may be useful in telling the difference between fluid-filled cysts and solid masses. If the tumor is solid, it is most likely cancerous.

Computed tomography as well as ultrasound may be used to diagnose malignant germ cell tumors in undescended testes.

Blood tests

Certain blood tests can be helpful in diagnosing some testicular tumors. **Tumor markers** are substances often found in higher-than-normal amounts in cancer patients. Some testicular cancers secrete high levels of certain proteins such as alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG), and enzymes like lactate dehydrogenase (LDH). These markers may help find a tumor that is too small to be felt during a physical examination. In addition, these tests are also helpful in determining how much cancer is actually present, and in evaluating the response to treatment to make sure the tumor has not returned.

Surgery

If a suspicious growth is found, a surgeon will need to remove the tumor and send it to the laboratory for

testing. A pathologist examines the testicular tissue microscopically to determine whether cancer cells are present. If cancer cells are found, the pathologist sends back a report describing the type and extent of the cancer. In almost all cases, the surgeon removes the entire affected testicle through an incision in the groin, though not through the scrotum. This procedure is called radical inguinal **orchiectomy**.

Once testicular cancer is determined, further tests are necessary to find out if the cancer has metastasized (spread) to other parts of the body, and to ascertain the stage or extent of the disease. This information helps the doctor plan appropriate treatment. These tests may include **computed tomography** (CT scan), **lymphangiography** (x rays of the lymph system), bone scans, and chest x rays.

Treatment team

From diagnosis through treatment and follow-up, several health care professionals participate in the care of the person with testicular cancer. Patients usually seek help from their primary physician after first noticing the lump or other suspicious symptom. A referral to the urologist will follow. The urologist usually performs any diagnostic tests as well as any necessary surgery. A pathologist makes the definitive cancer diagnosis by looking at the cells under a microscope. After the diagnosis is made, the patient will usually see a medical oncologist. If it is determined that **radiation therapy** is appropriate treatment, a visit to the radiation oncologist is recommended as well. Specially trained nurses will administer **chemotherapy** if necessary.

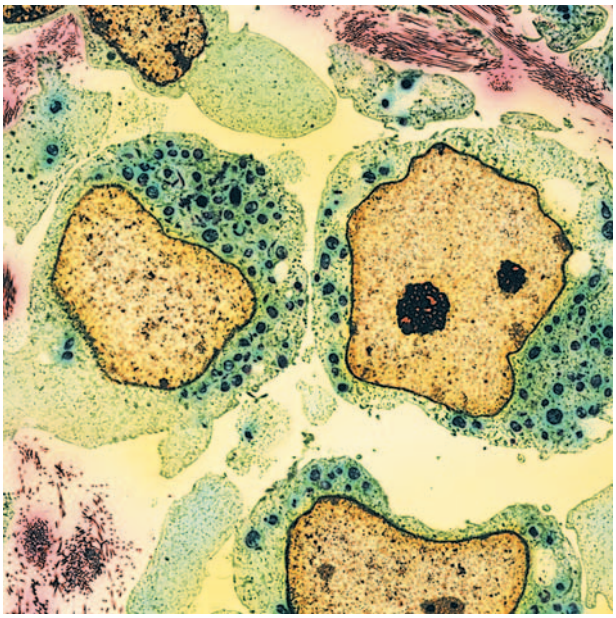
Clinical staging, treatments, and prognosis

Staging

One method the cancer treatment team uses to describe the scope of a patient's cancer is the use of a staging system. Testicular cancer is classified using the TNM system. However, in order to simplify and summarize this information, the TNM description can be grouped according to stages.

Stages of testicular cancer:

- Stage I. This stage refers to a cancer found only in the testicle, with no spread to the lymph nodes or to distant organs.
- Stage II. This indicates that the cancer has spread to the lymph nodes in the abdomen, but not to lymph nodes in other parts of the body.
- Stage III. In this stage, the cancer has spread beyond the lymph nodes in the abdomen, and/or the cancer is in parts of the body far away from the testicles, such as the lungs or the liver.
- Recurrent. Recurrent disease indicates that the cancer has come back after it has already been treated. Testicular cancer can come back in the same testicle (if it was not surgically removed) or in some other body part.



Colored transmission electron micrograph (TEM) of a section through teratoma cancer cells in a testis. Three rapidly dividing cells are seen at center left, center right, and lower right. They have large, irregular nuclei (pale brown) and green cytoplasm. *(Copyright Quest, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

Treatment

The treatment decisions for testicular cancer are dependent on the stage and cell type of the disease, as well as the patient's age and overall health. The four kinds of treatment most commonly used are surgery, radiation therapy, chemotherapy, and bone marrow or stem cell transplantation.

Surgery is normally the first line of treatment for testicular cancer and involves the removal of the affected testicle. This procedure is known as a radical inguinal orchiectomy. Depending on the type and stage of the cancer, some lymph nodes may also be removed at the same time, or possibly in a second operation. This procedure is called a retroperitoneal **lymph node dissection**, and can be a major operation. Some patients will experience temporary complications after surgery, including infections and bowel obstruction. If both of the testicles are taken out, a man will have no ability to

produce sperm cells and will become infertile (unable to father a child). Surgery removing the lymph nodes may cause some damage to nearby nerves, which may interfere with the ability to ejaculate. Men undergoing surgery for testicular cancer may wish to discuss nerve-sparing surgery with their doctor, as well as sperm banking.

Radiation therapy for testicular cancer is delivered from a machine and is known as external beam radiation. One potential problem with this type of radiation is that it can also destroy nearby healthy tissue as well as cancer cells. Other potential side effects include nausea, **diarrhea** and **fatigue**. A special device can be used to protect the unaffected testicle to preserve fertility.

Chemotherapy refers to the use of drugs in treating cancer. Since the drugs enter the bloodstream and circulate throughout the body, chemotherapy is considered a systemic treatment. The drugs primarily used in the treatment of testicular cancer are **cisplatin**, **vinblastine**, **bleomycin**, **cyclophosphamide**, **etoposide**, and **ifosfamide**. These drugs are given in various combinations, since the use of two or more drugs is considered more effective than using only one drug.

Since chemotherapy agents can affect normal as well as cancerous cells, several side effects are possible. These side effects include:

- **nausea and vomiting**
- changes in appetite (anorexia)
- temporary hair loss (alopecia)
- mouth sores
- increased risk of infections
- bleeding or bruising
- fatigue
- diarrhea or constipation

Several drugs are available to assist in treating these side effects, most of which will disappear after the treatment is completed. However, some of the chemotherapy agents used during treatment of testicular cancer may cause long-term side effects. These include hearing loss, nerve damage, and possible kidney or lung damage. Another potentially serious long-term complication is an increased risk of leukemia. This is a rare side effect, however, as it occurs in less than 1% of testicular cancer patients who receive chemotherapy. Chemotherapy may also interfere with sperm production. This may be permanent for some, but many will regain their fertility within a few years.

Studies are ongoing to determine whether high doses of chemotherapy combined with stem-cell transplantation will prove effective in treating some patients with advanced testicular cancer. In this treatment, blood-forming cells called stem cells are taken from the patient (either from the bone marrow or filtered out of the patient's blood). These cells are kept frozen while high-dose chemotherapy is administered. After receiving the chemotherapy, the patient is given the stem cells through an infusion. This treatment enables the use of extra large doses of chemotherapy that might increase the cure rate for some testicular cancers.

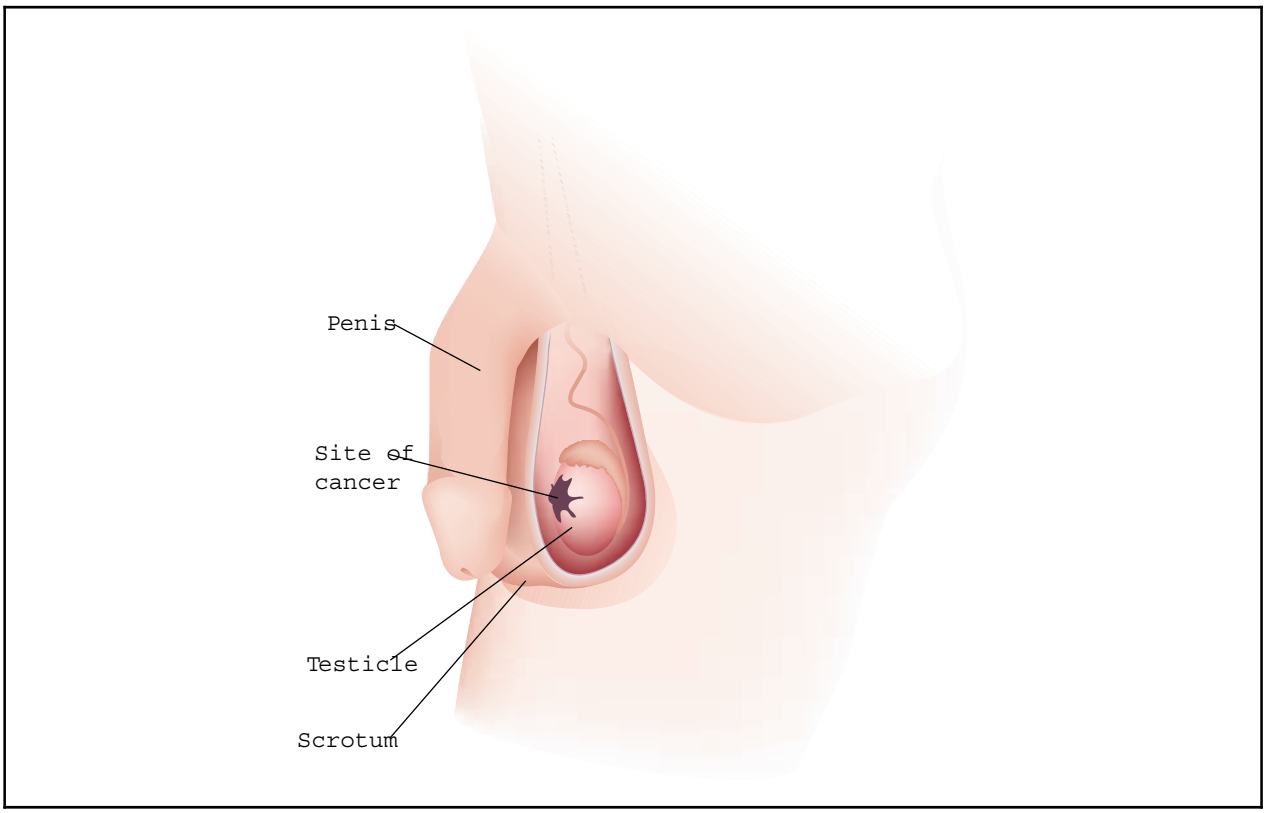
Preferred treatment plans by stage of disease

Stage I: Stage I seminomas are normally treated with a radical inguinal orchiectomy followed by radiation treatment aimed at the lymph nodes. More than 95% of Stage I seminomas are cured through this method. Another approach is to perform surgery only. Patients are then followed closely for several years with blood tests and **imaging studies**. If the cancer spreads later on, radiation or chemotherapy can still be used. Stage I non-seminomas are also highly curable with surgery, followed by one of three options. These options include the performance of a retroperitoneal lymph node dissection, two cycles of chemotherapy, or careful observation for several years.

Stage II: Stage II seminomas and non-seminomas are cured in 90% to 95% of the cases. For the purposes of treatment, stage II testicular cancers are classified as either bulky or nonbulky. Nonbulky seminomas (no lymph nodes can be felt in the abdomen) are treated with an orchiectomy followed by radiation to the lymph nodes. Men with bulky seminomas have surgery, which may be followed by either radiation or a course of



A cancerous growth on the testicle. *(Illustration by Argosy Publishing Inc. Reproduced by permission of The Gale Group.)*

chemotherapy. Nonbulky Stage II non-seminomas are treated with surgery and lymph node removal, with possible chemotherapy. Men with bulky disease have surgery followed by chemotherapy.

Stage III: Stage III seminomas and non-seminomas are treated with surgery followed by chemotherapy. This produces a cure in about 70% of the cases. Those who are not cured may be eligible to participate in **clinical trials** of other chemotherapy agents.

Recurrent: Treatment of recurrent testicular cancer is dependent upon the initial stage and the treatment given. This might include further surgery and chemotherapy. Many men whose disease comes back after chemotherapy are treated with high-dose chemotherapy followed by bone marrow or stem cell transplantation.

Alternative and complementary therapies

There are currently no scientifically proven alternative treatments known for testicular cancer. Nothing has been shown to be as successful as conventional treatment. However, some patients may find certain alternative or complementary treatments supportive while undergoing surgery, chemotherapy or radiation. For example, meditation and relaxation exercises may prove effective in reducing nausea and vomiting. Some dietary modifications and nutritional supplements may be helpful in assisting with recovery after surgery. The testicular cancer patient considering alternative treatments should talk it over with members of the cancer care team. They may be able to offer additional information.

Coping with cancer treatment

Coping with the effects of cancer treatment can often prove challenging. One of the most common effects of treatment is fatigue. The man going through treatment for testicular cancer should allow time for recovery, and not rush back to normal activities. Eating a balanced diet of healthy foods may be helpful as well. Enlisting friends and family members to aid with transportation and responsibilities at home is another way of coping. Most of the side effects of treatment for testicular cancer can be alleviated. In addition, many men experience some levels of anxiety and/or **depression** during diagnosis and treatment. These can also be treated through medication and/or counseling.

KEY TERMS

Cryptorchidism—A condition that occurs when a boy is born with one or both testicles in the lower abdomen rather than the scrotum. Known also as undescended testicles, it is the primary risk factor for testicular cancer.

Metastatic testicular cancer—Testicular cancer that has spread to other parts of the body.

Radical inguinal orchiectomy—Surgical procedure performed to remove one or both testicles. It is done via a groin incision.

Testicles—Also called testes or gonads, they are part of the male reproductive system, and are located beneath the penis in the scrotum.

QUESTIONS TO ASK THE DOCTOR

- How do I perform a testicular self examination?
- What kind of testicular cancer do I have?
- What treatment choices do I have?
- What side effects can I expect from my treatment?
- How long will it take me to recover?
- What are the chances that the cancer will come back?
- Is there a chance I will become infertile?

Clinical trials

Important research into testicular cancer is ongoing at many medical institutions around the country. Scientists are examining the changes that occur to the DNA of testicular cancer cells, in order to improve their understanding of the causes of the disease, and to find more effective treatments. Clinical trials are a method for doctors to explore new treatment options. For example, stem cell transplantation is being studied as one way to help men with recurrent cancer or a poor prognosis. Various chemotherapy regimens are being tested to find out if changing doses or specific drugs might reduce the incidence of side effects without reducing the effectiveness of treatment. For information on specific clinical trials, patients may ask the cancer care team or get a list of current clinical trials from the National Cancer Institute (see Resources.)

Prevention

The main risk factors associated with testicular cancer—cryptorchidism, family history of the disease, and being Caucasian—are unavoidable since they are present at birth. In addition, many men diagnosed with the disease have no known risk factors. Because of these reasons, it is not possible to prevent most incidences of testicular cancer.

Special concerns

For many men, testicles are symbolic of manhood, and the removal of one can lead to embarrassment, or fear about a partner's reaction. Indeed, after surgical removal, the affected side of the scrotum does look and feel empty. To correct this, a patient can have a testicular prosthesis implanted in his scrotum. This prosthesis looks and feels like a real testicle, and the surgical procedure usually leaves only a small scar.

As of 2004, there is growing evidence that men treated with cisplatin for testicular cancer are at increased risk of coronary artery disease ten years or longer after treatment. In addition, men who have had an orchiectomy followed by external beam radiation therapy have a significantly increased risk of dying from heart disease or a second cancer.

Testicular self-exam

Definition

A testicular self-examination (TSE) is the procedure by which a man checks the appearance and consistency of his testes.

Purpose

Most testicular cancers are first noticed by the man himself, many times after a blow or other injury to the scrotum. Men should perform a TSE every month to find out if the testes contain any suspicious lumps or other irregularities, which could be signs of cancer or infection.

It is particularly important for adult male survivors of childhood cancers to perform TSE on a regular basis. A group of researchers at the University of Minnesota reported in 2004 that only 17% of male survivors of childhood cancer examine their own testes as a form of cancer screening. The researchers urged primary care physicians to teach cancer survivors about the importance of regular self-examination in adult life.

Precautions

None.

Description

A TSE should take place during a warm shower or bath, when the skin is warm, wet, and soapy. The man needs to step out of the tub so that he is in front of a mirror. The heat from the tub or shower will relax the scrotum (sac containing the testes) and the skin will be softer and thinner, making it easier to feel a lump. It is important that the exam be done very gently.

The man should stand facing his mirror and look for swelling on the scrotum. Using both hands, the scrotum should be gently lifted so that the area underneath can be checked.

The next step is the exam by hand. The index and middle fingers should be placed under each testicle, with the thumbs on top. The testes should be examined one at a time. The man should roll each testicle between his fingers and thumbs. He should feel for lumps of any size (even as small as a pea) particularly on the front or side of each testicle. He should also look for soreness or irregularities. Next, the epididymis and vas deferens, located on the top and back of the testes, should be felt. This area feels like a cord, and should not be tender.

KEY TERMS

Epididymis—A tube in the back of the testes which transports sperm.

Scrotum—The pouch containing the testes.

Testes (singular, testis)—Egg-shaped male gonads located in the scrotum. Testes is the plural form of testis, which is a testicle.

Vas deferens (plural, vasa deferentia)—A tube that is a continuation of the epididymis. This tube transports sperm from the testis to the prostatic urethra.

Normal results

It is normal for one testicle to be larger than the other, and for them to hang at different levels; but the size should stay the same from one month to the next. The testes should be free from lumps, pain, irregularities and swelling.

Abnormal results

A TSE is considered abnormal if any swelling, tenderness, lumps, or irregularities are found. Hard, unmoving lumps are abnormal, even if they are painless. A lump could be a sign of an infection or a cancerous tumor. A change in testicle size from one month to the next is also abnormal. A feeling of heaviness in the scrotum is another abnormal sign. If any abnormality is found, a man is encouraged to check with his doctor as soon as possible because **testicular cancer** is highly curable if found early.

QUESTIONS TO ASK THE DOCTOR

- How long should a testicular self-examination take?
- What should be done if the presence of a lump is uncertain during a TSE?
- What action should be taken if a lump or abnormality is definitely found during TSE?
- What medical tests are done to confirm testicular cancer?
- How often is a testicular examination performed as part of a physical examination?
- What are the other signs of testicular cancer?

Testolactone

Definition

Testolactone is a synthetic drug related to the male hormone **testosterone**. It is used to reduce the size of tumors in some women with advanced **breast cancer**. Testolactone is available in the U.S. under the brand name Teslac.

Purpose

Testolactone is used in treating advanced breast cancer in postmenopausal women and in women who have had their ovaries removed. It is never used in treating breast cancer in men.

Description

Testolactone is approved by the United States Food and Drug Administration (FDA), and its cost usually is covered by insurance. It is classified as an antineoplastic agent, which means that it stops or slows the growth of malignant cells. One advantage of testolactone is that, although it is related to testosterone, it does not cause women to develop male characteristics such as a deep voice or facial hair.

As noted above, testolactone is related to the male hormone testosterone. The way in which it inhibits the growth of breast cancer cells is not clear. However, it is known that the hormone estrogen stimulates the growth of some breast cancer cells, and testolactone seems to interfere with estrogen production. The resulting reduction in estrogen levels may slow the growth of breast cancers sensitive to this hormone.

In breast cancer, testolactone is a palliative treatment. This means that it helps relieve symptoms, but does not cure the cancer. It is effective only in about 15% of the women who take it. In these women, however, it helps reduce the size of half or more tumors. Normally testolactone is used along with other **chemotherapy** drugs for fighting advanced breast cancer.

Recommended dosage

Testolactone comes as a 50 mg tablet. The dose will depend on the patient's body weight and her general health, as well as other drugs she may be taking. However, a standard dose is 250 mg (5 tablets) four times a day for three months. It takes at least several weeks before the drug begins to be effective. Tablets should be stored at room temperature.

Precautions

People with a history of heart or kidney disease should be sure to tell their doctor, as this may affect their use of testolactone.

Side effects

Testolactone often causes nausea, vomiting, and loss of appetite (anorexia). Because testolactone must

KEY TERMS

Malignant—Cancerous. Malignant cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Ovaries—A pair of female reproductive organs that release eggs. They are the main source of the female hormone estrogen.

Postmenopausal—Older women who no longer menstruate because of their age.

Testosterone—The main male hormone. It is produced in the testes and is responsible for the development of primary and secondary male sexual traits.

be taken over many months to be effective, people who experience these symptoms should talk to their doctor about medications to relieve the **nausea and vomiting** so that they can continue to take testolactone.

Other side effects reported with testolactone include numbness or tingling in the toes, fingers, and face, **diarrhea**, swelling and water retention in the feet and legs, and swelling of the tongue, hair loss (alopecia), and abnormal nail growth. However, since women who take this drug are receiving other chemotherapy drugs and are in an advanced stage of cancer, it is difficult to pinpoint whether testolactone is exclusively responsible for some of these side effects.

Interactions

Many drugs interact with nonprescription (over-the-counter) drugs and herbal remedies. Patients should always tell their health care providers about these remedies, as well as any prescription drugs they are taking. Patients should also mention if they are on a special diet such as low salt or high protein. They should not take calcium supplements, since testosterone already has the potential to increase circulating calcium to dangerous levels.

Testolactone may increase the effect of anticoagulants (blood thinning medication). In women where cancer has spread to the bones, testolactone may increase the circulating level of calcium in the body. Calcium levels need to be tested regularly.

Tish Davidson, A.M.

Testosterone

Definition

Synthetic derivatives of the natural hormone testosterone are used to reduce the size of hormone-responsive tumors.

Purpose

Testosterone-related drugs are used to treat advanced disseminated **breast cancer** in women.

Description

Testosterone belongs to a class of hormones called androgens. These are male hormones responsible for the development of the male reproductive system and secondary male sexual characteristics such as voice depth and facial hair. Testosterone is normally produced by the testes in large quantities in men. It also occurs normally in smaller quantities in women.

Several man-made derivatives of testosterone are used to treat advanced disseminated breast cancer in women, especially when cancer has spread to the bones. The most common of these testosterone-like drugs are **fluoxymesterone** (Halotestin) and methyltestosterone (Testred). These androgens are used only in women who have late-stage breast cancer and who meet specific criteria. These criteria include:

- The patient is postmenopausal.
- The tumors have been shown to be hormone-dependent.
- The tumors have spread, often to the bone, or recurred after other hormonal cancer treatments.

Using testosterone derivatives to treat breast cancer is a palliative treatment. This means that the treatment helps relieve symptoms but does not cure the cancer. These drugs are approved by the United States Food and Drug Administration (FDA), and their cost is usually covered by insurance.

Clinical trials are currently underway that involve the use of testosterone-related androgens in varying combinations with other drugs to treat advanced cancers. The selection of clinical trials changes constantly. Current information on the availability and location of clinical trials can be found at the following web sites:

- National Cancer Institute. (800) 4-CANCER or <http://cancertrials.nci.nih.gov>.
- National Institutes of Health Clinical Trials. <http://clinicaltrials.gov>.

KEY TERMS

Hormone—A chemical produced by a gland in one part of the body that travels through the circulatory system and affects only specific receptive tissues at another location in the body.

Postmenopausal—Women have stopped menstruating, usually because of their age.

Testes—Egg-shaped male sexual organs contained in the scrotum that produce testosterone and sperm.

- Center Watch: A Clinical Trials Listing. <http://www.centerwatch.com>.

Recommended dosage

Dosage is individualized and depends on the patient's body weight and general health, as well as the other drugs she is taking and the way her cancer responds to hormones. Halotestin comes in tablets of 2 mg, 5 mg, or 10 mg. A standard dose of Halotestin for inoperable breast cancer is 10 to 40 mg in divided doses daily for several months. Tablets should be stored at room temperature. Testred comes in 10 mg capsules. A standard dose for women with advanced breast cancer is 50 to 200 mg daily.

Precautions

Women who take testosterone derivatives for advanced breast cancer are postmenopausal, so the usual precautions about avoiding pregnancy when receiving androgen therapy do not apply.

Side effects

The most serious side effect of these drugs is **hypercalcemia**, a condition in which too much calcium circulates in the blood. This occurs because these drugs liberate calcium from bones. Calcium levels are monitored regularly, and the drug is discontinued if hypercalcemia occurs. Another serious (but less common) side effect is the development of tumors in the liver. Other side effects include deepening of the voice, development of facial hair and acne, fluid retention, and nausea.

Interactions

As with any course of treatment, patients should alert their physician to any prescription, over-the-counter, or herbal remedies they are taking in order to avoid harmful drug interactions. Patients should also mention if they are on a special diet, such as low salt or high protein. They should not take calcium supplements, since testosterone already has the potential to increase circulating calcium to dangerous levels.

Testosterone derivatives may interact with anticoagulant drugs (blood thinners) such as Coumadin.

Tish Davidson, A.M.

Tetrahydrocannabinol

Definition

Tetrahydrocannabinol (THC) is the main psychoactive substance found in the hemp plant *Cannabis sativa*, or marijuana.

Purpose

A number of studies indicate medical benefits of THC for cancer and AIDS patients by increasing appetite and decreasing nausea, blocking the spread of some cancer-causing **herpes simplex** viruses. It has been shown to assist some glaucoma patients by reducing pressure within the eye, and is used, in the form of cannabis, by a number of multiple sclerosis patients for relieving spasms. Effects include relaxation; euphoria; altered space-time perception; enhancement of visual, auditory, and olfactory senses; disorientation; and appetite stimulation. Synthetic THC, also known under the substance name *dronabinol*, is available as a prescription drug under the trade name Marinol in several countries including the United States, Netherlands, and Germany.

Description

The issue of medical uses of THC is politicized in the United States because of its status as a Schedule I drug under the U.S. Controlled Substances Act of 1970. Schedule I drugs are defined as those considered to have high potential for abuse, with no recognized medical use in treatment in the United States. In this drug's case, its recreational use is distinguished from its medical use. Marijuana is Schedule I, but tetrahydrocannabinol (THC, Marinol) is Schedule II.

There have been major advances in THC pharmacology and in understanding of the cancer disease process. In particular, research has demonstrated the

presence of numerous cannabinoid (chemical constituents of marijuana) receptors in the nucleus of the solitary tract, a brain center that is important in the control of vomiting. While other anti-vomiting drugs are equally or more effective than oral THC, Marinol, or smoked cannabis, for certain individuals unresponsive to conventional anti-emetic drugs, the use of smoked cannabis can provide relief more effectively than oral preparations which may be difficult to swallow or be expelled in vomit before having a chance to take effect. The euphoria effect of THC or smoked cannabis improves mood, whereas several conventional tranquilizers, also used in the treatment of psychoses such as schizophrenia, may produce unwanted side effects such as excessive sedation, flattening of mood, and distressing physical symptoms such as uncontrolled or compulsive movements.

There would appear to be growing evidence of direct anti-tumor activity of cannabinoids, specifically CB1 and CB2 agonists, in a range of cancer types, including brain (gliomas), skin, pituitary, prostate, and bowel. The anti-tumor activity has led in laboratory animals and in-vitro human tissues to regression of tumors, reductions in vascularisation (blood supply) and metastases (secondary tumors), as well as direct inducement of death among cancer cells. Indeed, the complex interactions of cannabinoids and receptors contribute to scientific understanding of the mechanisms by which cancers develop. However, smoking of cannabis releases a number of non-cannabinoid carcinogens into the lungs and upper respiratory tract, and a number of researchers have identified pre-cancerous changes in lung cells. The failure of these researchers to discover significant evidence of actual cancer cells in the lung may be attributed to these anti-cancer activities of cannabinoids, including THC, counteracting the effects of other carcinogens in smoked cannabis. Some researchers have investigated the link between mental and spiritual state and cancer remission, associating the cannabinoid system with the expression of pleasure on the one hand and stress on the other.

Recommended dosage

The average dose of Marinol is 5–20 mg daily. Most patients respond to 5 mg three or four times daily. Dosage may be escalated during a **chemotherapy** cycle or at subsequent cycles, based upon initial results. Therapy should be initiated at the lowest recommended dosage and increased based on clinical response. Marinol is a small soft gel and is available in three strengths: 2.5, 5, and 10 mg. The pediatric dosage for the treatment of chemotherapy-induced emesis is the same as in adults. Caution is recommended in prescribing Marinol for children because of the psychoactive effects.

KEY TERMS

Cannabinoid—Chemical constituents of marijuana, such as THC.

Carcinogens—Cancer-causing agents.

Chemotherapy—The use of chemical agents to treat diseases, especially cancer.

Glaucoma—An eye disorder marked by abnormally high pressure within the eyeball.

Herpes simplex—Either of two viral diseases marked by clusters of small watery blisters, one affecting the area of the mouth and lips and the other the genitals.

Multiple sclerosis—A serious progressive disease of the central nervous system.

Precautions

THC and Marinol should be carefully evaluated in patients with the following medical conditions because of individual variation in response and tolerance to the effects of the drugs: patients with cardiac disorders; patients with a history of **substance abuse**, including alcohol abuse or dependence; mania (a psychiatric disorder characterized by excessive physical activity, rapidly changing ideas, and impulsive behavior); **depression**; or schizophrenia. Marinol and THC should be used with caution in patients receiving sedatives, hypnotics, or other psychoactive drugs because of the potential for additive or synergistic effects on the central nervous system. Marinol should be used with caution in pregnant patients, nursing mothers, or pediatric patients because it has not been studied in these populations.

Side effects

Some negative effects are associated with constant, long-term use, including memory loss, depression, and loss of motivation. The long-term effects of THC on humans is highly disputed.

Interactions

No clinically significant drug-to-drug interactions were discovered in Marinol **clinical trials**.

Ken R. Wells

Thalidomide

Definition

Thalidomide, which is also known as Thalomid, is a drug used to fight aggressive cancers, particularly those that have metastasized, or spread.

Purpose

There are many studies, either in progress or recently completed, that suggest thalidomide can slow or stop the spread of cancer of the brain, breast, colon, and prostate, as well as **multiple myeloma** (a cancer of the bone marrow). Research studies that consider the benefit of thalidomide in treating other cancers are multiplying rapidly. The use of the drug in cancer therapy is likely to increase.

Description

Thalidomide was first introduced in 1957 primarily as a tranquilizer, a medication prescribed particularly for imparting drowsiness and sleep. Then, it was given to pregnant women to provide them with relief from morning sickness. Soon after being prescribed to pregnant women, thalidomide was linked to death or severe disabilities in newborns. Some children who had been exposed to thalidomide while in the womb (in utero) failed to develop limbs or had very short limbs. Others were born blind or deaf or with other physical problems.

The same action of thalidomide that harms babies may make it useful as a powerful cancer fighter. Thalidomide interferes with the formation of blood vessels. It is called an antiangiogenic drug because angiogenesis refers to the formation of blood vessels. Studies in 2003 reported that thalidomide may use signal repression or have immunosuppression capabilities. This means it can act on the body's natural immune responses.

Cancers that spread have a lot of blood vessels (are highly vascularized). Thus, when cancer cells are not nourished by a blood supply, they die. One way to stop the spread of cancer is to stop the formation of the blood vessels that carry nourishment to the cancer cells, and that is what thalidomide is thought to do. Researchers also are interested in other activities of thalidomide, particularly the ones that make it capable of eliminating skin eruptions, such as sores, or ulcers, in the mouths of patients with AIDS and leprosy.

Recommended dosage

Dosages being used depend on the type of cancer being attacked. For example, in one study, to treat multiple myeloma, a starting dose of 200 mg per day was increased to 800 mg per day over a two-week period.

In a **colon cancer** study, 400 mg per day of thalidomide were given in combination with the anticancer drug **irinotecan**. The dose of irinotecan was between 300 and 350 mg per day. Used in combination with irinotecan, thalidomide contributed its own cancer-fighting properties and it also seemed to reduce the side effects of irinotecan.

In a trial using thalidomide to treat **prostate cancer**, both low doses (as low as 200 mg per day) and high doses (as high as 1200 mg per day) were tried. The patients taking high doses fared somewhat better.

KEY TERMS

Angiogenesis—The process by which tumors gain access to a blood supply, allowing tumor growth.

Fetus—Human embryo.

Kilogram—Metric measure that equals 2.2 pounds.

Milligram—One-thousandth of a gram; there are 1,000 grams in a kilogram. A gram is the metric measure that equals about 0.035 ounces.

Sedation—Process of reducing a particularly excited or agitated state.

Precautions

The serious threat thalidomide poses to fetuses cannot be overstated. No pregnant woman and no woman who has any chance of becoming pregnant should take thalidomide. (Only women who have had a hysterectomy or who are at the age of menopause and have been in a menopausal state, which is no menses, or periods, for 24 consecutive months, can be considered as having no chance of becoming pregnant.)

Patients taking thalidomide must meet strict criteria for use. Pharmacies that dispense thalidomide must have special registration.

Side effects

Besides the extreme risk thalidomide poses to fetuses, it also produces side effects in the person taking the drug. The side effects of thalidomide are much milder than many other anticancer drugs, and because the drug poses less discomfort than other cancer-fighting drugs, it is particularly attractive to oncologists, or physicians who treat cancer patients.

Among the side effects are erratic heartbeat, swelling (edema), digestive upsets of all sorts, including both constipation and **diarrhea**, pain in back and neck muscles, and skin problems.

Interactions

Barbiturates, salts, and esters used to encourage sleep, and alcohol increase the effect of thalidomide's power of sedation. They should not be taken with the drug. Food interferes with the absorption of thalidomide; it should be taken when the stomach is empty.

Resources

Teresa G. Odle

Thioguanine

Definition

Thioguanine is an anticancer (antineoplastic) agent belonging to the class of drugs called antimetabolites. It also acts as a suppressor of the immune system. It is available only in the generic form in the United States, or under the brand name Lanvis in Canada. Other common designations for thioguanine include 6-thioguanine (6-TG) and TG.

Purpose

Thioguanine is used to treat various forms of acute and nonlymphocytic leukemias. It is usually used in combination with other **chemotherapy** drugs, such as **cyclophosphamide**, **cytarabine**, prednisone, and/or **vincristine**.

Description

Thioguanine chemically interferes with the synthesis of genetic material of cancer cells. It acts as a false building block for DNA and RNA, which, when used to copy DNA and RNA, leads to cell death.

Recommended dosage

Thioguanine is administered orally. It is generally given once per day in a dosage of 2 mg per kg (2.2 pounds) of body weight. This dosage may be increased to 3 mg per kg if the patient does not respond to the medication within three weeks.

Precautions

Thioguanine can cause an allergic reaction in some people. Patients with a prior allergic reaction to thioguanine or **mercaptopurine** should not take thioguanine.

Thioguanine can cause serious birth defects if either the man or the woman is taking this drug at the time of conception or if the woman is taking this drug during pregnancy. Because thioguanine is easily passed from mother to child through breast milk, breast feeding is not recommended while thioguanine is being taken.

This drug suppresses the immune system and interferes with the normal functioning of certain organs and tissues. For these reasons, it is important that the prescribing physician is aware of any of the following pre-existing medical conditions:

- a current case of, or recent exposure to, chicken pox
- herpes zoster (shingles)
- a current case, or history of, gout or kidney stones
- all current infections
- kidney disease
- liver disease

Also, because thioguanine is such a potent immunosuppressant, patients receiving this drug must exercise extreme caution to avoid contracting any new infections, and should make an effort to:

- avoid any individual with any type of infection
- avoid bleeding injuries, including those caused by brushing or flossing the teeth
- avoid contact of the hands with the eyes or nasal passages
- avoid contact sports or any other activity that could cause a bruising or bleeding injury

Side effects

A common side effect of thioguanine use is **myelosuppression** with decreases in white blood cell and platelet counts. Other possible side effects include:

- increased susceptibility to infection
- nausea and vomiting

KEY TERMS

Antineoplastic—A drug that prevents the growth of a neoplasm by interfering with the maturation or proliferation of the cells of the neoplasm.

Neoplasm—New abnormal growth of tissue.

- diarrhea
- mouth sores
- skin rash, **itching**, or hives
- swelling in the feet or lower legs

A doctor should be consulted immediately if the patient experiences:

- black, tarry or bloody stools
- blood in the urine
- persistent cough
- fever and chills
- pain in the lower back or sides
- painful or difficult urination
- unusual bleeding or bruising

Interactions

Thioguanine should not be taken in combination with any prescription drug, over-the-counter drug, or herbal remedy without prior consultation with a physician. It is particularly important that the prescribing physician be aware of the use of any of the following drugs:

- antithyroid agents
- azathioprine
- chloramphenicol
- colchicine
- flucytosine
- interferon
- plicamycin
- probenecid
- sulfinpyrazone
- zidovudine
- any **radiation therapy** or chemotherapy medicines

See also Cancer genetics; Chemoprevention; DNA flow cytometry; Drug resistance.

Paul A. Johnson, Ed.M.

Thiotepa

Definition

Thiotepa is a **chemotherapy** drug used to reduce the size of a cancerous tumor and prevent the growth of new cancer cells. This drug is sometimes referred by the brand name Thioplex.

Purpose

Thiotepa has been used in the treatment of many types of tumors, but it is most often used as a treatment for the advanced stages of **breast cancer**, **ovarian cancer**, the middle and late stages of **bladder cancer**, and to control body cavity effusions, such as **pleural effusion** and **pericardial effusion**, that occur with some cancers. It is also sometimes used for the treatment of **Hodgkin's disease** and other lymph system cancers.

Description

Thiotepa was developed in the 1950s. It has been an approved cancer drug in the United States for over 20 years.

This drug is included in the cancer drug category termed **antineoplastic agents**, which slow or prevent the growth of cancerous tumors. Specifically, thiotepa is among a group of antineoplastic agents that were designed to alter the structure of the DNA in cells, causing a cell to die or to fail to replicate itself. These drugs do not distinguish between normal and cancerous cells and thus affect both equally.

Thiotepa is among several chemotherapy drugs being investigated for use in experimental high-dose chemotherapy, where a cancer patient is given a combination of several chemotherapy drugs at higher than normal dose levels. This treatment approach has been the focus of numerous **clinical trials**, most commonly for advanced breast cancer. One high-dose breast cancer chemotherapy treatment uses a combination of thiotepa, **cyclophosphamide**, and **carboplatin**. However, based on results from studies dating from 1999 to 2000, the effect of high-dose chemotherapy treatments, including those using thiotepa, have not conclusively improved the outcome or quality of life for breast cancer patients.

One approved chemotherapy treatment for advanced stages of breast cancer, where patients have not responded to other chemotherapy treatments or have experienced a relapse after a chemotherapy treatment, is a combination drug therapy of thiotepa, **doxorubicin**, and **vinblastine**. However, the results of this and other treatment options for late-stage breast cancer are not good. Treatment with a combination of chemotherapy

drugs results in approximately 10% to 20% of patients showing no signs of cancer, and the duration of this response is usually less than 12 months.

Thiopeta is about as equally effective as the other chemotherapy drugs recommended for treating bladder cancer, including **mitomycin-C**, doxorubicin, ethoglucid, or **epirubicin**. Research results suggest that these drugs may reduce the chance for cancer recurrence but has little effect on reducing the **metastasis** of the disease. After surgical removal of a tumor, thiotepa has been shown to reduce the size of the remaining tumor in 29% of bladder cancer patients.

Body cavity effusions are a known complication for the advanced stages of many cancers, including lung cancer and breast cancer. Fluid in the heart cavity, or pericardial effusion, can be managed with the use of a procedure called a **pericardiocentesis** and the injection of thiotepa into the cavity. This treatment has been shown to result in the absence of pericardial effusion in approximately 70% to 90% of all cancer patients for at least 30 days. In a 1998 study of 23 cancer patients with pericardial effusion, 83% responded to this treatment, and the condition did not worsen for about nine months.

Recommended dosage

Patients are usually given thiotepa intravenously (directly into the vein) either as a rapid injection or through an intravenous (IV) infusion (drip). It can also be administered as an injection into a muscle or into the fluid that surrounds the spinal cord. For the treatment of body cavity effusions, it is injected through a tube into the site where this condition occurs. In bladder cancer patients, it is instilled directly into the bladder.

Each dosage is calculated based on a patient's weight at the start of each treatment. The correct dosage is carefully matched and adjusted to an individual's overall condition and response to the treatment. There is a range of doses for each method used to administer the drug, and the initial dose is usually the higher value in the range. How well the patient tolerates the treatment and the effectiveness of the dosage in treating the cancer will determine the final dosage on which the patient is maintained for the duration of the therapy.

When given intravenously, such as for breast or ovarian cancer, the initial dose is 0.4 milligram per kilogram (mg/kg) of body weight. Once the best dose for an individual patient is determined, it is given every one to four weeks.

For bladder cancer patients, an initial treatment of 60 mg of thiotepa that has been dissolved in 60 milliliters (ml) of sodium chloride is instilled directly into the bladder. If a patient has difficulty retaining this volume for two hours, the dose is reduced to 30 ml. The typical treatment cycle is once a week over a four-week period.

The dosage of thiotepa for the treatment of effusion ranges from 0.6 to 0.8 mg/kg. The dosage and duration of treatment varies with the specific site of the condition, and can be as frequent as one to two times per week.

Because **myelosuppression** is a common reaction to this drug treatment, white blood cell and platelet counts are carefully monitored, usually weekly during the treatment and for three weeks after. This condition may limit the dose level that a patient can tolerate. If blood counts are below a certain level, treatment is either postponed or the dosage is decreased in the next treatment cycle.

Precautions

As with many chemotherapy drugs, **vaccines** should not be given to patients taking thiotepa, and patients should avoid contact with people who have recently taken the oral polio vaccine. Myelosuppression can increase the chance for infection and bleeding. Contact with people who have an infection should be avoided. To decrease the chance for bleeding, aspirin or aspirin-containing medicines should not be taken. High doses of thiotepa can lead to severe cases of myelosuppression and may increase a patient's chance for a later occurrence of leukemia.

Side effects

Myelosuppression, usually **neutropenia** (decrease of the infection-fighting white cells) or **thrombocytopenia** (decrease of the platelets responsible for blood clotting), is common and usually occurs one to three weeks after each treatment, but may last throughout the therapy. **Nausea and vomiting** are uncommon and are most likely to occur six to twelve hours after the drug is given. Dizziness or a mild headache can occur within the first few hours after a treatment. **Anorexia**, **stomatitis**, **diarrhea**, infertility, **fever**, and **alopecia** are uncommon. Severe myelosuppression, stomatitis, **memory change**, and problems with thinking or speaking may result from high dose treatments. Side effects for bladder cancer treatment can include pain when urinating, blood in the urine, or inflammation of the bladder.

Coping with side effects may require making some life-style changes or in some cases, such as nausea, taking medication. Treatment options for side effects should be discussed with a doctor.

According to reports, Thiotepa conditioning regimen in patients with advanced hematologic neoplasms is associated with renal and hepatic toxicity. Relapse of hematologic malignancies after allogeneic stem cell

KEY TERMS

DNA (Deoxyribonucleic acid)—The genetic material found in each cell in the body that plays an important role in controlling many of the cell's functions. When a cell divides to create two new cells, an identical copy of its DNA is found in each. If there is an error in a cell's DNA, division may not occur.

Effusion—The collection of fluid in a body cavity or tissue due to the rupture of a blood or other body vessel, resulting from type of trauma, cancer, or other condition.

Lymph system—This system is involved in preventing bacteria and other infection-causing particles from entering into the bloodstream. It is made up of small organs called lymph nodes, which make and store infection-fighting cells, and thin tubes, or vessels, that branch into all parts of the body.

Myelosuppression— The suppression of bone marrow activity, resulting in reduction in the number of platelets, red cells, and white cells found in the circulation.

transplantation remains a common problem, in particular for patients who have advanced disease at the time of transplantation. Researchers concluded that this regimen requires modification to reduce toxicity.

Interactions

Thiotepa combined with nitrogen mustard chemotherapy drugs such as cyclophosphamide or combined with **radiation therapy** does not improve the response to this treatment and can intensify some side effects, such as myelosuppression and infertility.

Thoracentesis

Definition

Also known as pleural fluid analysis, thoracentesis is a procedure that removes an abnormal accumulation of fluid or air from the chest through a needle or tube.

Purpose

Thoracentesis can be performed as a diagnostic or treatment procedure. For diagnosis, only a small amount of fluid is removed for analysis. For treatment, larger amounts of air or fluid are removed to relieve symptoms.

The lungs are lined on the outside with two thin layers of tissue called pleura. The space between these two layers is called the pleural space. Normally, there is only a small amount of lubricating fluid in this space. Liquid and/or air accumulates in this space between the lungs and the ribs from many conditions. The liquid is called a **pleural effusion**; the air is called a pneumothorax. Most pleural effusions are complications emanating from metastatic malignancy, or the movement of cancer cells from one part of the body to another; these are known as malignant pleural effusions. Other causes include trauma, infection, congestive heart failure, liver disease, and renal disease. Most malignant pleural effusions are detected and controlled by thoracentesis.

Symptoms of a pleural effusion include shortness of breath, chest pain, **fever**, **weight loss**, cough, and edema. Removal of air is often an emergency procedure to prevent suffocation from pressure on the lungs. Negative air pressure within the chest cavity allows normal respiration. The accumulation of air or fluid within the pleural space can eliminate these normal conditions and disrupt breathing and the movement of air within the chest cavity. Fluid removal is performed to reduce the pressure in the pleural space and to analyze the liquid.

Thoracentesis often provides immediate abatement of symptoms. However, fluid often begins to re-accumulate. A majority of patients will ultimately require additional therapy beyond a simple thoracentesis procedure.

Precautions

Thoracentesis should never be performed by inserting the needle through an area with an infection. An alternative site needs to be found in these cases. Before undergoing this procedure, a patient must make their doctor aware of any allergies, bleeding problems or use of anticoagulants, pregnancy, or possibility of pregnancy.

Description

Prior to thoracentesis, the location of the fluid is pinpointed through **x ray**, **computed tomography** (CT) scan, or ultrasound. Ultrasound and CT are more accurate methods when the effusion is small or walled off in a pocket (loculated). A sedative may be administered in some cases but is generally not recommended. Oxygen may be given to the patient.

KEY TERMS

Axilla—Armpit.

Catheter—A tube that is moved through the body for removing or injecting fluids into body cavities.

Hypovolemic shock—Shock caused by a lack of circulating blood.

Osmotic pressure—The pressure in a liquid exerted by chemicals dissolved in it. It forces a balancing of water in proportion to the amount of dissolved chemicals in two compartments separated by a semi-permeable membrane.

Pleura—Two thin layers lining the lungs on the outside.

QUESTIONS TO ASK THE DOCTOR

- How will thoracentesis benefit me?
- Will I have to have this procedure more than once?
- How soon after this procedure can I resume my normal activities?
- Will this procedure cure my problem?
- Will I require hospitalization?

The usual place to tap the chest is below the armpit (axilla) or in the back. Under sterile conditions and local anesthesia, a needle, a through-the-needle-catheter, or an over-the-needle catheter may be used to perform the procedure. Overall, the catheter techniques may be safer. Once fluid is withdrawn, it is sent to the laboratory for analysis. If the air or fluid continue to accumulate, a tube is left in place and attached to a one-way system so that it can drain without sucking air into the chest.

Preparation

Patients should check with their doctor about continuing or discontinuing the use of any medications (including over-the-counter drugs and herbal remedies). Unless otherwise instructed, patients should not eat or drink milk or alcohol for at least four hours before the procedure, but may drink clear fluids like water, pulp-free fruit juice, or tea until one hour before. Patients should not smoke for at least 24 hours prior to thoracentesis. To avoid injury to the lung, patients should not cough, breathe deeply, or move during this procedure.

Aftercare

After the tube is removed, x rays will determine if the effusion or air is reaccumulating, though some researchers and clinicians believe chest x rays do not need to be performed after routine thoracentesis.

Risks

Reaccumulation of fluid or air are possible complications, as are hypovolemic shock (shock caused by a lack of circulating blood) and infection. Patients are at increased risk for poor outcomes if they have a recent history of anticoagulant use, have very small effusions, have significant amounts of fluid, have poor health leading into this condition, have positive airway pressure, or have adhesions in the pleural space. A pneumothorax can sometimes be caused by the thoracentesis procedure. The use of ultrasound to guide the procedure can reduce the risk of pneumothorax.

Thoracentesis can also result in hemothorax, or bleeding within the thorax. In addition, internal structures, such as the lung, diaphragm, spleen, or liver, can be damaged by needle insertion. Repeat thoracenteses can increase the risk of developing hypoproteinemia (a decrease in the amount of protein in the blood).

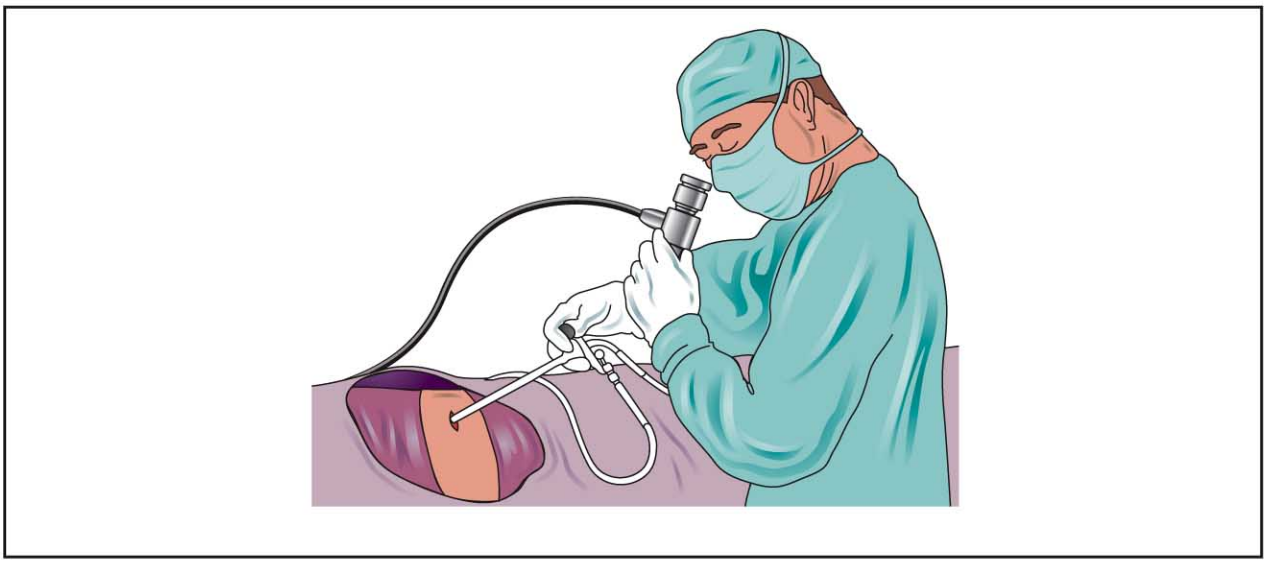
Thoracoscopy

Definition

Thoracoscopy is the insertion of an endoscope, a narrow diameter tube with a viewing mirror or camera



Thoracoscopy is a procedure in which a physician can view the chest cavity and the lungs by inserting an endoscope through the chest wall. Thoracoscopy is less invasive than surgical lung biopsy. *(Illustration by Electronic Illustrators Group.)*

attachment, through a very small incision (cut) in the chest wall.

Purpose

Thoracoscopy makes it possible for a physician to examine the lungs or other structures in the chest cavity, without making a large incision. It is an alternative to **thoracotomy** (opening the chest cavity with a large incision). Many surgical procedures, especially taking tissue samples (biopsies), can also be accomplished with thoracoscopy. The procedure is done to:

- assess lung cancer
- take a **biopsy** for study
- determine the cause of fluid in the chest cavity
- introduce medications or other treatments directly into the lungs
- treat accumulated fluid, pus (empyema), or blood in the space around the lungs

For many patients, thoracoscopy replaces thoracotomy. It avoids many of the complications of open chest surgery and reduces pain, hospital stay, and recovery time.

Precautions

Because one lung is partially deflated during thoracoscopy, the procedure cannot be done on patients whose lung function is so poor that they do not receive enough oxygen with only one lung. Patients who have had previous surgery that involved the chest cavity, or who have blood-clotting problems, are not good candidates for this procedure.

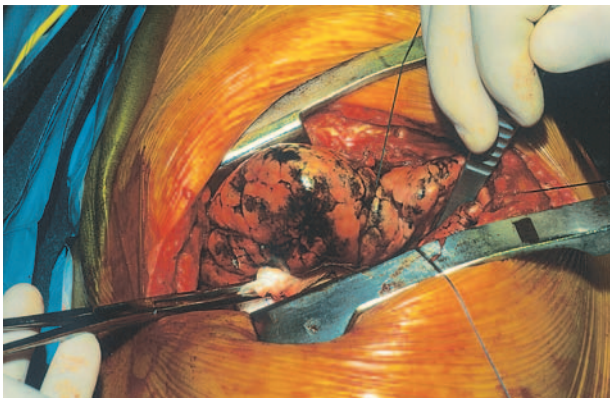
Thoracoscopy gives physicians a good but limited view of the organs, such as lungs, in the chest cavity. Endoscope technology is being refined every day, as is what physicians can accomplish by inserting scopes and instruments through several small incisions instead of making one large cut.

Description

Thoracoscopy is most commonly performed in a hospital, and general anesthesia is used. Some of the procedures are moving toward outpatient services and local anesthesia. More specific names are sometimes applied to the procedure, depending on what the target site of the effort is. For example, if a physician intends to examine the lungs, the procedure is often called pleuroscopy. The procedure takes two–four hours.

The surgeon makes two or three small incisions in the chest wall, often between the ribs. By making the incisions between the ribs, the surgeon minimizes damage to muscle and nerves and the ribs themselves. A tube is inserted in the trachea and connected to a ventilator, which is a mechanical device that assists the patient with inhaling and exhaling.

The most common reason for a thoracoscopy is to examine a lung that has a tumor or a metastatic growth of cancer. The lung to be examined is deflated to create a space between the chest wall and the lung. The patient



Thoracotomy for left upper lobectomy. The cancer is visible just above the sponge stick. *(Custom Medical Stock Photo. Reproduced by permission.)*

breathes with the other lung with the assistance of the ventilator.

A specialized endoscope, or narrow diameter tube, with a video camera or mirrored attachment, is inserted through the chest wall. Instruments for taking necessary tissue samples are inserted through other small incisions. After tissue samples are taken, the lung is re-inflated. All incisions, except one, are closed. The remaining open incision is used to insert a drainage tube. The tissue samples are sent to a laboratory for evaluation.

Preparation

Prior to thoracoscopy, the patient will have several routine tests, such as blood, urine and chest **x ray**. Older patients must have an electrocardiogram (a trace of the heart activity) because the anesthesia and the lung deflation put a big load on the heart muscle. The patient should not eat or drink from midnight the night before the thoracoscopy. The anesthesia used can cause vomiting, and, because anesthesia also causes the loss of the gag reflex, a person who vomits is in danger of moving food into the lungs, which can cause serious complications and death.

KEY TERMS

Endoscope—Instrument designed to allow direct visual inspection of body cavities, a sort of microscope in a long access tube.

Thoracotomy—Open chest surgery.

Trachea—Tube of cartilage that carries air into and out of the lungs.

QUESTIONS TO ASK THE DOCTOR

- How soon will you know the results?
- When can I resume any medications that were stopped?
- When can I resume normal activities?
- What future care will I need?

Aftercare

After the procedure, a chest tube will remain in one of the incisions for several days to drain fluid and release residual air from the chest cavity. Hospital stays range from two–five days. Medications for pain are given as needed. After returning home, patients should do only light lifting for several weeks.

Risks

The main risks of thoracoscopy are those associated with the administration of general anesthesia. Sometimes excessive bleeding, or hemorrhage, occurs, necessitating a thoracotomy to stop it. Another risk comes when the drainage tube is removed, and the patient is vulnerable to lung collapse (pneumothorax).

Thoracotomy

Definition

Thoracotomy is the process of making of an incision (cut) into the chest wall.

Purpose

A physician gains access to the chest cavity by cutting through the chest wall. Reasons for the entry are var-

KEY TERMS

Aorta—The major artery that carries blood away from the heart.

Catheter—A tube inserted into a body cavity to drain fluid. An example would be a urinary catheter used to drain urine from the urethra.

Diaphragm—The large flat muscle that runs horizontally across the bottom of the chest cavity.

Esophagus—The muscular tube that connects the mouth and the stomach.

Trachea—The tube made of cartilage that carries air from the nose and mouth to the lungs.

Urethra—The tube that carries urine from the bladder to the outside of the body.

QUESTIONS TO ASK THE DOCTOR

- If a biopsy is the only reason for the procedure, are thoracoscopy or a guided needle biopsy options (instead of thoracotomy)?

ied. Thoracotomy allows for study of the condition of the lungs, or removal of a lung or part of a lung, removal of a rib, and examination, treatment or removal of any organs in the chest cavity. Thoracotomy also gives access to the heart, esophagus, diaphragm and the portion of the aorta that passes through the chest cavity (thorax).

Lung cancer is the most common cancer for which a thoracotomy is necessary. Tumors and metastatic growths can be removed through the incision. A **biopsy**, or tissue sample for study, can also be taken through the incision.

Precautions

Patients must tell their physicians about all known allergies so that the safest anesthetics can be selected for the surgery. Older patients must be evaluated for heart ailments (usually with an electrocardiogram) before surgery because the anesthesia, as well as the thoracotomy, put an additional strain on the heart.

Description

The chest cavity can be entered from the side (laterally) or the front (also known as anterior or sternal aspect) or the back (also known as posterior aspect). The exact place in which the cut is made depends on why the surgery is being done. In some cases, the physician is able to make the incision between ribs (called an intercostal approach) to minimize the cuts through bone, nerves and muscle.

The incision is quite long, about seven inches. During the surgery, a tube is passed through the trachea. It usually has a branch to each lung. One lung is deflated so that it can be examined or surgery performed on it. The other lung remains expanded, and the patient breathes with the assistance of a mechanical device (a ventilator).

The pressure differences that are set up in the thoracic cavity by the movement of the diaphragm (the large muscle at the base of the thorax) make it possible for the lungs to expand and contract. The phases of expansion and contraction move air in and out of the lungs. If the pressure in the chest cavity changes abruptly, the lungs can collapse. Any fluid that collects in the cavity puts a patient at risk for infection and for reduced lung function, even collapse (pneumothorax). Thus, any entry to the chest usually requires that a chest tube remain for several days after the incision is closed.

Preparation

Patients are told not to eat after midnight the night before, or at least 12 hours before surgery. The advice is important because vomiting during surgery can cause serious complications and death. For surgery in which a general anesthetic is used, the gag reflex is often lost for several hours or longer, making it much more likely that food will enter the lungs if vomiting occurs.

Aftercare

Opening the chest cavity means cutting through muscle, nerves and often, ribs. It is a major procedure. Consequently, it most often involves a hospital stay as long as five to seven days. The skin around the drainage tube to the thoracic cavity must be kept clean and the tube must be kept unblocked.

The first two days after surgery may be spent in the intensive care unit of the hospital. A variety of tubes, catheters and monitors may be required after surgery.

Risks

The rich supply of blood vessels to the lungs makes hemorrhage, or uncontrolled bleeding, a risk. General anesthesia is required in most cases, and carries a risk, particularly unanticipated allergic reaction. After a thoracotomy, there may be drainage from the incision. There

is also the risk of infection. The patient must learn how to keep the incision clean and dry as it heals.

After a chest tube is removed, a patient is vulnerable to lung collapse (pneumothorax). Physicians aim to reduce the risk of collapse by timing the removal the tube. Doing so at the end of inspiration (breathing in) or the end of expiration (breathing out) poses less risk. Deep breathing and coughing should be emphasized as an important way patients can help themselves and prevent **pneumonia**.

Thrombocytopenia

Description

Thrombocytopenia (thrombocythemia) is a blood disorder characterized by an abnormally low number of circulating platelets (thrombocytes) in the bloodstream. Because platelets play an important role in the process of coagulation (blood clotting) and in the plugging of damaged blood vessels, persons with decreased platelets bruise easily and can have episodes of excessive bleeding (hemorrhage). Thrombocytopenia is usually an acquired disorder, but it can also be congenital, as in neonatal rubella (German measles).

Platelets are irregular, disc-shaped fragments of large cells called megakaryocytes, which are found in the spongy center of long bones (bone marrow). They are the smallest cell-like structures in the blood. When a blood vessel is punctured or damaged, normal mature platelets have a tendency to aggregate (group) together at the site, forming a plug that stops the bleeding. The lifespan of platelets in the blood is relatively short (five to ten days), so the bone marrow of healthy individuals is continually producing new platelets to replace the old ones.

Doctors usually use a combination of the physical examination, the medical history, and laboratory testing to diagnose this disorder. The platelet count, which is part of a complete blood count (CBC), is a key diagnostic tool. It measures the number of platelets in a volume of blood. The blood normally contains between 150,000 and 400,000 platelets per microliter (cubic millimeter or mm^3) of blood. (A million microliters is equal to one liter, or about 1.1 quarts.) In adults, a platelet count of less than 100,000/microliter is considered low, but might occur without symptoms. Abnormal bleeding often occurs when the platelet count is below 30,000/microliter. If the count falls below 10,000/microliter, abnormal external bleeding is usually evident, and serious internal bleeding can be life threatening.

Causes

Thrombocytopenia occurs when any of the following abnormal conditions exist:

- decreased production of platelets by the bone marrow
- increased destruction of circulating platelets
- increased trapping of platelets by the spleen
- platelet loss from hemorrhage

The most common cause of thrombocytopenia is a decrease in the production of platelets by the bone marrow. When abnormalities develop in the bone marrow, the megakaryocytes (platelet precursors) can lose their ability to produce platelets in sufficient amounts. This is a common side effect of blood cancers such as leukemia, which causes an abnormal growth of white blood cells in the bone marrow. These abnormal cells crowd out the normal bone marrow cells, including the platelets. Other diseases that cause this condition are tumors that spread (metastasize) to the bone, aplastic **anemia**, and viral infections such as rubella. Radiation and drugs used in cancer **chemotherapy** and in the treatment of other serious diseases can also cause the bone marrow to malfunction in this way, especially if they are used together. Some drugs, such as aspirin or **heparin**, do not actually cause a decrease in the number of platelets, but they destroy the functional ability of the platelets to aggregate.

Platelets can break down in unusually high amounts in persons with abnormalities in their blood vessel walls, with blood clots, or with man-made replacement heart valves. Devices (stents) placed inside blood vessels to keep them from closing (because of weakened walls or fat build-up) can also cause an increased destruction of platelets. In addition, severe microbial infections, infection with the human immunodeficiency virus (HIV), the virus that causes AIDS, and other changes in the immune system can speed up the removal of platelets from the circulation.

Normally, the spleen holds about one-third of the body's platelets as part of this organ's function to recycle certain aging or damaged blood cells. When liver disease or cancer of the spleen is present, the spleen can become enlarged (a condition called splenomegaly) and trap

KEY TERMS

Asymptomatic—Without symptoms.

Congenital—Existing at birth.

Gamma globulin—One of a group of proteins found in the blood that is involved in helping the body to fight infections.

Microliter—Same as a cubic millimeter. One million microliters = 1 liter = about 1.06 quarts.

Neonatal—Relating to a newborn child.

Stent—A man-made surgical device, usually tube-shaped, that is placed into a blood vessel to keep it from closing.

Transfusion—The transfer of blood from one person to another. Transfusions can be direct, in which blood is transferred from the donor to the recipient; or indirect, in which the blood is taken from the donor, stored in a container, and then given to the recipient.

many more platelets than normal. Because a greater number of platelets remain in the enlarged organ, fewer platelets are circulating in the bloodstream.

Treatments

Sometimes this disorder is asymptomatic and does not require any treatment. This is often the case when thrombocytopenia occurs in children following a viral infection. Even when the disorder is a side effect of both **radiation therapy** and chemotherapy, if the thrombocytopenia is not severe, it is often reversible on its own once the therapies end.

Treatments, when necessary, vary with the severity of the disorder, the abnormal condition that caused the disorder, and any underlying or secondary cause. When possible, the best form of treatment is to eliminate whatever is causing the condition. For example, if a drug is causing the thrombocytopenia, eliminating that drug would be the ideal solution. However, when the disorder is a side effect of chemotherapy, the patient might need to continue the drug therapy. In such cases, the doctor must decide whether it is in the best interest of the patient to continue with the same dosage, to lower the dosage, to try an alternative drug, or to give the patient a platelet transfusion. For diseases other than blood cancers, doctors can sometimes continue the chemotherapy at full dosage by also giving the patient a platelet growth factor called **Oprelvekin** (marketed as Neumega) to boost the production of normal platelets in the bone marrow.

If a dysfunctional immune system is destroying the patient's platelets, the doctor might use a corticosteroid (such as prednisone) or gamma globulin to suppress the patient's **immune response** and to help maintain adequate platelet levels. **Corticosteroids** can also have unwanted side effects, so doctors usually do not use this treatment for very long.

If an enlarged spleen is the underlying cause of the thrombocytopenia, the doctor might want to try corticosteroids or epinephrine to release platelets from the spleen. If these methods fail, surgical removal of the spleen (**splenectomy**) can help to raise the platelet level since the spleen is no longer there to capture the platelets. However, the disease that caused the enlarged spleen, such as **lymphoma** or cancer that spread to the spleen from another area of the body, should be treated as well.

If the patient is having severe external or internal bleeding as the result of injury or disease, a platelet transfusion might be necessary for immediate results. This is especially true if laboratory tests show a decreased production of platelets in the bone marrow.

Alternative and complementary therapies

A natural substance called **thrombopoietin** shows promise as a regulator of platelet production.

Many over-the-counter medicines, herbal supplements (such as garlic, ginger, feverfew, and ginko biloba) and **vitamins** can affect the ability of platelets to function properly. To determine the best treatment for a patient and to avoid drug interactions, the doctor needs to know every drug and remedy a patient is taking.

Thrombopoietin

Definition

Thrombopoietin is an investigational or experimental drug that may increase the number of platelets in the bloodstream.

Purpose

Thrombopoietin is an experimental drug that may be used to treat **thrombocytopenia** (a reduced number of platelets in the blood).

Description

Thrombocytopenia, or a low number of platelets in the blood, can be a life-threatening condition. Platelets are necessary for the normal process of blood clotting. When someone experiences thrombocytopenia, a cut or bruise might not heal quickly, or at all, without medical intervention. Therefore, patients with a low platelet cell count must take special precautions, and suffer significant risk.

Thrombocytopenia is a common side effect from many common **chemotherapy** agents. These agents temporarily decrease the production of platelets, as well as white blood cells that fight infection and red blood cells that carry oxygen. **Carboplatin** is an example of an agent that has a tendency to lower platelet counts. Like other cells of the blood (white blood cells and red blood cells), the number of platelets will generally increase and return to normal over days and weeks following the administration of chemotherapy.

By reducing the severity of platelet-related side effects, thrombopoietin could allow the antitumor medication to be used at higher doses and/or for longer periods of time. Thrombopoietin may also be used in other situations in which patients have low platelet cell counts.

Thrombopoietin is derived from the gene of the same name. A laboratory-synthesized version of the human gene product encourages the development of platelet cells from precursor cells in the blood.

Thrombopoietin is an investigational, or an experimental, drug in the U.S.. This means that the FDA has not approved this drug for general use as of mid-2001. Generally, investigational drugs are made available through participation in **clinical trials**.

Recommended dosage, precautions, side effects, and interactions

As noted above, investigational drugs generally are prescribed as part of a clinical trial. Clinical trials seek to determine how effective a drug is at treating the targeted condition, the effective dose of the drug, any precautions patients should take before the drug is administered, any side effects the drug may have, and any interactions the **investigational drug** may have with other drugs. Since thrombopoietin is investigational, it is premature to discuss dosage, precautions, side effects, and interactions.

Michael Zuck, Ph.D.

KEY TERMS

Investigational drug—A drug that has not been approved for marketing by the FDA. These drugs are generally available to patients through participation in clinical trials/research studies.

Thrombocytopenia—A condition characterized by a reduced number of platelets in the blood.

Thrush

Description

Thrush (Candidiasis)is a superficial yeast infection of the mouth and throat. Other names for this common condition include oral candidiasis, oropharyngeal candidiasis, pseudomembranous candidiasis, and mycotic **stomatitis**. Thrush is characterized by the presence of thick, curd-like white patches on the tongue and inside of the cheeks. The underlying tissue is red and inflamed. The roof and floor of the mouth and the gums may also be affected. Thrush may be easily diagnosed by the appearance of the lesion. To confirm the diagnosis, a sample for microscopic analysis may be taken by scraping the lesion with a tongue depressor.

Thrush itself is a harmless infection; however, *Candida* may spread throughout the body (systemic infection) to the kidneys, lungs, joints, bones, and brain and spinal cord (central nervous system). A systemic infection can be very serious, especially in a cancer patient with a weakened immune system.

Causes

Thrush may be caused by several different species of *Candida*. Thrush rarely occurs in healthy persons. Three factors contribute to infection *Candida*: impairment of the immune system (immunosuppression), injury to the tissues (mucosa, mucous membranes) of the

This patient's tongue is infected with oral candidiasis, or thrush. *(Photograph by Edward H. Gill. Custom Medical Stock Photo. Reproduced by permission.)*

mouth, and decrease in saliva flow. In addition, thrush can occur following treatment with **antibiotics**, when normal mouth (oral) bacteria have been eliminated allowing for overgrowth of *Candida*. In addition to standard intravenous chemotherapeutic agents, **corticosteroids**, **cyclosporine** A, and interleukin-2 (aldesleukin) suppress the immune system, placing the patient at a higher risk of infection. Patients who have been treated with myeloablative therapy, as in preparation for **bone marrow transplantation**, are at a very high risk of infection. In addition, certain cancers predispose the patient to developing candidiasis, including **multiple myeloma**, **chronic lymphocytic leukemia**, **hairy cell leukemia**, **Hodgkin's disease**, and **adrenal tumors**. Malnutrition, which is not uncommon among cancer patients, also suppresses the immune system.

Patients undergoing **chemotherapy** and/or head and neck radiation are at an increased risk of developing thrush. These therapies target the rapidly dividing cancer cells.The mucosal cells which line the mouth are also rapidly dividing. The skin and mucous membranes make up the first line of defense against invading organisms and, when damaged by cancer treatments, these tissues become susceptible to infection. Chemotherapy can decrease the number of neutrophils, a type of white blood cell, causing a condition called **neutropenia**. Neutropenia significantly increases the patient's risk of infection. **Radiation therapy** reduces the number of white blood cells which impairs the immune system.

KEY TERMS

Immunosuppression—Impairment or weakening of the immune system caused by chemotherapy or radiation therapy.

Neutropenia—The condition of having low numbers of the white blood cells called neutrophils.

Oral—Pertaining to the mouth.

Systemic—Affecting the entire body.

Thrush is a temporary side effect of cancer treatment. It can take up to a year for the immune system to recover from intensive radiation therapy. Thrush that is related to the cancer may be persistent or recurrent.

Treatments

Thrush is usually treated with the antifungal drugs clotrimazole, nystatin, or amphotericin. Clotrimazole is taken as a lozenge which is allowed to dissolve slowly in the mouth. The commonly used nystatin is taken as a solution that is swished through the mouth, although recent studies have shown that nystatin may not be as effective as the newer antifungals. Amphotericin is taken as a tablet or solution. The duration of treatment may range from five to 14 days. Often, thrush resolves with local treatment alone, however, systemic medication (such as fluconazole) may be used in some cases.

The patient with thrush should faithfully conduct a daily oral hygiene routine consisting of tooth brushing two to three times, flossing once, utilizing medicated rinses as prescribed by the physician. Brushing and flossing should be performed carefully to prevent damage to the weakened oral mucosa. Dentures and other mouth appliances, which can harbor the yeast and be a source for possible reinfection, need to be disinfected.

Alternative and complementary therapies

Because there is the risk that *Candida* may spread and cause a serious systemic infection, thrush should be treated with antifungal drugs. The patient with thrush can help fight the infection by eating a well-balanced diet to counteract immunosuppression caused by malnutrition. Nutritional supplements may also be useful. Some practitioners claim that herbs (such as goldenseal or garlic) can be used to kill yeasts and boost the immune system. However, these complementary therapies should be discussed with the patient's physician because of thrush's potentially serious threat to the cancer patient.

Thymic cancer

Definition

Thymic cancer refers to any one of several different types of tumors that have originated within the thymus gland.

Description

The thymus is located in the upper chest just below the neck. It is a small organ that produces certain white blood cells before birth and during childhood. These white blood cells are called lymphocytes and are an important part of the body's immune system. Once released from the thymus, lymphocytes travel to lymph nodes where they help to fight infections. The thymus gland becomes smaller in adulthood and is gradually taken over by fat tissue.

Three cell types of the thymus can give rise to cancer. The epithelial cells that make up the outer covering of the thymus can become cancerous resulting in thymic **carcinoma** and **thymoma**. When the lymphocytes in the thymus or lymph nodes become cancerous, the resulting cancers are called **Hodgkin's disease** or **non-Hodgkin's lymphomas**. A third, less common, cell type in the thymus is called Kulchitsky cells (neuroendocrine cells). These cells release chemical messengers called hormones. Cancer that originates from Kulchitsky cells is called thymic carcinoid tumors. Another type of thymic cancer, thymolipoma, is composed of thymic tissue and fatty tissue.

Although rare, thymomas are the most common type of thymic cancer. With fewer than 200 cases reported each, thymic cancer and thymic carcinoid tumors are very rare. Thymic carcinomas tend to spread more rapidly and are more aggressive than thymomas. Taken together, thymic cancers represent only about 1.5% of all malignancies.

Demographics

Thymic cancer is more common in the middle-aged and elderly; according to the National Cancer Institute (NCI), most patients diagnosed with these cancers are between 40 and 60 years of age. Thymoma and thymic carcinoma affect men and women equally. Thymic carcinoid tumors most frequently afflict men.

Causes and symptoms

The cause of thymic cancer is unknown. Cancer is caused when the normal mechanisms that control cell growth become disturbed, causing the cells to grow continually without stopping. This is caused by damage to the DNA in the cell.

Although some researchers think that previous exposure to radiation of the upper chest may be a risk factor for thymic cancer, the association has not been proved as of 2004.

Thymic tumors are not usually evident until the enlarged thymus presses on the windpipe (trachea) or blood vessels, which cause symptoms. The symptoms of thymic cancer will vary depending on what type of cancer is present. Symptoms of any thymic tumor may include: shortness of breath, swelling of the face, coughing, and chest pain.

Thymic carcinoid tumors can release hormones that may cause symptoms. Symptoms of thymic carcinoid tumors may also include red and warm skin, (flushing), **diarrhea**, and asthma.

Approximately 40% of the patients diagnosed with thymoma have no symptoms. The signs and symptoms of thymoma are vast and are related to the many disorders caused by thymoma. The most common conditions related to thymoma (**paraneoplastic syndromes**) are red cell aplasia, **myasthenia gravis**, and hypogammaglobulinemia. These conditions are autoimmune diseases, those in which the body mounts an attack against certain normal cells of the body. About 47% of thymomas are associated with myasthenia gravis. Symptoms of thymoma may also include:

- muscle weakness (especially in the eyes, neck, and chest, causing problems with vision, swallowing, and breathing)
- weakness
- dizziness

- shortness of breath
- **fatigue**

Diagnosis

The physician will conduct a complete physical examination. He or she may be able to feel a fullness in the lower neck region. Routine blood tests may be performed. **Imaging studies** are necessary because the symptoms of thymic cancer can be caused by many other diseases. Thymic tumors can be identified by chest **x ray**, **magnetic resonance imaging** (MRI), and **computed tomography** (CT). About half of these tumors can be detected by a plain-film chest x-ray.

A **biopsy** may be performed, in which a small sample of the tumor is removed and examined under the microscope. However, because of the risk of "seeding" cancerous cells, biopsies are not routinely performed. Because other tumors can lie in the region of the thymus, thymic cancer can be diagnosed only by identification of the cells that make up the tumor. There are a few different methods for biopsy of a thymic tumor. For a **mediastinoscopy**, a wand-like lighted camera (endoscope) and special instruments are passed through a small cut in the lower neck. The surgeon can see the tumor on a monitor and can cut off small samples for microscopic analysis. Mediastinoscopy is performed under general anesthesia. Alternatively, a needle biopsy will be taken in which a long needle is passed through the skin and into the tumor. Fine needle biopsy uses a thin needle and larger-core needle biopsy uses a wider needle. Needle biopsies may be performed in conjunction with computed tomography imaging.

Patients who are having difficulty breathing may have a **bronchoscopy** performed to examine the wind pipe. An endoscope, in this case a bronchoscope, is inserted through the mouth and into the windpipe. The physician will look for tumors and may perform biopsies.

Treatment team

The treatment team for thymic cancer may include a hematologist, pulmonologist, immunologist, oncologist, thoracic surgeon, cardiologist, radiation oncologist, nurse oncologist, psychiatrist, psychological counselor, and social worker.

Clinical staging, treatments, and prognosis

Clinical staging

There is more than one type of staging system for thymic cancer but the Masaoka system is used most often. This staging system was developed for thymoma, however, it is sometimes used to stage the other thymic cancers as well. Thymic carcinoma is graded (low or high) based on the cell type present in the tumor. Thymoma is categorized into four stages (I, II, III, and IV) which may be further subdivided (A and B) based on the spread of cancerous tissue. The Masaoka staging system is as follows:

- Stage I. The thymoma lies completely within the thymus.
- Stage II. The thymoma has spread out of the thymus and invaded the outer layer of the lung (pleura) or nearby fatty tissue.
- Stage III. The thymoma has spread to other neighboring tissues of the upper chest including the outer layer of the heart (pericardium), the lungs, or the heart's main blood vessels.
- Stage IVA. The thymoma has spread throughout the pericardium and/or the pleura.
- Stage IVB. The thymoma has spread to organs in other parts of the body.

Treatments

The treatment for thymic cancer depends on the type and stage of cancer and the patient's overall health. Because thymic cancers are so rare, there are no defined treatment plans. Treatment options include surgery, **radiation therapy**, and/or **chemotherapy**. Surgical removal of the tumor is the preferred treatment. Surgery is often the only treatment required for stage I thymic cancers. A treatment that is intended to aid the primary treatment is called adjuvant therapy. For instance, chemotherapy may be used along with surgery to treat thymic cancer. Stages II, III, and IV thymic cancers are often treated with surgery and some form of adjuvant therapy.

As of 2004, the preferred approach to thymic carcinoma is a combination of aggressive surgical treatment, chemotherapy using platinum-based compounds, and radiation treatments.

SURGERY Thymic cancer may be treated by resection (surgical removal) of the tumor and some of the nearby healthy tissue. Removal of the entire thymus is called a thymectomy. Surgery on the thymus is usually performed through the chest wall by splitting open the breast bone (sternum), a procedure called a median sternotomy. When complete removal of the tumor is impossible, the surgeon will remove as much of the tumor as possible (debulking surgery, subtotal resection). In these cases, If the tumor has spread, surgery may include removal of other tissues such as the pleura, pericardium, blood vessels of the heart, lung, and nerves.

RADIATION THERAPY Radiation therapy uses high-energy radiation from x rays and gamma rays to kill the cancer cells. Radiation given from a machine that is outside the body is called external radiation therapy. Radiation therapy is often used as adjuvant therapy following surgery to reduce the chance of cancer recurrence. Radiation may be used to kill cancer cells in cases in which the tumor was only partially removed. It may be used before surgery to shrink a large tumor. Radiation therapy is not very effective when used alone, although it may be used alone when the patient is too sick to withstand surgery.

The skin in the treated area may become red and dry and may take as long as a year to return to normal. Radiation to the chest may damage the lung causing shortness of breath and other breathing problems. Also, the tube that goes between the mouth and stomach (esophagus) may be irritated by radiation causing swallowing difficulties. Fatigue, upset stomach, diarrhea, and nausea are also common complaints of patients having radiation therapy. Most side effects go away about two to three weeks after radiation therapy has ended.

CHEMOTHERAPY Chemotherapy uses anticancer drugs to kill the cancer cells. The drugs are given by mouth (orally) or intravenously. They enter the bloodstream and can travel to all parts of the body. Chemotherapy may be given before surgery to shrink a tumor, which is called neoadjuvant therapy. Thymic tumor cells are very sensitive to anticancer drugs, especially **cisplatin**, **doxorubicin**, and **ifosfamide**. Generally, a combination of drugs is given because it is more effective than a single drug in treating cancer.

The side effects of chemotherapy are significant and include stomach upset, nausea and vomiting, appetite loss (anorexia), hair loss (**alopecia**), mouth sores, and fatigue. Women may experience vaginal sores, menstrual cycle changes, and premature menopause. There is also an increased chance of infections.

Prognosis

The approximate five-year survival rates are 35% for thymic carcinomas and 60% for thymic carcinoids. The five-year survival rates for thymomas are 96% for stage I, 86% for stage II, 69% for stage III, and 50% for stage IV.

Thymomas rarely spread (metastasize) but thymic carcinomas frequently spread to distant organs. Thymic carcinomas spread most often to the pleura, lung, local lymph nodes (bean-sized structures that contain lymphocytes), bone, and liver. Thymic carcinoid tumors commonly spread to local lymph nodes.

KEY TERMS

Adjuvant therapy—A treatment that is intended to aid the primary treatment. Adjuvant treatments for thymic cancer are radiation therapy and chemotherapy.

Lymphocyte—A type of white blood cell that is found in the thymus.

Neoadjuvant therapy—Radiation therapy or chemotherapy used to shrink a tumor before surgical removal of the tumor.

Paraneoplastic syndrome—A set of symptoms that is associated with cancer but is not directly caused by the cancer.

Pleura—The outer covering of the lungs.

Resection—Surgical removal of all or part of an organ or tissue.

Thymomas are prone to recurrence, even 10–15 years following surgery. For thymomas, recurrence rates are drastically reduced and the five-year survival rates are drastically increased in patients who receive adjuvant radiation therapy. Recurrence of thymic carcinoid tumors is common.

Thymomas are also associated with an increased risk of second malignancies.

Alternative and complementary therapies

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques such as prayer, biofeedback, visualization, meditation, and yoga, have not shown any effect in reducing cancer but they can reduce stress and lessen some of the side effects of cancer treatments. Gerson, macrobiotic, orthomolecular, and Cancell therapies are ineffective treatments for cancer.

Clinical studies of hydrazine sulfate found that it had no effect on cancer and even worsened the health and well-being of the study subjects. One clinical study of the drug amygdalin (Laetrile) found that it had no effect on cancer. Laetrile can be toxic and has caused deaths. Shark cartilage, although highly touted as an effective cancer treatment, is an improbable therapy that has not been the subject of clinical study. Although the results are mixed, clinical studies suggest that melatonin may increase the survival time and quality of life for cancer patients.

Selenium in safe doses may delay the progression of thymic cancer. Laboratory and animal studies suggest

that curcumin, the active ingredient of turmeric, has anticancer activity. Maitake mushrooms may boost the immune system, according to laboratory and animal studies. The results of laboratory studies suggest that mistletoe has anticancer properties; however, clinical studies have not been conducted.

For more comprehensive information, the reader may wish to consult the book on complementary and alternative medicine published by the American Cancer Society listed in the Resources section.

Coping with cancer treatment

The patient should consult his or her treatment team regarding any side effects or complications of treatment. Many of the side effects of chemotherapy can be relieved by medications. Patients should consult a psychotherapist and/or join a support group to deal with the emotional consequences of cancer and its treatment.

Clinical trials

As of late 2004, there were two active **clinical trials** studying thymic cancer, both sponsored by the National Cancer Institute. One trial (#E-1C99) was studying the effectiveness and toxicity of **carboplatin** and **paclitaxel** on thymic cancers. This study was open to patients with invasive, recurrent, or metastatic thymoma or thymic carcinoma. The other clinical trial was an evaluation of the effectiveness of BG00001, an investigational drug. The National Cancer Institute web site has information on these and other studies. Patients should consult with their treatment team to determine if they are candidates for these or any other ongoing studies.

Prevention

Because there are no risk factors for the development of thymic cancer known with certainty, there are no preventive measures. However, there may be an association between thymic cancer and exposure of the chest to radiation.

Special concerns

Damage to the lungs and/or esophagus caused by radiation therapy to the upper chest is a concern. Biopsy runs the risk of seeding tumor cells to other parts of the body.

Because of the increased risk of second malignancies, patients diagnosed with thymomas should have lifelong surveillance.

QUESTIONS TO ASK THE DOCTOR

- What type of thymic cancer do I have?
- What stage of cancer do I have?
- Has the cancer spread?
- What is the five-year survival rate for patients with this type of cancer?
- Will you perform a biopsy?
- What type of biopsy will you perform?
- What is the risk of seeding cancerous cells during a biopsy?
- What are my treatment options?
- What are the risks and side effects of these treatments?
- What medications can I take to relieve treatment side effects?
- Are there any clinical studies underway that would be appropriate for me?
- What effective alternative or complementary treatments are available for thymic cancer?
- How debilitating is the treatment? Will I be able to continue working?
- What is the chance that the cancer will recur?
- What are the signs and symptoms of recurrence?
- What can be done to prevent recurrence?
- How often will I have follow-up examinations?

Thymoma

Definition

Thymomas are the most common tumor of the thymus.

Description

The thymus is located in the upper chest just below the neck. It is a small organ that produces certain white blood cells before birth and during childhood. These white blood cells are called lymphocytes and are an important part of the body's immune system. Once released from the thymus, lymphocytes travel to lymph nodes where they help to fight infections. The thymus gland becomes smaller in adulthood and is gradually taken over by fat tissue.

Although rare, thymomas are the most common type of thymic tumor. The term thymoma traditionally refers to a non-invasive, localized (only in the thymus) type of thymic tumor. Thymomas arise from thymic epithelial cells, which make up the covering of the thymus. Thymomas frequently contain lymphocytes, which are non-cancerous. Thymomas are classified as either noninvasive (previously called benign) or invasive (previously called malignant). Noninvasive thymomas are those in which the tumor is encapsulated and easy to remove. Invasive thymomas have spread to nearby structures (such as the lungs) and are difficult to remove. Approximately 30% to 40% of thymomas are of the invasive type.

Demographics

Thymoma affects men and women equally. It is usually diagnosed between the ages of 40 and 60 years. Thymomas are uncommon in children.

Causes and symptoms

The cause of thymoma is unknown. Cancer is caused when the normal mechanisms that control cell growth become disturbed, causing the cells to grow continually without stopping. This is caused by damage to the DNA in the cell.

Approximately 40% of the patients diagnosed with thymoma have no symptoms. The symptoms in the remaining 60% of patients are caused by pressure from the enlarged thymus on the windpipe (trachea) or blood vessels or by **paraneoplastic syndromes**. Paraneoplastic syndromes are collections of symptoms in cancer patients that cannot be explained by the tumor. Seventy-one percent of thymomas are associated with paraneoplastic syndromes. The most common syndromes related to thymoma are pure red cell aplasia (having abnormally low levels of red blood cells), **myasthenia gravis** (a muscular disorder), and hypogammaglobulinemia (having abnormally low levels of antibodies). These conditions are autoimmune diseases, those in which the body mounts an attack against certain normal cells of the body. Regarding myasthenia gravis, 15% of patients with this syndrome have thymomas. Alternately, 50% of patients with thymomas have myasthenia gravis. The relationship between the two entities is not clearly understood, though it is believed that the thymus may give incorrect instructions about the production of acetypcho-

line receptor antibodies, thus setting the state for faulty neuromuscular transmission. The confirmed presence of either thymomas or myasthenia gravis should prompt investigation for the other condition.

Symptoms of thymoma may include:

- shortness of breath
- swelling of the face
- coughing
- chest pain
- muscle weakness (especially in the eyes, neck, and chest, causing problems with vision, swallowing, and breathing)
- weakness
- dizziness
- shortness of breath
- **fatigue**

Diagnosis

The physician will conduct a complete physical exam. He or she may be able to feel a fullness in the lower neck region. Routine blood tests may be performed. **Imaging studies** are necessary because the symptoms of thymoma can be caused by many other diseases. Thymomas can be identified by chest **x ray**, **magnetic resonance imaging** (MRI), and **computed tomography** (CT).

A **biopsy** may be performed, in which a small sample of the tumor is removed and examined under the microscope. However, because of the risk of "seeding" cancerous cells, biopsies are not routinely performed. There are a few different methods to biopsy a thymoma. For a **mediastinoscopy**, a wand-like lighted camera (endoscope) and special instruments are passed through a small cut in the lower neck. The surgeon can see the tumor on a monitor and can cut off small samples for microscopic analysis. Mediastinoscopy is performed under general anesthesia. Alternatively, a needle biopsy will be taken in which a long needle is passed through the skin and into the tumor. Fine needle biopsy uses a thin needle and larger-core needle biopsy uses a wider needle. Needle biopsies may be performed in conjunction with computed tomography imaging.

Patients who are having difficulty breathing may have a **bronchoscopy** performed to examine the wind pipe. An endoscope, in this case a bronchoscope, is inserted through the mouth and into the windpipe. The physician will look for tumors and may perform biopsies.

Treatment team

The treatment team for thymoma may include a hematologist, pulmonologist, immunologist, oncologist, thoracic surgeon, cardiologist, radiation oncologist, nurse oncologist, psychiatrist, psychological counselor, and social worker.

Clinical staging, treatments, and prognosis

Clinical staging

There is more than one type of staging system for thymoma but the Masaoka system, a surgical staging system developed in 1981, is used most often. Thymoma is categorized into four stages (I, II, III, and IV) which may be further subdivided (A and B) based on the spread of cancerous tissue. The Masaoka staging system is as follows:

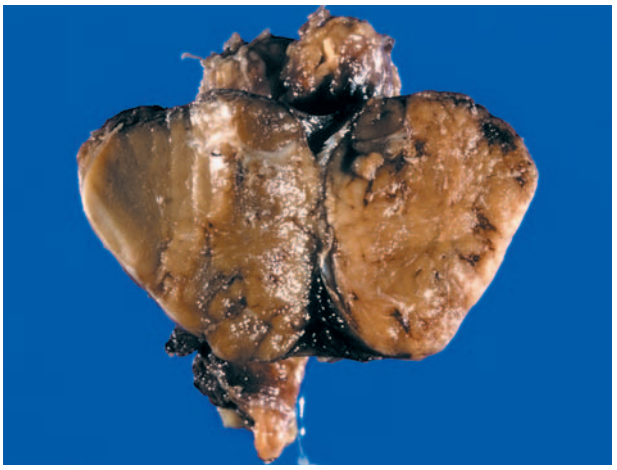
- Stage I. The thymoma lies completely within the thymus.
- Stage II. The thymoma has spread out of the thymus and invaded the outer layer of the lung (pleura) or nearby fatty tissue.
- Stage III. The thymoma has spread to other neighboring tissues of the upper chest including the outer layer of the heart (pericardium), the lungs, or the heart's main blood vessels.
- Stage IVA. The thymoma has spread throughout the pericardium and/or the pleura.
- Stage IVB. The thymoma has spread to organs in other parts of the body.

In 1999, the World Health Organization (WHO) adopted a new classification system for thymic tumors. This system is a histologic classification, which means that it is based on the microscopic features of the cells that make up the tumor. The WHO classification system ranks thymomas into types A, AB, B1, B2, B3, and C, by increasing severity.

Treatments

The treatment for thymoma cancer depends on the stage of cancer and the patient's overall health. Because thymomas are so rare, there are no defined treatment plans. Treatment options include surgery, **radiation therapy**, and/or **chemotherapy**. Surgical removal of the tumor is the preferred treatment. Surgery is often the only treatment required for stage I tumors. Treatment of thymoma often relieves the symptoms caused by paraneoplastic syndromes.

A treatment that is intended to aid the primary treatment is called adjuvant therapy. For instance, chemotherapy may be used along with surgery to treat



Gross specimen of the human thymus gland cut through showing a tumor (thymoma). *(Copyright Science Source/Photo Researchers, Inc. Reproduced by permission.)*

thymoma. Stages II, III, and IV thymomas are often treated with surgery and some form of adjuvant therapy.

SURGERY Thymoma may be treated by surgically removing (resecting) the tumor and some of the nearby healthy tissue. Removal of the entire thymus gland is called a thymectomy. Surgery on the thymus is usually performed through the chest wall by splitting open the breast bone (sternum), a procedure called a median sternotomy. When complete removal of the tumor is impossible, the surgeon will remove as much of the tumor as possible (debulking surgery, sub-total resection). In these cases, if the tumor has spread, surgery may include removal of other tissues such as the pleura, pericardium, blood vessels of the heart, lung, and nerves.

RADIATION THERAPY Radiation therapy uses high-energy radiation from x rays and gamma rays to kill the cancer cells. Radiation given from a machine that is outside the body is called external radiation therapy. Radiation therapy is often used as adjuvant therapy following surgery to reduce the chance of cancer recurrence. Radiation may be used to kill cancer cells in cases in which the tumor was only partially removed. It may be used before surgery to shrink a large tumor. Radiation therapy is not very effective when used alone, although it may be used alone when the patient is too sick to withstand surgery.

The skin in the treated area may become red and dry and may take as long as a year to return to normal. Radiation to the chest may damage the lung causing shortness of breath and other breathing problems. Also, the tube that goes between the mouth and stomach (esophagus) may be irritated by radiation causing swallowing difficulties. Fatigue, upset stomach, **diarrhea**, and nausea are also common complaints of patients having radiation therapy. Most side effects go away about two to three weeks after radiation therapy has ended.

CHEMOTHERAPY Chemotherapy uses anticancer drugs to kill the cancer cells. The drugs are given by mouth (orally) or intravenously. They enter the bloodstream and can travel to all parts of the body. Chemotherapy may be given before surgery to shrink a tumor, which is called neoadjuvant therapy. Thymoma cells are very sensitive to anticancer drugs, especially **cisplatin**, **doxorubicin**, and **ifosfamide**. Generally, a combination of drugs is given because it is more effective than a single drug in treating cancer. **Corticosteroids** are also used to treat thymoma.

The side effects of chemotherapy are significant and include stomach upset, nausea and vomiting, appetite loss (anorexia), hair loss (**alopecia**), mouth sores, and fatigue. Women may experience vaginal sores, menstrual cycle changes, and premature menopause. There is also an increased chance of infections.

Prognosis

The five-year survival rates for thymomas are 96% for stage I, 86% for stage II, 69% for stage III, and 50% for stage IV. Thorough (radical) surgery is associated with a longer survival rate. Almost 15% of thymoma patients develop a second cancer.

Thymomas rarely spread (metastasize) outside of the chest cavity. **Metastasis** is usually limited to the pleura. Invasive thymomas are prone to recurrence, even 10 to 15 years following surgery. The recurrence rates are drastically reduced and the five-year survival rates are drastically increased in patients who receive adjuvant radiation therapy.

Alternative and complementary therapies

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques such as prayer, biofeedback, visualization, meditation, and yoga have not shown any effect in reducing cancer but they can reduce stress and lessen some of the side effects of cancer treatments. Gerson, macrobiotic, orthomolecular, and Cancell therapies are ineffective treatments for cancer.

Thyroid nuclear medicine scan *see* **Thyroid scan**

Thyroid cancer

Definition

Thyroid cancer is a disease in which the cells of the thyroid gland become abnormal, grow uncontrollably and form a mass of cells called a tumor.

Description

The thyroid is a hormone-producing, butterfly-shaped gland located in the neck at the base of the throat. It has two lobes, the left and the right. The thyroid uses iodine, a mineral found in some foods, to make several of its hormones. Thyroid hormones regulate essential body processes such as heart rate, blood pressure, body temperature, metabolism, and affect the nervous system, muscles and other organs. These hormones also play an important role in regulating childhood growth and development.

Types of thyroid cancer

Thyroid cancer is grouped into four types based on how its cells appears under a microscope. The types are papillary, follicular, medullary and anaplastic thyroid cancers. They grow at different rates and can spread to other parts of the body if left untreated.

PAPILLARY The papillary type (60%–80% of all thyroid cancers) is a slow-growing cancer that develops in the hormone-producing cells that contain iodine.

FOLLICULAR The follicular type (30%–50% of thyroid cancers) also develops in the hormone-producing cells.

MEDULLARY The medullary type (5%–7% of all thyroid cancers) develops in the parafollicular cells (also known as the C cells) that produce **calcitonin**, a hormone that does not contain iodine.

ANAPLASTIC The fourth type of thyroid cancer, anaplastic (2% of all thyroid cancers), is the fastest growing, most aggressive thyroid cancer type.

Demographics

Diseases of the thyroid gland affect millions of Americans. The most common diseases of the thyroid are either hyperthyroidism (Grave's disease) or hypothyroidism, an overactive or an underactive gland, respectively. Sometimes lumps or masses may develop in the thyroid. Although most (95%) of these lumps or nodules are noncancerous (benign), all thyroid lumps should be taken seriously. The American Cancer Society estimates that in 2001, approximately 19,500 new cases of thyroid cancer will have been diagnosed in the United States.

Women are three times more likely to develop thyroid cancer than men. Although the disease affects teenagers and young adults, most people who develop thyroid cancer are over 50 years of age. Caucasians are affected more often than African Americans.

Causes and symptoms

The exact cause of thyroid cancer is not known but some risk factors have been identified. Radiation was

used in the 1950s and 1960s to treat acne and to reduce swelling in infections of the tonsils, adenoids and lymph nodes. It has been proven that this exposure is a risk factor for thyroid cancer. In some areas of the world, diets are low in iodine. Papillary and follicular cancers occur more frequently in these areas. Iodine deficiency is not a large problem in the United States because iodine is added to table salt and other foods. Approximately 7% of thyroid cancers are caused by the alteration (mutation) of a gene called the RET oncogene, which can be inherited.

Symptoms are rare, and the lump is not usually painful. The symptoms of thyroid nodules are:

- A lump or nodule that can be felt in the neck is the most frequent sign of thyroid cancer.
- The lymph nodes may be swollen and the voice may become hoarse because the tumor presses on the nerves leading to the voice box.
- Some patients experience a tight or full feeling in the neck and have difficulty breathing or swallowing.

Diagnosis

Physicians use several tests to confirm the suspicion of thyroid cancer, to identify the size and location of the lump and to determine whether the lump is non-cancerous (benign) or cancerous (malignant).

A blood test called the thyroid stimulating hormone (TSH) test checks thyroid function. The blood is drawn by a technician with a needle and the test takes a few minutes. The results take several days to be interpreted by a pathologist.

A test known as the calcitonin test may be ordered. Calcitonin is a hormone produced by the C cells (parafollicular cells) of the thyroid gland. The hormone is produced in excess when the parafollicular cells of the thyroid become cancerous. Blood calcitonin levels are used to confirm the diagnosis of medullary thyroid cancer if it is suspected.

Computed tomography scan (CT scan) or **ultrasonography** (an ultrasound scan) are imaging tests used to produce a picture of the thyroid. A radiologist usually interprets the results of these tests within 24 hours. In ultrasonography, high-frequency sound waves are bounced off the thyroid. The pattern of echoes that is produced by these waves is converted into a computerized image on a television screen. This test can determine whether the lumps found in the thyroid are benign fluid-filled cysts or solid malignant tumors.

A radioactive scan (a thyroid nuclear medicine scan) may take several hours and can be used to identify any abnormal areas in the thyroid. For this test, the patient is given a very small amount of radioactive iodine which can either be swallowed or injected. Since the thyroid is the only gland in the body that absorbs iodine, the radioactive iodine accumulates there. An x-ray image can then be taken or an instrument called a "scanner" can be used to identify areas in the thyroid that do not absorb iodine normally. These abnormal spots are called "cold spots" and further tests are performed to check whether the cold spots are benign or malignant tumors. If a significant amount of radioactive iodine is concentrated in the nodule, then it is termed "hot" and is usually benign. Again a radiologist interprets the results within a day.

The most accurate diagnostic tool for thyroid cancer is a **biopsy**. In this process, a sample of thyroid tissue is withdrawn and examined under a microscope by a pathologist. This usually takes a day or so. The tissue samples can be obtained either by drawing out a sample of tissue through a needle (needle biopsy) or by surgical removal of the nodule (surgical biopsy). A needle biopsy takes a few minutes and can be done by any trained physician, usually a radiologist. The surgical biopsy is done by a surgeon under general anesthesia with the help of an anesthesiologist and will take a few hours. If thyroid cancer is diagnosed, further tests may be done to learn about the stage of the disease and help doctors plan appropriate treatment.

Treatment team

The types of healthcare providers often involved in the care of patients are surgeons, internal medicine specialists, pathologists, radiologists, endocrinologists, anesthesiologists, hematologist-oncologists (cancer specialists) and radiation-oncologists.

Clinical staging, treatment and prognosis

Staging

The aggressiveness of each type of thyroid cancer is different. Cancer staging considers the size of the tumor, whether it has grown into surrounding lymph nodes and whether it has spread to distant parts of the body (metastasized). Age and general health status are also taken into account. The **American Joint Commission on Cancer** (AJCC) staging is summarized below for each thyroid cancer type.

PAPILLARY AND FOLLICULAR In patients younger than 45 years:

- Stage I refers to patients without evidence of cancer beyond the thyroid.
- Stage II refers to patients with spread of cancer outside the thyroid gland.

In patients over 45:

- Stage I: Tumors are smaller than one cm (0.3 in).
- Stage II: Tumors have not broken through the capsule (covering) of the thyroid.
- Stage III: Tumors have spread locally to the nearby lymph nodes.
- Stage IV: Tumors have spread outside the thyroid area (distant metastases). In the case of Stage IV cancer, the places to which thyroid cancer often metastasizes are the lungs and bone.

MEDULLARY

- Stage I: Tumor is less than 1 cm (0.3 in) or is only detected by a provocative screening test.
- Stage II: Tumor is between 1 and 4 cm (between 0.3 and 1.5 in).
- Stage III: Nearby lymph nodes reveal cancer.
- Stage IV: Evidence of distant metastases.

ANAPLASTIC All cases of anaplastic thyroid cancer are considered Stage IV, because this cancer is extremely aggressive.

Treatments

Papillary thyroid cancer can be treated successfully. Follicular thyroid cancer also has a good cure rate but may be difficult to control if the cancer invades blood vessels or grows into nearby structures in the neck. Medullary thyroid cancers are more difficult to control because they often spread to other parts of the body. Anaplastic thyroid cancer is the fastest growing and tends to respond poorly to all treatments.

Like most cancers, cancer of the thyroid is best treated when it is found early by a primary physician. Treatment depends on the type of cancer and its stage. Four types of treatment are used: surgical removal, **radiation therapy**, hormone therapy, and **chemotherapy**.

SURGERY Surgical removal is the usual treatment if the cancer has not spread to distant parts of the body. It is the primary treatment for earlier stage papillary, follicular, and medullary thyroid cancers. The surgeon may remove the side or lobe of the thyroid where the cancer is found (**lobectomy**) or all of it (total thyroidectomy). If the adjoining lymph nodes are affected, they may also be removed during surgery.

RADIATION For papillary and follicular thyroid cancers, radioactive iodine may be used in addition to surgery. In this treatment, the patient would be asked to swallow a drink containing radioactive iodine. Because the thyroid cells take up iodine, the radioactive iodine collects in any thyroid tissue remaining in the body and kills the cancer cells. External beam radiation may also be used if the radioactive iodine is unsuccessful.

For medullary cancers, radioactive iodine is not used. External beam radiation may be used as a palliative therapy. (A palliative therapy is one intended to make the patient more comfortable, not to cure the cancer.)

HORMONE THERAPY When the thyroid gland is removed and levels of thyroid hormones decrease, the pituitary gland produces TSH that would normally stimulate the thyroid gland to make thyroid hormone. TSH also stimulates thyroid cells to grow, and it probably also promotes thyroid cancer growth. Hormone therapy uses hormones after surgery to stop this growth and the formation of new cancerous thyroid cells. To prevent cancerous growth, the natural hormones that are produced by the thyroid are taken in the form of a pill. Thus, their levels remain normal and inhibit the pituitary gland from making TSH. If the cancer has spread to other parts of the body and surgery is not possible, hormone treatment is aimed at killing or slowing the growth of cancer cells throughout the body.

CHEMOTHERAPY For advanced thyroid cancers for which surgery was not an option or that have not responded well to other treatments, chemotherapy may be tried. For advanced papillary, follicular, and anaplastic thyroid cancers, no chemotherapeutic regimen can be considered standard, and several clinical studies may be ongoing for which patients with these cancers may be eligible. For anaplastic thyroid cancer, some chemotherapeutic agents (**doxorubicin**, doxorubicin/cisplatin combination) have effected partial remission in some patients, but not on a large scale. Patients with anaplastic thyroid cancer may also be eligible for ongoing **clinical trials**.

Prognosis

More than 90% of patients who are treated for papillary or follicular cancer will live for 15 years or longer after the diagnosis of thyroid cancer. Eighty percent of patients with medullary thyroid cancer will live for at least 10 years after surgery. Three to seventeen percent of patients with anaplastic cancer survive for five years.

Alternative and complementary treatments

Alternative treatments are treatments used instead of conventional treatments. Complementary therapies are intended to supplement traditional therapies and usually have the objective of relieving symptoms or helping cancer patients cope with the disease or traditional treatments. Common complementary therapies that may be employed by cancer patients are aromatherapy, art therapy, journal therapy, massage, meditation, music therapy, prayer, t'ai chi, and yoga or other forms of exercise, which can reduce

anxiety and increase a patient's feeling of well-being. A well-balanced diet can also enhance a patient's sense of well-being, and can help cancer patients better manage their treatments and the side effects of those treatments.

A powerful phytochemical (a chemical found in plants), lycopene, gives tomatoes their red color and appears to act as an antioxidant. **Antioxidants** such as lycopene help inhibit DNA oxidation (which can lead to certain forms of cancer), repair damaged cells, and scavenge free radicals. (Free radicals are the molecules thought to be responsible for most types of degenerative diseases and aging.) While it is not being suggested that thyroid cancer could be prevented with antioxidants, patients receiving plenty of antioxidants in their diets may feel healthier and more energetic. Lycopene is a normal constituent of human blood and tissues, where it is found in greater concentrations than beta-carotene or any other carotenoid. Tomatoes, including cooked or processed tomatoes, tomato juices, soups, sauces, paste and ketchup, contain more lycopene than any other food. Guava, rose hip, watermelon and grapefruit also contain lycopene.

Other antioxidants are: Vitamin E, Vitamin C, Beta carotene, Lutein, Pycnogenol, Green tea, Grape-seed extract, Alpha lipoic acid, N-acetylcysteine, and Selenium. Pregnant women should consult a physician before taking any medication, and all patients should discuss the complementary therapies and nutritional supplements they are considering with their physician. Some therapies may interfere with patients' prescribed treatments.

Coping with cancer treatment

After thyroid surgery, some patients experience:

- difficulty swallowing
- voice change
- damage to the parathyroid glands

To cope with difficult swallowing, once patients are able to eat after the surgery, many patients start with soft foods, like milkshakes, bananas, applesauce, yogurt, mashed potatoes, and pureed foods. A consultation before the surgery with a dietitian may be helpful, so that the patient can be prepared.

Hoarseness after surgery is usually temporary. Patients may have difficulty hitting high notes when singing, but, the voice change and hoarseness is usually not a major issue for most patients. (Professional singers are advised to discuss their surgery in great detail with their surgeons beforehand.)

If all four parathyroid glands are injured or damaged, it may be necessary for patients to take calcium supplements for a few weeks. Rarely, these supplements may be prescribed for longer periods of time, or even indefinitely.

Thyroid cancers

Cancer type	Characteristics	Prognosis
Papillary	60–80% of thyroid cancers Slow-growing cancer in hormone — producing cells	90% of patients will live for 15 years or longer after diagnosis
Follicular	30–50% of thyroid cancers Found in hormone— producing cells	90% of patients will live for 15 years or longer after diagnosis
Medullary	5–7% of Thyroid cancers Found in calcitonin— producing cells Difficult to control as it often spreads to other parts of the body	80% of patients will live for at least 10 years after surgery
Anaplastic	2% of Thyroid cancers Fastest growing Rapidly spreads to other parts of the body	3–17% of patients will survive for five years

After radioiodine treatment, some patients experience neck tenderness, nausea and stomach irritation, and dry mouth (xerostomia). These side effects are rare, but if they occur, patients can try to eat foods that are easy to digest, drink plenty of water to keep the mouth and throat moist, keep lips moist with lip balm, and patients can try sucking on hard candies to alleviate the dry mouth.

The side effects of chemotherapy are bone marrow suppression causing **anemia** and low platelets. This causes weakness or bleeding. Other problems are **nausea and vomiting**, hair loss (alopecia), and inflammation of the oral mucosa. The symptoms are improved with medications.

Depression, if it occurs, is often temporary and can be managed by counseling and family support. Medication is usually not necessary.

Clinical trials

Seven clinical trials taking place for patients diagnosed with various types of thyroid cancer were studying the effectiveness of radioimmunotherapy and peripheral stem cell transplants, combination chemotherapy (using such drugs as **paclitaxel**, **trastuzumab**, and interleukin-12), and vaccine therapy. Information about current clinical trials is available through the National Institutes of Health.

Prevention

Because most people with thyroid cancer have no known risk factor, it is not possible to prevent this

KEY TERMS

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Calcitonin—A hormone produced by the parafollicular cells (C cells) of the thyroid. The main function of the hormone is to regulate calcium levels in body serum.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing them.

Hormone therapy—Treatment of cancer by inhibiting the production of hormones such as testosterone and estrogen.

Hyperthyroidism—A condition in which the thyroid is overactive due to overstimulation of the thyroid cells.

Hypothyroidism—A condition in which the thyroid gland is underactive.

Lobectomy—A surgical procedure that removes one lobe of the thyroid.

Radiation therapy—Treatment with high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Total thyroidectomy—A surgical procedure that removes the entire thyroid gland.

QUESTIONS TO ASK THE DOCTOR

- What type of thyroid cancer do I have?
- Has it spread?
- Is my thyroid cancer hereditary? Should other members of my family be tested?
- What treatment do you recommend? Do you recommend a clinical trial?
- What are the advantages, disadvantages, and side effects of this treatment?
- How much experience do you have treating thyroid cancer/performing thyroid surgery?

disease completely. However, the risk for radiation-related thyroid cancer can be reduced by avoiding radiation to the neck when possible, and inherited cases of medullary thyroid cancer can be prevented. If a family member has had this disease, the rest of the family can be tested and treated early. Carriers of the RET mutation may want to consider undergoing prophylactic thyroidectomy at an early age. The National Cancer Institute recommends that every one or two years, a doctor examine anyone who has received radiation to the head and neck during childhood. The neck and the thyroid should be carefully examined for any lumps or enlargement of the nearby lymph nodes. Ultrasound may also be used to screen for the disease in people at risk for thyroid cancer.

Special concerns

Complications of surgery are very rare with experienced surgeons. Sometimes injury to the nerves in the neck can cause a husky voice or difficulty singing high notes. This can be improved with collagen injection after surgery. Occasionally there is bleeding after the surgery and the incision is reopened to evacuate the clot and stop the bleeding. Patients may have a slightly increased risk of developing another cancer (such as leukemia) in the future after undergoing radioiodine treatment, but this correlation has not been proven. Because thyroid cancers may grow slowly and may recur decades after treatment, follow-up care is important.

Thyroid nuclear medicine scan

Definition

A thyroid nuclear medicine scan is a diagnostic procedure to evaluate the thyroid gland, which is located in the front of the neck and controls the metabolism of the body. A radioactive substance that concentrates in the thyroid is taken orally or injected into a vein (intravenously), or both. There are three types of radioactive iodine used in these scans. A special camera is used to take an image of the distribution of the radioactive substance in and around the thyroid gland. This is interpreted to evaluate thyroid function and to diagnose abnormalities. Although other imaging methods exist for evaluating thyroid disease, thyroid scanning is the most commonly used and is the most cost-effective.

Purpose

A thyroid scan can help assess the overall structure and function of the thyroid. It can be used to identify benign cancers, to assess nodules, to evaluate masses, to locate the source of a painful gland, to assess gland size, to find differentiated carcinomas, and to identify thyroid tissue. A thyroid scan may be ordered by a physician when the gland becomes abnormally large, especially if the enlargement is greater on one side, or when hard lumps (nodules) are felt. The scan can be helpful in determining whether the enlargement is caused by a diffuse increase in the total amount of thyroid tissue or by a nodule or nodules. The thyroid scan plays a critical role in the diagnosis of **thyroid cancer**.

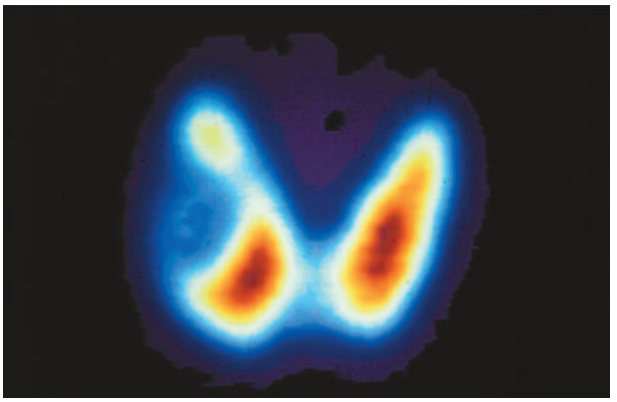
When other laboratory studies show an overactive thyroid (hyperthyroidism) or an underactive thyroid (hypothyroidism), a radioactive iodine uptake scan is often used to confirm the diagnosis. A thyroid scan is often performed in conjunction with this scan. Thyroid radionuclide scanning is being considered as a means to screen individuals at risk for thyroid disease following **radiation therapy**.

Precautions

Women who are pregnant should not have this test. Any person with a history of allergy to iodine, such as those with shellfish allergies, should notify the physician before the procedure is performed.

Description

This test is performed in a radiology facility, either in an outpatient x-ray center or a hospital department. Most often, the patient is given the radioactive substance in the form of a tasteless liquid or capsule. It may be injected into a vein (intravenously) in some instances. Generally, the patient lies on an examination table as the scanning is performed. Images will be taken at a specified amount of time after this, depending on the radioisotope used. Most often, scanning is done 24 hours later, if the radioisotope is given orally. If it is given intravenously, the scan is performed approximately 20 minutes later.



A gamma scan of the human thyroid gland revealing cancer. *(Custom Medical Stock Photo. Reproduced by permission.*

For a thyroid scan, the patient is positioned lying down on his or her back, with the head tilted back. The radionuclide scanner, also called a gamma camera, is positioned above the thyroid area as it scans. This takes 30–60 minutes.

The uptake study may be done with the patient sitting upright in a chair or lying down. The procedure is otherwise the same as described for the thyroid scan. It takes approximately 15 minutes. There is no discomfort involved with either study.

A thyroid scan may also be referred to as a thyroid scintiscan. The name of the radioactive substance used may be incorporated and the study called a technetium thyroid scan or an iodine thyroid scan. The radioactive iodine uptake scan may be called by its initials, an RAIU test, or an iodine uptake test.

Preparation

Certain medications can interfere with iodine uptake. These include certain cough medicines, some oral contraceptives, non-steroidal anti-inflammatory drugs, epilepsy drugs, and thyroid medications. The patient is usually instructed to stop taking these medications for a period of time before the test. This period may range from several days up to three to four weeks, depending on the amount of time the medicine takes to clear from the body.

Other **nuclear medicine scans** and x-ray studies using contrast material performed within the past 60 days

KEY TERMS

Adenoma—A type of non-cancerous tissue that emanates from glands.

Benign—A type of tissue overgrowth that is not progressive, unlike malignant tissue.

Graves' disease—A condition characterized by bulging eyeballs, among other symptoms, that is synonymous with hyperthyroidism.

Radioisotope—A radioactive or radiation-emitting form of an element.

Radionuclide—A substance that emits radiation as it disintegrates.

may affect this test. Therefore, patients should tell their doctors if they have had either of these types of studies before the thyroid scan is begun, to avoid inaccurate results.

Thyroid scan test results can be affected by other conditions, such as kidney failure, cancer, cancer **chemotherapy**, hepatitis, cirrhosis of the liver, infections, trauma, poor nutrition, and mental illness.

Some institutions prefer that the patient have nothing to eat or drink after midnight on the day before the radioactive liquid or capsule is to be taken. A normal diet can usually be resumed two hours after the radioisotope is taken. Dentures, jewelry, and other metallic objects must be removed before the scanning is performed. No other physical preparation is needed.

The patient should understand that there is no danger of radiation exposure to themselves or others. Only very small amounts of radioisotope are used. The total amount of radiation absorbed is often less than the dose received from ordinary x rays. The scanner or camera does not emit any radiation, but detects and records it from the patient.

Aftercare

No isolation or special precautions are needed after a thyroid scan. The patient should check with his or her physician about restarting any medications that were stopped before the scan.

Risks

There are no risks with this procedure.

Normal results

A normal scan will show a thyroid of normal size, shape, and position. The amount of radionuclide uptake by the thyroid will be normal, according to established laboratory figures. There will be no areas where radionuclide uptake is increased or decreased.

Abnormal results

An area of increased radionuclide uptake may be called a hot nodule or "hot spot." This means that a benign growth is overactive. Despite the name, hot nodules are unlikely to be caused by cancer. Increased radionuclide uptake is indicative of hyperthyroidism and may suggest Graves' disease or an active pituitary **adenoma**.

An area of decreased radionuclide uptake may be called a cold nodule, or "cold spot." This indicates that this area of the thyroid gland is underactive. A variety of conditions, including cysts, hypothyroidism, nonfunctioning benign growths, localized inflammation, or cancer, may produce a cold spot. Single nodules that are not functioning are malignant in about 10–20% of cases. Completely nonfunctioning nodules have a higher probability of being malignant than those that have some degree of function.

A thyroid nuclear medicine scan is rarely sufficient to establish a clear diagnosis. A majority of nonfunctioning nodules are not malignant, but their presence increases the probability of a malignancy. Nodules that are functioning are rarely malignant. Frequently, the information revealed will need to be combined with data from other studies to determine the problem.

Topotecan

Definition

Topotecan is a drug used to treat certain types of cancer. Topotecan is available under the trade name Hycamtin, and may also be referred to as topotecan hydrochloride or topotecan HCl.

Purpose

Topotecan is an antineoplastic agent used to treat small cell lung cancer, and certain cancers of the ovary.

As of late 2003, clinical trials are underway in Italy and France to test the effectiveness of topotecan in treating tumors of the brain (glioblastomas) and autonomic nervous system (neuroblastomas). In the French study, topotecan is given together with radiotherapy while the Italian trial uses topotecan as part of combination chemotherapy. Early results indicate that the drug may be useful in treating cancers of the nervous system as well as ovarian and small-cell lung cancers.

Description

Topotecan is a synthetic derivative of the naturally occurring compound camptothecin. Camptothecin belongs to a group of chemicals called alkaloids, and is extracted from plants such as *Camptotheca acuminata*. Captothecin was initially investigated as a chemotherapeutic agent due to its anti-cancer activity in laboratory studies. The chemical structure and biological action of topotecan is similar to that of camptothecin and **irinotecan**.

Topotecan inhibits the normal functioning of the enzyme topoisomerase I. The normal role of topoisomerase I is to aid in the replication, recombination and repair of deoxyribonucleic acid (DNA). Higher levels of topoisomerase I have been found in certain cancer tumors compared to healthy tissue. Inhibiting topoisomerase I causes DNA damage. This damage leads to apoptosis, or programmed cell death.

Topotecan is used in patients whose cancer of the ovary has recurred or progressed after platinum-based treatment such as **cisplatin**. Topotecan is also used to treat relapse of small cell lung cancer that initially responded to other drugs. Increases in survival times have been observed in patients treated with topotecan compared to control populations treated with **paclitaxel**.

Tumors that are targeted by topotecan sometimes develop resistance to the drug. Although the reasons for this resistance are not fully understood as of late 2003, researchers think that they may be related either to inadequate amounts of drug in the tumor or to alterations in topoisomerase I that make the enzyme resistant to topotecan.

KEY TERMS

Alkaloid—A nitrogen containing compound occuring in plants

Anorexia—Loss of appetite and the inability to eat

Apoptosis—An active process in which a cell dies due to a chemical signal. Programmed cell death.

Recommended dosage

Patients should be carefully monitored before and during topotecan treatment for bone marrow function.

Topotecan is administered intravenously over 30 minutes once per day for five consecutive days followed by 16 days of rest. This schedule may be repeated every 21 days. The initial dose of topotecan may be adjusted downward depending on patient tolerance to the toxic side effects of topotecan.

The dose of topotecan may be reduced in patients with kidney dysfunction.

No dose modification is necessary for patients with liver impairment.

No dose modification is necessary for elderly patients.

Precautions

Topotecan should be used only under the supervision of a physician experienced in the use of cancer chemotherapeutic agents. Certain complications will only be possible to manage if the necessary diagnostic and treatment resources are readily available. Topotecan should not be used in patients with bone marrow **depression** before starting treatment. Skin that comes in contact with topotecan must be washed thoroughly with soap and warm water.

The dose of topotecan may be reduced in patients with moderate kidney dysfunction. Topotecan is not recommended for use in patients with severe kidney dysfunction.

Topotecan should not be administered to pregnant women. Women of child bearing age are advised not to

become pregnant during treatment. Women should discontinue nursing prior to taking topotecan.

Side effects

Suppression of bone marrow function is the most serious side effect commonly observed in this treatment and can lead to death. Bone marrow reserves should be monitored by blood cell counts for all patients before and during topotecan treatment. The suppression of bone marrow is not cumulative over time. Additional side effects including nausea and vomiting, **anorexia**, **diarrhea**, constipation, headache and hair loss (alopecia) may occur.

Interactions

Suppression of bone marrow is more severe when topotecan is given with platinum drugs. G-CSF (**filgrastim**) may extend the duration of bone marrow suppression. If G-CSF is used, it should not be administered until day six of the 21-day course.

Toremifene

Definition

Toremifene, also known as Fareston, is a synthetic compound similar to estrogen. It mimics the action of estrogen on the bones and uterus, but blocks the effects of estrogen on breast tissue.

Purpose

Toremifene is used as adjuvant hormone therapy immediately after surgery in early stages of **breast cancer** and also to treat advanced metastatic breast cancer (stages III and above) in postmenopausal women. Postmenopausal women at high risk of developing breast cancer may take toremifene to reduce risk.

Description

Toremifene is similar to **tamoxifen** in structure and action. Toremifene can be given as sole treatment, but it is often given in combination with other chemotherapeutic drugs.

Toremifene belongs to a family of compounds called **antiestrogens**. Antiestrogens are used in cancer therapy by inhibiting the effects of estrogen on target tissues. Estrogen is a steroid hormone secreted by granulosa cells of a maturing follicle within the female ovary. Depending on the target tissue, estrogen can stimulate the growth of female reproductive organs and breast tissue, play a role in the female menstrual cycle, and protect against bone loss by binding to estrogen receptors on the outside of cells within the target tissue. Antiestrogens act selectively against the effects of estrogen on target cells in a variety of ways, thus they are called selective estrogen receptor modulators (SERMs).

Toremifene selectively inhibits the effects of estrogen on breast tissue, while mimicking the effects of estrogen on bone (by increasing bone mineral density) and uterine tissues. The former makes toremifene an excellent therapeutic agent against breast cancer. Although researchers are unclear of the precise mechanism by which toremifene kills breast cancer cells, it is known to compete with estrogen by binding to estrogen receptors, therefore limiting the effects of estrogen on breast tissue. Toremifene also may be involved in other anti-tumor activities affecting oncogene expression, promotion of apoptosis and growth factor secretion.

In 2003, clinical trials were underway to test toremifene citrate for treating complications of certain therapies for prostate cancer patients. For example, androgen deprivation therapy results in increased bone fractures

among prostate cancer patients. Researchers believe that toremifene citrate will help reduce these and other effects.

Recommended dosage

Toremifene is taken orally, and the recommended dose is usually 40 to 60 milligrams once a day, although larger doses are sometimes prescribed. If a dose is missed, patients should not double the next dosage. Instead, they should return to their regular schedule and contact their doctor.

Precautions

Toremifene is not recommended for use in children. Women who are pregnant or nursing should not use this drug since it has several side effects that, although rare, can be severe. It is known to cause miscarriages and birth defects. Women are encouraged to use birth control while taking toremifene. However, oral contraceptives can negatively alter the effects of toremifene. Therefore, patients should explore other birth control options.

Great care should be exercised when toremifene is used with **warfarin**, an anticoagulant, because toremifene can amplify the effects of warfarin, prolonging bleeding times. The result could possibly be fatal. Patients who are predisposed to the formation of thromboembolisms should use toremifene with caution, because toremifene can increase the risk.

Side effects

Although toremifene is usually well tolerated by patients, there are some side effects. One of the most serious side effects is development of uterine cancer. Less common effects include eye problems such as retinal lesions, macular edema and corneal changes (most resolve themselves after use is discontinued); neurological problems such as **depression**, dizziness, confusion, and **fatigue**; and genital problems such as vaginal bleeding, vaginal discharge, and endometriosis. Patients also may experience liver problems.

Interactions

Toremifene can interfere with the anticoagulant drug warfarin, resulting in severe consequences and death. If these two drugs are used together, patients will be monitored closely. Oral contraceptives and estrogen supplements can also interfere with the action of toremifene.

See also Raloxifene.

KEY TERMS

Adjuvant—a treatment added to curative procedures such as surgery to prevent the recurrence of cancer

Anticoagulant—an agent preventing the coagulation of blood

Apoptosis—a type of cell death where cells are induced to commit suicide

Granulosa cells—cells that form the wall of the ovarian follicle

Oncogene—a gene whose presence can cause cancer; these genes usually arise through mutation of a normal gene

Ovarian follicle—several layers of cells that surround a maturing egg in the ovary

Thromboembolism—a blood clot that blocks a blood vessel in the cardiovascular system

Tositumomab

Definition

Tositumomab is a mouse monoclonal antibody that directly targets and binds with the CD20 receptor of normal and malignant B-cell lymphocytes. When linked with iodine I-131, Tositumomab creates an effective radioimmunotherapy agent, Iodine I-131 Tositumomab; also known as the BEXXAR® therapeutic regimen.

Purpose

As part of the BEXXAR@reg; therapeutic regimen, Tositumomab is used in the treatment of patients with CD20 positive, follicular, **non-Hodgkin's lymphoma** (NHL), with or without transformation, whose disease is untreatable with **Rituximab** and has relapsed following **chemotherapy**. Clinical studies of the BEXXAR® therapeutic regimen have shown positive overall response

rates (approximately 63%) and prolonged response durations (upwards of 25 months).

Description

Tositumomab, a monoclonal antibody, can recognize and target the protein produced by the CD20 receptor commonly found on the surface of normal and malignant B-cell lymphocytes. Once injected into the body, the monoclonal antibody seeks out and binds with the CD20 receptor, much as a key fits into a lock. Once attached to the CD20 receptor, the antibody produces a cytotoxic effect and triggers the body's immune system against the cancer cell. This, in turn, exposes the cancer cell, making it more susceptible to radiation. When combined with a radioactive substance, in this case Iodine I-131, the monoclonal antibody allows the ionizing radiation to directly target the cancerous lymphocytes. As lymphomas are particularly vulnerable to radiotherapy, the BEXXAR® therapeutic regimen increases the chance of destroying malignant **lymphoma** B-cells.

The Food and Drug Administration (FDA) approved the Corixa Corporation's BEXXAR® (Tositumomab and Iodine I-131 Tositumomab) therapeutic regimen for the treatment of NHL in June 2003. Clinical studies based on cumulative clinical experience between 1995 and 2005 showed the benefits of the BEXXAR® therapeutic regimen, based on durable responses without evidence of an effect on patient survival.

Recommended dosage

Intended for a single course of treatment, the BEXXAR® therapeutic regimen is administered in two discrete stages over a period of one to two weeks. These stages, the dosimetric stage and the therapeutic stage, are conducted over a period of four hospital visits.

Before treatment begins, and for two weeks subsequent to the therapeutic stage, the patient is provided with daily iodine supplements, typically provided in the form of liquid drops or tablets. The supplements protect the patient's thyroid gland from the radioactive I-131 during the treatment.

At the beginning of the dosimetric stage of the BEXXAR® treatment, paracetamol and antihistamine drips are administered to counteract possible side effects. The patient is provided with a sequential infusion of Tositumomab, totaling 450 mg, over the next hour. This step of the treatment assures that the infusion of Iodine I-131 Tositumomab will spread evenly throughout the patient's body. Finally, an infusion of 35 mg Tositumomab and 5 mCi Iodine I-131 (Iodine I-131 Tositumomab) is administered for 20 minutes. The patient then undergoes the first of three body scans to determine the levels of radioactivity within the patient's body and where it is located. The patient undergoes a second and third body scan at days two to four and days six to seven, respectively. These scans allow the doctor to determine the appropriate dosage for the therapeutic stage of the treatment. This is a complicated evaluation process, and as such, the BEXXAR® treatment is only available to physicians with the required training to make proper assessments.

The therapeutic stage begins on the fourth hospital visit, which typically takes place 7 to 14 days after the dosimetric stage. Once again, the patient is provided with a sequential infusion drip of Tositumomab, totaling 450 mg, over a one-hour period. This is followed by an infusion of Iodine I-131 Tositumomab, consisting of 35mg Tositumomab and a dosage of Iodine I-131 determined by the findings from the dosimetric stage. Additional factors, such as the presence of **thrombocytopenia**, can require the dosage of Iodine I-131 to be reduced.

Precautions

The BEXXAR® therapeutic regimen is contraindicated for patients with known hypersensitivity to murine (mouse) proteins and/or intolerance to thyroid-blocking agents. Patients should be screened for human hypersensitivity antibodies (HAMA) to avoid risk of serious reactions, including anaphylaxis. Patients with impaired hepatic or renal function, impaired bone marrow reserves, and/or more than 25% lymphoma marrow involvement should use caution when considering the BEXXAR® therapeutic regimen, as safety and efficacy have not as of 2005 been clinically established.

Due to the radioactive components of this treatment, the BEXXAR® therapeutic regimen can cause fetal harm and, as such, is contraindicated for pregnant woman. Additionally, an effective contraceptive should be used during and for at least a year following therapy to prevent possible birth defects. Patients wishing to have children should speak with their healthcare provider, as Iodine I-131 tositumomab possesses the risk of toxic effects on male and female fertility.

Patients must strictly follow all safety measures associated with radioactivity during and after therapy, as their bodies will remain radioactive during this time. Healthcare providers will inform their patients of specific safety instructions and their duration. Typical precautions include minimizing close contact (within six feet) with family members. Infants, young children, and pregnant women are particularly susceptible and should be strictly avoided. Nursing is strongly contraindicated, as radioiodine is excreted in breast milk and can build up to levels equal to or greater than those found in the mother.

KEY TERMS

Cytopenias—Disorders which cause a severe deficiency in the production of one or more the blood cell types; red blood cells (anemia), white blood cells (neutropenia), and platelets (thrombocytopenia). Cytopenias can be caused by cancer, chemotherapy, and radiation therapy.

Monoclonal antibodies—Monoclonal antibodies recognize and lock onto the proteins found on the surface of cancer cells. They can cause the cancer cells to destroy themselves, as well as directly target the body's immune system against the cancer cells. This form of passive immunotherapy can even be effective for treating patients with weakened immune systems, as the monoclonal antibodies are mass produced outside the body in a laboratory setting.

Myelodysplasia—A group of disorders in which the bone marrow does not function normally and produces insufficient number of normal blood cells.

Non-Hodgkin's lymphoma—A disease that causes malignant cancer cells to form in the lymphatic system and is unpredictable in nature and more likely to spread to other sites.

Radioimmunotherapy—A treatment modality, in which cytotoxic radiation is delivered directly to a tumor via binding antibodies. Also known as targeted radiotherapy.

Patients should avoid sharing the same bed or using the same hygienic facilities as other people. Finally, prolonged travel (three to four hours) in close proximity to others should be avoided, such as cars, trains, or airplanes. If possible, the patient should remain as far as possible from others during short trips.

Side effects

Clinical studies of the BEXXAR® therapeutic regimen have shown prolonged and severe cytopenias to be the most common adverse reactions, occurring in 71% of the patients studied. Thrombocytopenia and **neutropenia** were the primary forms of cytopenia, documented in 63% and 53% of patients undergoing therapy, respectively. **Anemia** also appeared in 27% of the studied patients. These adverse effects also included the consequences commonly associated with cytopenias, such as infections, hemorrhaging, and the requirement of blood growth factors and/or blood support.

Allergic reactions (angiodema and bronchospasm), **pneumonia**, secondary leukemia, solid tumors, and myelodysplasia were also observed. The most frequent non-hematological adverse effects observed in patients included asthenia (weakness), **fever**, nausea, gastrointestinal symptoms, chills, and pruritus (intense **itching**). Other known side effects include back pain, constipation, **diarrhea**, dizziness, and headache. The BEXXAR® therapeutic regimen is also associated with further risks of infusion-related reactions, delayed-onset hypothyroidism, and HAMA. Health providers should inform patients of these risks before beginning treatment.

Interactions

Although no formal drug interaction studies have been conducted on the BEXXAR® therapeutic regimen, patients should avoid certain drugs unless specifically prescribed by their health provider. These drugs include aspirin, ibuprofen, ketoprofen, and naproxen, as these drugs may mask a fever or increase the risk of hemorrhaging. Additionally, anticoagulants and agents interfering with platelet function may increase the risk of bleeding. Tositumomab may decrease the response to and increase the risk of adverse reactions to live-virus **vaccines**. As such, patients undergoing the BEXXAR® therapeutic regimen are strongly urged to consult with their health provider before undergoing any form of immunization.

Tracheostomy

A tracheostomy is an artificial airway, which is surgically inserted through the windpipe to allow normal respiration.

The key purpose of a tracheostomy is to provide a patient with an open, functional airway. Normal respiration can become hindered or blocked by an obstruction to the upper respiratory tract; the area between the nose and mouth down through the larynx. When a serious obstruction occurs, normal respiratory techniques, such as oral or nasal intubation, may be inadequate or completely ineffective. Obstructions can come from several sources, including foreign bodies, swollen soft tissue, and injury to the larynx and/or trachea. Furthermore, proper respiration can also be obstructed by the growth of malignant tumors in the mouth, larynx, trachea, nasopharynx (the space above and behind the soft palate), and the nasal cavity and paranasal sinuses.

Proper oxygenation of the lungs may also require the use of a tracheostomy. Malignant pulmonary cancers, such as bronchioloalveolar **carcinoma** and **mesothelioma**, can cause serious respiratory problems, including hypoxia (an insufficient oxygen level in the blood and tissues) or hypercapnia (excess levels of carbon dioxide in the blood due to hypoventilation). A tracheostomy can provide the required oxygen levels via the tracheobronchial tree, also known as the bronchia.

A tracheostomy may also be used to clean and remove secretions that build up in the bronchia and throat due to injury, disease, and tumors. This excess fluid can cause obstructions and/or restrict proper oxygenation. Blood and secretions can be suctioned out through the trachea to relieve breathing problems.

There are no known contraindications for the use of a tracheostomy. However, some surgical modalities, such as removal of malignancies, may be required prior to the tracheotomy procedure.

At the simplest level, a *tracheostomy* is an artificial airway that is inserted into the trachea (windpipe) to bypass the upper airway. The surgical procedure to create this secondary airway is known as a *tracheotomy*. Tracheostomies provide physicians with one of the most effective methods to relieving breathing problems due to obstruction. Indeed, historical evidence reveals that tracheostomies may have been used as far back as 2000B.C. Since Antonio Brasavola performed the first documented tracheotomy in the 16th century, surgeons and doctors have been developing and refining this effective medical procedure.

The most common form of tracheostomy is a hollow tube of plastic, silicon, or metal, also known as a tracheostomy tube or trach. During a tracheotomy, this tube is surgically inserted into the patient's neck just beneath the larynx to provide access to the trachea, thus acting as a secondary airway. The surgical opening through which the tracheostomy is inserted is also known as the stoma. Depending on the underlying cause of obstruction and/or respiratory distress, a tracheostomy may be temporary or permanent in nature. Tracheostomies are far more effective for suctioning purposes and maintaining respiratory function than other artificial airways. There are three key types of tracheotomies: *Elective*, *Awake*, and *Emergent*.

- Elective—The majority of tracheotomy procedures are elective in nature. Most patients will have already been intubated by this point in time and may require more prolonged and/or more effective form of intubation. These procedures are conducted under controlled conditions, usually performed in a hospital's operating room under the supervision of a surgeon and anesthesiologist.
- Awake—Acute respiratory distress may require an "awake" tracheotomy. These procedures are typically conducted under controlled conditions and using local anesthesia. However, the patient remains conscious throughout the procedure, which can be extremely disconcerting for the patient. The operating surgeon must be prepared for difficulties caused the heightened levels of anxiety the patient will undoubtedly exhibit.
- Emergent—Emergent tracheotomies, sometimes crudely referred to as "slash" tracheostomies, generally

should not be considered unless the patient is in extremis and intubation is inadvisable. Even in these extreme cases, a cricothyrotomy is more advisable to relieve respiratory distress that a tracheotomy.

There are several variations of the tracheotomy, but follow a basic guideline. Once the patient is anesthetized, either generally or locally, the neck is cleaned and positioned. Surgical incisions expose the tough cartilage rings that form the trachea's outer wall. An incision is made through two of these rings and a tracheostomy tube inserted into the windpipe.

Tracheostomy tubes come in a variety of shape, sizes, and compositions. Tubes are generally designed to meet specific medical requirements, and can be either disposable or reusable in nature. The Universal is most commonly used tracheostomy tube. Also known as the "double-luman" or "double-cannula" tube, the Universal consists of three parts: the outer cannula (with cuff and pilot tube), the inner cannula, and the obturator. Other commonly used tracheostomy tubes include:

- Single cannula (used for patients with long and/or thin necks)
- Fenestrated (allow speech and improve swallow function)
- Tracheostomy Button (used to wean patients before final removal of tracheostomy tubes or in the treatment of sleep apnea)
- Cuffed tube (used commonly when mechanical ventilation is required and prevents aspiration of secretions)
- Cuffless tube (used in long-term management)

If possible, the patient should fully discuss the procedure and other viable opinions with their physician at length before undergoing a tracheostomy. Additionally, cancers of the upper airway and throat may require the use of other surgical procedures beforehand. In these cases, an effective treatment plan incorporating the tracheostomy should be established. Stabilization of precipitating factors may also be required beforehand.

Successful tracheostomies require effective and thorough postoperative care. Patients may require one to three days to breathe normally following the insertion of a tracheostomy tube. The tube may prevent verbal communication for a prolonged period, and other methods of communication should be utilized. All patients with tracheostomy tubes require humidification to prevent further complications associated with inspired gases. Aftercare modalities should strive to accomplish four key goals:

- Maintain the patient's airway
- Maintain tracheal integrity
- Avoid infections
- Avoid tube displacement

Patients and family members should be educated in aftercare modalities and information as soon as possible. Home nursing service may be required for patients. Otherwise, a return to regular home life is encouraged. However, while outdoors, a scarf or similar covering around the throat is indicated.

Directly following the procedure, the trachea will produce excessive secretions due to trauma. In addition to monitoring of these secretions, continual saline irrigation and suctioning will be required. Mucolytic (antimucus) agents can be utilized to prevent dangerous obstructions. Assessment of the patient's vital signs should also be maintained, in addition to monitoring for other complications associated with surgery.

Further complications can be encountered at all stages of recovery following a tracheotomy: *immediate*, *early*, and *late*.

Immediate complications can occur directly following the tracheotomy and include:

- Apnea
- Bleeding
- Pneumothorax (accumulation of air or gas in the pleural cavity)
- Pneumomediastinum (escape of air into the pleural tissues)
- Injury to adjacent structures
- Postobstructive pulmonary edema (accumulation of fluid in the lungs)

Early complications typically occur within seven days of the tracheotomy and include:

- Bleeding
- Mucus obstructions
- Inflammation of the trachea
- Inflammation of subcutaneous or connective tissue around the incision
- Tube displacement
- Subcutaneous emphysema (air or gas in subcutaneous tissues)
- Total or partial collapse of the lung

Late complications can occur at any time seven days following the tracheotomy and can include:

- Bleeding

KEY TERMS

Cricothyrotomy—Aprocedure in which an incision is made through the skin and the cricothyroid-membrane for emergency relief of upper respiratory obstruction, used prior toor in place of tracheotomy.

Larynx—The section of theupper respiratory tract between the pharynx and the trachea.

Trachea—Alsoknown as the windpipe, the trachea is a thin-walled, cartilaginous tubedescending from the larynx to the bronchi.

Tracheobronchial tree —Ananatomical structure in the chest, which appears like an upside-down tree andis composed of the trachea and bronchi.

- Tracheomalacia (degeneration of the elastic and connective tissue of the trachea)
- Tracheoesophageal fistula (an abnormal connection between the trachea and the esophagus)
- Tracheocutaneous fistula (an abnormal connection between the trachea and the surface of the neck)
- Granulation and scarring
- Failure to remove the tracheostomy tube

The normal tracheostomy can be used for days, weeks, and even or years with proper treatment. However, tracheostomy tubes should be downsized and removed as quickly as medically viable. Once the tracheostomy is removed, the stoma is sealed and allowed to heal over a period of five to seven days. Typically, a full recovery can be expected within two weeks with little to no scarring.

Several abnormal results of varying seriousness areassociated with tracheostomies. However, patients should contact localemergency services if their tracheostomy tube is dislodged and cannot bereplaced. Additional concerns include:

- Infection
- Fever
- Chills
- Incision sites problems, such asswelling, increased pain, and excessive bleeding
- Nausea and/orvomiting
- Shortness of breath and/or cough despite suctioning
- Persistent speech difficulties after tracheostomy removal

Transfusion therapy

Definition

The process of transferring whole blood or blood components from one person (donor) to another (recipient).

Purpose

Transfusions are given to restore lost or depleted blood components, to improve clotting time, and to improve the ability of the blood to deliver oxygen to the body's tissues. Typical reasons cancer patients receive blood transfusions are for **anemia** (low red blood cell count) and for clotting factors or platelets (for example, in certain types of leukemia).

Precautions

For donors, the process of giving blood is very safe. Only sterile equipment is used and there is no chance of catching an infection from the equipment. There is a slight chance of infection at the puncture site if the skin is not properly washed before the collection needle is inserted. Some donors feel light-headed upon standing for the first time after donating. Occasionally, a donor will faint. Donors are advised to drink plenty of liquids

to replace the fluid lost with the donation of blood. It is important to maintain the fluid volume of the blood so that the blood pressure will remain stable. Strenuous exercise should be avoided for the rest of the day. Most patients have very slight symptoms or no symptoms at all after donating blood. People who have cancer usually are not considered candidates for blood donation.

For recipients, a number of precautions must be taken by the blood bank. The blood given by transfusion must be matched with the recipient's blood type. Incompatible blood types can cause a serious adverse reaction (transfusion reaction). Blood is introduced slowly by gravity flow directly into the veins (intravenous infusion) so that medical personnel can observe the patient for signs of adverse reactions. People who have received many transfusions (such as leukemia patients) can develop an **immune response** to some factors in foreign blood cells. This immune reaction must be checked before giving new blood. Infectious diseases can also be transmitted through donated blood. However, many safeguards are in place in the United States to minimize the risk of transmission of blood-borne pathogens (agents in the blood that cause disease) to recipients.

Description

WHOLE BLOOD Either whole blood or blood components can be used for transfusion. Whole blood is used exactly as it was received from the donor. Blood components are parts of whole blood, such as red blood cells (RBCs), plasma, platelets, clotting factors, immunoglobulins, and white blood cells. Whole blood is used only when needed or when components are not available. Most of the time, whole blood is not used because the patient's medical condition can be treated with a blood component. Too much whole blood can fluid-overload a patient's circulatory system. This can create high blood pressure and congestive heart failure (overwork of the heart muscle to pump the extra fluid volume). The use of blood components is more efficient and effective because blood that has been fractionated (processed) into components can be used to treat more than one person.

PLASMA Plasma is the liquid portion of blood. It contains many useful proteins, especially clotting factors and immunoglobulins. After they are processed, plasma or plasma factors (fractions) are usually frozen. Some plasma fractions are freeze-dried. These fractions include clotting factors I through XIII. Some people have an inherited disorder in which the body produces too little of the plasma clotting factors VIII (hemophilia A) or IX (hemophilia B). Transfusions of these clotting factors help people with hemophilia to stop bleeding. Frozen plasma must be thawed before it is used and freeze-dried plasma must be mixed with liquid (reconstituted). In both cases, these blood fractions are usually small in volume and can be injected by syringe and needle.

RED BLOOD CELLS Red blood cells are the blood component most frequently used for transfusion. RBCs are the only cells in the body that transport oxygen. A transfusion of RBCs increases the amount of oxygen that can be carried to the tissues of the body. RBCs that have been separated from the liquid plasma (packed RBCs) are given to people who have anemia (low red cell count) or who have lost a lot of blood. There are many causes of anemia. In cancer, anemia is caused by the destruction of red blood cells by disease, by medications such as **chemotherapy**, or by disease in the bone marrow where red blood cells are produced. To determine how serious the anemia is, the physician will do a CBC (complete blood count) to look at the hemoglobin level (the oxygen-carrying capacity of the red blood cells), and a hematocrit (the percentage of RBCs in a given volume of blood).

PLATELETS Platelets are another component frequently given by transfusion. Platelets are a key factor in blood clotting. The clear fluid that carries blood cells (plasma) also contains blood-clotting factors. The platelets and plasma clotting factors are extracted from donated blood and concentrated for use. These factors are used to treat cancer patients whose bone marrow has been destroyed by disease. Cancer patients may need platelet transfusions when their bone marrow is not producing enough platelets, either because the bone marrow has been damaged by chemotherapy or because it has been replaced by the growth of cancer cells. Dangerous bleeding may occur if the platelet count is too low. However, if there is no evidence of bleeding (no clinical signs of bleeding), platelets may not be given even if the count is low.

IMMUNOGLOBULINS Immunoglobulins, also called gamma globulin or immune serum, are collected from plasma for use in temporarily boosting the immune capability of a patient. White blood cells (WBCs) are another infection-fighting component of the blood. White blood cells are given by transfusion only rarely. Immunoglobulins are the infection-fighting fraction of blood plasma. This blood fraction is given to people who have difficulty fighting infections, especially people whose immune systems are depressed by diseases, such as HIV/AIDS and cancer. Immmunoglobulins are also used to prevent tetanus after cuts, to treat animal bites when rabies infection is suspected, or to treat severe childhood diseases. Immunoglobulins can also be used to treat idiopathic thrombocytopenic purpura (ITP), a condition characterized by a low platelet count and excessive bruising.

This boy is receiving a transfusion for sickle cell anemia. Cancer patients may receive blood transfusions to treat anemia, or to receive clotting factors or platelets (in certain types of leukemia, for example). *(Custom Medical Stock Photo. Reproduced by permission.)*

COLONY-STIMULATING FACTORS OR GROWTH FACTORS Granulocytes are a type of white blood cell that fight infection. Granulocyte transfusion is no longer done because of the **fever** it produces and the potential transmission of infectious diseases through white cells. These infections (CMV or cytomegalovirus) would be particularly dangerous to a cancer patient with a weakened immune system. Chemotherapy patients can develop a low WBC (white cell count). A specific white blood cell called the neutrophil is carefully monitored because it is very important in fighting multiple types of infection. If neutrophil counts are very low, the physician may order special medications that stimulate the production of neutrophils in the bone marrow. These medicines are called colony-stimulating factors or growth factors, and include granulocyte colony-stimulating factor (G-CSF, or filgrastim), granulocyte macrophage colony-stimulating factor (GM-CSF, or sargramostim), and interleukin-3.

ALTERNATIVES TO BLOOD TRANSFUSION Researchers have been working to develop a substitute for blood that will avoid the risks associated with blood transfusion. Products are being developed that will perform the functions of red blood cells, such as carrying oxygen through the blood stream, but there is no real substitute for the transfusion of human blood. Two products that are currently available are known as hemoglobin-based oxygen carriers and perfluorochemical compounds. These products can be used on a short term basis to perform the function of blood, but are still considered experimental.

Other types of products that can help patients in need of large volumes of body fluids are volume expanders such as normal saline solution, lactated ringers, or dextran. These are IV (intravenous) solutions that can replace lost fluid volume but not the red blood cells' function of carrying oxygen to the body. Other volume expanders include albumin, a protein solution used to stabilize oncotic pressure (pressure within the veins) and prevent or treat shock. Growth factors, as mentioned earlier, help promote the production of specific white cells needed to fight infections. **Erythropoietin** and **thrombopoietin** are products available to help stimulate the production of red blood cells and platelets. None of these products replace the benefits of blood or blood component transfusions.

New cancer treatments under research

Researchers are looking at the efficacy of using sibling blood components, specifically transfusions of stem cells and T cells, a part of the immune system that can attack and destroy cancer cells. Blood from tissue-matched sibling donors reduces the rejection rate by the patient's body chemistry. This technique is being studied in renal (kidney) tumors, and early results show promise. Researchers are particularly interested in this therapy for renal tumors with **metastasis** (spreading of the cancer to other parts of the body) because this type of cancer does not usually respond to standard cancer therapy protocols. While blood transfusions and bone marrow transplants have been used extensively for cancers of the blood, this is the first time transfusions have been successful in the treatment of solid tumors (such as renal tumors).

Researchers are also looking at the placenta and umbilical cord as a source for blood stem cells for transplant. This method is called cord blood transplantation. It offers an alternative for patients who do not have a sibling donor, or cannot locate a match in the National Marrow Donor Program (NMDP) registry.

Blood donation

Each year in the United States, about 14,000,000 pints of blood are donated. Blood collection is strictly

regulated by the Food and Drug Administration (FDA). The FDA has rules for the collection, processing, storage, and transportation of blood and blood products. In addition, the American Red Cross, the American Association of Blood Banks, and most states have specific rules for the collection and processing of blood. The main purpose of regulation is to ensure the quality of blood and to prevent the transmission of infectious diseases through donated blood. Before blood and blood products are used, they are extensively tested for infectious agents, such as hepatitis and HIV/AIDS. Screening prevents blood donation by people who could transmit diseases or by people whose medical condition would place them at risk if they donated blood. Some geographical areas or communities have a high rate of hepatitis or HIV/AIDS. Blood collection in most of these areas has been discontinued.

SPECIAL DONATIONS: AUTOLOGOUS TRANSFUSION Autologous transfusion is a procedure in which patients donate blood for their own use. Patients who are to undergo surgical procedures for which a blood transfusion might be required may elect to donate a store of blood for the purpose ahead of time. The blood is stored at the hospital for the exclusive use of the patient. This procedure assures that the blood type is an exact match. It also assures that no infection will be transmitted through the blood transfusion. This is most helpful to cancer patients because of the reduction of risk for a transfusion reaction and for infection risks associated with transfusions. As with other forms of specialized blood donations, there is a processing fee for collection and delivering each unit of blood, which may not be reimbursed by **health insurance**.

SPECIAL DONATIONS: DIRECTED DONATION Directed donors are family or friends of the patient who needs a transfusion. Some people think that family and friends provide a safer source of blood than the general blood supply. Studies do not show that directed donor blood is any safer. Blood that is not used for the identified patient becomes part of the general blood supply.

SPECIAL DONATIONS: APHERESIS Apheresis is a special procedure in which only the necessary components of a donor's blood are collected. The remaining components are returned to the donor. A special blood-processing instrument is used in apheresis. It separates the blood into components, saves the desired component, and pumps the other components back into the donor. Because donors give only part of their blood, they can donate more frequently. For example, people can give almost ten times as many platelets by apheresis as they could give by donating whole blood.

KEY TERMS

ABO blood groups—A system in which human blood is classified by whether the red blood cells contain A or B antigens. Type A blood has the A antigen; type B has the B antigen, AB has both, and 0 has neither.

Antibody—A simple protein produced by the body to destroy bacteria, viruses, or other foreign bodies. Production of each antibody is triggered by a specific antigen.

Antigen—A substance that stimulates the immune system to manufacture antibodies (immunoglobulins). The function of antibodies is to fight off intruder cells, such as bacteria or viruses, in the body. Antigens stimulate the blood to fight other blood cells that have the wrong antigens. If a person with blood type A is given a transfusion with blood type B, the A antigens will fight the foreign blood cells as though they were an infection.

Immunoglobulin—An antibody.

Infusion—Introduction of a substance directly into a vein or tissue by gravity flow.

Injection—Forcing a fluid into the body by means of a needle and syringe.

Rh (rhesus) factor—An antigen present in the red blood cells of 85% of humans. A person with Rh factor is Rh positive (Rh+); a person without it is Rh negative (Rh-). The Rh factor was first identified in the blood of a rhesus monkey.

Preparation

The person receiving a transfusion is made comfortable and vital signs (temperature, blood pressure, pulse and respirations) are monitored closely. The site where the needle will be inserted is carefully washed with a soap-based solution, followed by an iodine-containing antiseptic. The skin is then dried and the transfusion needle inserted into the recipient's vein. During the early stages of a transfusion, the recipient is monitored closely to detect any adverse reactions. If no signs of adverse reaction are evident, the patient is monitored routinely for the duration of the transfusion period. Upon completion of the transfusion, a pressure bandage is placed over the needle-insertion site to prevent bleeding.

Aftercare

Recipients of a blood transfusion have their vital signs monitored during and after the transfusion for signs

QUESTIONS TO ASK THE DOCTOR

- Am I a candidate for autologous transfusion?
- Am I a candidate for a directed donation?
- How often will I have blood work done to determine my hemoglobin and hematocrit levels?
- Can I get a stem cell transfusion at this facility if I need one?
- Is a blood transfusion necessary before I have surgery?

of adverse reaction. The physician usually orders laboratory tests to check hemoglobin and hematocrit levels, as well as platelet count once the transfusion has ended. This data will help the physician determine if the transfusion of blood or blood products was sufficient.

Risks

Adverse reaction to mismatched blood (transfusion reaction) and transmission of infectious disease are the two major risks of blood transfusion. Transfusion reaction occurs when antibodies in the recipient's blood react to foreign blood cells introduced by the transfusion. The antibodies bind to the foreign cells and destroy them (hemolytic reaction). Transfusion reaction may also cause a hypersensitivity of the immune system that, in turn, may cause tissue damage within the patient's body. The patient may also have an allergic reaction to mismatched blood. The first symptoms of transfusion reaction are a feeling of general discomfort and anxiety. Breathing difficulties, flushing, a sense of pressure in the chest, and back pain may develop. Evidence of a hemolytic reaction can be seen in the urine, which will be colored from the waste of destroyed red blood cells. Severe hemolytic reactions are occasionally fatal. Reactions to mismatches of minor factors are milder. These symptoms include itchiness, dizziness, fever, headache, rash, and swelling. Sometimes, the patient will experience breathing difficulties and muscle spasms. Most adverse reactions from mismatched blood are not life-threatening.

Although transfusions are often necessary, some studies have noted a poorer prognosis if transfusions are done before surgery for **breast cancer**, **colon cancer**, non-small cell lung cancer, and **sarcomas**. A National Institutes of Health (NIH) consensus was that transfusion before surgery should not be given simply to raise the hemoglobin level above 10g/dl. The growth factor erythropoietin may be used more in the future to decrease the need for red blood cell transfusions.

Transitional care

Definition

According to the National Cancer Institute (NCI), transitional care may refer either to a patient's movement from one level of cancer care to another, or from one place of care to another. Levels of cancer care are defined as active (intended to cure the cancer), supportive (intended to relieve discomfort associated with the symptoms of the cancer or the side effects of treatment), or palliative (intended to manage pain when cure is no longer possible). Places of care are categorized as acute care facilities, subacute care facilities (e.g., rehabilitation centers, nursing homes, and hospices), and home care (usually the patient's or family's house).

Description

Transitional care for cancer patients has become a pressing health care issue in the early 2000s. One reason is that health care in the United States and Canada has become increasingly specialized in terms of facilities as well as care givers; in addition, the NCI states that almost 90 percent of care for cancer patients is now given on an outpatient basis. In an acute care hospital or cancer center, a cancer patient may have a health care team that consists of three or more doctors in various medical and surgical specialties as well as nurses, physical therapists, social workers, nutritionists, and others. As the patient undergoes various forms of cancer therapy, his or her response to treatments as well as financial concerns, family issues, and other considerations may lead to transfer to a subacute care facility or to home care.

Another factor that has led to a new understanding of the importance of transitional care is the growing number of long-term survivors of cancer. Although these people may be able to live at home by themselves or return to work, they still require various types of follow-up to monitor the long-term physical and psychological side effects of the cancer treatment they received.

Because of the growing complexity of cancer treatment and the risk that the patient's care may be fragmented or interrupted by changes in caregivers or facilities, medical professionals and policy makers presently emphasize the importance of integrated or "seamless" care. This concern for continuity is reflected both in the NCI's recommendations about changes in patient care and in its use of the biopsychosocial model of health care. The biopsychosocial model is the medical term for understanding the patient as a human being with thoughts, emotions, spiritual needs, and important relationships with family members and friends as well as physical symptoms related to the cancer. The NCI recommends the use of community liaison nurses and social workers as coordinators of patient care in order to relieve the patient or family members of the stress of relaying information from one health care professional to another, and to prevent the patient's care from being i! nterrupted or weakened during transfers from one care facility to another.

The biopsychosocial model is the basis for the comprehensive assessment that precedes planning for transitional care. The patient's health care team will evaluate his or her needs in each of the following areas:

- Physical. This area includes nutritional status, ability to function, smoking history, and future treatment options as well as the current stage of the patient's disease and symptom profile.
- Demographics of the patient and his or her family. This area includes marital status, other family members at home, primary language, cultural background, and educational level.
- Psychological. This part of the assessment covers the patient's (and family members') attitudes toward the cancer, fears and anxieties, habitual coping patterns, history of psychiatric illness, and overall level of family stability.
- Social. This area includes the patient's social support networks, employment history, insurance coverage, availability of transportation, and the patient's knowledge and use of resources in the community.
- Spiritual. This part of the assessment includes the patient's religious beliefs and the level of importance of religion in their life, the extent of their support network in their faith community, and the ways in which their religious beliefs or practices may affect their cancer treatment.
- Legal. This area concerns such matters as the patient's will, estate planning, living will, end-of-life care directives, etc.

This comprehensive assessment should be made at regular intervals during the patient's treatment in order to make any necessary adjustments due to changes in the patient's physical symptoms and level of functioning, family situation, employment, etc.

KEY TERMS

Biopsychosocial model—A way of evaluating a patient that stresses the importance of considering his or her thinking processes, emotions, and social relationships as well as the physical aspects of his or her disease. The biopsychosocial model was first proposed in 1977 by an American psychiatrist named George Engel.

Hospice—A health care facility for supportive and palliative care of people with a terminal disease.

Special concerns

The NCI notes that some groups of cancer patients are at risk of not receiving adequate treatment planning or transitional care. These patients include low-income and homeless people; members of minority groups living in the inner city; and people living in rural areas.

Treatments

The treatments given during transitional care are highly individualized; they depend on the specific

QUESTIONS TO ASK YOUR DOCTOR

- What types of care will I need after I leave the hospital?
- Can I have these services delivered to my home, or must I go to a special facility of some kind?
- Is there someone you would recommend as a transitional care coordinator?
- How much experience do you have in following patients through transitions in their health care?

patient's health status, type of cancer, and the types of treatments (surgery, **chemotherapy**, radiotherapy, etc.) that he or she received in the acute care hospital or cancer center. Advances in medical technology, however, have increased the range and variety of treatments that can be delivered by visiting health care professionals in the patient's home. These advances make transitional care at home a possibility for many cancer patients in the early 2000s.

Alternative and complementary therapies

It is usually possible to integrate CAM therapies into transitional care, provided that the patient discusses the specific alternative treatments desired with his or her doctor. Some types of movement or massage therapy may not be suitable immediately following surgery, however, while some herbal preparations or traditional Chinese medicines may interact with the drugs given to treat the cancer itself or to relieve the side effects of treatment.

Patient participation

In addition to consulting with a social worker or other professional coordinator, patients and their families should be actively involved in planning for transitional care. They can gather information about various therapies, care facilities, local support groups and other resources, and discuss these among themselves as well as with members of the patient's treatment team. The patient and his or her family should not hesitate to ask questions or bring up issues that are not mentioned by the health care team during the patient's evaluation for transitional care. A new interactive resource that may be helpful to many patients in making decisions about treatment is the NexProfiler Tool for Cancer on the ACS website. The patient chooses a specific type of cancer from a menu, which then allows him or her to locate a detailed analysis of that cancer, statistics about treatment types, and topics for discussion with his or her doctor.

Rebecca Frey, PhD

Transitional cell carcinoma

Definition

Transitional cell carcinoma (TCC) is a type of cancer that usually originates in the kidney, bladder, or ureter (the tube that carries urine from the kidney to the bladder). It has also been recently recognized as a subtype of ovarian cancer.

Description

A transitional cell is intermediate between the flat squamous cell and the tall columnar cell. It is restricted to the epithelium (cellular lining) of the urinary bladder,

ureters (tubes that carry urine from the kidneys to the bladder), and the pelvis of the kidney (that portion of the kidney collecting the urine as it leaves the kidneys and enters the ureters). Transitional cell carcinomas have a wide range in their gross appearance depending on their locations. Some of these carcinomas are flat in appearance, some are papillary (small elevation), and others are in the shape of a node. Under the microscope, however, most of these carcinomas have a papillary-like look. There are three generally recognized grades of transitional cell carcinoma. The grade of the carcinoma is determined by particular characteristics found in the cells of the tumor. Transitional cell carcinoma typically affects the mucosa (the moist tissue layer that lines hollow organs or the cavity of the body) in the areas where it originates.

The most common site of transitional cell carcinoma is in the urinary bladder. Transitional cell carcinoma is the form of cancer in about 90% of cancers found in the bladder. The highest grade of transitional cell carcinoma is very likely to spread to other parts of the body. There are two primary ways that transitional cell carcinoma spreads into the surrounding structures. The first is by way of epithelial cells that line the body cavity and many of the passageways that exit the body. The other means of spread is through the lymphatic (network that resembles the circulatory system but transports proteins, salts, water, and other substances) system.

Demographics

Most patients who develop transitional cell carcinoma are older than 40 years of age; the peak age of incidence is 60–70 years of age. The male:female ratio for this type of cancer is about 5:2. About 93% of all bladder cancers in North American are of the transitional cell carcinoma type. Only 8% of all renal cancers are of the transitional cell carcinoma type. According to the American Cancer Society (ACS), 60,240 Americans will be diagnosed with bladder cancer in 2004 and 12,710 will die from the disease.

Causes and symptoms

The causes and mechanisms of transitional cell carcinoma, like all forms of cancer, are not entirely known or understood. However, researchers have isolated several factors that have been associated with an increased risk for developing this carcinoma.

Cigarette smoking is the strongest risk factor for transitional cell carcinoma. Researchers have found smoking increases the risk for developing this condition by three to seven times. In men with **bladder cancer**, 50% to 80% have a history of smoking **cigarettes**. Other methods of using tobacco, such as cigar and pipe smoking and chewing tobacco, have been shown to increase the risk of developing this carcinoma but at a reduced rate compared with smoking.

Individuals who have undergone long-term exposure to industrial chemicals, such as the class of compounds known as arylamines, are known to have an increased risk of developing transitional cell carcinoma. One of the most dangerous of these chemicals is one known as 2-naphthylamine. Individuals who develop these carcinomas usually do so anywhere from 15 to 40 years following the first exposure to these chemicals. Arsenic is another chemical that has been recently implicated in the development of TCC.

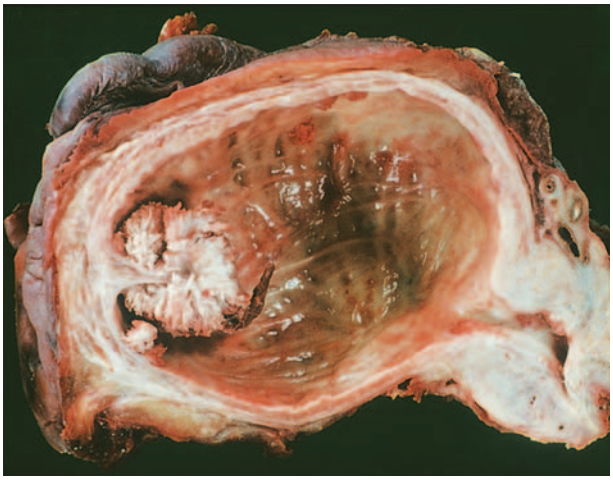
Individuals who have used analgesics for many years, or have used them excessively in the short-term, are at an increased risk for developing transitional cell carcinoma. Many of these patients have suffered at least some damage to the kidneys before developing the carcinoma. Drugs given to patients to treat an earlier cancer, such as the commonly used **cyclophosphamide**, increase the risk of developing transitional cell carcinoma at a later time.

Researchers believe these factors somehow alter genes that are important in the development of transitional cell carcinoma. These changes most often involve the deletions of certain chromosomes but also may result from mutations.

The most common symptom of transitional cell carcinoma is blood in the urine without accompanying pain. There may also be changes in the urge for the patient to urinate and in the frequency of urination. In some cases, urine may be partially obstructed by a tumor in the ureter. Rarely, pain occurs in the pelvic region. Physicians rarely detect a tumorous mass by touch during the first examination.

Diagnosis

There are a variety of ways that can be used to help diagnose transitional cell carcinoma. Many of these involve the use of **imaging studies**. In some cases, traditional x rays may be used to image upper urinary tract tumors. One of the things that physicians look for in patients suspected of having transitional cell carcinoma is the abnormal filling of structures in the urinary system. A type of imaging called excretory urography can help detect such flaws in the system. A different imaging method called retrograde urography can help physicians image the process of urinary collection and detect irregularities. **Computed tomography** (CT), more commonly called the CAT scan, is a very useful tool in the imaging of tumors in the upper tract of the urinary system. CT is



Transitional-cell carcinoma. Seen arising from the dome of the bladder as a fronded cauliflower-like lesion. *(Copyright Biophoto Associates, Science Source/Photo Researchers, Inc. Reproduced by permission.)*

more sensitive than traditional x rays. In some cases, however, small tumors can be missed using this method.

Ultrasound may also be used to help tell the difference between tumors and normal structures in this region. **Magnetic resonance imaging**, more commonly referred to as MRI, has not been found to have any significant advantage over computed tomography in the diagnosis of transitional cell carcinoma.

Cystoscopy is the examination of the bladder using a cystoscope, an instrument that allows the interior imaging of the ureter and bladder. Cystoscopy is usually mandatory in patients suspected of having transitional cell carcinoma and can be helpful in determining the origin of the bleeding in these patients. Patients who are suspected of having transitional cell carcinoma, or other type of cancer in the upper urinary tract, need to have laboratory analysis of the cells in the suspected mass. This cell analysis tells the physician what type and stage of cell is present.

The easiest but least accurate way to study these cells is to have the patient provide urine samples. Patients who have a low-grade tumor in the upper urinary tract will have normal results in up to 80% of cases when urinalysis is used. However, such urinalysis can be more effective in diagnosis of bladder tumors. Obtaining urine samples from the upper urinary tract using a catheter can provide more accurate analysis of upper urinary tract tumors.

A technique called the brush **biopsy** involves the placing of a tiny brush into a catheter. The catheter is then placed in the ureter and moved into the upper urinary tract where the brush scrapes off cells for later analysis. More modern techniques of imaging and sampling use tiny tubes with attached videocameras called endoscopes. These tubes can be moved into the upper urinary tract to locate bleeding and tumors and can be used to obtain biopsy samples.

Treatment team

The treatment team that treats the patient with suspected and confirmed transitional cell carcinoma usually involves a primary care physician who refers to a specialist, a specialist such as a urologist or nephrologist (kidney specialist), a radiologist who performs the imaging, a pathologist who studies the sampled cells, an oncologist who monitors the overall course of the cancer, and a surgeon who performs the surgical removal of the carcinoma.

Clinical staging, treatments, and prognosis

The International Society of Urological Pathology has developed a classification scheme for grading transitional cell carcinoma. These four grades are urothelial papilloma, urothelial neoplasms of low malignant potential, low-grade urothelial carcinoma, and high-grade carcinoma. Papilloma is usually seen in younger patients and is rare. Neoplasms of low malignant potential are sometimes difficult to differentiate from low-grade urothelial carcinomas. These tumors rarely become invasive to nearby tissue. Low-grade urothelial carcinoma tends to appear in the form of papillomas as well. These tumors can invade nearby tissue but usually do not progress. High-grade carcinomas are flat, papillary, or both. These tumors are larger and are more likely to invade nearby muscle tissue.

The most common means to treat papillary transitional cell carcinoma in the bladder is with surgery. When these tumors are classified as low grade, they can typically be removed completely. Unfortunately, these carcinomas recur 50% to 70% of the time. Because of this high rate of cancer recurrence, patients with transitional cell carcinoma have to be carefully monitored following surgery with cystoscopy and regular urinalysis.

Other types of therapy called immunologic therapy (immunotherapy) and **chemotherapy** are often used in treating bladder carcinoma. These methods use agents that are directly applied to the bladder. The most commonly used agent in these therapies is called bacillus Calmette-Guérin (BCG). When BCG is placed in the bladder, the body begins an **immune response** that sometimes destroys the tumor. Patients usually receive one treatment per week for six weeks. After this period, a maintenance program involving three-week BCG courses of treatment for up to two years is used. The most common chemotherapy used for transitional cell

carcinoma in the past is a combination of the drugs **cisplatin**, adriamycin, **vinblastine**, and **methotrexate**. Newer and less toxic drugs, such as celecoxib, bortezomib, ixabepilone, and gallium maltolate are being tested to replace these older agents. A combination regimen of chemotherapy and radiation is being considered as a therapy when the carcinoma invades the muscle surrounding the bladder. The effectiveness of this method has not been studied yet in research studies. **Radiation therapy** alone is not an effective treatment.

Transitional cell carcinoma in the upper urinary tract is also treated with surgical procedures. Affected areas in this region, including the kidney, are sometimes removed. Part or all of the ureter and parts of the bladder are also removed, in some cases.

The noninvasive papilloma rarely recurs once removed. If urothelial neoplasms of low malignant potential recur, they are usually benign tumors. However, in about 3% to 5% of cases, these recurrences are of a higher grade. These carcinomas rarely become invasive, and patients with them have a one-year survival rate of 95% to 98%. Low-grade urothelial carcinomas often show signs of invasion during diagnosis, but are not associated with a high risk for malignancy. High-grade carcinomas have considerable invasiveness into nearby tissue, particularly muscle, and are associated with a very high risk for **metastasis** (movement of cancer cells from one part of the body to another).

Those with superficial, noninvasive, or nonmalignant disease should receive a cystoscopy and a thorough examination every three months for two years followed by a regimen every six months for an additional two years. In those with advanced disease but who did not receive complete bladder removal, a cystoscopy with a thorough examination should be performed every three months for two years, followed by every six months for an additional two years, and then one per year. These patients should also receive a computed tomography (CT) scan of the pelvis and abdomen every six months for two years. Chest x rays, liver function tests, and serum creatinine tests should also be performed on this schedule. Those who had bladder removal should have chest x rays, liver function tests, computed tomography scan of abdomen and pelvis, and serum creatinine tests performed every six months for two years. In addition, an endoscopy of the newly formed bladder structure should be performed.

Coping with cancer treatment

A variety of issues need to be considered when the patient is receiving cancer treatment. One of the most important of these issues is the ability to cope with the emotion of having cancer in the first place. Several techniques, such as relaxation training, meditation, and biofeedback, may be beneficial to the patient in reducing anxiety. Other issues such as missed work and other daily activities need to be planned before the treatment period to reduce emotional stress. The patient needs to consider worst-case scenarios, such as side effects from chemotherapy, when planning these future events. Participation in cancer support groups helps many patients with the stress of the treatment period.

There are physical issues as well during this period. Pain following surgery can be a significant problem. Fortunately, there are many effective pain medications available to handle most pain events. Nausea and hair loss (alopecia) are two of the more notable effects of chemotherapy. Nausea can be effectively treated with drugs in most cases. Hair loss is only a temporary event, but it often has significant psychological effects that can be somewhat alleviated through social support.

Clinical trials

As of 2004 the National Cancer Institute (NCI) lists 46 clinical trials in progress for treating bladder cancer.

KEY TERMS

Analgesic—Drug that relieves pain.

Arylamine—Radical group of the amine chemical family.

Benign—Not progressing or malignant.

Biopsy—Removal of a small piece of living tissue for examination.

Bladder—Muscular and membranous reservoir for urine.

Catheter—Tube that is passed through the body for injecting or removing fluids from body structures.

Chromosomes—Thread in the nucleus of the cell that contains DNA.

Creatinine—End product of creatine metabolism that is found in increased levels in advanced kidney disease.

Immunotherapy—Enhancement of the body's immunity, usually through a biologic agent.

Papilloma—Benign tumor of epithelial tissue.

Tumor—Spontaneous new tissue growth that can be benign or malignant.

Urothelial—Epithelial cells that line the urinary system.

QUESTIONS TO ASK THE DOCTOR

- What type of type of tests are necessary to make an accurate diagnosis?
- Are these tests painful?
- How long will it take to get results?
- If the tests are positive for cancer, what happens then?
- If it is transitional cell carcinoma, is the tumor invasive?
- Has the carcinoma spread to other tissues?
- What stage is the carcinoma?
- What treatment alternatives are there?
- If surgery is necessary, what will the surgery entail?
- What is the recuperation period like after the surgery?
- How long will I be in the hospital?
- If radiation is necessary, what sort of side effects are common?
- If chemotherapy or immunotherapy is necessary, what side effects are common?
- Will chemotherapy cause my hair to fall out?
- Are there any clinical trials that I can participate in?
- What type of surveillance schedule will I be on following the initial surgery and therapy?

Several new drugs are being tested, as well as various combinations of drugs, surgery, and BCG therapy. The best way to obtain the most current information is to call the Cancer Information Service at (800) 4-CANCER. The Cancer Information Service is part of CancerNet, a service of the National Cancer Institute. It can also be accessed at <http://cancernet.nci.nih.gov>.

Prevention

Cigarette smoking is a major risk factor for the development of transitional cell carcinoma. Cigarette smoking has been associated with 25% to 65% of all cases of bladder cancer. Smokers are two to four times more likely to develop transitional cell carcinoma than nonsmokers. Smoking increases the risk of developing tumors that are at a higher grade, in greater number, and of larger size. Those individuals who have abused analgesics are at an increased risk for developing transitional cell carcinoma. Exposure to the human papillomavirus type 16 also increases the risk of developing transitional cell carcinoma. Petroleum, dye, textile, tire, and rubber workers are at increased risk for developing this carcinoma. Exposure to chemicals, such as 2-naphthylamine, benzidine, 4-amino-biphenyl, nitrosamines, or O-toluidine can also increase the risk of developing transitional cell carcinoma. Eliminating exposure to these substances substantially reduces the risk of developing transitional cell carcinoma.

Trans-rectal ultrasound *see* **Endorectal ultrasound**

Transvaginal ultrasound

Definition

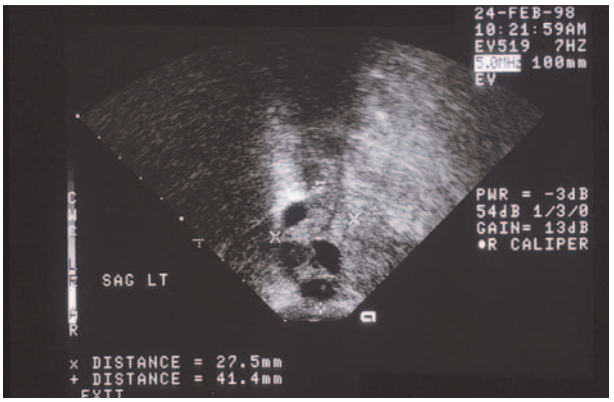
A transvaginal ultrasound, also called transvaginal sonogram (TVS), is an ultrasound that uses an internal probe, or transducer, that enters the vaginal cavity. Either a radiology technician or physician performs the test, and a radiologist interprets the results.

Purpose

An internal probe allows for closer access to the structures that need evaluation. With closer access, higher frequency sound waves can be used, which provides a clearer image due to better resolution. It is often used to evaluate suspected cancer or abnormal growths in the female reproductive system.

Precautions

While the transvaginal ultrasound produces a clearer image, it may also create false positive results. This can lead to unnecessary testing to further evaluate the condition, with its accompanying physical and emotional impact.



Normal transvaginal ultrasound. The plus marks and x marks show that measurements were taken. Measurements of internal structures, such as ovaries, are often taken to compare one ovary with the other, or to compare this woman's ovaries with other women her age, in order to detect possible abnormal growths. *(Custom Medical Stock Photo. Reproduced by permission.)*

Description

The transvaginal ultrasound uses a small, wand-like transducer, or probe, which is inserted into the vagina. The probe emits high-frequency sound waves, which are not audible by humans. These sound waves painlessly bounce off the structures in its path. The returning echo wave is picked up by the probe. This information is fed into an attached computer that then creates an image, or sonogram, on a screen. It can differentiate between structures that are solid, such as a tumor, or filled with fluid, such as a cyst. It can be used to measure the thickness of the lining of the uterus, as well as of other organs.

A technique called color flow Doppler imaging may be used to evaluate the blood flow to certain structures. This can be helpful in establishing whether blood flow has been obstructed or enhanced to an organ. It cannot tell if a solid mass is malignant or benign. Other tests, such as a **biopsy**, would be needed to gather that information. It is done on an outpatient basis, is less expensive than imaging tests such as **magnetic resonance imaging** (MRI), and is considered safe, using sound waves rather than radiation to generate an image.

Preparation

Little preparation is needed for the transvaginal ultrasound. A woman will need to undress from the waist down, and lie face-up on the examination surface. Legs may be put in stirrups, or a bolster may be placed under

KEY TERMS

Radiologist—A physician with special training in radiology, the study of x rays, Magnetic resonance imaging (MRI), ultrasound, and other imaging technology to assist in the diagnosis of a disease or condition.

False positive—A false positive is a positive finding of a test when, in fact, the true result was negative. This would mean that the test results indicate that a patient had a particular condition or disease when they do not.

QUESTIONS TO ASK THE DOCTOR

- What are you looking for with this test?
- Who will perform the test? Is that person board-certified?
- Who will read the results? Is that person board-certified?
- Does the facility utilize color flow Doppler imaging?
- When, how and from whom will I receive the results?
- If the result is positive, how will you evaluate if it was a false positive?
- Will my insurance cover the cost of this test?

the hips to tilt the pelvic area upwards to facilitate use of the probe, both for insertion as well as for the ultrasound process itself. The test is done with an empty bladder, which is more comfortable than the full bladder required for the abdominal ultrasound. This method may be a preferred choice for women who have difficulty with bladder control. A woman may wish to request that she insert the probe herself, which is similar to the insertion of a tampon. Gel that has been warmed will make insertion more comfortable.

Aftercare

Because of the small amount of gel used on the probe for easier insertion, a woman may wish to use a sanitary pad to protect her underpants from any minor leakage after she stands up. After the test a woman will be able to resume her regular scheduled activities.

Risks

The risk involved in using the transvaginal ultrasound is that of obtaining a false positive result, any resulting tests that would be ordered unnecessarily, and their accompanying emotional burden.

Normal results

The normal results of a transvaginal ultrasound are the finding of the normal shape and size of any structure evaluated, with no abnormal thickness, masses or growths of any kind found.

Abnormal results

Abnormal results include the finding of growths, such as masses or cysts, and any unexpected thickness of the structures evaluated. Because of the risk of false positive results, any abnormal findings should be further evaluated and confirmed before undergoing surgery or treatment for the suspected condition. Magnetic resonance imaging (MRI) is often ordered to further evaluate masses. An endometrial biopsy is performed to further evaluate a thickened uterine lining.

Transverse myelitis

Description

Transverse myelitis (TM) is an inflammation or infection of the spinal cord in which the effect of the lesion spans the width of the entire spinal cord at a given level. The spinal cord consists of four regions: the

cervical (neck), followed by the thoracic (chest), the lumbar (lower back) and the sacral (lowest back). TM can occur in any of these regions. The disease is uncommon, but not rare, as it occurs in one to five persons per million population in any given year in the United States. It is equally diagnosed in both adults and children. TM may occur by itself or in conjunction with other illnesses such as viral or bacterial infectious diseases, autoimmune diseases such as multiple sclerosis, vascular illnesses such as thrombosis, and cancer.

The symptoms of TM depend on the level of spinal cord lesion with sensation usually diminished below the spinal cord level affected. Some patients experience tingling sensations or numbness in the legs with bladder control also being disturbed. The condition is usually diagnosed following **magnetic resonance imaging** (MRI) or **computed tomography** (CT) with "spinal taps" (lumbar punctures) taken for additional analysis. Recovery depends on the general health status of the patient and is usually considered unlikely if no improvement is observed within three months.

Causes

The exact cause of TM is unknown but research results point to autoimmune deficiencies, meaning that the patient's own immune system abnormally attacks the spinal cord, resulting in inflammation and tissue damage.

There is also evidence suggesting that TM occurs as a result of **spinal cord compression** by tumors or as a result of direct spinal cord invasion by infectious agents, especially the human immunodeficiency virus (HIV) and the human T-lymphotropic virus type I (HTLV-1).

TM is also listed among the spinal cord disorders occurring in patients diagnosed with AIDS.

Treatments

There is no specific treatment for transverse myelitis. Treatment of the illness is largely symptomatic, meaning that it depends on the specific symptoms of the patient. The region in which the spinal cord has been infected is critical but a course of intravenous steroids is generally prescribed at the onset of treatment.

Treatment of the bladder function impairment resulting from TM include drugs, external catheters for men and padding for women, with surgery recommended in certain cases. A common TM side effect is difficulty with stool evacuation and this condition can be treated by diets that include stool softeners and fiber.

As a result of TM, muscle groups below the affected level may become spastic. Treatment of spasticity usually involves prescriptions of drugs such as Baclofen (Lioresal), which stops reflex activity, and Dantrolene sodium (Dantrium) which acts directly on muscle. A new very well-tolerated drug, Tizanidine, has also recently been introduced in the United States. Muscle pain is generally treated with analgesics such as acetaminophen (Tylenol) or ibuprofen (Naprosyn, Aleve, Motrin). Nerve disorders might be treated with anticonvulsant drugs such as **carbamazepine**, **phenytoin** or **gabapentin** (Tegretol, Dilantin, Neurontin).

Alternative and complementary therapies

Individuals with TM may experience serious difficulty with common tasks such as dressing, bathing and eating. Complementary TM therapies may accordingly include a course of physical therapy so as to help patients recover mobility. This can be achieved with special exercises, canes, walkers and custom-designed braces.

KEY TERMS

Autoimmune disease—An illness which occurs when the body tissues are attacked by its own immune system. The immune system is a complex defense mechanism of the body whose primary function is to seek out and destroy invaders of the body, especially infections.

Catheter—A tubular, flexible instrument used to withdraw fluids from a body cavity, especially urine from the bladder.

Infectious disease—A disease caused by a virus or a bacterium. Examples of viruses causing an infectious disease are: HIV-1 virus, herpes simplex, cytomegalovirus, Epstein-Barr virus, leukemia virus. Examples of bacterial infectious diseases are: syphilis and tuberculosis.

Spinal cord—Elongated part of the central nervous system of vertebrates that lies in the vertebral canal and from which the spinal nerves emerge.

Spinal cord compression—A condition resulting from pressure being applied on the spinal cord, as from a tumor or spinal fracture. Depending on the location of the pressure, symptoms may include pain, numbness, tingling and prickling sensations as well as lock of sensory or motor functions.

Spinal tap—A diagnostic procedure by which a needle is introduced into the lower spine to collect cerebrospinal fluid for diagnostic testing.

After the acute phase, people with TM start the rehabilitation process. During this period, the focus of care is shifted from designing an effective TM treatment to learning to cope with a serious disease. TM patients must learn to cope with the loss of abilities which healthy people take for granted and this process is necessarily harder if TM is associated with AIDS or another serious autoimmune disease. Resources that may help this required adjustment are psychological assistance from counselors, relatives and friends, and making contact with TM support groups. The Transverse Myelitis Association may also be contacted: 3548 Tahoma Pl. West, Tacoma, WA 98466-2141 (info@myelitis.org; www.myelitis.org) Phone:253-565-8156.

Trastuzumab

Definition

Trastuzumab is a humanized monoclonal antibody produced by recombinant DNA technology that binds specifically to the human epidermal growth factor receptor 2 protein (also known as HER2 or neu or c-erb-2) that is found on the cell surface of some cancer tumors, most notably **breast cancer**. The drug is marketed in the United States under the Herceptin brand name.

Trastuzumab for potential treatment of gastric cancer is expected to commence during 2005 and a regulartory filing for this indication is due in 2008.

Purpose

Trastuzumab is a monoclonal antibody used to treat breast cancers that overexpress the HER2 protein, which occurs in about 25–30% of breast malignancies. By binding the HER2 protein on the tumor cell, the antibody targets it for destruction by the immune system. Based on data gathered in the laboratory, developers believe that trastuzumab triggers cell-mediated means to kill the tumor cells, through the action of natural killer cells and monocytes, two types of white blood cells. As binding of the antibody also slows growth of the tumor, it is theorized that the antibody may also block the interaction of the HER2 protein with a not yet identified growth factor that triggers rapid cell divisions.

Clinical trials have also begun or are soon to begin to test the use of trastuzumab against **osteosarcoma**, as well as endometrial, colorectal, kidney, pancreatic, prostate, ovarian, salivary gland, lung, and bladder cancers, as all of these tumor types can overexpress the HER2 protein on their surface.

Description

Trastuzumab is a genetically engineered monoclonal antibody. In 1998 it was approved by the FDA as a method of slowing growth of breast cancer tumors that overexpress the HER2 protein on the cell surface. Overexpression or overproduction of the HER2 protein is associated with aggressive disease and increased mortality.

Trastuzumab is approved for use either alone, or in combination with **paclitaxel**, a drug used for chemotherapeutic treatment of breast cancer. In clinical trials treating patients having breast cancer that has spread beyond the breast (metastatic breast cancer), trastuzumab had an overall response rate of 14%, with 2% having a complete response. When used in combination with paclitaxel treatment, the antibody reduced the risk of death by 24%. Higher expression of the HER2 protein on the tumor surface correlates with an increased chance of response to the drug. Additionally, clinical trials using trastuzumab in the TCH **chemotherapy** regime (Taxotere, **cisplatin** or **carboplatin**, and Herceptin) appears to avoid risk of heart problems (cardiotoxicity) seen with the paclitaxel/Herceptin combination.

Other clinical trials have begun testing the use of trastuzumab with other chemotherapy drugs such as **doxorubicin** (an antitumor anitbiotic), **cyclophosphamide** (an alkylating agent that interferes with mitosis and cell division), celecoxib (an aspirin-like drug called a cyclooxygenase-2, or COX-2, inhibitor), **capecitabine** (an antimetabolite that interferes with DNA and RNA growth), and others. Testing the combination of the monoclonal antibody and various cytokines, such as interleukins 2 and 12, is also ongoing. Additionally, doc-

KEY TERMS

Antibody—A protective protein made by the immune system in response to an antigen, also called an immunoglobulin.

Humanization—Fusing the constant and variable framework region of one or more human immunoglobulins with the binding region of an animal immunoglobulin, done to reduce human reaction against the fusion antibody.

IgG—Immunoglobulin type gamma, the most common type found in the blood and tissue fluids.

Interleukins—Cytokines responsible for the activation of B and T cells of the immune system.

Monoclonal—Genetically engineered antibodies specific for one antigen.

tors are also studying the combination of the antibody with other cancer treatments such as radiation and transplantation with peripheral stem cells.

Most of the trastuzumab sequence is derived from human sequences, while about 10% are from the mouse. The human sequences were derived from the constant domains of human IgG1 (called "constant" because it is essentially the same for all IgG antibodies) and the variable framework regions of a human antibody. These areas do not bind to the epidermal growth factor receptor 2. Using human sequences in this part of the antibody helps to reduce patient **immune response** to the antibody itself and is called humanization. The actual binding site of trastuzumab to the receptor is from a mouse anti-HER2 antibody.

Recommended dosage

Trastuzumab is administered intravenously, at a dose of 4 mg/kg for the initial administration, and 2 mg/kg for weekly maintenance until the disease progresses. The antibody can be given for longer periods to maintain tumor shrinkage.

Precautions

Extreme caution should be exercised when using trastuzumab to treat patients with existent heart problems. Also, patients with lung problems have an increased risk of side effects. Because the drug can pass to the fetus through the placenta and is present in breast milk, the drug should be used during pregnancy and nursing only if clearly indicated.

Side effects

The most severe side effects seen with this drug are heart and lung problems, which tend to occur most often in patients with a history of heart or lung disease. The use of anthracyclines and cyclophospamide in combination with trastuzumab also appears to increase these types of side effects.

The most common side effects with trastuzumab are infusion-associated symptoms, usually consisting of **fever** and chills on first infusion. The symptoms are often mild to moderate in severity and are treated with acetaminophen, **diphenhydramine**, and/or **meperidine**. Other common side effects include nausea and vomiting, and pain (in some cases at tumor sites), which occur less often after the first dose. Lowered red blood cell count (**anemia**), lowered white blood cell count (leukopenia), **diarrhea**, and infection occur more often in patients receiving Herceptin plus chemotherapy as compared to chemotherapy alone. The severity of these symptoms usually do not result in discontinuation of therapy with Herceptin.

Other less common side effects are headache, abdominal pain, back pain, flu-like symptoms, sinusitis, rhinitis, pharyngitis, fluid retention (edema), insomnia, dizziness and **depression**.

Interactions

There have been no formal drug interaction studies done for trastuzumab. However, in clinical trials, this drug has a decreased clearance rate (time of removal from the body) when combined with some chemotherapeutic drugs including paclitaxel.

See also Monoclonal antibodies.

Michelle Johnson, M.S., J.D.

Tretinoin

Definition

Tretinoin, a natural vitamin A metabolite, is an anticancer drug used in the treatment of acute promyelocytic leukemia (APL). Tretinoin is more commonly used to treat such skin disorders as acne, warts, hyperpigmentation, and reactions to sunlight.

Purpose

Tretinoin is given to APL patients with the goal of bringing on a remission. The drug is being investigated

as a treatment for skin cancer, and it is also available in an acne cream commonly called Retin-A.

As of 2004, tretinoin is also being investigated as a possible chemopreventive for breast cancer. The drug is thought to slow the spread of tumors and speed up the process of tumor cell self-destruction (apoptosis).

Description

Tretinoin causes abnormal leukemia cells in the blood to mature into normal cells (granulocytes). The exact mechanism of action is not known. In **clinical trials** 72–94% of APL patients experienced a complete remission when taking this drug. Tretinoin can be used to induce remission and to maintain remission.

Recommended dosage

The recommended dosage for adults with APL is 45 milligrams per square meter taken by mouth as two evenly divided doses. The physician will calculate the specific dose for each patient. The drug should be discontinued 30 days after remission or 90 days after treatment begins, whichever comes first.

Precautions

Patients who are hypersensitive to vitamin A or other retinoids should not take this drug. People should avoid tretinoin if they are sensitive to parabens, a preservative used in the drug's capsule. Pregnant or breastfeeding women should not take tretinoin. Women of childbearing age should take a pregnancy test to assure that they are not pregnant prior to starting this drug.

Side effects

Tretinoin has a number of side effects. Patients should discuss the risk of complications with their physician. Some side effects resemble symptoms that are common in APL patients. All side effects should be reported to a patient's doctor.

Side effects that are more commonly reported include headache, **fever**, dry skin and mucous membranes, **bone pain**, rash, **itching**, inflamed lips, sweating, nausea and vomiting, abdominal pain, **diarrhea**, constipation, indigestion, bloating, irregular heart beat, visual disturbances, earache, hair loss (alopecia), skin changes (including formation of inflammatory growths known as granulomas), vision changes, and bone inflammation.

Hemorrhage is a life-threatening complication. Blood coagulation studies are done while the patient is taking the drug to monitor the risk of hemorrhage. Hepatitis is another life-threatening side effect. Liver function tests can be abnormal in 50–60% of patients taking the drug. Liver function is monitored periodically while a person is taking the drug.

KEY TERMS

Leukocyte—White blood cell. Leukocytosis is the medical term for an excess number of white blood cells, and is seen in conditions such as infection and leukemia.

Metabolite—A product of metabolism.

Retinoid—Natural or artificial compound that is similar to vitamin A.

In addition, approximately one-quarter of patients taking tretinoin develop retinoic-acid-APL (RA-APL) syndrome. Symptoms include fever, weight gain, difficulty breathing, and other respiratory disorders. Some patients have cardiac changes and low blood pressure as part of this syndrome. The syndrome can occur two days after treatment begins or three to four weeks later. Symptoms must be reported to the patient's physician immediately so that treatment can begin. In rare cases this syndrome is fatal. Most patients do not need to stop taking tretinoin if the syndrome develops.

Approximately 40% of patients taking tretinoin develop high white blood cell counts (leukocytosis). If the number of white blood cells increases rapidly there is a higher chance of developing life-threatening complications. White blood cell counts are monitored during treatment. As many as 60% of patients taking tretinoin develop increased cholesterol and triglyceride levels. The levels drop when the medication is stopped. Cholesterol and triglyceride levels are monitored while the drug is being taken.

Tretinoin has other side effects that may impact the heart, skin, digestive tract, lungs, central nervous system, and other parts of the body. Patients should report all unusual symptoms to the doctor immediately.

Interactions

Tretinoin interacts with:

- Cimetidine (antipeptic ulcer drug)
- Cyclosporine (immunosuppressant)
- Dilitiazem (heart medication)
- Erythromycin (antibiotic)

- Glucocorticoids (steroids)
- Ketoconazole (antifungal drug)
- Phenobarbital (sedative/hypnotic)
- Pentobarbital (sedative/hypnotic)
- Rifampicin (an antituberculosis drug, also known as rifampin)
- Verapamil (heart medication)

Trichilemmal carcinoma

Definition

Trichilemmal carcinoma is an uncommon malignant tumor of the hair follicle, and is assumed to be the malignant counterpart of the benign trichilemmoma.

Description

Trichilemmal carcinomas most often occur on part of the skin that has been often exposed to the sun, like the face. The tumors look like tan or flesh-colored spots. They can resemble warts and sometimes have a hair in them. Usually, a trichilemmal carcinoma will occur as an isolated lesion.

Trichilemmal carcinomas are thought to be the malignant form of the non-cancerous tumors called trichilemmomas, which are seen in Cowden syndrome. Cowden syndrome is an inherited disorder that predisposes individuals to breast and **thyroid cancer**. The disease is inherited in an autosomal dominant inheritance pattern. With autosomal dominant inheritance, men and women are equally likely to inherit the syndrome. In addition, children of individuals with the disease are at 50% risk of inheriting it. **Genetic testing** is available for Cowden syndrome but, due to the complexity, genetic counseling should be considered before testing. Although they are thought to be related to trichilemmomas, none of the reports of trichilemmal carcinomas have been seen in patients with Cowden syndrome.

It is important to note that trichilemmal carcinoma is not the same as "malignant proliferating trichilemmal tumor," which is usually seen on the scalp and the back of the neck.

Demographics

Trichilemmal carcinomas are most often seen in older people. They occur with equal frequency in both males and females.

Causes and symptoms

The causes of trichilemmal carcinoma are unknown. The only recognizable symptom is the presence of an unusual, tan or flesh-colored spot on the skin.

Diagnosis

Diagnosis of a trichilemmal carcinoma is very important. Because the tumors are so rare, a physician may not immediately recognize its exact diagnosis. A dermatologist will suspect an abnormality on the skin

KEY TERMS

Metastasize—Cancer spreads to remote parts of body.

Pathologic examination—When a physician examines a small section of the tumor under a microscope.

and have it removed. It is only on the pathologic examination (when a physician examines the abnormality under a microscope) that the tumor can be correctly classified.

Treatment team

The treatment of trichilemmal carcinoma will involve a dermatologist (a physician who specializes in diseases of the skin) and a surgeon (a physician who will surgically remove the tumor).

Clinical staging, treatments, and prognosis

Once a trichilemmal carcinoma has been diagnosed, a surgeon must remove it. It is necessary that documented clear margins are obtained, indicating that the entire tumor has been removed. There is a chance that the tumor will recur (return) locally (in the same spot or near the same spot). If this occurs, the recurrent tumor needs to be surgically removed as well. It is very unlikely that a trichilemmal carcinoma will metastasize (spread to other parts of the body), and further treatment with **chemotherapy** is not needed.

Alternative and complementary therapies

Because trichilemmal carcinoma is easily treated with removal, there are no suggested alterative and/or complementary therapies.

Coping with cancer treatment

The surgical procedure to remove a trichilemmal carcinoma is relatively straightforward and low-risk. Most surgeries will be done on an outpatient basis, requiring no stay in the hospital. A small scar on the skin may be left after the tumor is removed.

Clinical trials

No **clinical trials** for trichilemmal carcinoma could be identified.

Prevention

Because the underlying cause of trichilemmal carcinoma is largely unknown, preventive strategies have not been suggested.

Trimethoprim *see* **Antibiotics**

Trimetrexate

Definition

Trimetrexate (Neutrexin) is a drug that was first used to treat bacterial infections, and is now being investigated as a treatment for several different cancers.

Purpose

Trimetrexate is most commonly used to treat **pneumonia** in patients with acquired immunodeficiency syndrome (AIDS). However, it was recently discovered that the drug was able to kill a variety of different cancer cells. As a result, trimetrexate is now considered to be an **investigational drug** for cancer treatment.

Ongoing **clinical trials** are using trimetrexate to treat a number of cancers including advanced colon and rectal cancers, advanced pancreatic cancer, and advanced squamous cell cancers of the head and neck. Results from many trials are still preliminary, but trimetrexate appears to be most promising as a treatment for advanced colon and rectal cancers.

Description

Trimetrexate glucoronate works by stopping cells from using **folic acid** (vitamin B9). As a result, cells cannot make essential components they need to survive, and they die. Because trimetrexate is toxic to both cancer cells and healthy cells, it is always used in combination with **leucovorin** (Wellcovorin, citrovorum factor). Leucovorin is a drug that protects healthy cells from the harmful effects of certain types of **chemotherapy**.

Trimetrexate can also enhance the anti-cancer effect of another chemotherapy drug called **fluorouracil** (Adrusil, 5-FU). Fluorouracil is frequently used to treat patients with colon and rectal cancers.

Recommended dosage

In clinical trials, patients with colon and rectal cancers were given trimetrexate, fluorouracil and leucovorin for 8-week cycles. A cycle consisted of six weeks of treatment followed by two weeks rest with no treatment. Patients received trimetrexate intravenously, with the dose depending on their weight. Twenty-four hours after trimetrexate treatment, patients received intravenous fluorouracil and leucovorin treatment. Some patients also took oral leucovorin every six hours for several days after their intravenous chemotherapy.

Patients with squamous cell cancer of the head and neck received trimetrexate in combination with **cisplatin** (Platinol), leucovorin and fluorouracil in a 21-day cycle. These patients also received surgery or **radiation therapy**. Pancreatic cancer patients received 8-week cycles of trimetrexate, fluorouracil and leucovorin, similar to that given to patients with **colon cancer**.

Precautions

Patients who are given oral leucovorin as part of their chemotherapy must take their medication. Trimetrexate is a toxic drug, and patients who do not take leucovorin may experience severe side effects. Pregnant women should not take trimetrexate because it may harm the fetus. Women who are taking trimetrexate should avoid becoming pregnant. In addition, women should not breast feed while taking this drug. The liver and kidney are used to break down and eliminate trimetrexate from the body. As a result, patients with a history of liver or kidney disease should tell their doctor.

Side effects

Patients taking trimetrexate will have their blood monitored regularly to check for the development of **myelosuppression**. Myelosuppression is a condition where a patient's bone marrow makes fewer blood cells and platelets than normal. As a result of this condition, patients have an increased risk of infection, may bleed more, and may experience symptoms of **anemia**. Trimetrexate may also cause damage to the kidneys and the liver. Some patients also experience **nausea and vomiting**, and may develop a rash or inflammation and sores in their mouths. Taking leucovorin with trimetrexate helps to reduce or eliminate the risk of experiencing many of these side effects.

KEY TERMS

Leucovorin—A drug used to protect healthy cells from toxic chemotherapy.

Myelosuppression—A condition where the bone marrow makes fewer blood cells and platelets than normal.

Interactions

Trimetrexate is known to interact with several other drugs. Some antifungal drugs such as ketoconazole (Nizoral) and fluconazole (Diflucan) interfere with the way the body breaks down trimetrexate. The antibiotic erythromycin also has this effect. Patients taking these drugs will be monitored carefully. The toxic effects of trimetrexate can be increased by other drugs. Patients should therefore tell their doctor about any medication they are taking whether it is prescription or over the counter.

Alison McTavish, M.S.

Triptorelin pamoate

Definition

Triptorelin pamoate is a synthetic luteinizing hormone-releasing hormone (LHRH) agonist, that is, a substance that reduces the level of sexual hormones in the system.

Purpose

Since its approval by the FDA (Food and Drug Administration) in June of 2000, triptorelin pamoate has been recognized as a successful option in the treatment of long-term cancer of the prostate gland. The prostate gland is a solid, chestnut-shaped organ surrounding the male urethra. It produces secretions that become part of seminal fluid. In the case of cancer of the prostate gland, it is advantageous to reduce prostate gland cell activity. One way to do this is to reduce the amount of hormones circulating in the system that will stimulate prostate activity. LHRH-agonists, such as triptorelin, are indicated when either **orchiectomy** (surgical removal of one of both testes) or the administration of the female hormone estrogen is either inadvisable or considered unacceptable by the person suffering from the cancer.

Triptorelin pamoate has been successfully used to alleviate symptoms in cases of such advanced **prostate cancer**, and is now being used and researched as a treatment for:

- all prostate cancers
- ovarian cancer
- *in vitro* fertilization
- endometriosis, or chronic disease of the mucous membrane lining the uterus
- uterine leiomyoma, also called uterine fibroids, a non-cancerous growth on the smooth muscle of the uterine wall
- precocious puberty, a condition in which children of either sex may undergo pubescent changes at an abnormally early age
- fibrocystic breast disease, or the presence of one or more benign tumors in the breast

Description

The human body provides balance in the provision of all chemicals necessary to its function. The pituitary gland and hypothalamus in the brain interact to release substances called gonadotropins, which trigger and regulate the production of estrogen (female) and androgen (male) hormones. Synthetic LHRH medications (similar in chemical makeup to natural LHRH enzymes) reduce the quantity of natural gonadotropins released. This reduces cell activity occurring in organs affected by these hormones, such as the prostate gland, ovaries, testes, uterus, and breasts, therefore slowing the growth of cancerous cells.

Triptorelin is a potent synthetic LHRH medication, effectively reducing gonadotropins if administered to maintain a continuous, therapeutic level in the body. Initially, there is often a temporary surge in circulating amounts of both male and female hormones, but usually within two to four weeks of beginning therapy, there is a marked reduction of these sex hormones. In men, there is a reduction in **testosterone** in the blood stream comparable to the level usually seen in surgically castrated men. Consequently, cells that rely upon these hormones for stimulation become less active. In most cases, the effect of triptorelin pamoate on sexual hormones is reversible once treatment is completed.

Recommended dosage

For advanced prostate cancer, the most common application for triptorelin, the usual dose is 3.75 milligrams (mg) given once per month as a single intramuscular injection. This will normally maintain a therapeutic level. If necessary, this medication may also be given intravenously.

KEY TERMS

Anaplastic—Poorly differentiated; immature and abnormal in function.

Benign tumor—A non-cancerous tumor that is incapable of invading surrounding tissue and spreading to other areas of the body.

Differentiated—Description of the similarity of function and appearance of cancer cells when compared to the normal, healthy tissue.

Exfoliative cytology—Evaluating cells that are shed from the body's surface.

Malignant tumor—A tumor that is capable of invading surrounding tissue and spreading to other areas of the body.

Pap smear—Analysis of cells found in vaginal secretions to determine the presence of uterine cancer. Also called a Pap test.

Pathologist—A doctor that examines cells under a microscope to determine the presence of the disease.

Pleomorphic—Irregular shape.

Tumor stage—An objective measurement gauging the cancer's progression.

Precautions

In the treatment of prostate cancer, there have been reported flare-ups of the disease at the onset of therapy. Patients with a prostate tumor affecting the spinal cord or urinary flow should use caution, as an increase in tumor activity may initially worsen symptoms. Triptorelin pamoate is capable of causing harm to fetuses if administered to pregnant women. During long-term treatment of endometriosis or uterine fibroids, bone loss has been reported.

Side effects

The following side effects have either been reported or were observed:

- nausea and vomiting
- hot flashes
- vaginal dryness
- impotence

- loss of sex drive
- breakthrough bleeding
- sleep disturbance
- diarrhea
- fatigue
- hair loss (alopecia)
- mouth sores
- breast tenderness
- weight gain
- pain at injection site
- increases in cholesterol
- headache

Interactions

Because triptorelin pamoate has only had FDA approval since June of 2000, not all information in known regarding its interactions with other medicines. Currently, no drug interactions have been reported.

Joan Schonbeck, R.N.

Tumor grading

Definition

Tumor grading is an estimate of the tumor's malignancy and aggressiveness based on how the tumor cells appear under a microscope and the number of malignant characteristics they possess.

Purpose

Tumor grading, together with the stage of the tumor, assists doctors in planning treatment strategies. Although grading is an important part of describing most cancers, it is extremely important in helping to determine the course of treatment for specific cancers such as soft tissue **sarcomas**, brain tumors, lymphomas, breast and **prostate cancer**. Generally higher grade and higher stage tumors require more drastic therapy than lower grade and stage tumors. Tumor grade and stage also help doctors give an estimation of the prognosis of the patient. Patients with lower grade and stage tumors usually have a more positive prognosis than patients with higher grade and stage tumors. Patients should thoroughly discuss the grade and stage of their tumor with their physician, asking about necessary treatments and prognosis.

KEY TERMS

Dialysis—A medical procedure that uses a special machine to filter waste products from the blood and restore it. It is a life-sustaining procedure in end-stage kidney failure.

Electrolytes—Substances or particles that dissolve into ions, (atoms with a positive or negative charge) such as potassium or sodium, and carry water molecules across cell membranes, regulating electric charge in order to maintain the proper oxygen flow of body fluids.

Metabolic—Pertaining to the physical and chemical process of synthesis and breakdown of substances necessary to sustain life.

Nephrology—The study of the kidneys—their structure and function.

pH—A measure of the alkalinity or acidity of a substance.

Description

Before a tumor can be assigned a grade, a sample of tissue must be removed for microscopic evaluation. Tissue samples can be obtained through one of various types of **biopsy** or through exfoliative **cytology** (e.g. Pap smear). A pathologist analyzes various characteristics of the tissue. Some characteristics include the size and shape of the nucleus; the ratio of the volume of the nucleus to the volume of the cytoplasm; the relative number of dividing cells called the mitotic index; the organization of the tissue; the boundary of the tumor; and how well-differentiated the cells appear—how close to normal the cells seem in maturity and function.

Benign tumors have normal-looking cells. That is, they have small and regular shaped nuclei, small nuclear volume relative to the rest of the cellular volume, a relatively low number of dividing cells, normal and well-differentiated tissue that has a well-defined tumor boundary. However, malignant tumors generally have all or several of the following characteristics: large and pleomorphic (irregular-shaped) nuclei, large nuclear volume compared to the rest of the cellular volume, a high number of dividing cells, disorganized and anaplastic (poorly differentiated) tissue that has a poorly defined tumor boundary.

Depending on the number of malignant characteristics present, the **American Joint Commission on Cancer** has recommended that the tumor be given a grade using G0 through G4.

QUESTIONS TO ASK THE DOCTOR

- What are the microscopic characteristics this cancer presents?
- What grade is this cancer?
- What courses of treatment do you recommend for this grade of this type of cancer?

- G1 Well-differentiated (Low-grade and less aggressive)
- G2 Moderately well-differentiated (Intermediate-grade and moderately aggressive)
- G3 Poorly differentiated (High-grade and moderately aggressive)
- G4 Undifferentiated (High-grade and aggressive)

Alternatively, Roman numerals I through IV may be used. Low-grade tumors are assigned lower Roman numerals (e.g. grade I), indicating that the tumor is less aggressive. High-grade tumors are assigned higher Roman numerals (e.g. grade IV), indicating that the tumor is very aggressive, growing and spreading quickly.

- I Well-differentiated (Low-grade and less aggressive)
- II Moderately well-differentiated (Intermediate-grade and moderately aggressive)
- III Poorly differentiated (High-grade and moderately aggressive)
- IV Undifferentiated (High-grade and aggressive)

There are some cancers that have their own grading convention. For example, the Gleason system is a unique grading system that was developed to describe adenocarcinoma of the prostate. Pathologists analyze prostate tissue and give a Gleason score ranging from 2 to 10, subject to the number of malignant characteristics observed. Well-differentiated, less aggressive prostate tumors with only a few malignant characteristics are given lower Gleason numbers, while inadequately differentiated, more aggressive prostate tumors that possess many malignant characteristics are assigned higher Gleason numbers.

Tumor lysis syndrome

Description

Tumor lysis syndrome is a life-threatening metabolic emergency frequently associated with certain types of tumors (neoplasms). Concentrations of intracellular electrolytes, those that are within the cell, differ from extracellular electrolytes, or those that are outside the cell and in the bloodstream. In tumor lysis syndrome, tumor cells lyse, or break apart, releasing their contents into the blood stream. The result is a dangerous alteration in the normal balance of serum electrolytes—potassium, phosphate and uric acid levels are elevated, while calcium levels are decreased. The changes occur so quickly and can be so dramatic, that immediate death can result.

Causes

Many factors contribute to the development of tumor lysis syndrome. Most of the research performed to date revolves around high-grade non-Hodgkin's **lymphoma** cases, 40% of which demonstrate laboratory evidence of tumor lysis syndrome. (An estimated 6% demonstrate clinical evidence of the syndrome.) Tumors that carry the highest risk of the development of tumor lysis syndrome are those that are large and bulky, usually greater than eight to ten cm (3-4 in.), and comprised of rapidly dividing cells. In addition, tumors that respond well to treatment are associated with tumor lysis syndrome because treatment results in rupture of a large number of cells.

Most often, the syndrome is associated with blood-based (hematologic) tumors, such as non-Hodgkin's lymphoma, particularly **Burkitt's lymphoma**, and **acute leukemia**. Though less likely because of lower rates of cell division, tumor lysis syndrome can also occur in solid tumors such as **breast cancer**. The Washington Manual of Medical Therapeutics associates the following cancer types with tumor lysis syndrome:

- Non-Hodgkin's lymphoma (NHL)
- Acute lymphocytic leukemia (ALL)
- Acute myelocytic leukemia (AML)
- Chronic lymphocytic leukemia (CLL)
- Chronic myelocytic leukemia (CML)
- Breast cancer
- Testicular cancer
- Medulloblastoma
- **Merkel cell carcinoma**
- Neuroblastoma
- Small cell **carcinoma** of the lung

Usually, tumor lysis syndrome develops after the administration of combination **chemotherapy** regimens, but it may also occur spontaneously or as a result of radiation or corticosteroid therapy. Lactic acid dehydrogenase (LDH) is an enzyme found in cells of body tissues. An increase in the LDH level is considered a marker of bulky disease that correlates with the risk of tumor lysis syndrome.

Patients with underlying kidney (renal) dysfunction and/or decreased urine output are at a higher risk of developing tumor lysis syndrome. Without optimal kidney functioning, waste products that build up cannot be excreted in the urine at a high enough rate. Patients with cancer may be predisposed to conditions that increase the risk of renal failure due to increased uric acid buildup. For example, a patient undergoing chemotherapy may experience **nausea and vomiting**, and may, as a result, be dehydrated, increasing the risk. The same patient may have decreased white blood cell counts, making him or her more susceptible to infections. Many **antibiotics** adversely affect the kidneys, also increasing the risk.

Treatments

Treatment is aimed at prevention and supportive care, with the main goals being to prevent renal failure and severe electrolyte imbalances. Patients at risk receive treatment on an inpatient basis to allow for close monitoring by medical personnel. At all times, patients should have reliable intravenous access. Prior to initiating treatment, a patient's hydration status and electrolyte levels are carefully evaluated. If there are abnormalities, a treatment delay may be considered, though this is not always an option.

Laboratory tests are done frequently to monitor levels of calcium, potassium, phosphate, magnesium and uric acid. A typical hospital protocol may require blood be drawn for these tests every two to six hours over the course of two to three days. Following are prevention and management strategies for each of the major electrolyte imbalances, hyperuricemia, hyperkalenia, hyperphosphatemia, and hypocalcemia.

Hyperuricemia is a medical term used to describe an abnormal increase of uric acid levels in the blood that can lead to acute renal failure. There are several methods employed to prevent kidney damage—aggressive hydration being a major focus. Intravenous (IV) hydration is started before treatment and continues throughout to maintain a urine output of 100 to 200 milliliters per hour (ml/hr). Medications called diuretics, such as furosemide or acetazolamide, are given to help increase urine output when necessary.

Urine may be alkalized to prevent uric acid buildup. Alkalization can be accomplished by adding sodium bicarbonate to the patient's IV fluid. For example, the basic maintenance IV fluid may consist of 5% dextrose in 0.25 normal saline, to which sodium bicarbonate, in amounts ranging from 50 to 200 milliequivalents (mEq—the total number of charges of electrolytes in solution), may be added. Urine pH is routinely tested, and the sodium bicarbonate is periodically increased or decreased to maintain a pH level between 7 and 8.

Urine alkalinization is somewhat controversial. If urine is too alkaline, calcium phosphate crystal formation may occur, increasing the likelihood of renal failure. However, it is generally believed that if urine output levels are appropriately maintained, calcium phosphate will be diluted, and the possibility of crystal formation will diminish.

Patients at risk for tumor lysis syndrome may also be given **allopurinol** prophylactically. One dose of 600 milligrams (mg) may be given the day before treatment, followed by 300 mg once a day for the remainder of treatment days. Allopurinol is effective because it inhibits the formation of uric acid. In 2004, a new drug called rasburicase became available in the United States. It prevents the damaging effects of tumor lysis syndrome with fewer side effects.

Hyperkalemia is a medical term used to describe an abnormal increase of potassium levels in the blood that can cause dangerous abnormalities in heart rhythms, heart attack, and muscle weakness. Frequent monitoring with electrocardiography (EKG) is recommended in patients at risk for tumor lysis syndrome so that alterations in the electrical activity of the heart can be caught early. Potassium-rich foods may also be restricted to prevent already elevated levels from increasing. Sometimes, medications such as Kayexalate are administered to help reduce potassium levels.

Hyperphosphatemia is a medical term used to describe an abnormal increase on phosphate levels in the blood that can cause neuromuscular irritability and worsen kidney function. Malignant cells may contain up to four times as much phosphate as non-malignant cells. Patients experiencing acute tumor lysis syndrome may be instructed to reduce their dietary intake of phosphate. In addition, they may be given medications that bind to phosphate, thereby inhibiting its absorption in the intestines.

Hypocalcemia is a medical term used to describe an abnormal decrease in calcium levels in the blood that can cause muscle spasms (tetany), muscle cramps, and seizures. A calcium supplement may be required.

Dialysis is a procedure used to normalize electrolyte imbalances through the diffusion and ultrafiltration of

KEY TERMS

AFP (Alpha-fetoprotein)—A tumor marker associated with liver, testicular, and ovarian cancer.

Beta-HCG (Beta-human chorionic gonadotropin)—A tumor marker associated with testicular cancer and tumors, such as choriocarcinoma and molar pregnancies, that begin in placental cells called trophoblasts.

Biopsy—The process of taking a sample of tumor tissue through a needle.

CA 15-3 (Cancer antigen 15-3)—A tumor marker associated with breast cancer.

CA 19-9 (Cancer antigen 19-9)—A tumor marker associated with pancreatic cancer.

CA 27-29 (Breast carcinoma-associated antigen)—A tumor marker associated with breast cancer.

CA 125 (Cancer antigen 125)—A tumor marker associated with ovarian cancer.

CEA (Carcinoembryonic antigen)—A tumor marker associated with many cancers, especially liver, intestinal, and pancreatic.

Prognosis—The predicted outcome of a disease.

PSA (Prostate specific antigen)—A tumor marker associated with prostate cancer.

Sensitivity—A test's ability to detect all cases of a disease.

Serial measurements—A series of measurements looking for an increase or decrease over time.

Specificity—A test's ability to detect only the disease in question.

Tumor markers—Biochemicals produced by tumor cells or by the body in response to tumor cells. Their levels in the blood help evaluate people for certain kinds of cancer.

fluid. Potassium, for example, can be separated and filtered from fluid, bringing levels back to a safer range. Hemodialysis is a procedure that removes waste products through the blood. Dialysis can alternatively be performed through the peritoneum, the tissue that lines the abdominal area and surrounds the organs in what is called peritoneal dialysis. Because peritoneal dialysis does not clear phosphate and urate as efficiently, and because it is not feasible in patients with abdominal tumors, hemodialysis is the preferred method. A doctor who specializes in nephrology will generally examine a high-risk patient before cancer treatment begins, to prepare for the possibility of dialysis treatment. In some cases, dialysis is started as a preventive measure, either before or during chemotherapy treatment.

Tumor markers

Definition

Tumor markers are measurable biochemicals that are associated with a malignancy. They are either produced by tumor cells (tumor-derived) or by the body in response to tumor cells (tumor-associated). They are typically substances that are released into the circulation and thus measured in the blood. There are a few exceptions to this, such as tissue-bound receptors that must be measured in a **biopsy** from the solid tumor or proteins that are secreted into the urine.

Purpose

Though tumor markers are rarely specific enough to be used alone to diagnose cancer, they do have a number of clinical uses. They can be used to stage cancer, to indicate a prognosis, to monitor treatment, or in follow-up to watch for cancer recurrence. Changes in some tumor markers have been sensitive enough to be used as targets in **clinical trials**. When used for diagnosis, tumor markers are used in conjunction with other clinical parameters such as biopsy and radiological findings. Although there are a multitude of tumor markers, very few of them have found their way into clinical practice because of their lack of specificity. However, some of

these non-specific markers have found a place in monitoring cancer treatment rather than in diagnosis.

Description

As tumor cells grow and multiply, some of their substances can increase and leak into the bloodstream or other fluids. Depending upon the tumor marker, it can be measured in blood, urine, stool or tissue. Some widely used tumor markers include: AFP, beta-HCG, CA 15-3, CA 19-9, CA 27.29, CA 125, CEA, and PSA. Some tumor markers are associated with many types of cancer; others, with as few as one. Some tumor markers are always elevated in specific cancers; most are less predictable. However, no tumor marker is specific for cancer and most are found in low levels in healthy persons, or can be associated with non-neoplastic diseases as well as cancer. Also, no tumor marker test is free of false negatives or false positives.

Once cancer is diagnosed, tumor marker levels sometimes help to determine the extent of cancer. Higher levels can indicate more advanced cancer and a worse prognosis in some cases. The patient and their physician may use this information to choose between more or less aggressive treatments.

Monitoring cancer treatment is the most common use of tumor markers. As cancer is reduced, levels often decrease. Stable or increasing levels often indicate that the cancer is not responding to treatment. The choice of tumor marker to use for monitoring is important. Only a marker elevated before treatment should be used to monitor a person during or after treatment. Timing of the tests is also important. Each tumor marker has a unique life span in the blood. To monitor a treatment's success, enough time must have passed for the initial marker to be cleared from the blood. Tests done too soon may be falsely elevated because the marker produced by the untreated cancer is still present.

Watching for cancer recurrence after treatment is another reason for tumor marker testing. Periodic testing can sometimes detect a recurrence often months earlier than could an ultrasound, x ray, or physical examination.

Tumor marker tests are performed in a lab using immunological techniques. A sample of blood or other tissue is mixed with a substance containing specific antibodies to each tumor marker. If that tumor marker is present, these very specific antibodies bind to the markers. Some type of label, often a radioactive substance, is then used to measure the amount of bound marker and antibody. From this measurement, the amount of tumor marker is calculated. The results are usually available within a few days.

Conclusions based on tumor marker tests are seldom based on one test result but on a series of test results, called serial measurements. A series of increasing or decreasing values is more significant than a single value.

Tumor marker testing is currently the object of much research and attention. Their use is directed by approval from the Food and Drug Administration (FDA) and guidelines established by organizations such as the American Society of Clinical Oncology and the American Cancer Society. Not all tumor receptor marker tests are widely available nor are they widely accepted.

Oncofetal antigens

There are two common oncofetal antigens, alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA). Carcinoembryonic antigen CA 72-4 is a more recently discovered oncofetal antigen just coming into usage. The oncofetal antigens are so named because they are normally produced during embryonic development and decrease soon after birth. Cancer cells tend to dedifferentiate, or revert to a more immature tissue and begin to produce fetal antigens again. Oncofetal antigens are very non-specific and expressed by a wide number of cancer types. However, they are used both to monitor a patient's progress and their response to treatment over time.

ALPHA-FETOPROTEIN (AFP) Elevated AFP typically indicates a primary liver tumor or a germ cell tumor of the ovary or testicle. AFP is a glycoprotein produced in high amounts by fetal tissue and is elevated during pregnancy. It is most widely used as a marker for hepatocellular **carcinoma** and **testicular cancer** but is also associated with **ovarian cancer**. Seventy percent of people with liver cancer have increased AFP levels. In China, where liver cancer rates are high, AFP is used as a **screening test** for that disease. AFP levels indicate the extent of cancer, and serial measurements are used to monitor treatment response. Non-cancerous liver conditions such as cirrhosis and hepatitis have moderately increased levels of AFP.

CARCINOEMBRYONIC ANTIGEN (CEA) CEA is a glycoprotein most often associated with colorectal cancer, and used to monitor patients with this type of cancer. Its most popular use is in early detection of relapse in individuals already treated for colorectal cancer. After surgery, serial measurements indicate the surgery's success and are used to detect early signs of recurrence. It has recently been found to be useful when measured during surgery for colorectal cancer to help determine prognosis and who will benefit from adjuvant treatment.

CEA is measured in the blood plasma. It is very non-specific and can be increased in many types of cancer: gastrointestinal, colorectal, ovarian, bladder, cervical, stomach, kidney, lung, pancreatic, liver, prostate, thyroid, **melanoma**, **lymphoma**, and breast. People with

noncancerous conditions, such as cirrhosis or peptic disease, or inflammatory intestinal conditions such as colitis or diverticulitis, may also have increased levels. CEA levels can be elevated in elderly patients and in those who smoke.

CANCER ANTIGEN 72-4 (CA 72-4) The more recently identified carcinoembryonic protein is CA 72-4. Although it is slightly elevated with most carcinomas, it is mostly associated with gastric carcinoma (stomach cancer). CA 74-2 is finding a role in the management of patients with gastric carcinoma.

Cancer antigen 15-3 (CA 15-3)

CA 15-3 is produced by cells in the breast and increased levels can be associated with **breast cancer**. Rarely increased in women with early breast cancer, it may be used to detect recurrence of cancer in women following treatment or **mastectomy** and to monitor treatment for women with advanced breast cancer. However, **adenocarcinomas** of the ovary, lung, colon, and pancreas also express elevated CA 15-3 levels. Non-cancerous conditions sometimes associated with elevated CA 15-3 include benign breast or ovarian disease, endometriosis, pelvic inflammatory disease, and hepatitis. Pregnancy and lactation are also related to high CA 15-3 levels.

Cancer antigen 27-29 (CA 27-29)

CA 27-29, also called breast carcinoma-associated antigen, is used as a marker for breast cancer. Eighty percent of women with breast cancer have an increased CA 27-29 level. This marker may be used with other procedures and tumor marker levels such as CA 15-3 to check for recurrences of cancer in previously treated women. Serial measurements monitor treatment response and identify recurrence.

Levels of CA 27-29 may also be increased in cancers of the colon, stomach, kidney, lung, ovary, pancreas, uterus, and liver. Noncancerous conditions associated with elevated CA 27-29 include first trimester pregnancy, endometriosis, ovarian cysts, non-cancerous breast disease, kidney disease, and liver disease.

HER-2/neu

HER-2/neu is an oncogenic growth factor receptor also known as c-erbB-2. It is measured in the tissue from a biopsy either by immunological assays of the protein or polymerase chain reaction (PCR) to identify the DNA. The presence of HER-2/neu is generally associated with a poorer prognosis for breast cancer. It can also help to determine treatment options, since newer drugs can block this protein and decrease cancer growth. The most widely known of these drugs is **trastuzumab** (brand name Herceptin).

Estrogen receptor

Measurement of the estrogen receptor (ER)is used specifically to evaluate breast cancers. It gives an indication of prognosis and responsiveness to therapy. Tissue from a biopsy is used to measure the estrogen receptor. Most breast cancers in post-menopausal women are ER-positive, meaning that they require estrogen to grow. These ER positive breast cancers are less aggressive than ER negative breast cancers, which are found generally in pre-menopausal women.

Cancer antigen 125 (CA 125)

Although produced by a number of cell types, CA 125 is primarily produced by ovarian cancer cells. Eighty percent of women with ovarian cancer have increased CA 125 levels. Although the test is not sensitive or specific enough to be used for screening, it contributes to a diagnosis when combined with an ultrasound and pelvic examination. Blood levels of CA 125 are used primarily to monitor the treatment of ovarian cancer. A falling CA 125 level usually indicates that cancer is responding to the treatment. After diagnosis and treatment, serial measurements help detect remaining or recurrent cancer. A negative or normal result, however, does not guarantee the absence of cancer.

Women may have increased CA 125 levels during menstruation and pregnancy. Increased levels are also found in pelvic inflammatory disease, endometriosis, pancreatitis, and liver disease. Elevated levels are also associated with non-ovarian cancers including cancers of the uterus, cervix, pancreas, liver, colon, breast, lung, or digestive tract.

Prostate specific antigen (PSA)

Prostate specific antigen (PSA) levels, along with the digital rectal examination, are used to screen for **prostate cancer**. PSA is a protein produced by the prostate gland and can be overproduced in prostate cancer. It is perhaps the best tumor marker in use because of its tissue specificity, meaning that it is produced only by the prostate. Men over the age of 50 years are advised to consider annual screening for prostate cancer. Men at high risk for prostate cancer, such as African Americans or those with a family history of the disease, should begin screening at age 40. Once a diagnosis of prostate cancer is made, PSA levels can help determine the stage of the cancer, monitor the response to treatment, and watch for recurrence.

Measurements of PSA following **prostatectomy** are useful in determining the success of surgery. Any PSA level following surgery would indicate residual prostate tissue, possibly from **metastasis**. PSA levels can also be used to detect a recurrence of prostate cancer. PSA is also increased in benign prostatic hyperplasia (BPH), an enlarged prostate condition common in older men.

PSA can be found in the serum in two states, bound and free. Measuring both PSA levels can provide more specificity to the test and reduce unnecessary biopsies. The percentage of free PSA is greater in BPH than prostate cancer. If the total PSA level is higher than 4.0 nanogram/milliliter (ng/mL) and the free PSA level is less than 25%, a prostate biopsy is indicated.

PSA levels may increase after ejaculation. Men are recommended to abstain from sexual intercourse or masturbation for 48 hours before the test. PSA levels may also increase after prostate manipulation following the digital rectal exam.

Prostatic acid phosphatase (PAP) originally found to be produced by the prostate and thought to be a marker for prostate cancer. It is now found to be elevated with testicular cancer, leukemia, non-Hodgkin's lymphoma and several noncancerous conditions.

Cancer antigen 19-9 (CA 19-9)

CA 19-9 has been identified in patients with digestive tract or intra-abdominal carcinomas such as colorectal cancer, pancreatic cancer, **stomach cancer** and **bile duct cancer**. In pancreatic cancer, higher levels are associated with more advanced disease. After diagnosis, levels help predict the success of surgery and monitor the course of the cancer. Not all people with pancreatic cancer have increased CA 19-9 levels. This antigen is related to the Lewis blood group and so only patients positive for the Lewis blood group antigen will test positive for CA 19-9. It is also increased in liver and **gastrointestinal cancers** and in noncancerous diseases, including pancreatitis, gallstones and jaundice.

Human chorionic gonadotropin (hCG)

Human chorionic gonadotropin is normally produced by the placenta during pregnancy. There are two protein subunits that make up HCG, beta and alpha. It is the beta subunit that is increased in women's serum during early pregnancy. It is also the beta subunit that is increased in some malignant tumors. Tumors that secrete beta-hCG are typically **germ cell tumors** such as teratocarcinomas. These are tumors found in the ovaries and testes that contain embryonal tissue. Rarely, these types of tumors are found in the pineal region of the brain where beta-hCG can serve as a marker. Levels of hCG rise with choriocarcinoma and with trophoblastic disease, a rare cancer that develops from an abnormally fertilized egg. **Gestational trophoblastic tumors** also secrete AFP and this test is often used in combination.

HCG is most often used to screen for cancer of the testis or ovary. Serial measurements monitor the progress and treatment of these cancers. This marker can be elevated in individuals who use **marijuana**.

Squamous cell carcinoma (SCC) Antigen

Squamous cell carcinoma (SCC) antigen was first identified in **cervical cancer**. It is a marker for squamous cell cancers, which can occur in the cervix, head and neck, lung, and skin. Levels of SCC can be used as an aid to stage the carcinoma and to determine the response to treatment.

Bence-Jones protein

Patients with plasmacytomas such as **myeloma** overproduce monoclonal immunoglobulins, also called M proteins. The Bence-Jones protein refers to the immunoglobulin light chain, a portion of these immunoglobulins. The Bence-Jones protein is secreted into the urine where it can be measured. It was the first tumor marker identified.

Neuron-specific enolase (NSE)

NSE is a protein found mainly in neurons and neuroendocrine cells. It is elevated in tumors derived from these tissues, including **neuroblastoma** and small cell lung cancer. It can give information about the extent of the disease, the patient's prognosis and the patient's response to treatment. NSE can also be elevated in medullary thyroid cancers, carcinoid tumors, pancreatic endocrine tumors, and melanoma.

Hormone assays

Tumors of the endocrine glands oversecrete their corresponding hormones. By measuring particular hormones, clues can be obtained regarding certain cancers. For instance, breast cancer cells may secrete prolactin and estrogen. Medullary carcinoma can secrete **calcitonin**. Pheochromocytomas secrete catecholamines. Tumors of the pituitary gland may secrete growth hormone or cortisol. Carcinoid tumors secrete serotonin. Some tumors of the pancreas secrete insulin. Serial measurements can also monitor treatment for these tumors.

Enzymes

Several serum enzymes can be measured to help detect metastases in cancer patients. Tumors that

metastasize to the liver cause increases in serum alkaline phosphatase, gamma-glutamyltransferase, and transaminases. Although these are not necessarily tumor markers, they indicate liver damage that may be caused by metastatic cancer. Tumors that metastasize to the bone sometimes secrete elevated alkaline phosphatase. Lactate dehydrogenase is an enzyme found throughout the body. Because of this it cannot be used as a marker for cancer. It can, however, be used to monitor the treatment of some types of cancer including germ cell tumors, testicular cancer, **Ewing's sarcoma**, non-Hodgkins lymphoma and some types of leukemia.

Precautions

There is not a good consensus in the medical community about the value of most tumor markers. Because they lack specificity and accuracy, their use is limited. False positives can cause emotional distress and fear. It is not yet determined if there is a savings of life or money with testing. Currently, much controversy surrounds the issue of mass screening for cancer using tumor markers.

Preparation

Tumor marker tests usually require 5-10 mL of blood. A healthcare worker ties a tourniquet on the patient's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes a few minutes and results are available within a few days.

Some markers, such as those for **bladder cancer**, **multiple myeloma**, and plasmacytomas, are measured in the urine. Typically this requires a 24-hour urine sample, which means that the individual must collect all of his or her urine for 24 hours. This is usually about 1.5 quarts or more. These results are then available within a few days.

Other tumor markers require tissue samples for analysis. These include **receptor analysis** such as estrogen receptor and Her-2/neu. Tissue samples are obtained by biopsy. This is usually done by inserting a needle through the skin and into the tumor. The area is typically numbed prior to the procedure. These results are also available within two to three days.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

KEY TERMS

Cachexia—A side effect of cancer therapy characterized by weight loss due to lack of appetite and wasting away due to malnutrition.

Cytokines—Molecules released by cells to regulate the length and intensity of an immune response and to mediate intercellular communication.

Macrophage—A type of white blood cell that produces antibodies and molecules for cell-to-cell immune responses.

Regional perfusion—Forcing a liquid through the blood at the capillary beds at or near a specific site.

There is a rare chance of infection occurring especially after biopsy. Any sign of infections should be watched for such as pain and redness.

Normal results

- AFP: 99% of (nonpregnant) people have less than 15 ng/mL; 95% have less than 6 ng/mL. Serum AFP levels higher than 400 micrograms/L are associated with cancer or some other pathology.
- Beta-HCG: in males, less than 2.5 IU/L; in females, less than 5.0 IU/L; in postmenopausal females, less than 9.0 IU/L.
- CA 15-3: less than 40 U/mL.
- CA 19-9: less than 40 U/mL.
- CA 27.29: less than or equal to 38 U/mL.
- CA 125: less than 35 U/L.
- CEA: less than or equal to 5 ng/mL.
- PSA: less than 4 ng/mL; PSA levels increase with age. Age-specific values range from 2.0 micrograms/L at age 40 to 7.2 micrograms/L at age 80. Typically, levels below 4.0 micrograms/L rule out prostate cancer.

Abnormal results

The meaning of an increased tumor marker level depends on the specific marker, the person's medical history, and why the test was done. Knowledge of the patient's history and additional tests and physical examinations are needed to correctly interpret tumor marker test results.

Tumor necrosis factor

Definition

Tumor necrosis factor is a protein produced by several of the body's cell types, such as white blood cells, red blood cells, and other cells that line the blood vessels. It promotes the destruction of some types of cancer cells.

Description

In the 1970s, researchers took sarcoma cells in culture and exposed them to a protein produced by white blood cells. The protein caused necrosis (death) of the sarcoma cells but had little effect on normal cells in the culture. Hence, the protein was called "tumor necrosis factor" (TNF).

TNF is a type of cytokine released by white blood cells. Cytokines are a group of molecules that are released by many different cells to communicate with other cells and regulate the duration of an **immune response**. There are many different kinds of cytokines, each with a different effect on specific target cells. Once a cell releases the cytokines, they bind to corresponding receptors located on target cells, thus causing a change to take place within the target cell. Tumor necrosis factor is released by special white blood cells called macrophages. Although researchers are still investigating the exact mechanism by which TNF kills cancer cells, it is clear that TNF binds to receptors located on the surface of cancer cells, causing a change and then death of the cell. This was found to be true in animal models. As a result, researchers thought TNF might enhance the reaction of the human immune system to cancer cells.

In the mid-1980s, TNF became available in recombinant form and was analyzed in clinical human trials. At that time, researchers discovered that TNF administered systemically was toxic to humans' normal tissues at the maximum doses required to kill all of the cancer cells, thus limiting its usefulness. At maximum doses required to kill cancer cells, patients experienced **fever**, loss of appetite (anorexia), and cachexia (severe **weight loss**, malnutrition, and wasting away of the body).

However, TNF can be effectively combined with other systemic chemotherapeutic drugs such as **doxorubicin** and **etoposide**. TNF in conjunction with the above drugs enhances DNA breakage in tumor cells, contributing to their death. In addition to administering TNF systemically, TNF (with or without other chemotherapeutic drugs) can be forced through the blood at the capillary beds at or near the site of the tumor. The regional perfusion of TNF allows larger dosages to be administered only in the area requiring the treatment. Therefore, less

KEY TERMS

Disseminated disease—The presence of widespread malignancy implying a stage of IV.

Malignancy—A general term for cancers of all tissue types, sarcomas, and leukemias.

Metastasis—The spread of malignancy to another site within the body. To regional lymph nodes: regional metastasis. To distant sites: distant metastasis.

Prognosis—The expected outcome

Systemic disease—Disease that is widely metastatic or present throughout the body.

normal and healthy tissue is disrupted before reaching the maximum tolerable limits. Research performed in 1998 (by Lejeune, et al.) found regional perfusion to be especially successful in the case of **melanoma metastasis**, resulting in complete remission of 70% to 80% of patients.

Although TNF is valuable in killing cells in melanoma and sarcoma tumors, it can promote growth of other kinds of cancers. Therefore, the action of TNF is continually under research with the hope of increasing its effectiveness on killing cancer cells, while decreasing the toxic side effects on healthy tissue.

Tumor staging

Definition

Tumor staging is the process of defining at what point in the natural history of the malignant disease the patient is when the diagnosis is made. The organ and cell type in which the malignancy has developed defines the type of malignancy. For example, adenocarcinoma of the lung defines that the cancer originated in the mucus-secreting cells lining the airways of the lung. Staging is different than defining the type of cancer; it is the process of defining the degree of advancement of the specific type of malignancy in the patient at the time of presentation (the time when the diagnosis is made). Because there are many different types of malignancy arising from many different organs in body, the specifics of staging systems vary.

Purpose

Staging fulfills an organizational role that is central to treatment of cancer. After the tumor is staged, the treatment team knows to what degree the cancer has evolved in its natural history. This knowledge will provide the information necessary to formulate a plan of treatment and will allow an estimate of the success of that treatment (prognosis). Finally, by establishing uniform criteria for staging, people with the same type of malignancy presenting at the same stage can be treated equivalently. If a new treatment is tested that improves the long-term prognosis then that treatment will become the new standard of care. Thus, staging is vital to the processes of research and scientific reporting.

Prognosis

The first question that most patients want answered when they find they have cancer is "How am I going to do?" They want to know the ultimate outcome—their prognosis. Because of the existing research on the natural history, or progression, of the disease, this information is available on a statistical basis. Staging, then, helps define the patient's prognosis. Intuitively, one would think that those presenting with an earlier stage have a better prognosis. For the most part, that is correct.

Scientific reporting and research

When a patient develops a life-threatening disease such as cancer, the physicians and other members of the treatment team intervene in an effort to improve the prognosis. Treatment regimens are defined as good or bad based on how they influence the prognosis of the disease. Staging allows medical professionals to interpret whether or not their efforts are favorably influencing the natural history of the disease. Once a patient's cancer stage has been established, a baseline exists against which to measure the efficacy of the cancer treatment that follows for that patient.

Staging plays a similar "baseline" role when considering a large group of cancer patients. In order to gauge accurately the effectiveness of any cancer treatment, researchers must know if the patients' conditions really are comparable. If they are, comparisons between treatments are fair. If the patients' conditions vary at the outeset of a study, then comparing the outcomes of different treatments is not useful.

Staging provides that useful, objective standard so that researchers can accurately compare specific treatments in certain stages of particular cancers. Staging

allows uniformity in treatment protocol and reporting of the data related to outcome. As new treatment protocols are developed, they can be tested on patients with the same type and stage of cancer and the two groups compared. If there is improvement with a new treatment protocol, that treatment regimen will be adopted as standard. Physicians can use these established best practices to determine treatments for their patients.

Criteria for staging

As it became apparent to medical professionals that staging of malignancies was necessary for accurate assessment of treatment regimens and defining the treatment recommendations themselves, criteria for staging needed to be developed. Initially this was done for individual tumors separately. Because of the need for uniformity, a universal set of criteria was desired. The TNM system of staging has been adopted for the most part for this reason. It has been developed and updated by The American Joint Committee on Cancer (AJCC). Some of the types of malignancy do not fit well into the TNM criteria and others have older systems that are still in use because they are effective and are deeply established in scientific literature.

TNM system

This system of staging is the general format used for staging cancer of all types and is updated and maintained by the AJCC. The "T" stands for tumor size. The "N" stands for spread to lymph nodes, (nodal **metastasis**). The "M" stands for metastasis, (spread of the cancer to sites in the body other than the organ of origin. When the diagnosis of cancer is made, the physical examination along with laboratory testing and **imaging studies** will be performed to define the TNM status of the patient. The TNM status will define stage.

The tumor size, "T" will be assessed by physical examination or various imaging modalities depending on the accessibility of the tumor. The "T" value is generally defined as 1 through 4 on the basis of size and whether or not the tumor is invading structures that surround it. In cancer so early that it is felt to be incapable of spreading, it is assigned a "T" value of 0. The "T" value is, in essence, a description of the tumor in its local place of origin. As time passes and the staging system is updated, the "T" value is being subdivided in certain types of cancer. The subdivisions are indicated by letters "a" through "d" and also have a graduated value system. For example: T1 **breast cancer** is a tumor sized 2 cm or less in greatest dimension. T1a is less than 0.5 cm, T1b is 0.5 to 1.0 cm, and T1c is 1.0 to 2.0 cm.

In many cancers, there seems to be a progression from the place of primary origin, then to the regional lymph nodes, and then throughout the body. Lymph nodes can be thought of as filters that drain tissue fluid coming from a particular organ. If that organ has developed a cancer and some of the cells flow away with the tissue fluid to the lymph node filter that is draining that organ, the cancer may begin to grow there also. Assessment of lymph node involvement thus becomes the next step in staging and defines the "N" value. Since the word metastasis means that the cancer has spread from its point of origin to somewhere else in the body and the lymph nodes are in the region, the "N" value defines presence of regional metastasis. The assessment is performed by physical examination and imaging studies of the region involved. "N" is assigned a value of 0 for no nodes involved, or depending on the anatomic nature of the region, values 1 through 3.

"M" stands for distant metastasis. As mentioned previously, metastasis is the spread of the primary tumor to elsewhere in the body. When that spread or metastasis is outside the region of the primary tumor, the patient has distant metastasis. The "M" value is assessed by physical exam, laboratory studies, and imaging studies. Different cancers have different typical patterns of metastasis. Common areas of metastatic involvement are lung, liver, bone, and brain. The "M" value is assigned either 0 or 1. Another term used to describe the patient who has distant metastasis is that of having systemic disease. In the TNM system virtually all patients with an "M" value of 1 have stage IV disease. The "M" value may also have a subscript defining the organ of metastatic involvement.

After the values for TNM have been determined as accurately as possible, the values are grouped together and a stage value is assigned. The stage value is usually I through IV, (and is written in roman numerals). Each stage may be subdivided, (A,B,C...), if it is useful for treatment recommendations and reporting. In general, stage I implies the tumor is confined to its source of origin and stage IV implies distant metastasis or systemic disease. Because of different anatomical, prognostic, and treatment considerations, the intermediate stages are defined by different tumor sizes, the presence or absence of local invasion of the tumor into surrounding structure, or the number and/or presence of involved lymph nodes. Treatment recommendations and expected outcome are both defined to a large extent by stage. The specific criteria for each stage are contained in the *AJCC Cancer Staging Manual*.

An example of TNM staging follows. This example is the staging criteria for non-small-cell lung cancer.

- Stage 0: A small group of cancerous cells have been found in one location in the lung.

- Stage I: The cancer is only in the lung and has not spread anywhere else.
- Stage II: The cancer has spread to nearby lymph nodes.
- Stage III: The cancer has spread to more distant lymph nodes, and/or other parts of the chest like the diaphragm.
- Stage IV: The cancer has spread to other parts of the body (distant metastasis).

Special staging systems

In the development of staging systems it has been recognized that some malignancies do not fit well into the scheme of the TNM system or that the system in place reflects the same information as the TNM system. Thus there are a few special staging systems in use for specific organs of involvement. The goal is the same for these schema as for TNM; to define the point in the natural history at presentation, to allow establishment of prognosis and treatment recommendations, and to facilitate scientific research and reporting.

COLON CANCER: DUKE'S STAGING The Duke's staging system is similar to the TNM system when describing colo-rectal cancer. This was the original staging system for colon and rectal cancers; however, the TNM staging sytem has begun to replace the Duke's system for colon and rectal cancers.

OVARIAN CANCER: FIGO SYSTEM FIGO stands for the International Federation of Gynecology and Obstetrics. This organization developed staging criteria for the various gynecologic malignancies and the one for cancer of the ovary is still used somewhat though the TNM criteria are gradually replacing the FIGO system. In the FIGO system, **ovarian cancer** is staged I through IV similar to the TNM scheme then each stage is subdivided into A, B, or C, depending on defined criteria.

LYMPHOMA: ANN-ARBOR STAGING Anatomically, the lymph system and its nodes are found throughout the body. Malignancies involving the lymph system (lymphomas), do not fit the typical TNM scheme well. The Ann Arbor staging criteria are instead utilized to classify this group of malignancies. The goals of the Ann Arbor **lymphoma** staging system are to define the degree of advancement of the disease so that treatment recommendations can be made and prognosis can be estimated, and to facilitate consistent reporting and research.

The Ann Arbor system classifies lymphoma into four stages based on anatomic lymph nodal group involvement. Disease confined to one nodal group or location defines stage I. Disease limited to one side of the diaphragm, (the muscle separating the chest from the abdomen), defines stage II. Stage III patients have disease on both sides of the diaphragm and stage IV patients once again have disseminated disease. Consideration of involvement of the liver, spleen, and bone marrow are also considered in this system. Finally, the stage is subdivided into categories of A and B depending on the presence of symptoms of **itching**, **weight loss**, **fever**, and **night sweats**. Those having symptoms receive the designation "B" and have a worse prognosis.

LEUKEMIA: THE FAB AND RAI/BINET STAGING SYSTEMS Leukemia is the type of malignancy that begins in the cells of the marrow that produce the cellular components of blood, the progenitor cells. These malignancies are truly systemic from their outset and do not fit any form of the TNM system. Still there is need to categorize the presenting features of the patients with these diseases to help make treatment recommendations, estimate prognosis, and to facilitate scientific research and reporting. The acute leukemias are staged by the FAB (French, American, British) system, and **chronic lymphocytic leukemia** is classified by the Rai/Binet system.

LUNG CANCER, SMALL CELL Unlike other types of lung cancer, the staging of small cell lung cancer is relatively simple. This is because approximately 70% of patients already have metastatic disease when they are diagnosed, and small differences in the amount of tumor found in the lungs do not change the prognosis. Small cell lung cancer is usually divided into three stages:

- Limited stage: The cancer is found only in one lung and in lymph nodes close to the lung.
- Extensive stage: The cancer has spread beyond the lungs to other parts of the body.
- Recurrent stage: The cancer has returned following treatment.

Defining the stage

The process of defining stage is quite simple. First, the diagnosis is established by study of the patient and by tissue **biopsy**. Once the cell type and organ of origin are established, the staging criteria are reviewed. The patient will undergo a series of diagnostic tests to define the various parameters of the staging criteria. The results of these tests define the extent of the disease and establish the stage. The known typical natural history of the disease dictates the types of testing done. The tests differ for each type of malignancy.

Special concerns

Clinical vs. pathological stage

The stage of the patient's disease may be categorized into clinical or pathological. As mentioned, the

known natural history of the disease and the staging criteria are utilized to define the stage of the patient at the time of presentation. The investigations performed often involve an initial degree of uncertainty when they are based on clinical grounds alone. For example, the physical exam or the imaging of a particular group of lymph nodes may show that they are enlarged but the enlargement may not accurately define whether they are truly involved with cancer. This issue may only be resolved by removing some or all of the suspect enlarged nodes, sometimes by biopsy before treatment or sometimes by the removal of the questionable nodes at the time of definitive treatment. The evaluation under the microscope of the clinically enlarged nodes will define whether they are really involved with cancer or merely enlarged. When staging criteria are based on clinical assessment alone, it is referred to as the clinical stage. Once the results of the microcopic evaluation are known the true stage or pathologic stage may be assigned.

Stage is uniform and accurate

One of the main goals of staging is to facilitate communication so that like patients are compared to like patients. It is imperative that the adopted staging criteria are rigidly adhered to or inaccurate comparisons may be made and the results of research to develop better treatment regimens will be difficult to interpret.

Tumor grade

When the tissue obtained for diagnosis is evaluated under the microscope for cell type, often another index called grade is defined. As the pathologist analyzes the malignant cells, attention will be given to how close to a normal cell the malignant cells appear to be. If they are very similar, the malignant cells are not felt to be too aggressive and a low grade value is assigned. The more atypical the malignant cells appear to be, the more aggressive the tumor is and a higher grade value is assigned. Grade is usually assigned a value of I through IV though more levels can be assigned depending on the particular cancer.

The estimate of grade is just that—an estimation. It is subjective in nature and cannot be determined quantitatively. Though useful in predicting prognosis, the correlation is not exact. Rather, grade is included as only one of the factors influencing prognosis. Grade may be included as part of the actual staging criteria; however, it usually is not part of the scheme.

Tumor boards

A tumor board is a body of specialists in the treatment of cancer that convenes to discuss the aspects of patients presenting with cancer. The AJCC encourages the development of tumor boards throughout the nation to facilitate the use of staging and reporting of cancer statistics from region to region throughout the country. In addition to allowing the collection of vital cancer statistics, local tumor boards create a forum where the clinical aspects of a patient's cancer may be discussed to provide recommendations or to play a role in education.

U

Ultrasonography

Definition

Ultrasonography is the study of internal organs or blood vessels using high-frequency sound waves. The actual test is called an ultrasound scan or sonogram. Duplex ultrasonography uses Doppler technology to study blood cells moving through major veins and arteries. There are several types of ultrasound. Each is used in diagnosing specific parts of the body.

Purpose

An ultrasound is a noninvasive, safe method of examining a patient's eyes, pelvic or abdominal organs, breast, heart, or arteries and veins. It is often used to diagnosis disease, locate the source of pain, or look for stones in the kidney or gallbladder. Ultrasound produces images in real time. Images appear on the screen instantly. It may also be used to guide doctors who are performing a needle **biopsy** to locate a mass. (Needle biopsies are often used to obtain a sample of breast tissue to test for cancer cells.) Duplex/Doppler ultrasound aids in diagnosing a blockage in or a malformation of the vessel. Different color flows aid in identifying problem areas in smaller vessels. Endoscopic ultrasound combines a visual endoscopic exam, during which a flexible tube called an endoscope is threaded down the throat, with an ultrasound test. The ultrasound probe is attached to the end of the endoscope. An endoscopic ultrasound is helpful in determining how deeply a tumor has grown into normal tissues or the gastrointestinal tract. During a transvaginal ultrasound, the ultrasound probe is inserted into the vagina to obtain better images of the ovaries and uterus. Color flow Doppler imaging, using a transvaginal probe, is being performed to detect abnormal blood flow patterns associated with **ovarian cancer**.

Precautions

Ultrasound is considered safe with no known risks or precautions. The exam uses no radiation. Under normal circumstances the exam is normally painless. However, if the patient has a full bladder, pressure exerted during the exam may feel uncomfortable. An ultrasound conducted in conjunction with an invasive exam carries the same risks as the invasive exam.

Description

The patient will be asked to lie still on an exam table in a darkened room. The darkness helps the technician see images on a screen, which is similar to a computer monitor. Sometimes the patients are positioned so they can watch the screen. The technician will apply a lubricating gel to the skin over the area to be studied. Ultrasound uses high-frequency sound waves to produce an image. A small wand-like device called a transducer produces sound waves that are sent into the body when the device is pressed against the skin. The gel helps transmit the sound waves, which do not travel through the air. Neither the patient nor the technician can hear the sound waves. The technician moves the device across the skin in the area to be studied. The sound waves bounce off the fluids and tissues inside the body. The transducer picks up the return echo and records any changes in the pitch or direction of the sound. The image is immediately visible on the screen. The technician may print a still picture of any significant images for later review by the radiologist.

Preparation

Depending on the type of ultrasound ordered, patients may not need to do anything prior to the test. Other ultrasound studies may require that the patient not eat or drink anything for up to 12 hours prior to the exam, in order to decrease the amount of gas in the bowel. Intestinal gas may interfere in obtaining accurate results. The patient must have a full bladder for some exams and an empty bladder for others.

KEY TERMS

Biopsy—Removal of a tissue sample for examination under a microscope to check for cancer cells.

Endoscopy—Examination of the upper gastrointestinal tract using a thin, flexible instrument called an endoscope.

Radiologist—Doctor who has received special training and is experienced in performing and analyzing ultrasounds and other radiology exams.

QUESTIONS TO ASK THE DOCTOR

- Did you see any abnormalities?
- What future care will I need?

Aftercare

Remove any gel still left on the skin. No other aftercare is required following an ultrasound.

Risks

Standard, diagnostic ultrasound is considered risk-free. Risks may be associated with invasive tests conducted at the same time, such as an endoscopic ultrasound or an ultrasound-guided needle biopsy.

Normal results

An ultrasound scan is considered normal when the image depicts normally shaped organs or normal blood flow.

Abnormal results

Abnormal echo patterns may represent a condition requiring treatment. Any masses, tumors, enlarged organs or blockages in the blood vessel are considered abnormal. Additional testing may be ordered.

Upper gastrointestinal endoscopy

Definition

Upper gastrointestinal endoscopy is a procedure that allows the doctor to visually examine the upper portions of the gastrointestinal tract, using a flexible tool called an endoscope. The endoscope has a light source and projects an image on a video screen. An endoscope may also be used to assist with other diagnostic exams and procedures. For instance, an ultrasound probe can be placed on the end of the endoscope to evaluate how deeply a tumor has penetrated the esophagus or wall of the stomach. An endoscope may be used to assist with placement of a permanent feeding tube or to treat a bleeding ulcer.

Purpose

An upper gastrointestinal endoscopy aids in the investigation of the source of pain, difficulty swallowing, bleeding or other symptoms of an upper abdominal problem. During an endoscopy the doctor can obtain samples of tissue for **biopsy**, to check for the presence of cancer cells or the bacteria responsible for most stomach ulcers. Various instruments can be passed through the endoscope to treat problems, such as controlling bleeding due to an ulcer. The procedure may be performed on patients who have had stomach surgery to assess for cancer or the return of an ulcer. It may also be used to monitor patients at high risk for upper **gastrointestinal cancers**.

Precautions

Patients with a history of heart and lung disease and those with blood-clotting problems require special precautions. For instance, a patient with artificial heart valves or a history of infection of the lining of the heart will need **antibiotics** to prevent infection. Patients with an intestinal perforation, or puncture in the gastrointestinal tract, should not have an upper gastrointestinal endoscopy. Patients must be able to cooperate during the procedure. Those who are not able to cooperate are not good candidates for an endoscopy.

Description

An endoscopy may take place in the physician's office or in a hospital. An intravenous (IV) line will be started in a vein in the arm. Through the IV line, the patient generally receives a sedative and a pain-killer if needed. The medication will help the patient feel relaxed and drowsy. A local anesthetic is usually sprayed into the throat to prevent a gag reflex. Dentures are removed.

Doctors performing an endoscopy examination of a woman's stomach and taking a biopsy. The endoscope has been inserted through the patient's mouth and fed down her throat. The image obtained by the endoscope is on the screen at upper left. *(Copyright Deep Light Productions, Science Source/Photo Researchers, Inc. Photo reproduced by permission.)*

KEY TERMS

Biopsy—Removal of a tissue sample for examination under a microscope to check for cancer cells.

Duodenum—The first portion of the small intestine.

Endoscope—A thin, flexible, lighted tube that is passed down the throat and enables the doctor to view the esophagus, stomach lining and duodenum.

Perforation—Puncture or tear.

Staging—Determination of how advanced the cancer is.

Ultrasound—The study of internal organs using high-frequency sound waves.

A mouthpiece will help to keep the mouth open. Patients are positioned onto their sides. The doctor slowly advances the lubricated endoscope down the throat, into the stomach. Air will be passed through the endoscope to make it easier for the doctor to see the lining of the gastrointestinal tract. The endoscope will be repositioned to see different parts of the stomach and the small intestine. The exam usually takes less than an hour. The patient is able to breathe independently during the exam. In some cases a biopsy may be taken. Biopsy forceps or a brush used to secure cells are passed through the endoscope. The tissue sample is taken and then removed through the endoscope.

Preparation

The doctor should be informed of any allergies as well as all the medications that the patient is currently taking. The doctor may instruct the patient not to take certain medications, like aspirin and anti-inflammatory drugs that interfere with clotting, for a period of time prior to the procedure. The patient should not eat or drink anything for at least eight hours prior to the endoscopy. The doctor should be informed if the patient has had heart valves replaced or a history of an inflammation of the inside lining of the heart, so that appropriate antibiotics can be administered to prevent any chance of infection. Risks and benefits of the procedure will be explained to the patient. The patient will be asked to sign a consent form.

Aftercare

The patient will be monitored for an hour or two after the procedure, while the effects of the medication wear off. Due to the sedative, the patients will need to arrange for someone to drive them home after the procedure.

Patients may feel bloated due to the air that is introduced into the stomach during the procedure, and may have a sore throat for a couple of days. Patient should contact the doctor if they develop difficulty swallowing, chest pain, severe abdominal pain, throat soreness that becomes more severe or rectal bleeding.

Risks

Endoscopy is usually considered safe when performed by a specially trained physician. As with any invasive procedure it is not risk-free. Complications include bleeding and perforation (puncturing a hole in the lining of the gastrointestinal tract). Scopes are cleaned and disinfected between patients so any risk of transmitting infectious disease from one patient to another by the endoscope would be negligible.

Normal results

A pale reddish pink lining with no abnormal-looking masses or ulcerations is considered a normal result.

QUESTIONS TO ASK THE DOCTOR

- Did you see any abnormalities?
- How soon will you know the results of the biopsy (if one was done)?
- When can I resume any medications that were stopped?
- What future care will I need?
- Which problems should prompt me to call you?

Abnormal results

Evidence of an ulcer or other lesion would be considered an abnormal result. If the biopsy determines the presence of cancer cells, a diagnosis of cancer is made. The appearance of the lesion, including its size or if there are multiple lesions, often helps with staging and treatment plans. An ultrasound probe attached to the endoscope also may help with staging.

Upper GI series

Definition

An upper GI examination is a fluoroscopic examination (a type of x-ray imaging) of the upper gastrointestinal tract, including the esophagus, stomach, and upper small intestine (duodenum).

Purpose

An upper GI series is frequently requested when a patient experiences unexplained symptoms of abdominal pain, difficulty in swallowing (dysphagia), regurgitation, **diarrhea**, or **weight loss**. It is used to help diagnose disorders and diseases of, or related to, the upper gastrointestinal tract, including cases of hiatal hernia, diverticuli, ulcers, tumors, obstruction, **enteritis**, gastroesophageal reflux disease, Crohn's disease, and pulmonary aspiration.

Precautions

Because of the risks of radiation exposure to the fetus, pregnant women are advised to avoid this procedure. Patients with an obstruction or perforation in their bowel should not ingest barium (a radioactive substance used to show contrast in the images) for an upper GI, but may still be able to undergo the procedure if a water-soluble contrast medium is substituted for the barium.

Glucagon, a medication sometimes given prior to an upper GI procedure, may cause nausea and dizziness.

Description

An upper GI series takes place in a hospital or clinic setting and is performed by an x-ray technician and a radiologist. A radiologist typically is in attendance to oversee the procedure and view and interpret the fluoroscopic pictures. Before the test begins, the patient is sometimes administered an injection of glucagon, a medication which slows stomach and bowel activity, to allow the radiologist to get a clearer picture of the gastrointestinal tract. In order to further improve the clarity of the upper GI pictures, the patient may be given a cup of baking soda crystals to swallow, which distend the stomach by producing gas.

Once these preparatory steps are complete, the patient stands against an upright x-ray table, and a fluoroscopic screen is placed in front of him. The patient will be asked to drink from a cup of flavored barium sulfate, a thick and chalky-tasting liquid that allows the radiologist to see the digestive tract, while the radiologist views the esophagus, stomach, and duodenum on the fluoroscopic screen. The patient will be asked to change positions frequently in order to coat the entire surface of the gastrointestinal tract with barium. The technician or radiologist may press on the patient's abdomen in order to spread the barium. The x-ray table will also be moved several times throughout the procedure. The radiologist will ask the patient to hold his breath periodically while exposures are being taken. The entire procedure may take up to 45 minutes.

In some cases, in addition to the standard upper GI series, a doctor may request a detailed intestine, or small

KEY TERMS

Dysphagia—An inability to swallow, or difficulty with swallowing.

Fluoroscopy—Also called radioscopy, this procedure involves the examination of internal body structures using x-rays and projecting images on a fluorescent screen.

Necrosis—Death of cells in a body tissue.

Radiologist—A doctor who specializes in an area of medicine that focuses on the use of radiation to diagnose and treat disease.

QUESTIONS TO ASK THE DOCTOR

- What is the purpose of this examination?
- When will I know the results?
- How will I be notified of the results?
- How will the examination results help to determine the next step in management of my condition?
- What are the alternatives to this diagnostic exam?

bowel, radiography and fluoroscopy series; it is also called a small bowel follow-through (SBFT). Once the preliminary upper GI series is complete, the patient will be escorted to a waiting area while the barium travels down the rest of the small intestinal path. Every 15 to 30 minutes, the patient will return to the x-ray suite for additional x rays. Once the barium has traveled down the small bowel tract, the test is complete. This procedure can take anywhere from one to four hours.

Esophageal radiography, also called a barium esophagram or a barium swallow, is a study of the esophagus only, and is usually performed as part of the upper GI series. It is commonly used to diagnose the cause of difficulty in swallowing (dysphagia) and for detecting hiatal hernia. A barium sulfate liquid, and sometimes pieces of food covered in barium or a barium tablet, are given to the patient to drink and eat while a radiologist examines the swallowing mechanism on a fluoroscopic screen. The test takes approximately 30 minutes.

Preparation

Patients must not eat, drink, or smoke for eight hours prior to undergoing an upper GI examination. Longer dietary restrictions may be required, depending on the type and diagnostic purpose of the test. Patients undergoing a small bowel follow-through exam may be asked to take **laxatives** the day prior to the test. Upper GI patients are typically required to wear a hospital gown, or similar attire, and to remove all jewelry, so the camera has an unobstructed view of the abdomen. Patients who are severely ill may not be able to tolerate the procedure.

Aftercare

No special aftercare treatment or regimen is required for an upper GI series. The patient may eat and drink as soon as the test is completed. The barium sulfate may make the patient's stool white for several days, and patients are encouraged to drink plenty of fluids in order to eliminate it from their system.

Risks

Because the upper GI series is an x-ray procedure, it does involve minor exposure to ionizing radiation. Unless the patient is pregnant, or multiple radiological or fluoroscopic studies are required, the small dose of radiation incurred during a single procedure poses little risk. However, multiple studies requiring fluoroscopic exposure that are conducted in a short time period have been known, on rare occasions, to cause skin death (necrosis) in some individuals. This risk can be minimized by careful monitoring and documentation of cumulative radiation doses administered to these patients.

Another risk is barium impaction, which occurs when the patient is unable to completely expel the barium contrast agent before it eventually dries and hardens. The risk of barium impaction is greatest in elderly patients and those with colon obstruction or colon motility disorder.

Normal results

A normal upper GI series will show a healthy, functioning, and unobstructed digestive tract.

Abnormal results

Obstructions or inflammation, including ulcers of the esophagus, stomach, or small intestine, or irregularities in the swallowing mechanism are some of the possible abnormalities that may show up on an upper GI series. Other abnormalities may include polyps, foreign bodies, or congenital anomalies. Upper GI series are helpful in the diagnosis of gastric (stomach) cancer.

Urethral cancer

Definition

A rare form of cancer that can affect both men and women, urethral cancer is a type of cancer that develops in a person's urethra.

Description

The urethra is the tube in a person's body that empties urine from the bladder. In women, the urethra is a very short tube that opens to the outside of the body just above the vagina, whereas in men it is a much longer tube that goes through the prostate gland and penis to the outside of the body.

In both men and women, urethral cancer has a tendency to invade local and adjacent soft tissues. By the time of diagnosis, the majority of tumors are locally advanced, which sometimes results in a poor prognosis despite aggressive treatment. Urethral cancer rarely metastasizes (spreads) to distant locations. In women, the most common sites of tumor invasion are the vagina and bladder, whereas in men, tumor invasion most commonly occurs in the deep tissues of the perineum, the prostate, and the penile and scrotal skin. Most of the urethral tumors, in both men and women, are the squamous-cell type. The second most common type is transitional-cell **carcinoma**.

Demographics

Because urethral cancer is so rare (approximately 600 cases a year), there is not much data validating the best methods of treatment. Generally speaking, urethral cancer is found more often in women than in men. Although people of many different ages have been diagnosed with urethral cancer, it is usually found in people over the age 50. Urethral cancer is more common in white people than in black people; however, blacks tend to have a worse prognosis after urethral cancer has been diagnosed.

Causes and symptoms

Patients with a history of **bladder cancer** have an increased risk of urethral cancer. Although cigarette smoking and exposure to certain chemicals, such as the ones that used to be used in the rubber industry, can contribute to the development of bladder cancer, the same correlation does not exist with urethral cancer. Certain types of human papillomavirus are suspected as the cause of urethral cancer in some people, although in many cases the cause is unknown.

Often the first symptom of urethral cancer is blood in the urine, although it may be present in such small amounts that it can only be detected in a microscope. Sometimes, however, the urine may be visibly red. There may be pelvic pain and the flow of urine may be obstructed, making it difficult to urinate. A lump may be present on the urethra. In women, tiny growths that bleed may be present at the external opening of the urethra.

Diagnosis

To diagnose urethral cancer, a physician will examine the patient physically for any lumps. A urinalysis may also be done to check for the microscopic presence of blood and to check for infection. Patients may need to have a **cystoscopy**, which will allow the physician to see inside the urethra. In adults, the procedure is usually done under local anesthesia, which means that the area around the urethral opening is injected with an anesthetic. The cystoscope, which is a long, flexible tube made of plastic or metal, is inserted through the urethra. The tube has a lens and a fiberoptic light that allows the physician to examine the area through a scope. It may be necessary to take a small sample of the tissue, which is referred to as a **biopsy**. The sample will then be viewed under a microscope to check for any signs of cancer.

Treatment team

The treatment team is comprised of physicians from a variety of medical specialties. For example, a patient

diagnosed with urethral cancer may have a treatment team that includes the patient's primary care physician and urologist, as well as a radiologist, oncologist, surgeon, and **pain management** specialist. Women may also seek the advice of their gynecologist. At home caretakers are also part of the treatment team, providing important physical and emotional support to the patient. Physicians and patients that value a holistic approach to fighting cancer may add a variety of other advisors to the treatment team, such as psychologists, pastors, and alternative medicine specialists.

Clinical staging, treatments, and prognosis

After a diagnosis of cancer has been made, patients will need to have more tests to determine if the cancer has spread to other areas of the body. The treatment is gauged depending on the stage of the disease. The stage of urethra cancer is determined by the cancer's location and whether it has metastasized. According to the National Cancer Institute, the following are used to describe the different stages of urethral cancer:

- Anterior urethral cancer: the cancer is located on the urethra near the outside of the body
- Posterior urethral cancer: the cancer is located on the urethra near the bladder
- Urethral cancer associated with invasive bladder cancer: the cancer has spread to the urethra because of the presence of bladder cancer

Surgery, **radiation therapy**, and **chemotherapy** are the conventions treatment options for urethral cancer. According to the National Cancer Institute, the surgeon may remove the cancerous tumor in one of three ways:

- Electrofulguration: electric current is used to kill the cancer cells
- Laser therapy: a narrow beam of powerful light is used to kill the cancer cells
- Cystourethrectomy: the urethra and bladder are removed

Surgical requirements vary depending on the severity of the cancer. The removal of the urethra will require the surgeon to create something called a urinary diversion, meaning another way to urinate will need to be constructed. In some cases, the patient's physician may recommend that men have part or their entire penis removed, which is called a penectomy. If a penectomy (the total removal of the penis) is done, the patient will need plastic surgery to make a new penis. Lymph nodes in the pelvis may also be removed. In women, surgery to remove the urethra, bladder, and/or vagina may be necessary. Plastic surgery will be necessary to create a new vagina.

When a patient's bladder is removed, the surgeon may use part of the small intestine to create a tube so that the patient can urinate and a mouth-like opening, referred to as a stoma, is made surgically on the outside of the body. This procedure is called an ostomy. The patient then uses glue to connect a bag that is designed especially for the purpose of being connected to the stoma. As a patient urinates, the urine collects in the bag. The patient can then throw the bag away and replace it with a new one. The bag is hidden under the patient's clothing. Ostomy patients can be more prone to infection and some patients with sensitive skin may experience occasional skin irritation due to the glue that holds the bag in place.

It is psychologically difficult for some patients to get used to urinating in a bag. Fears of having "accidents" or "smelling bad" sometimes overwhelm ostomy patients. Support groups and special counseling can be very helpful to patients who are having a difficult time adjusting to their new situation.

Based on the severity and extent of the cancer, radiation and/or chemotherapy treatments may be recommended. The prognosis of urethral cancer depends on a variety of factors, such as the tumor's size and location, as well as the extent of the cancer and the patient's general health. For example, in an article published in the *Journal of Urology*, Drs. Grisby and Corn reported that women who have been diagnosed with posterior urethral cancer that do not have tumors larger than 2 centimeters can be effectively treated with radiation alone, surgery alone, or a combination of the two treatment options. In fact, studies such as the one conducted by Dr. Sailer and colleagues, which was also published in the *Journal of Urology*, have shown that 60% of the women diagnosed with posterior urethral cancer that have tumors smaller than 2 centimeters can expect a five-year survival, whereas only 13% of the women can expect a five-year survival if their tumors exceed 4 centimeters.

Coping with cancer treatment

Patients having difficulty coping with the pain associated with cancer and chemotherapy might find it helpful to be referred to a physician who specializes in pain management or a pain clinic. Physicians specializing in the treatment of pain come from a variety of medical backgrounds, such as anesthesiology, urology, and surgery. Because of the complicated nature of cancer and cancer-related pain, ideally a pain management team should be formed that works with the patient's primary care physician, oncologist, and radiologist to provide comprehensive care to the patient.

But what about the emotional pain that is associated with urethral cancer? Much has been written about

QUESTIONS TO ASK YOUR DOCTOR

- How will having a penectomy affect my survival time?
- When is it safe for me to resume sexual relations?
- Are there any clinical trials I should consider joining?
- How successful is the reconstructive surgery?
- How will the treatment affect my ability to have children?
- How will my ability to urinate be affected if I have an ostomy?

coping with the physical side effects of cancer treatment; however, patients with urethral cancer also face emotional challenges associated with their treatment. For example, men and women may be concerned how the treatment will affect their sexual relations. They may have to deal with a variety of psychological issues, such as body image versus self-image. Patients may need to be reminded, especially by family members and friends, that they are more than a collection of body parts. Patients having difficulty dealing with the emotional aspects of their cancer may find it useful to see a psychologist. Psychologists can help patients identify a variety of coping mechanisms designed to enable them to deal with what lies ahead.

It is important for cancer patients to understand that they are not alone. Support groups exist to help patients cope not only with the physical aspects of having cancer, but with the psychological ones as well. Patients should be encouraged to talk about their feelings. The positive support (both emotional and otherwise) provided by caregivers can help to improve a patient's quality of life. In addition, support groups on the Internet have made it possible for patients, even those in rural or remote areas, to reach out to one another in ways that allow anonymity.

Urostomy

Definition

Urostomy is a surgical procedure that creates an opening (stoma) in the abdominal wall through which urine leaves the body.

Purpose

Doctors perform urostomy when a patient has **bladder cancer**, spinal cord injury, specific types of birth defects, or when the bladder is not functioning properly and must be removed.

Precautions

In an individual who is obese or who has folds in the skin or scars in the abdominal wall, an internal collection sac (reservoir) the patient can empty (catheterize) works better than a passage that lets urine flow out of the body into a collection bag (pouch) worn next to the skin under the clothes.

Description

Urostomy is a form of urinary diversion. Surgeons perform this reconstructive procedure when disease, infection, injury, or congenital abnormality makes it necessary to remove a patient's bladder and create a new channel (conduit) for urine to leave the body.

Surgeons perform urostomy by separating a short piece of the large or small intestine from the rest of the intestine. They attach the separated intestine to the two thick tubes (ureters) that carry urine from the kidneys to the bladder and connect the ureters to the stoma.

Continent and incontinent diversions

An incontinent ostomy drains continuously into a small pouch fitted over the stoma and worn under the

patient's clothes. The patient wears a collection pouch at all times and empties it several times a day.

To perform a continent urinary diversion, the surgeon uses a piece of the patient's intestine to create an internal reservoir to store urine. The patient does not wear an ostomy pouch but empties the reservoir four to six times a day by inserting a drainage tube (catheter) into the stoma.

Types of urostomy

The most common types of urostomy are the ileal conduit, which uses a piece of the small intestine (ileum) and the colonic conduit, which uses a piece of the large intestine (colon). Orthotopic neobladder is a new type of continent diversion that channels urine into the tube that drains urine from the bladder (urethra) and enables the patient to urinate almost normally.

Temporary urostomy does not involve severing the ureters and is most often performed in children.

Doctors consider the likelihood of disease recurring in the pelvis or urethra as well as the patient's gender to determine which type of urostomy is most appropriate. Neobladders are not appropriate for female patients whose cancer involves the bladder neck or male patients with problems affecting the right colon or small bowel.

If bladder cancer has metastasized or cannot be surgically removed, the surgeon may perform a urostomy without removing the patient's bladder.

Preparation

Before undergoing a urostomy, the patient learns where on the abdomen the stoma will be created, what type of collection device (if any) will be worn, and what changes in appearance the operation may cause.

Nurses encourage the patient preparing to undergo an incontinent urostomy to become familiar with the collection device that will be worn after the operation. They may arrange to have someone who has already had the operation (ostomate) reassure the patient preparing for either an incontinent or continent procedure and answer questions about life after the surgery.

Preoperative restrictions

The patient may be told not to eat certain foods before surgery and must fast for eight hours and have a cleansing enema before the operation.

Fluid and **antibiotics** may be given to a patient who is frail.

KEY TERMS

Bladder neck—The narrowest part of the bladder.

Cystoscopy—Diagnostic procedure that allows the doctor to view the entire bladder wall.

Kidney failure—Inability of the kidneys to excrete waste and maintain a proper chemical balance. Also called renal failure.

Aftercare

A patient who has undergone an incontinent diversion wears a collection device that is odor-free, not visible under clothing, disposable or reusable, and available at drug stores or medical supply houses or through the mail.

To prevent urine leakage, infection, skin irritation, and odor, the patient should re-measure the stoma and make any necessary adjustments in the size of the flat sponge-like patch that covers and protects it. This should be done during the first few months after the operation (when shrinkage occurs) or whenever gaining or losing weight. Measuring devices and instructions are included in every box of collection pouches.

Some doctors recommend taking Vitamin C to prevent infection- and odor-causing bacteria from accumulating in the urine. Other recommendations include drinking eight to 10 glasses of water a day to reduce the likelihood of kidney infection.

Risks

Because tumors sometimes develop in neobladders, a patient who undergoes this procedure must have a **cystoscopy** within five years.

Normal results

A patient who has had a urostomy can:

- Shower or bathe with or without the collection pouch.
- Usually wear the clothes worn before the operation.
- Return to work shortly after leaving the hospital, although a doctor's permission is required before doing heavy lifting.
- Enjoy intimate relationships.
- Participate in athletic activities, but should avoid strenuous contact sports like football or wrestling.

Dietary restrictions are rare.

QUESTIONS TO ASK THE DOCTOR

- What type of urostomy will I have?
- Will I have to wear a pouch after the operation?
- Will I be able to take care of myself after the operation?
- Will other people be able to tell that I have had a urostomy?

A woman who has undergone a urostomy should talk with her doctor before becoming pregnant.

Abnormal results

Almost half (40%) of patients who undergo continent diversions and 24.1% of those who undergo ileal or colonic conduits require subsequent surgery to repair leaks or obstructions and correct other surgery-related problems.

A patient who has had a urostomy may also experience:

- kidney damage, infection, or failure
- swelling, shrinkage (stenois), or displacement (prolapse) of the stoma
- infections of the stoma or urinary tract
- fever
- hernia
- diarrhea
- urinary problems
- chills
- pain in the leg or abdomen
- blood or pus in the urine

V

Vaccines

Definition

A cancer vaccine is a method of treating the disease involving administration of one or more substances characteristic of the cancer, called antigens, often in combination with factors that boost immune function. This induces the patient's immune system to attack and eliminate the cancerous cells.

Purpose

Unlike traditional vaccines for infectious diseases, at this time cancer vaccines are not given to prevent the initial development of cancer. Instead, cancer vaccines are a method of treating cancer that has already occurred and are given to patients already diagnosed with cancer.

As a cancer treatment method, the ultimate goal of most cancer vaccines is the elimination of tumor or cancerous cells from the body. Other vaccines are given after the use of more traditional treatments, such as **chemotherapy**, radiation, or surgery, with the aim of suppressing the recurrence of the cancer.

Precautions

No vaccine has yet been approved by the Food and Drug Administration (FDA) for the treatment of cancer. Accordingly, vaccines are not standard treatments and other more traditional treatments should be investigated first. Vaccines are available only through participation in **clinical trials**. Each trial has its own criteria that can limit who can participate. However, many cancers have a current trial for one or more types of vaccines. The American Society for Gene Therapy states that as of late 2000, vaccines were the most common approach to gene therapy being studied by researchers.

Most vaccine trials test the response of the disease with and without the vaccine or the effect of substances added to the vaccine, called adjuvants. Such trials usually only accept patients who have already tried the standard treatment methods. Others test a standard treatment method with and without the addition of the vaccine. A very few compare the standard treatment to the vaccine.

Looking at cancer vaccines overall, this treatment method has been more successful eliminating very small tumors rather than the getting rid of a large tumor load. So if the size of the tumor is significant, a more realistic goal is to shrink the tumor and reduce its effect on the patient's body, rather than total elimination of the cancer.

The complexity of the human immune system has made it very difficult to develop an effective vaccine. Tumors have strategies to evade detection by the immune system. Most notably, they mimic the outward appearance and antigens of the body's own cells. The immune system's built-in lack of response against "self" allows the tumor to escape notice by the body. Now fully aware of this phenomenon, researchers are working to develop methods of circumventing this problem to develop a highly effective vaccine system.

Description

There are three general types of cancer vaccines, those that use whole tumor cells, those that use only one or more substances derived from the tumors, or those that administer primed cells from the patient's immune system.

Whole cell vaccines

Whole cell vaccines are autologous when they contain only inactivated tumor cells from the patient's own tumors. The cells have been isolated from the tumor and made to grow in the laboratory, a process known as creating a cell line. Allogeneic whole cell vaccines are made from inactivated tumor cells isolated from one or more other people. The main advantage to autologous vaccines is the direct relation between the vaccine and

the tumor target. However, because of the screening of self antigens away from a body's own immune system, **immune response** to tumor antigens in autologous whole cells vaccines can be low.

Allogeneic vaccines avoid some of the problems of autologous vaccines. First, cell lines do not have to be created for each patient, a labor-intensive process that can have highly variable results. Second, the same vaccine can be given to all patients, making the response to the vaccine more predictable. Third, a use of a pool of tumor cells can increase the possibility of having the full repertoire of the tumor antigens in the vaccine. This helps to overcome the ability of tumor cells to escape notice by the immune system. Finally, by using well-characterized cell lines, it is much easier for the researcher to add genetic modifications that increase the immune system's response to the cells.

Isolated antigen vaccines

There are many kinds of vaccines that deliver only a portion of the tumor cell that will elicit an immune response, called an antigen. Some antigens are unique to a cancer type, some are unique to an individual tumor, while a very few are found in more than one cancer type. For example, vaccines against telomerase and human chorionic gonadotripin (hCG), two proteins produced by many cancers, have been developed, raising hopes for the development of a universal cancer vaccine.

The most common kind of antigen used in cancer vaccines is a protein or a part of a protein. The protein can actually be isolated from the tumor cells, or more commonly, produced in large quantity using genetic engineering techniques. When a part of a protein is used, experimental efforts generally preceded the vaccine production to determine what parts of the protein were often the target of immune responses. Parts of proteins that elicit immune responses are called epitopes.

Antigens do not necessarily have to be proteins. Immune responses are also mounted against the carbohydrate (sugar) molecules present on the surface of the proteins. Tumor proteins can have unusual carbohydrate structures that set them apart from cells from normal tissue. Carbohydrates are also found in abundant numbers on the surface of the tumor cells. Accordingly, researchers have developed cancer vaccines that combine the tumor-characteristic carbohydrates anchored on protein bases. These vaccines are being tested for their ability to reduce the recurrence of **prostate cancer**.

Vaccines can also contain the naked genetic material encoding the protein (either deoxyribose nucleic acid, DNA, or ribose nucleic acid, RNA). After the genetic material gains entry to the cell, the cellular machinery uses it to produce the antigen and an immune response is mounted against it. Animal studies have found that these types of vaccines are very dependent on the particular antigen and the mode of administration of the vaccine. A unique method of delivery used with DNA or RNA vaccines is the coating of tiny gold beads with the genetic material and shooting the beads into the skin.

Genetically engineered viruses can also be used to bring the DNA or RNA into the cell. When used in this way the viruses are called viral vectors. One example of a viral vector currently being used as a cancer vaccine is one based on the adenovirus. When viruses are used as vectors they have been altered to no longer cause disease, but they do retain the ability to infect human cells. Instead of making new viruses, the infected cells make the desired antigen, and the body will respond against it. Viral vectors can also carry the genetic instructions for factors, called cytokines, which boost the immune system's response to the antigen.

Antigen-presenting cell (APC) vaccines

Vaccines can also be made that contain cells from the patient's own immune system, in particular antigen-presenting cells (APCs). These cells play a central role in the development of an immune response against a particular antigen. Specifically, APCs ingest the antigen and present them to the T cells, a type of immune cells responsible for targeting and killing cells seen as foreign to the body. If T cells are exposed to the antigen by an APC, as opposed to seeing the antigen on the cell itself, they are more strongly activated. That is, more T cells that specifically attack that antigen are produced and the immune response against the foreign cell is stronger.

Dendritic cells are a type of APC that is most effective in activating T cells. For this reason, they are often the kind of cells used in APC vaccines. Unfortunately, the number of dendritic cells circulating in the blood at any one time is relatively low. However, new techniques have been developed that allow that small number of dendritic cells to be isolated and then stimulated outside the body to result in a usable number. During stimulation, the dendritic cells are exposed to the tumor antigen, a process known as priming. Thus, when injected into the body, the dendritic cells are primed to recruit large numbers of T cells specific against the tumor antigen.

Cyokines and adjuvants

Because of the ability of tumor cells to escape detection by the immune system, an important component of many cancer vaccines is the addition of biological factors or chemical adjuvants to help boost immune response. One type of adjuvant is a cytokine, a factor

normally produced by cells of the immune system to help recruit cells to the site of the foreign cells or help T cells function. Some examples of cytokines used in vaccines are granulocyte/macrophage colony stimulating factor (GM-CSF, or sargramostim), the interleukins (especially IL-2), the **interferons** (INFs), and **tumor necrosis factor** alpha (TNF-α).

Adjuvants are chemical additions to vaccines that help boost the response to the contained cells or antigens. Adjuvants are derived from a variety of sources and can be isolated from animals, plants, or are synthetic chemical compounds. Several adjuvants in use with cancer vaccines are keyhole lympocianin (KLH, derived from shell-dwelling sea animals), incomplete Freud's adjuvant (IFA, mineral oil and an emulsifying agent), and QS-21 (a chemical derived from the soapbark tree).

Administration

The particular administration method and schedule will vary from clinical trial to clinical trial. Administration methods can include intradural (injection within the skin), subcutaneous (injection below the skin), injection into the lymph nodes, or intravenous (injection into the veins). Typically, vaccines are administered as a series of several doses (initial challenge and boosters). Many clinical trials utilize various administration methods and timing strategies in order to try to determine the best means of inducing an anti-tumor immune response.

Preparation

Before enrolling in a clinical trial, patients should discuss the potential benefits and risks with their doctor. Clinical trials can be located by contacting the research institutes directly or by searching the Internet. A particularly good site for getting information about clinical trials for cancer treatment is run by the National Cancer Institute (<http://www.clincialtrials.gov>).

Aftercare

One of the most striking advantages of vaccines compared to other cancer treatments is the relatively low incidence of side effects. Particularly if IFN is used as an immunoadjuvant, patients sometimes experience flu-like symptoms. However, other than some soreness at the site of injection, vaccine patients generally have no adverse reactions to this kind of treatment.

Risks

The greatest risk with cancer vaccines is that there will be no immune response and the treatment will be ineffective. Although serious adverse reactions to the antigens, such as the attack of healthy cells, are theoretically possible, these fears have not materialized. Other than some mild adverse reactions, such as **fever** and redness of the skin at the injection site, vaccine treatment appears relatively low-risk in the traditional sense.

KEY TERMS

Adjuvant—A substance added to a vaccine to increase the immune system's response to the vaccine contents.

Allogeneic—A type of vaccine made up of tumor cells derived from persons other than the patient.

Antigen—A substance characteristic of a tumor that evokes an immune response.

Antigen presenting cell—A cell of the immune system that ingests antigens and exposes them to cells of the immune system in a way that activates the cells to seek out and destroy any other cells displaying that antigen.

Autologous—A type of vaccine made up of tumor cells from the patient's own tumor.

Cytokine—A substance made by cells of the immune system that increases the response to a foreign substance.

Dendritic cell—A special type of antigen-presenting cell that is effective in stimulating T cells.

Epitope—A portion of a protein or other molecule that is the specific target of an immune response.

Normal results

Based on a review of published clinical trials as of 2000, normal results for this treatment is, unfortunately, little or no effect. Although a response by the immunized patient's T cells against the tumor is often documented by testing, the effect on disease is generally marginal. These results could be at least partially due to the selection process for patients in the trials, who are often suffering from late-stage cancers.

Abnormal results

For each trial, there are a small percentage of patients who have complete, partial, or mixed response to the vaccine. Others show a stabilization of the disease where deterioration of condition would be expected. As

QUESTIONS TO ASK THE DOCTOR

- Have all the standard treatment methods for my cancer been tried?
- Is there a vaccine in clinical trials for my kind of cancer?
- Do I fulfill the requirements necessary for the clinical trial for this vaccine?
- Has this vaccine been tried on human patients before?
- If so, what were the results?

traditional treatments were often unsuccessful with these patients, these results are significant. However, the very low rate of success underscores the complexity of the human immune system, the number of variables in the vaccine method, and the amount of research that will need to be done to develop an effective vaccine treatment for this disease.

Vaginal cancer

Definition

Vaginal cancer refers to an abnormal, cancerous growth in the tissues of the birth canal (vagina).

Description

Vaginal cancer is rare and accounts for only 1% to 2% of all **gynecologic cancers**. In the United States, there are approximately 2,000 cases of vaginal cancer diagnosed, and approximately 600 deaths, each year. Vaginal cancer can be either primary or metastatic. Cancer that originates in the vagina is called primary vaginal cancer; if cancer spreads to the vagina from another site, it is called metastatic cancer. Eighty-percent of vaginal cancers are metastatic. Metastatic cancers carry the name of the primary cancer site. For instance, cancer that has spread from the cervix to the vagina would be called "metastatic cervical cancer," not "vaginal cancer."

The vagina is a short tube that extends from the outer female genitalia (vulva) to the opening to the uterus (cervix). It serves to receive the penis during sexual intercourse, as an outlet for shed tissue and blood during menstruation, and as a passageway for a baby during childbirth. Most cancers are located in the upper third of the vagina.

Squamous **carcinoma** is the most common type of vaginal cancer and accounts for 85% of cases. Infrequent types of vaginal cancer include adenocarcinoma, **melanoma**, and **sarcomas**. Adenocarcinoma is usually found in young women (ages 12 to 30 years) while squamous cell cancer (squamous carcinoma) is usually found in older women (ages 60 to 80 years). Although vaginal melanoma can afflict adult women of any age, women are on average in their fifties at the time of diagnosis.

Demographics

Vaginal cancer is most common in women who are between the ages of 60 and 80.

Causes and symptoms

Cancer is caused when the normal mechanisms that control cell growth become disturbed, causing cells to grow and divide without stopping. This is usually the result of damage to the genetic material of the cell (deoxyribonucleic acid, or DNA). The cause of vaginal cancer is not known.

Symptoms of vaginal cancer appear when the cancer has become more advanced. Approximately 20% of vaginal cancer cases are asymptomatic (produce no symp-

toms) and are diagnosed following an abnormal **Pap test**. Symptoms of vaginal cancer include:

- abnormal vaginal bleeding or discharge
- pain during intercourse
- pain in the pelvic area
- difficult or painful urination
- constipation

Diagnosis

The diagnosis of vaginal cancer is made by physical examination and laboratory analysis of tissue samples. During the physical examination, the physician will place one or two fingers into the vagina and press down on the lower abdomen with his or her free hand to feel (palpate) the reproductive organs and any masses. During a routine speculum examination, the physician will obtain a sample of cervical and vaginal cells (using a swab, brush, or wooden applicator) for laboratory analysis (Pap test).

A special magnifying instrument, called a colposcope, may be used to view the vagina. Additionally, the surface of the vagina may be treated with a dilute solution of acetic acid, which causes some abnormal areas to turn white. Squamous carcinoma and adenocarcinoma usually appear as a growth on the surface of the vagina. Squamous carcinoma may present as an open sore (ulcer). Adenocarcinoma may lie deeper so that it is not visible and detected only by palpation. Vaginal melanoma appears as a brown or black skin tag (polypoid), growth attached to the vaginal wall by a stem (pedunculated), nipple-like growth (papillary), or fungus-like growth (fungating). Sarcomas often appear as a grape-like mass.

If any area appears abnormal, a tissue sample (**biopsy**) will be taken. The biopsy can be performed in the doctor's office with the use of local anesthetic. A small piece of tissue, which contains the suspect lesion with some surrounding normal skin and the underlying skin layers and connective tissue, will be removed. Small lesions will be removed in their entirety (excisional biopsy). The diagnosis of cancer depends on a microscopic analysis of this tissue by a pathologist.

Chest x rays and routine blood work are commonly employed in the diagnosis of any cancer. Endoscopic examination of the bladder (**cystoscopy**) and/or rectum (proctoscopy) may be performed if it is suspected that the cancer has spread to these organs.

Treatment team

The treatment team for vaginal cancer may include a gynecologist, gynecologic oncologist, radiation oncologist, plastic surgeon, gynecologic nurse oncologist, sexual therapist, psychiatrist, psychological counselor, and social worker.

Clinical staging, treatments, and prognosis

Clinical staging

The International Federation of Gynecology and Obstetrics (FIGO) has adopted a clinical staging system for vaginal cancer that is used by most gynecologic oncologists. Vaginal cancer is categorized into five stages (0, I, II, III, and IV) that may be further subdivided (A and B) based on the depth or spread of cancerous tissue. The FIGO stages for vaginal cancer are:

- Stage 0. Cancer is confined to the outermost layer (epithelium) of vaginal cells and is called carcinoma *in situ* or vaginal intraepithelial neoplasia (VAIN).
- Stage I. Cancer is confined to the vagina.
- Stage II. Cancer has spread to the tissues near the vagina.
- Stage III. Cancer has spread to the bones of the pelvis, local lymph nodes, and/or other reproductive organs.
- Stage IV. Cancer has spread to the bladder, rectum, or other parts of the body.

Treatments

The treatment of vaginal cancer varies considerably and depends on the type of cancer, stage of cancer, and the patient's age and overall health. Surgery is the most common treatment for vaginal cancer. **Radiation therapy** and **chemotherapy** are often used as adjuvant therapy to complement the surgical treatment.

SURGERY The amount of tissue removed depends upon the stage and type of cancer. The local lymph nodes may also be removed (lymphadenectomy). Laser surgery, which destroys the cancerous cells, may be used in the treatment of stage 0 vaginal cancer. With a wide local excision, the cancerous tissue and some surrounding healthy tissue is cut out. Wide local excisions may require skin grafts to repair the vagina.

For more extensive cancer, the vagina may be removed (vaginectomy). Following vaginectomy, skin grafts and plastic surgery are used to create an artificial vagina. Vaginal cancer that has spread to the other reproductive organs would be treated by radical hysterectomy in which the uterus, fallopian tubes, and ovaries are removed. Cancer that has spread beyond the reproductive organs may be treated by pelvic **exenteration**, in which the vagina, cervix, uterus, fallopian tubes, ovaries, and, as necessary, the lower colon, bladder, or rectum are removed.

Surgical complications include urinary tract infection, wound infection, temporary nerve injury, fluid accumulation (edema) in the legs, urinary **incontinence**, falling or sinking of the genitals (genital prolapse), and blood clots (thrombi).

RADIATION THERAPY Radiation therapy may be used as the sole treatment of vaginal cancer or as an adjuvant therapy to aid surgery. Radiation therapy uses high-energy radiation from x rays and gamma rays to kill the cancer cells. Radiation given from a machine that is outside the body is called external radiation therapy. Radiation given internally is called internal radiation therapy or brachytherapy. Sometimes applicators containing radioactive compounds are placed inside the vagina (intracavitary radiation) or directly into the cancerous lesion (interstitial radiation). External and internal radiation may be used in combination to treat vaginal cancer.

The skin in the treated area may become red and dry and may take as long as a year to return to normal. **Fatigue**, upset stomach, **diarrhea**, and nausea are also common complaints of women having radiation therapy. Radiation therapy in the pelvic area may cause the vagina to become narrow as scar tissue forms. This phenomenon, known as vaginal stenosis, makes intercourse painful.

CHEMOTHERAPY Chemotherapy is not very a very successful treatment of vaginal cancer and is generally reserved for patients with advanced disease. Chemotherapy uses anticancer drugs to kill the cancer cells. The drugs are usually given by mouth (orally) or intravenously. They enter the bloodstream and can travel to all parts of the body to kill cancer cells. Generally, a combination of drugs is given because it is more effective than a single drug in treating cancer. For vaginal cancer, anticancer drugs may be put into the vagina (intravaginal chemotherapy).

The side effects of chemotherapy are significant and include stomach upset, vomiting, appetite loss (anorexia), hair loss (alopecia), mouth or vaginal sores, fatigue, menstrual cycle changes, and premature menopause. There is also an increased chance of infections.

Prognosis

Survival is related to the stage and type of vaginal cancer. The five-year survival rates for squamous carcinoma and adenocarcinoma of the vagina are: 96%, stage 0; 73%, stage I; 58%, stage II; 36%, stage III; and 36%, stage IV. With a five-year survival rate of less than 20%, melanoma has a poor prognosis. Vaginal cancer most commonly spreads (metastasizes) to the lungs, but may spread to the liver, bone, or other sites.

KEY TERMS

Adjuvant therapy—A treatment that is intended to aid the primary treatment. Adjuvant treatments for vaginal cancer are radiation therapy and chemotherapy.

Biopsy—Removal of a small piece of tissue for microscopic examination. This is done under local anesthesia and removed by either using a scalpel or a punch, which removes a small cylindrical portion of tissue.

Colposcope—An instrument used for examination of the vagina and cervix. The instrument includes a light and magnifying lens for better visualization.

Intracavitary radiation—Radiation therapy for vaginal cancer in which a cylindrical container holding a radioactive substance is placed into the vagina for one or two days.

Metastasis—The movement of cancer cells from one area of the body to another. This occurs through the blood vessels or the lymph vessels.

Pelvic exenteration—Surgical removal of the organs of the pelvis which includes the uterus, vagina, and cervix.

Squamous cells—Scale-like cells that cover some body surfaces and cavities.

Vaginectomy—Surgical removal of the vagina. An artificial vagina can be constructed using grafts of skin or intestinal tissue.

Alternative and complementary therapies

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques such as prayer, biofeedback, visualization, meditation, and yoga have not shown any effect in reducing cancer but can reduce stress and lessen some of the side effects of cancer treatments.

Clinical studies of hydrazine sulfate found that it had no effect on cancer and even worsened the health and well-being of the study subjects. One clinical study of the drug amygdalin (Laetrile) found that it had no effect on cancer. Laetrile can be toxic and has caused death. Shark cartilage, although highly touted as an effective cancer treatment, is an improbable therapy that has not been the subject of clinical study.

The American Cancer Society has found that the ''metabolic diets'' pose serious risk to the patient. The

effectiveness of the macrobiotic, Gerson, and Kelley diets and the Manner metabolic therapy has not been scientifically proven. The Food and Drug Administration (FDA) was unable to substantiate the anticancer claims made about the popular Cancell treatment.

There is no evidence for the effectiveness of most over-the-counter herbal cancer remedies. However, some herbals have shown an anticancer effect. Some studies have shown that polysaccharide krestin (PSK), a substance from the mushroom *Coriolus versicolor*, has some effectiveness against cancer. In a small study, the green alga *Chlorella pyrenoidosa* has been shown to have anticancer activity. In a few small studies, evening primrose oil has shown some benefit in the treatment of cancer. Herbals can have a negative impact on conventional treatment; patients must discuss herbal use with a physician.

For more comprehensive information, the patient should consult the book on complementary and alternative medicine published by the American Cancer Society listed in the Resources section.

Coping with cancer treatment

The patient should consult her treatment team regarding any side effects or complications of treatment. Vaginal stenosis can be prevented and treated by vaginal dilators, gentle douching, and sexual intercourse. A water-soluble lubricant may be used to make sexual intercourse more comfortable. Women with a reconstructed vagina will need to use a water-soluble lubricant during sexual intercourse. Many of the side effects of chemotherapy can be relieved by medications. Women may wish to consult a psychotherapist and/or join a support group to deal with the emotional consequences of cancer and vaginectomy.

Clinical trials

As of 2001, there are no **clinical trials** underway that were specific for vaginal cancer. Women should consult with their treatment team to determine if they are candidates for any ongoing studies.

Prevention

Risk factors for vaginal cancer include:

- Diethylstilbestrol (DES). Young women whose mothers took DES during pregnancy are at a higher risk of developing vaginal cancer, particularly clear cell carcinoma. Between 1945 and 1970, DES was prescribed to pregnant women who were at risk of miscarriage.
- **Cervical cancer**. Women with a history of cervical cancer have a high risk of developing vaginal cancer.
- Hysterectomy. Up to half of all patients with vaginal cancer have had a hysterectomy. Their vaginal cancer may actually represent an earlier spread from the cervix.
- Chronic irritant vaginitis. Chronic irritation to the vagina, particularly from use of a vaginal pessary, is associated with vaginal cancer. A pessary is an instrument that is placed into the vagina to support the uterus or prevent pregnancy (contraception).
- Vaginal adenosis. This condition, in which cells that resemble those of the uterus are found in the vaginal lining, places a woman at a higher risk of developing vaginal cancer.

QUESTIONS TO ASK THE DOCTOR

- What type of cancer do I have?
- What stage of cancer do I have?
- What is the five-year survival rate for women with this type and stage of cancer?
- Has the cancer spread?
- What are my treatment options?
- How much tissue will you be removing? Can you remove less tissue and complement my treatment with adjuvant therapy?
- What are the risks and side effects of these treatments?
- What medications can I take to relieve treatment side effects?
- Are there any clinical studies underway that would be appropriate for me?
- What effective alternative or complementary treatments are available for this type of cancer?
- How debilitating is the treatment? Will I be able to continue working?
- Are there any restrictions regarding sexual activity?
- How is a vaginal reconstruction performed?
- How will a vaginal reconstruction affect sexual functioning?
- Are there any local support groups for vaginal cancer patients?
- What is the chance that the cancer will recur?
- Is there anything I can do to prevent recurrence?
- How often will I have follow-up examinations?

- Human papilloma virus (HPV) infection. Infection by this sexually transmitted virus, the cause of genital warts, increases a woman's risk of developing squamous carcinoma.
- Smoking. There appears to be an association between tobacco use and vaginal cancer.

All women, even those who have had a hysterectomy or are past menopause, should get an annual pelvic examination and Pap test. Women who had a hysterectomy because of cancer may benefit from more frequent Pap tests. The earlier that precancerous abnormalities or vaginal cancer are detected, the better the prognosis. Women whose mothers took DES during pregnancy and those with vaginal adenosis should be screened regularly. Women can reduce the risk of contracting HPV by avoiding sexual intercourse with individuals who have had many sexual partners, limiting their number of sexual partners, and delaying first sexual activity until an older age. Avoiding tobacco products may reduce a woman's risk of developing vaginal cancer.

Special concerns

Of special concern to women undergoing treatment of vaginal cancer is the effect surgery and/or radiation therapy will have on sexual functioning. Women of childbearing age may worry about their fertility and whether or not they will be able to bear children. **Depression**, due to the affects of surgery on **body image** and **sexuality**, may occur. Complications, both short term and long term, following extensive surgical treatment of vaginal cancer are not uncommon.

Valacyclovir HCl *see* **Antiviral therapy**

Valrubicin

Definition

Valrubicin (also known as Valstar) is a chemotherapeutic drug that interferes with the metabolism of DNA, thus disrupting the proliferation of cells, including cancer cells.

Purpose

Valrubicin is an antineoplastic drug that is used as a treatment for a form of **bladder cancer** called papillary bladder cancer when the bladder cannot be surgically removed due to increased risk of morbidity or mortality. It is also being tested as treatment for several other types of carcinoma *in situ*.

Description

The Food and Drug Administration approved valrubicin for bladder cancer treatment in 1998. As of 2000, it was being tested in **clinical trials** for both bladder and **ovarian cancer** treatments. It is an anthracycline-like compound that acts by penetrating cells and disrupting the dividing cell cycle by interfering with DNA metabolism. Valrubicin acts by inhibiting nucleoside incorporation into nucleic acids, thus, causing major damage to

DNA. Research performed in 1999 indicated that valrubicin entered cells faster than **doxorubicin**, another anthracycline. Research has also shown that complete response is seen in one in five patients.

Recommended dosage

Valrubicin is only available in instillation form and can only be administered under the supervision of a physician. During initial clinical trials patients received doses ranging from 200 milligrams to 900 milligrams each week. The normal dose is 800 milligrams once a week for six weeks. However, dosing may vary from patient to patient. The drug is administered intravesically (directly into the bladder) through a catheter tube that penetrates into the bladder wall. Once delivered to the bladder the solution should be maintained in the bladder for approximately two hours.

During clinical trials for ovarian cancer, valrubicin is administered through the abdomen.

Precautions

There are other bladder problems that may affect the use of valrubicin. Patients with bladder irritation can have an increased risk of unwanted effects. Patients with perforated bladders should not take this medication. Patients with small bladders could have trouble holding all of the medication. Finally, if patients have urinary tract infections, they should use caution when taking this medication.

Valrubicin has not been studied in pregnant women, but it has been studied in pregnant animals. In animals it can cause birth defects. Therefore, women who are pregnant or breast-feeding should not take valrubicin. Additionally, women should not become pregnant while on this medication. Men taking this medication should not engage in procreative activities. Both men and women should use appropriate forms for contraception to avoid causing pregnancy.

There have not been appropriate studies done specifically on children or the elderly to determine the risk of using this medication in these populations. However, this drug is not expected to act differently in the elderly than it does in younger adults.

Side effects

During the six-week course of treatment patients could experience one or more side effects. The most common are loss of bladder control, increased frequency of urination, and blood in the urine. Other less common and rare side effects are bladder pain, pelvic pain, urethral pain, and loss of the sense of taste.

KEY TERMS

Carcinoma *in situ*—A malignant tumor in a preinvasive stage

Instillation—Dropping a liquid into a body part such as the bladder.

Intravesical—Within the bladder.

Urethral—Relating to the urethra, a passageway from the bladder to outside the body

Interactions

As of 2000 there were no known drug-drug interactions with valrubicin.

Sally C. McFarlane-Parrott

Vancomycin *see* **Antibiotics**

Vascular access

Definition

Vascular access is the use of flexible tubes (catheters) that remain inserted into blood vessels for weeks or months, and provide a means of infusing **antibiotics**, **chemotherapy**, pain medications, or **nutritional support** into patients, and enable blood samples to be taken from patients.

Purpose

Cancer patients may require a variety of treatments over extended periods of time. Many of these treatments are infused directly into the bloodstream (intravenous or IV therapy). For example, a cancer patient may need chemotherapy given through a vein, as well as blood tests requiring frequent samples to be taken from their veins. Indwelling catheters, which stay in place for weeks or months, save the patient the discomfort of undergoing frequent needle sticks (venipuncture), and prevent veins from the trauma of repeated punctures and accidental release of harsh chemical agents into skin and subcutaneous tissues. The catheters are used for continuous, as well as intermittent, treatments and procedures.

Description

The two types of indwelling catheters are external and internal. These devices have been in use since the 1970s.

When deciding which catheter to use, the physician looks at the:

- patient's age and size
- length of time the catheter will be in place
- purpose of the catheter
- patient's previous history with indwelling devices
- condition of the blood vessels

Physicians also consider their own preferences, as well as the treatment team suggestions and any special needs the patient may have.

External catheters are usually made of polyurethane for short–term use, and silicone for long–term use. Long–term devices have an internal cuff surrounding them to prevent catheter movement and infection. They have one to three openings, called lumens. One may be used for chemotherapy, a second for nutritional support, and the third for drawing blood samples. The catheters may be inserted into a central vein in the neck or chest, or an arm vein, called a peripheral vein.

External central catheters

External central catheters are divided into the types designed to stay in place for just a week or so, and the long–term devices commonly known as Broviac, Groshong, and Hickman, which can remain in place for months. The short–term devices are placed directly into a vein, while the long–term catheters are tunneled under the skin to the point where they enter a central blood vessel, such as the cephalic, jugular or subclavian vein. Central catheters are inserted using sterile, surgical technique.

External peripheral catheters

A peripherally inserted central catheter, or PICC, is inserted through the arm, and threaded into a central vein. With proper insertion and care, a PICC can remain in place for months. It may be inserted in the patient's room by a specially trained nurse. A PICC may limit arm movement, and is usually placed in the patient's least dominant arm. For example, the left arm would be the ideal PICC insertion site for a right–handed person. However, if a procedure such as breast surgery has been performed on one side, the PICC will most likely be inserted into the arm on the other side.

KEY TERMS

Broviac—Long–term external central venous catheter.

Groshong—Long–term external central venous catheter, similar to Broviac or Hickman types, but with a different tip.

Hickman—Long–term external central venous catheter.

Lumen—An external opening in the catheter used for putting fluids in or drawing blood out.

Mediport—A defunct brand of implantable port now used to refer to any implantable port.

Pasport—Long–term implantable port inserted in the arm.

PICC—Long–term silicone or polyurethane catheter inserted into the arm, and threaded into central circulation.

Portacath—Long–term implantable port.

Internal catheters

An internal catheter, such as a Portacath or Pasport, is commonly called an implantable mediport because the catheter connects to a pocket, or reservoir, located under the skin, either in the chest or arm. While the system is entirely internal, the pocket is located near the surface and can be felt through the skin. The range of catheter materials includes plastic and titanium. Over the years, these devices have gotten smaller in size, making them more comfortable for patients. An implantable port is inserted and removed in a surgical or radiology setting using sterile technique. Functionality can be determined by injecting contrast material into the port, a procedure referred to as a port-o-gram. Fluid flow is regulated by a pump located on the outside or implanted internally during a surgical procedure. External pumps are usually portable so patients can move around.

Preparation

External long–term indwelling catheters, such as Hickmans, and internal catheters, such as Portacaths, are inserted in a surgical setting. Patients are positioned with their legs elevated during the procedure and are usually given a local anesthetic to help them relax. Some pediatric patients are given additional anesthesia.

Aftercare

After a long–term external or internal catheter is in place, patients have a chest **x ray** to assure that it is in the

QUESTIONS TO ASK THE DOCTOR

- What type of catheter will I have?
- Why was this particular type chosen?
- Will insertion be an outpatient procedure or require a hospital stay?
- Who will insert the catheter?
- How should I prepare for insertion?
- What are the risks of a complication during insertion?
- Will any special care be needed immediately after it is put into place?
- What treatments will I receive through the catheter?
- What special care does the device require?
- What are the symptoms of a catheter problem?
- Will the catheter cause any physical limitations?
- How long will my catheter be in place?
- How will the catheter be removed?

proper position, and that the procedure has occurred without complications.

Special concerns

Catheter Care

Indwelling catheters require frequent care so that they work properly and stay clean. The devices must be cleaned daily and handled carefully. They are flushed with **heparin** or saline, usually every day or every other day, depending on the device. Care techniques vary with the different catheters.

Risks

There are certain complications that may occur during catheter placement. Pneumothorax (air in the pleural cavity) or hemothorax (blood in the pleural cavity) rarely occurs during insertion, and is uncommon after the catheter is in place.

The catheter may leak due to a defect or as a result of being pinched between the collarbone and rib. More commonly, a blockage in the tubing may occur. The first sign of this problem is usually difficulty withdrawing blood, and the blockage can be confirmed with a chest x ray. Flushing will sometimes clear the blockage.

Another problem is that a catheter can move over the course of time. To get a dislodged catheter back into place, patients are sometimes instructed to raise their arms or attempt other maneuvers. If catheter movement recurs, the device will repeatedly malfunction, and may need to be removed.

Another risk over time is that of a vein thrombosis, commonly called a blood clot. The treatment varies for each patient. It may be as simple as changing the arm position or, in more serious cases, may involve removing the catheter. This condition may or may not have symptoms, but is important to diagnose because blood clots that break loose (emboli) can travel around the bloodstream and become potentially fatal.

Infection presents another risk, and may occur on the surface or internally, along the tubing itself. An infection at the surface is usually red, tender to the touch, and may contain discharge. A gram–positive bacteria, such as staphylococcus, is the most common culprit, although other bacteria have been found in these infections. Treatment is determined by the seriousness of the infection, the site of the problem, and the type of catheter involved. A minor infection may clear up with a topical antibiotic applied to the skin. In more severe cases, such as infections along the tubing, in the bloodstream, or in an implantable port, a course of antibiotics will be prescribed.

Vinblastine

Definition

Vinblastine is a drug used to treat certain types of cancer. Vinblastine is available under the trade names Velban and Velsar, and may also be referred to as vinblastine sulfate. The drug was previously known as vincaleukoblastine or VLB.

Purpose

Vinblastine is an antineoplastic agent used to treat **Hodgkin's disease**, **non-Hodgkin's lymphomas**, **mycosis fungoides**, cancer of the testis, **Kaposi's sarcoma**, Letterer-Siwe disease, as well as other cancers.

Description

Vinblastine was approved by the Food and Drug Administration (FDA) in 1961.

Vinblastine is a naturally occurring compound that is extracted from periwinkle plants. It belongs to a group of chemicals called alkaloids. The chemical structure and biological action of vinblastine is similar to **vincristine** and **vinorelbine**.

Vinblastine prevents the formation of microtubules in cells. One of the roles of microtubules is to aid in the replication of cells. By disrupting this function, vinblastine inhibits cell replication, including the replication the cancer cells.

Vinblastine is one the most effective treatments for Hodgkin's disease, and is typically used in combination with **doxorubicin**, **bleomycin** and **dacarbazine**. It is also used to treat non-Hodgkin's lymphomas, mycosis fungoides, and Letterer-Siwe disease. Vinblastine is also used to treat cancer of the testis in combination with other cancer drugs, and Kaposi's sarcoma alone, or in combination with other drugs. Vinblastine is also used less frequently to treat other types of cancer.

Recommended dosage

Vinblastine is administered by intravenous injection at intervals of at least seven days. Blood tests may be necessary every seven days to ensure that enough white blood cells are present to continue treatment. The initial dose of vinblastine may be adjusted upward or downward depending on patient tolerance to the toxic side effects of treatment. The minimum recommended treatment duration is four to six weeks.

Precautions

Vinblastine must only be administered by individuals experienced in the use of this cancer chemotherapeutic agent. Vinblastine must only be administered intravenously, that is, directly into a vein. Accidental administration of vinblastine into the spinal cord fluid is a medical emergency that may result in death. Vinblastine has a low therapeutic index. It is unlikely there will be therapeutic benefit without toxic side effects. Certain complications can only be managed by a physician experienced in the use of cancer chemotherapeutic agents.

Because vinblastine is administered intravenously, the site of infusion and surrounding tissue should be monitored for signs of inflammation and irritation.

Adverse side effects are more likely in patients with malnutrition or skin ulceration.

Blood tests may be necessary to ensure that the number of white blood cells is adequate for treatment to continue. Vinblastine is not recommended for use in patients with low white blood cell levels. Infections should also be controlled before vinblastine treatment.

Patients should inform their physician if they experience sore throat, **fever**, chills, or sore mouth and any serious medical event.

Vinblastine may cause harm to a fetus when administered to pregnant women. Only in life-threatening situations, should this treatment be used during pregnancy. Women of childbearing age are advised not to become pregnant during treatment. Women should stop nursing before beginning treatment, due to the potential for serious adverse side effects in the nursing infants.

Side effects

The side effects of vinblastine treatment are usually related to the dose of drug and are generally reversible. Toxic side effects are more common in patients with poor liver function. Studies have also shown that patients with advanced prostate cancer experienced toxic side effects of estramustine phosphage (EMP) plus vinblastine (VBL) and from EMP alone.

A decrease in the number of white blood cells is the principal adverse side effect associated with vinblastine treatment. Blood tests will allow a doctor to determine if there are an adequate number of white blood cells to begin or continue treatment. **Nausea and vomiting** may occur, for which antiemetic agents are usually effective. Shortness of breath is a potentially severe side effect that patients should report to their doctor.

Additional side effects, including loss of appetite (anorexia), **diarrhea**, constipation, pain, rectal bleeding, dizziness, hearing impairment, and hair loss (alopecia) may occur.

KEY TERMS

Alkaloid—A nitrogen-containing compound occurring in plants.

Microtubles—A tubular structure located in cells that help them to replicate.

Therapeutic index—A ratio of the maximum tolerated dose of a drug divided by the dose used in treatment.

Interactions

Drugs that may alter the metabolism of vinblastine, particularly itraconazole, should be used with caution due to the potential for interactions. Hearing impairment may be enhanced when vinblastine is used with other drugs that affect the ear. These drugs include platinum-containing **antineoplastic agents**, such as **cisplatin**. Seizures have been reported in patients taking vinblastine and **phenytoin**. The doses of vinblastine and phenytoin may need to be adjusted to decrease the chance of this problem.

Marc Scanio

Vincristine

Definition

Vincristine is a drug used to treat certain types of cancer. Vincristine is available under the trade names Oncovin, Vincasar, and Vincrex, and may also be referred to as vincristine sulfate, or VCR. The drug was previously known as leurocristine, or LCR.

Purpose

Vincristine is an antineoplastic agent used to treat leukemia, **Hodgkin's disease**, malignant lymphomas, **neuroblastoma**, **rhabdomyosarcoma**, **Wilms' tumor**, as well as other cancers.

Description

Vincristine was approved by the Food and Drug Administration (FDA) in 1984.

Vincristine is a naturally occurring compound that is extracted from periwinkle plants. It belongs to a group of chemicals called alkaloids. The chemical structure and biological action of vincristine is similar to **vinblastine** and **vinorelbine**.

Vincristine prevents the formation of microtubules in cells. One of the roles of microtubules is to aid in the replication of cells. By disrupting this function, vincristine inhibits cell replication, including the replication of the cancer cells.

Vincristine is used in combination with other drugs to treat leukemia. It is also used in combination with other drugs, such as **mechlorethamine**, **procarbazine** and prednisone, to treat Hodgkin's disease. It is also used in combination to treat **non-Hodgkin's lymphomas**, neuroblastoma, rhabdomyosarcoma, and Wilms' tumor. Vincristine is also used less frequently to treat other types of cancer.

Recommended dosage

Vincristine is administered by intravenous injection once per week. The initial dose of vincristine may be adjusted upward or downward depending on patient tolerance to the toxic side effects of treatment.

Precautions

Vincristine must only be administered by individuals experienced in the use of this cancer chemotherapeutic agent. Vincristine must only be administered intravenously, that is, directly into a vein. Accidental administration of vincristine into the spinal cord fluid is a medical emergency that may result in death. Vincristine has a low therapeutic index. It is unlikely there will be therapeutic benefit without toxic side effects. Certain complications can only be managed by a physician experienced in the use of cancer chemotherapeutic agents.

Because vincristine is administered intravenously and is extremely irritating, the site of infusion and surrounding tissue should be monitored for signs of inflammation.

Some experts recommend blood tests to ensure that the number of white blood cells is adequate for treatment to continue. Infections should also be controlled before vincristine treatment starts.

Vincristine is not recommended for use in patients with the demyelinating form of Charcot-Marie-Tooth syndrome.

Vincristine is not recommended for patients receiving **radiation therapy** though a port in the liver.

Vincristine may cause harm to a fetus when administered to pregnant women. Only in life-threatening

KEY TERMS

Alkaloid—A nitrogen-containing compound occurring in plants.

Microtubles—A tubular structure located in cells that help them to replicate.

Therapeutic index—A ratio of the maximum tolerated dose of a drug divided by the dose used in treatment.

situations, should this treatment be used during pregnancy. Women of childbearing age are advised not to become pregnant during treatment. Women should stop nursing before beginning treatment, due to the potential for serious adverse side effects in the nursing infants.

Side effects

The side effects of vincristine treatment are usually related to the dose of drug and are generally reversible. Toxic side effects may be more common in patients with poor liver function.

Toxicity of the nervous system is the principal adverse side effect associated with vincristine treatment. This toxicity may cause numbness, pain, especially of the jaw, tingling, and headaches. Lengthy treatment at high doses may cause even more severe toxicity. Constipation is a common side effect. **Laxatives** and enemas are typically used to prevent severe constipation. Shortness of breath is a potentially severe side effect that patients should report to their doctor. Additional side effects, including rash, an increase or decrease in blood pressure, dizziness, nausea and vomiting, hearing impairment, and hair loss (alopecia) may occur.

Interactions

Drugs that may alter the metabolism of vincristine, particularly itraconazole, should be used with caution due to the potential for interactions. Hearing impairment may be enhanced when vincristine is used with other drugs that affect the ear. These drugs include platinum-containing **antineoplastic agents**, such as **cisplatin**. Seizures have been reported in patients taking vincristine and **phenytoin**. The doses of vincristine and phenytoin may need to be adjusted to decrease the chance of this problem.

Marc Scanio

Vindesine

Definition

Vindesine (desacetyl **vinblastine** amide sulfate) is a synthetic derivative of vinblastine. Vindesine is a **chemotherapy** drug that is given as a treatment for some types of cancer. This drug belongs to the group of anticancer drugs known as vinca alkaloids. Vindesine is also called vindesine sulfate, desacetylvinblastine amide, DAVA, DVA, or VDS, and its brand name, Eldisine.

Purpose

Vindesine is used primarily to treat **acute lymphocytic leukemia**. Less frequently, it is prescribed for use in **breast cancer**, blast crisis of chronic myelocytic leukemia, colorectal cancer, non-small cell lung cancer, and renal cell cancer (kidney cancer).

Description

Vindesine binds to particular proteins and causes cell arrest or cell death. Metabolized by the liver, vindesine is primarily excreted through the biliary system.

Vindesine is used in other countries around the world such as Britain, South Africa, and several European countries, but it is not approved by the Food and Drug Administration, and is thus not commercially available in the U.S. Eli Lilly discontinued Eldisine in Canada in 1998 to make way for newer, more effective vinca alkaloid drugs.

For acute lymphocytic leukemia (ALL), vindesine is effective in both adult and pediatric populations. As an agent used alone, vindesine has produced response rates ranging from 5% to 63% in several clinical studies. Vindesine has been used in combination therapy using the following drugs: **daunorubicin**, **asparaginase**, prednisone, **cytarabine**, and **etoposide**.

The clinical response rate in children (41%) is better than in adults (26%) for treatment of ALL. Vindesine with combination therapy has shown very high response rates in childhood ALL.

For treatment during the blast crisis of chronic myelocytic (or myelogenous) leukemia, overall response rates of 51% have been reported in adults when vindesine was used alone or in combination therapy with prednisone. Efficacy has not been demonstrated in pediatric groups.

Vindesine may be effective in treating breast cancer. When used alone, one clinical trial reported that vinde-

sine showed an overall response rate of approximately 19% in treating advanced breast cancer.

Vindesine in combination with **cisplatin** is one of the most active treatments for non-small lung cancer, but **vinorelbine** substituted for vindesine has shown higher response rates in treating non-small lung cancer.

Vindesine is not effective for treating acute nonlymphocytic leukemia.

Recommended dosage

There are many dosing schedules that depend on the type of cancer, response to treatment, and other drugs that may be co-prescribed. Dosing guidelines also consider the white blood cell count.

Method of administration: Vindesine is injected intravenously through a fine needle (cannula). Alternatively, it may be given through a central line that is inserted under the skin into a vein near the collarbone.

- Intravenous administration for adults: Each one to two weeks a dose of 2-4 mg/m^2 is given; or each three to four weeks 1.5 mg/m^2/day for five to seven days as a continuous infusion is administered.
- Intravenous administration for children: Once a week with 4 mg/m ^{2} or twice weekly with 2 mg/m^2.

Precautions

Vindesine may cause fertility problems in men and women. In addition, it may harm the fetus or may damage sperm; therefore, it is not recommended for women to use vindesine during pregnancy or for men to father a child while taking this drug. The physician should be alerted immediately if pregnancy occurs. Due to possible secretion into breast milk, breast-feeding is not recommended.

Other considerations:

- Vindesine is potentially mutagenic or carcinogenic (cancer-causing).
- Vindesine may cause death if injected intrathecally (into the spinal cord). It is for intravenous use only.
- Prior injection sites should be carefully inspected because tissue damage may occur days or weeks after administration.
- Hepatic dysfunction increases the neurotoxic potential of this drug.
- Alert doctors or dentists about vindesine therapy before receiving any treatment.

KEY TERMS

Acute lymphocytic leukemia—A rapidly progressing disease where too many immature infection-fighting white blood cells called lymphoblasts are found in the blood and bone marrow. It is also known as ALL or acute lymphoblastic leukemia.

Intravenous (or intravenously)—Into a vein.

Vinblastine—A vinca alkaloid. See definition for vinca alkaloid.

Vinca alkaloid—A group of cytotoxic alkaloids extracted from a flower called Madagascar periwinkle. Cytotoxic chemotherapy kills cells, especially cancer cells. Vinca alkaloids are cell cycle phase specific, and exert their effect during the M phase of cell mitosis and cause metaphase cell arrest and death. These drugs are for antineoplastic therapy (chemotherapy) for cancer treatment. Other vinca alkaloids are: vinblastine, vincristine, vindesine, and vinorelbine.

Side effects

Possible side effects of vindesine therapy:

- pain or tenderness at injection site
- Hair loss (alopecia) is common.
- Vindesine can damage the surrounding tissue if it leaks into the tissue around the vein. If vindesine leaks under the skin, a burning or stinging sensation may be felt. Alert the doctor immediately if burning or stinging occurs while the drug is administered or if fluid is leaking from the site where the needle was inserted. Also tell the doctor if the area around the injection site becomes red or swollen at any time.
- Constipation or abdominal cramps. These can be alleviated by drinking plenty of water, eating a high-fiber diet, and light exercise.
- temporary decrease in white blood cell count and platelets
- Numbing of the fingers or toes may occur over the course of treatment. It may take several months to return to normal.
- Diarrhea occurs infrequently.
- mouth sores and ulcers
- Nausea and vomiting rarely occurs.
- Anaphylaxis is rare.
- Jaw pain may be severe, but it is rare.

- Thrombocytopenia (a decrease in the number of platelets in the blood) or thrombocytosis. These conditions are also rare.

Interactions

Vindesine may interact with mitomycin-C (brand name Mutamycin), causing acute bronchospasm within minutes or hours following administration. **Phenytoin** (brand name Dilantin) may also interact with vindesine, leading to decreased serum levels of phenytoin.

Other drug interactions may occur with:

- Itraconazole
- Live virus and bacterial **vaccines**. When taking immune suppressing chemotherapy drugs, live vaccinations should not be given.
- Quinupristin/dalfopristin
- Rotavirus vaccine
- Warfarin

Crystal Heather Kaczkowski, MSc.

Vinorelbine

Definition

Vinorelbine is a drug used to treat certain types of lung cancer. Vinorelbine is available under the trade name Navelbine. The drug may also be referred to as vinorelbine tartrate, or didehydrodeoxynorvincaleukoblastine.

Purpose

Vinorelbine is an antineoplastic agent used to treat non-small cell lung **carcinoma**.

More recently, vinorelbine has been used in the palliative treatment of patients with advanced esophageal cancer and advanced breast cancer. Early reports of its effectiveness are encouraging.

Description

Vinorelbine was approved by the Food and Drug Administration (FDA) in 1994.

Vinorelbine is a semisynthetic derivative of **vinblastine**, a naturally occurring compound that is extracted from periwinkle plants. It belongs to a group of chemicals called vinca alkaloids. The chemical structure and biological action of vinorelbine is similar to vinblastine and **vincristine**.

Vinorelbine prevents the formation of microtubules in cells. One of the roles of microtubules is to aid in the replication of cells. By disrupting this function vinorelbine inhibits cell replication, including the replication the cancer cells.

Vinorelbine is used alone and in combination with **cisplatin** (another anticancer drug) to treat non-small cell lung carcinoma. It has been used in combination with other drugs to treat **breast cancer**. As of 2000 vinorelbine was under investigation for the treatment for **cervical cancer**.

Recommended dosage

Vinorelbine is administered by intravenous injection (directly into a vein) once per week. The initial dose may be adjusted downward depending on patient tolerance to the toxic side effects of treatment. If toxic effects are severe, vinorelbine treatment may be delayed or discontinued.

Precautions

Vinorelbine must be administered only by individuals experienced in the use of this cancer chemotherapeutic agent. Vinorelbine must only be administered intravenously. Accidental administration of vinorelbine into the spinal cord fluid is a medical emergency that may result in death. Vinorelbine has a low therapeutic index, which means it is unlikely there will be therapeutic benefit without toxic side effects. Certain complications can only be managed by a physician experienced in the use of cancer chemotherapeutic agents.

Because vinorelbine is administered intravenously and is extremely irritating, the site of infusion and surrounding tissue should be monitored for signs of inflammation.

Blood tests are recommended to ensure that bone marrow function and the number of white blood cells is adequate for treatment to continue. Infections should also be controlled before vinorelbine treatment starts. Special caution should be used with patients whose bone marrow reserves have been reduced by previous radiation or **chemotherapy** treatment.

Vinorelbine may cause harm to a fetus when administered to pregnant women. Only in life-threatening situations should this treatment be used during pregnancy. Women of childbearing age are advised not to become pregnant during treatment. Women should stop nursing before beginning treatment due to the potential for serious adverse side effects in the nursing infants.

KEY TERMS

Alkaloid—A nitrogen-containing compound occurring in plants.

Microtubles—A tubular structure located in cells that help them to replicate.

Palliative—Referring to a treatment intended to relieve symptoms rather than cure a disease.

Therapeutic index—A ratio of the maximum tolerated dose of a drug divided by the dose used in treatment.

The safety of vinorelbine in children under 18 years of age has not been established.

Side effects

The side effects of vinorelbine treatment are usually related to the dose of drug and are generally reversible. It is possible that toxic side effects may be more common in patients with poor liver function, and should be used with caution in those patients.

Decreased bone marrow function is the principal adverse side effect. This can reduce the number of white blood cells and increase the chance of infections. Patients should report **fever** or chills to their doctors immediately. Patients should also inform their doctor if they experience abdominal pain, constipation, or an increase in shortness of breath.

Toxicity of the nervous system is another side effect. Shortness of breath is a potentially severe side effect that patients should report to their doctor. Additional side effects, including fever, **anemia**, an increase or decrease in blood pressure, dizziness, nausea and vomiting, hearing impairment, and hair loss (alopecia) may occur.

Several cases of heart attacks related to vinorelbine have been reported. A group of French researchers estimates that about 1% of patients treated with vinorelbine will develop heart problems; however, vinorelbine does not appear to have a higher rate of these side effects than other drugs in its class.

Interactions

The use of vinorelbine in combination with another anticancer drug, mitomycin-C, has caused severe shortness of breath. Patients taking vinorelbine and cisplatin are more likely to experience a decrease in the number of white blood cells. This side effect should be carefully monitored to ensure that the number of white blood cells is adequate for treatment to continue. Patients taking vinorelbine and another anticancer drug, **paclitaxel**, may be more likely to experience toxicity of the nervous system, and should be carefully monitored for this. Drugs that may alter the metabolism of vinorelbine should be used with caution due to the potential for interactions.

Patients who are treated with vinorelbine during or following radiotherapy may become hypersensitive to radiation treatment.

Vitamins

Definition

Vitamins are compounds that are essential in small amounts for proper body function and growth. Vitamins are either fat soluble: A, D, E, and K; or water soluble: vitamin B and C. The B vitamins include vitamins B_1(thiamine), B_2 (riboflavin), and B_6 (pyridoxine), pantothenic acid, niacin, biotin, **folic acid** (folate), and vitamin B_{12} (cobalamin). Vitamins also may be referred to as micronutrients.

Description

A guide to the amount an average person needs each day to remain healthy has been determined for each vitamin. In the United States, this guide is called the recommended daily allowance (RDA). Consuming too little of certain vitamins may lead to a nutrient deficiency. Consuming too much of certain vitamins may lead to nutrient toxicity.

Consumption of a wide variety of foods that have adequate vitamins and minerals is the basis of a healthy diet. Good nutrition may assist in the prevention of cancer or may help cancer patients to feel better and fight infection during treatments. Obtaining nutrients through food remains the best method for obtaining vitamins, however, requirements may be higher because of the tumor or cancer therapy. Therefore, supplements may be necessary.

The following vitamins are important in a healthy diet and also may assist in **cancer prevention**. Their role in maintaining health and the best food sources are listed below.

Vitamin A (retinal, carotene)

- role in growth and repair of body tissues
- important in night vision
- immune function
- Best sources: eggs, dark green and yellow fruits and vegetables, low-fat dairy products, liver

Vitamin B6 (pyridoxine)

- role in formation of antibodies
- important in carbohydrate and protein metabolism
- red blood cells
- nerve function
- Best sources: lean meat, fish, poultry, whole grains, and potatoes

Folic acid (folate)

- assists in red blood cell formation
- important in protein metabolism
- growth and cell division
- Best sources: green leafy vegetables, poultry, dried beans, fortified cereals, nuts, and oranges

Vitamin C (ascorbic acid)

- resistance to infection
- important in collagen maintenance
- contributes to wound healing
- strengthens blood vessels
- assists in maintaining healthy gums
- Best sources: citrus fruits, tomatoes, melons, broccoli, green and red peppers, and berries

Vitamin E (tocopherol)

- may assist in immune function
- important in preventing oxidation of red blood cells and cell membranes
- Best sources: vegetable oils, wheat germ, nuts, dark green vegetables, beans, and whole grains

Purpose

Specific nutrients have been linked to prevention of several cancers of the colon, breast, prostate, stomach, and other types of tumors. A high intake of fruits and vegetables as well as fiber appears particularly protective, while a diet high in fat has been implicated as a cancer risk.

Vitamins important for cancer prevention

Antioxidant vitamins are believed to protect the body from harmful free radicals that can contribute to diseases such as cancer. Antioxidant vitamins include vitamin A, C, and E. However, doses too high may increase oxidative stress and therefore may increase cancer risk.

A diet rich in fruits and vegetables (containing B6, folate, and niacin) appears to protect against **stomach cancer** and in particular, intestinal cancer.

One study reported that cruciferous vegetables, especially broccoli, brussel sprouts, cauliflower, and cabbage were associated with a decreased risk of **prostate cancer**. Other foods, such as carrots, beans, and cooked tomatoes, also were associated with a lower risk.

A component of Vitamin E, tocotrienol, has been linked to a decreased risk of **breast cancer** in lab animals. Tocotrienol has been shown to readily kill tumor

cells grown in culture. Tocotrienol is not the same type of substance found in generic Vitamin E supplements, but is plentiful in palm oil. Palm oil is difficult to obtain in the Western world, but lower concentrations of tocotrienol are found in rice bran oil and wheat bran oil. In 2004, research showed that the nutrient calcium and vitamin D worked together, not separately, to lower risk of colorectal cancer.

Researchers state that no single nutrient is the answer, but that the effects are cumulative and depend on eating a variety of fruits and vegetables. Because there are many more nutrients available in foods such as fruits and vegetables than in vitamin supplements, food is the best source for acquiring needed vitamins and minerals.

Special concerns

For many years, debate has continued regarding taking vitamin supplements to prevent cancer. In 2004, the U.S. Preventive Services Task Force concluded that the evidence is inadequate to recommend supplementation of vitamins A, C, or E, multivitamins with folic acid, or antioxidant combinations to decrease the risk of cancer. Beta-carotene supplements should not be used in patients with no symptoms because there is no evidence of risk reduction and some evidence that these supplements may cause harm to some patients.

There are concerns regarding antioxidant levels during **chemotherapy** and **radiation therapy**. Researchers report large amounts of Vitamin C are consumed by cancerous tumors during chemotherapy in studies with mice. Vitamin C is an antioxidant that consumes free radicals and is thought to perhaps interfere with the process of killing cancer cells during chemotherapy or radiation therapy. Cancer patients undergoing chemotherapy are advised against taking large amounts of Vitamin C. Another research study also has warned cancer patients about vitamin A and vitamin E during chemotherapy because it has demonstrated a protective effect on cancer cells in mice. These **antioxidants** may protect not only the normal cells from being destroyed, but also may protect dangerous cancer cells from being destroyed during cancer treatment. The researchers suggest an antioxidant-depleted diet may be prudent during cancer therapy.

Smokers are advised not to consume a diet high in beta-carotene (Vitamin A) because research has shown a link to increased lung cancer incidence.

Alternative and complementary therapies

There are a great many claims about particular vitamin and or antioxidants having beneficial health effects. Proper nutrition with an adequate diet is the best way to obtain vitamins, but a supplement may be required when intake is inadequate. It is important to check with a dietitian or doctor before taking nutritional supplements or alternative therapies because they may interfere with cancer medications or treatments.

KEY TERMS

Antioxidant—A substance that prevents damage caused by free radicals.

Cancer—A term for diseases in which abnormal cells divide without control. Cancer cells can invade nearby tissues and can spread through the bloodstream and lymphatic system to other parts of the body.

Free radicals—Free radicals are highly reactive chemicals that often contain oxygen. They are produced when molecules are split to give products that have unpaired electrons. This process is referred to as oxidation.

Malignant (also malignancy)—Meaning cancerous; a tumor or growth that often destroys surrounding tissue and spreads to other parts of the body.

Oxidative stress—A condition in which antioxidant levels are lower than normal. Antioxidant levels usually are measured in blood plasma.

von Hippel–Lindau disease

Definition

Von Hippel–Lindau disease (VHL) is a rare familial cancer syndrome. A person with VHL can develop both benign and malignant tumors and cysts in many different organs in the body. Tumors and cysts most commonly develop in the brain and spine, eyes, kidneys, adrenal glands, pancreas, and inner ear.

Description

VHL does not have a predictable set of symptoms. VHL affects approximately 1 in 35,000 people, and affects men and women equally. Some families may have different symptoms than other families. Even within a family, there may be people with very mild signs of VHL, and others with more severe medical problems. In one study of a Chinese family with 47 members, four were diagnosed as carriers of the VHL gene while 18 others were diagnosed as having VHL itself. Of these 18 patients, 10 had renal cell carcinoma, 9 had central nervous system hemangioblastomas, and 7 had multiple pancreatic cysts. The age when symptoms develop can range from infancy to late adulthood, although most people with VHL will have some clinical symptoms by age 65. It is important for a person with VHL to have regular physical examinations to check for signs of VHL in all areas of the body that may be affected.

Tumors in the brain and spine, or central nervous system, are called hemangioblastomas. Hemangioblastomas are benign growths (not cancerous), but they may cause such symptoms as headaches and balance problems if they are growing in tight spaces and pressing on surrounding tissues or nerves. The eye tumors in VHL are called retinal angiomas or retinal hemangioblastomas, and may cause vision problems and blindness if they are not treated. Kidney cysts rarely cause problems, but the kidney tumors can be malignant, and are called renal cell **carcinoma**. Tumors in the adrenal glands are called pheochromocytomas. Pheochromocytomas are usually not malignant, but they can cause serious medical problems if untreated. This is because pheochromocytomas secrete hormones that can raise blood pressure to dangerous levels, causing heart attacks or strokes. Benign cysts can be found in the pancreas, and pancreatic islet cell tumors can also occur. These tumors grow very slowly and are rarely malignant. Tumors that grow in the ear are called endolymphatic sac tumors, which can result in hearing loss if untreated. Occasionally men and women with VHL will have infertility problems if cysts are present in certain places in the reproductive organs, such as the epididymis (a duct in the testes)in men or the fallopian tubes in women. A few male patients with VHL develop large testicular masses that can be treated successfully with steroid therapy.

Diagnosis

A clinical diagnosis of VHL can be made in a person with a family history of VHL if he or she has a single retinal angioma, central nervous system hemangioblastoma, or **pheochromocytoma**, or if he or she has renal cell carcinoma. If there is no known family history of VHL, two or more retinal or central nervous system hemangioblastomas must be present, or one retinal or central nervous system hemangioblastoma and one other feature of VHL. Melmon and Rosen published these criteria in 1964, when they first described VHL as a disease with a specific set of features. Because not all people with VHL will meet these diagnostic criteria, VHL may be an under–diagnosed disease. **Genetic testing** can confirm a diagnosis of VHL in a person with clinical symptoms, who may or may not meet the above diagnostic criteria.

Causes

VHL is a genetic disease caused by a mutation of the VHL tumor suppressor gene on chromosome three. It is inherited as an autosomal dominant condition, which means that a person with VHL has a 50% chance of passing it on to each of his or her children. Usually a person with VHL will have a family history of VHL (a parent or sibling who also has VHL), but occasionally he or she is the first person in the family to have VHL. Screening and/or genetic testing of family members can help establish who is at risk for developing VHL. Identification of a person with VHL in a family may result in other family members with more mild symptoms being diagnosed, and subsequently receiving appropriate screening and medical care.

Risks

The United States National Institutes of Health (NIH) has determined risk ranges for a person with VHL to develop certain tumors. Persons with VHL have a 21–72% chance of developing hemangioblastomas of the

brain or spinal cord, a 43–60% chance of developing retinal angiomas, a 24–45% chance of developing cysts and tumors of the kidney, an 8–37% chance of developing pancreatic cysts, and an 8–17% chance of developing pancreatic islet cell tumors. It has been proposed that VHL be divided into subtypes depending on the types of tumors present in a family. It is likely that in the future, specific risk figures will be available for the different types of tumors depending on the specific genetic mutation in a family.

Genetic testing

Almost 100% of people with VHL will have an identifiable mutation in the VHL gene. There have been many different mutations found in the VHL gene, but all persons with VHL in the same family will have the same mutation. If a mutation is known in a family, genetic testing can be done on family members who have not had any symptoms of VHL. A person who tests positive for the family mutation is at risk for developing symptoms of VHL and can pass the mutation on to his or her children. A person who tests negative for the family mutation is not at risk for developing symptoms of VHL, and his or her children are not at risk for developing VHL. Screening is needed for people who test positive for a VHL mutation, and people who are found not to have the family mutation can be spared from lifelong screening procedures. Genetic testing can also be used to determine if a pregnant woman is carrying a fetus affected with VHL. Other techniques may become available which allow selection of an unaffected fetus prior to conception. Families work with a physician, geneticist, or genetic counselor familiar with the most up–to–date information on VHL when having genetic testing, in order to understand the risks, benefits, and current technological limitations prior to testing.

Screening and Treatment

Regular screening and monitoring of tumors in people with VHL allows early detection and treatment, before serious complications can occur. A physician familiar with all aspects of VHL can coordinate screening with a variety of specialists, such as an ophthalmologist for eye examinations. Ultrasounds, **computed tomography** scans (CT), and **magnetic resonance imaging** (MRI) may be used to screen and detect tumors and cysts. Whether or not treatment is necessary depends on the size of the tumor, where it is growing, what the symptoms are, and if the tumor is benign or malignant. Treatment for benign tumors may include surgery or laser treatments. Cancer in people with VHL is treated just as it would be in someone in the general population with that type of cancer. People with VHL who develop cancer have a better prognosis if the cancer is detected at an earlier stage before it has spread. Urine tests, ultrasound, CT and/or MRI screen for pheochromocytomas. It is especially important to screen for pheochromocytomas prior to surgery, because an undiagnosed pheochromocytoma can cause complications during surgery. Prior to becoming pregnant, a woman should have a full physical examination looking for all signs of VHL, but most importantly pheochromocytomas. It is best for a woman to avoid VHL-related surgery while she is pregnant unless medically necessary. Pregnancy itself does not seem to make VHL worse or make the tumors grow faster, but any tumors that are present should be evaluated, and a plan for surgical removal or monitoring should be in place.

KEY TERMS

Benign—Not cancerous, not able to spread to new places in the body.

Cyst—A fluid filled sac that can be normal or abnormal.

Hemangioblastoma—A benign tumor caused by the abnormal growth of blood vessels.

Malignant—Cancerous, able to spread to new places in the body.

Mutation—A change in the DNA code.

Tumor—An abnormal growth caused by the uncontrolled growth of cells.

von Recklinghausen's neurofibromatosis

Definition

Von Recklinghausen's neurofibromatosis is also called von Recklinghausen disease, or simply neurofibromatosis (NF)1. It is an automsomal dominant hereditary disorder. NF is the most common neurological disorder caused by a single gene. Patients develop multiple soft tumors (neurofibromas) and very often skin spots (freckling AND café au lait spots). The tumors occur under the skin and throughout the nervous system. The disease is named for Friedrich Daniel von Recklinghausen (1833–1910), a German pathologist, although cases of it have been described in European medical publications since the sixteenth century.

Description

There are three types of neurofibromatosis, although some researchers have proposed as many as eight categories. The two main types of neurofibromatosis are neurofibromatosis 1 (NF1), which affects about 85% of patients diagnosed with neurofibromatosis, and neurofibromatosis 2 (NF2), which accounts for another 10% of patients. NF1 affects approximately 1 in 2,000 to 1 in 5,000 births worldwide. NF2 affects 1 in 35,000 to 1 in 40,000 births worldwide. Recently, schwannomatosis has been recognized as a rare form of NF. Since NF is the most common neurological disorder, NF is more prevalent than the number of people affected by cystic fibrosis, hereditary muscular dystrophy, Huntington's disease, and Tay-Sachs disease combined. In addition to skin and nervous system tumors and skin freckling, NF can lead to disfigurement, blindness, deafness, skeletal abnormalities, loss of limbs, malignancies, and learning disabilities. The degree a person is affected with a form of neurofibromatosis may vary greatly between patients.

Causes and symptoms

A defective gene causes NF1 and NF2. NF1 is due to a defect on chromosome 17q. NF2 results from a defect on chromosome 22. Both neurofibromatosis disorders are inherited in an autosomal dominant fashion. In an autosomal dominant disease, one copy of a defective gene will cause the disease. However, family pattern of NF is only evident for about 50% to 70% of all NF cases. The remaining cases of NF are due to a spontaneous mutation (a change in a person's gene rather than a mutation inherited from a parent). As with an inherited mutated gene, a person with a spontaneously mutated gene has a 50% chance of passing the spontaneously mutated gene to any offspring.

NF1 has a number of possible symptoms:

- Five or more light brown skin spots (café au lait spots, a French term meaning "coffee with milk"). The skin spots measure more than 0.2 inches (5 millimeters) in diameter in patients under the age of puberty or more than 0.6 inches (15 millimeters) in diameter across in adults and children over the age of puberty. Nearly all NF1 patients display café au lait spots.
- Multiple freckles in the armpit or groin area.
- Ninety percent of patients with NF1 have tiny tumors in the iris (colored area of the eye) called Lisch nodules (iris nevi).
- Two or more neurofibromas distributed over the body. Neurofibromas are soft tumors and are the hallmark of NF1. Neurofibromas occur under the skin, often located along nerves or within the gastrointestinal tract. Neurofibromas are small and rubbery, and the skin overlying them may be somewhat purple in color.
- Skeletal deformities, such as a twisted spine (scoliosis), curved spine (humpback), or bowed legs.

- Tumors along the optic nerve, which cause visual disturbances in about 20% of patients.
- The presence of NF1 in a patient's parent, child, or sibling.

There are very high rates of speech impairment, learning disabilities, and attention deficit disorder in children with NF1. Other complications include the development of a seizure disorder, or the abnormal accumulation of fluid within the brain (hydrocephalus). A number of cancers are more common in patients with NF1. These include a variety of types of malignant brain tumors, as well as leukemia, and cancerous tumors of certain muscles (**rhabdomyosarcoma**), the adrenal glands (**pheochromocytoma**), or the kidneys (**Wilms' tumor**). Symptoms are often visible at birth or during infancy, and almost always by the time a child is about 10 years old.

In contrast to patients with NF1, patients with NF2 have few, if any, café au lait spots or tumors under the skin. Patients with NF2 most commonly have tumors (schwannomas) on the eighth cranial nerve (one of 12 pairs of nerves that enter or emerge from the brain), and occasionally on other nerves. The location of the schwann cell derived tumors determines the effect on the body. The characteristic symptoms of NF2 include dysfunction in hearing, ringing in the ears (tinnitus), and body balance. The common characteristic symptoms of NF2 are due to tumors along the acoustic and vestibular branches of the eighth cranial nerve. Tumors that occur on neighboring nervous system structures may cause weakness of the muscles of the face, headache, dizziness, numbness, and weakness in an arm or leg. Cloudy areas on the lens of the eye (called cataracts) frequently develop at an early age. As in NF1, the chance of brain tumors developing is unusually high. Symptoms of NF2 may not begin until after puberty.

Multiple schwannomas on cranial, spinal, and peripheral nerves characterize schwannomatosis. People with schwannomatosis usually have greater problems with pain than with neurological disability. The first symptom of schwannomatosis is usually pain in any part of the body without any source. It can be several years before a tumor is found. About 1/3 of patients with schwannomatosis have tumors in a single part of the body, such as an arm, leg or segment of spine. People with schwannomatosis do not develop vestibular tumors, any other kinds of tumors (such as meningiomas, ependymomas, or astrocytomas), do not go deaf, and do not have learning disabilities.

Diagnosis

Diagnosis of a form of neurofibromatosis is based on the symptoms outlined above. Although a visual inspection may be sufficient for inspection of tumors for a clinical diagnosis of neurofibromatosis, **magnetic resonance imaging** (MRI) is the most useful type of imaging study for early diagnosis of tumors while CT scans are better for detecting skeletal abnormalities. Diagnosis of NF1 requires that at least two of the above listed symptoms are present. A slit lamp is used to visualize the presence of any Lisch nodules in a person's eye. A person with a parent, sibling, or child with NF1 is another tool used to diagnose a person with NF1.

NF2 can be diagnosed three different ways and with symptoms different from NF1 symptoms:

- The presence of bilateral cranial eighth nerve tumors.
- A person who has a parent, sibling, or child with NF2 and a unilateral eighth nerve tumor (vestibular schwannoma or acoustic neuroma).
- A person who has a parent, sibling, or child with NF2 and any two of the following: glioma, **meningioma**, neurofibroma, schwannoma, or an early age cataract.

The presence of multiple schwannomas may be a symptom of NF2 or schwannomatosis. An older person with multiple schwannomas and no hearing loss probably does not have NF2. A high-quality MRI scan should be used to detect any possible vestibular tumors to differentiate between NF2 and schwannomatosis in a younger person with multiple schwannomas or any person with hearing loss and multiple schwannomas.

In prepubertal children a yearly assessment including blood pressure measurement, eye examination, development screening, and neurologic examination is recommended.

Monitoring the progression of neurofibromatosis involves careful testing of vision and hearing (audiometry). X-ray studies of the bones are frequently done to watch for the development of deformities. CT scans and MRI scans are performed to track the development/progression of tumors in the brain and along the nerves. Auditory evoked potentials (the electric response evoked in the cerebral cortex by stimulation of the acoustic nerve) may be helpful to determine involvement of the acoustic nerve, and EEG (electroencephalogram, a record of electrical currents in the brain) may be needed for patients with suspected seizures.

Treatment

There are no cures for any form of neurofibromatosis. To some extent, the symptoms of NF1 and NF2 can be treated individually. Skin tumors can be surgically removed. Some brain tumors, and tumors along the nerves, can be surgically removed, or treated with drugs

KEY TERMS

Audiometry—Testing a person's hearing by exposing ear to sounds in a soundproof room.

Autosomal dominant—Genetic information on a single non-sex chromosome that is expressed with only one copy of a gene. Child of an affected parent has a 50% chance of inheriting an autosomal dominant gene.

Cancer—Abnormal and uncontrolled growth of cells that can invade surrounding tissues and other parts of the body. Although some cancers are treatable, recurrence and death from cancer can occur.

Cataract—Lens of eye loses transparency and becomes cloudy. Cloudiness blocks light rays entering the eye that may lead to blindness.

Chromosome—A structure within the nucleus of every cell, that contains genetic information governing the organism's development. There are 22 non-sex chromosomes and one sex chromosome.

Ependymoma—Tumor that grows from cells that line the cavities of brain ventricles and spinal cord.

Gamma knife—A type of highly focused radiation therapy.

Gene—Piece of information contained on a chromosome. A chromosome is made of many genes.

Magnetic resonance imaging—Magnetic resonance imaging (MRI) measures the response of tissues to magnetic fields to produce detailed pictures of the body, including the brain.

Meningioma—Tumor that grows from the protective brain and spinal cord membrane cells (meninges).

Mutation—A permanent change to the genetic code of an organism. Once established, a mutation can be passed on to offspring.

Neurofibroma—A soft tumor usually located on a nerve.

Radiation therapy—Exposing tumor cells to controlled doses of x-ray irradiation for treatment. Although tumor cells are susceptible to irradiation, surrounding tissues will also be damaged. Radiation therapy alone rarely cures a tumor, but can be useful when used in conjunction with other forms of therapy or when a patient cannot tolerate other forms of therapy.

Schwannoma—Tumor that grows from the cells that line the nerves of the body (Schwann cells).

Tinnitus—Noises in the ear that can include ringing, whistling or booming.

Tumor—An abnormally multiplying mass of cells. Tumors that invade surrounding tissues and other parts of the body are malignant and considered a cancer. Non-malignant tumors do not invade surrounding tissues and other parts of the body. Malignant and non-malignant tumors can cause severe symptoms and death.

(**chemotherapy**) or x-ray treatments (**radiation therapy**, including gamma knife therapy). Twisting or curving of the spine and bowed legs may require surgical treatment or the wearing of a special brace.

Prognosis

Prognosis varies depending on the types of tumors which an individual develops. In general, however, patients with neurofibromatosis have a shortened life expectancy; the average age at death is 55–59 years, compared with 70–74 years for the general United States population. As tumors grow, they begin to destroy surrounding nerves and structures. Ultimately, this destruction can result in blindness, deafness, increasingly poor balance, and increasing difficulty with the coordination necessary for walking. Deformities of the bones and spine can also interfere with walking and movement. When cancers develop, prognosis worsens according to the specific type of cancer.

Clinical Trials

As of 2004 the National Cancer Institute (NCI) is sponsoring one clinical trial for children with neurofibromatosis type 1. The trial is an evaluation of tipifarnib (Zarnestra), a drug that inactivates certain proteins that encourage tumor growth. It is hoped that tipifarnib may prove to be an effective drug treatment for the disorder, as surgery is presently considered the only standard treatment.

The use of an auditory brainstem implant (ABI) as part of hearing rehabilitation in patients with NF2 has been tested in Europe and the United States.

Prevention

There is no known way to prevent the cases of NF that are due to a spontaneous change in the genes (mutation). Since genetic tests for NF1 and NF2 are available,

QUESTIONS TO ASK THE DOCTOR

- How can I tell if I have neurofibromatosis?
- Which type of neurofibromatosis do I have?
- Will I develop tumors? Will they be cancerous?
- Is my neurofibromatosis genetic?
- What medical tests are important?
- What treatments are available for neurofibromatosis?
- Will I die from neurofibromatosis?

new cases of inherited NF can be prevented with careful genetic counseling. A person with NF can be made to understand that each of his or her offspring has a 50% chance of also having NF. When a parent has NF, and the specific genetic defect causing the parent's disease has been identified, prenatal tests can be performed on the fetus during pregnancy. Amniocentesis and chorionic villus sampling are two techniques that allow small amounts of the baby's cells to be removed for examination. The tissue can then be examined for the presence of the parent's genetic defect. Some families choose to use this information in order to prepare for the arrival of a child with a serious medical problem. Other families may choose not to continue the pregnancy. **Genetic testing** may also be useful for evaluating individuals with a family history of neurofibromatosis, who do not yet show symptoms.

Vulvar cancer

Definition

Vulvar cancer refers to an abnormal, cancerous growth in the external female genitalia.

Description

Vulvar cancer is a rare disease that occurs mainly in elderly women. The vulva refers to the external female genitalia, which includes the labia, the opening of the vagina, the clitoris, and the space between the vagina and anus (perineum). There are two pairs of labia (a Latin term meaning lips). The labia meet to protect the openings of the vagina and the tube that connects to the bladder (urethra). The outer, most prominent folds of skin are called labia majora, and the smaller, inner skin folds are called labia minora. Vulvar cancer can affect any part of the female genitalia, but usually affects the labia.

Approximately 70% of vulvar cancers involve the labia (usually the labia majora), 15% to 20% involve the clitoris, and 15% to 20% involve the perineum. For approximately 5% of the cases, the cancer is present at more than one location. For approximately 10% of the cases, so much of the vulva is affected by cancer that the original location cannot be determined. Vulvar cancer can spread to nearby structures including the anus, vagina, and urethra.

Most vulvar cancers are squamous cell carcinomas. Squamous cells are the main cell type of the skin. Squamous cell **carcinoma** often begins at the edges of the labia majora or labia minora or the area around the vagina. This type of cancer is usually slow-growing and may begin with a precancerous condition referred to as vulvar intraepithelial neoplasia (VIN), or dysplasia. This means that precancerous cells are present in the surface layer of skin.

Other, less common types of vulvar cancer are **melanoma**, **basal cell carcinoma**, **adenocarcinomas**, Paget's disease of the vulva, and tumors of the connective tissue under the skin. Melanoma, a cancer that develops from the cells that produce the pigment that determines the skin's color, can occur anywhere on the skin, including the vulva. Melanoma is the second most common type of vulvar cancer, and accounts for 5% to 10% of the cases. Half of all vulvar melanomas involve the labia majora. Basal cell carcinoma, which is the most common type of cancer that occurs on parts of the skin exposed to the sun, very rarely occurs on the vulva. Adenocarcinomas develop from glands, including the glands at the opening of the vagina (Bartholin's glands) that produce a mucus-like lubricating fluid.

Vulvar cancer is most common in women over 50 years of age. The median age at diagnosis is 65 to 70 years old. Additional risk factors for vulvar cancer include having multiple sexual partners, **cervical cancer**, and the presence of chronic vaginal and vulvar inflammations. This type of cancer is often associated with sexually transmitted diseases.

Demographics

Vulvar cancer is most common in women who are between the ages of 65 and 75 years. In the United States there are approximately 3,000 new cases of vulvar cancer diagnosed each year. Vulvar cancer accounts for only 1% of all cancers in women. Approximately 5% of all **gynecologic cancers** occur on the vulva. For unknown reasons, the incidence of vulvar cancer seems to be rising.

Causes and symptoms

Cancer is caused when the normal mechanisms that control cell growth become disturbed, causing the cells to grow continually without stopping. This is usually the result of damage to the DNA in the cell. Although the cause of vulvar cancer is unknown, studies have identified several risk factors for vulvar cancer. These include:

- Vulvar intraepithelial neoplasia (VIN). This abnormal growth of the surface cells of the vulva can sometimes progress to cancer.
- Infection with human papillomavirus (HPV). This virus is sexually transmitted and can cause genital warts. Although HPV DNA can be detected in most cases of vulvar intraepithelial neoplasia, it is detected in fewer than half of all cases of vulvar cancer. Therefore, the link between HPV infection and vulvar cancer is unclear. As of 2001, it is theorized that two classes of vulvar cancer exist: one that is associated with HPV infection and one that is not.
- Herpes simplex virus 2 (HSV2). This sexually transmitted virus is also associated with increased risk for vulvar cancer.
- Cigarette smoking. Smoking in combination with infection by HPV or HSV2 was found to be a particularly strong risk factor for vulvar cancer.
- Infection with human immunodeficiency virus (HIV). This virus, which causes AIDS, decreases the body's immune ability, leaving it vulnerable to a variety of diseases, including vulvar cancer.
- Chronic vulvar inflammation. Long-term irritation and inflammation of the vulva and vagina, which may be caused by poor hygiene, can increase the risk of vulvar cancer.

- Abnormal Pap smears. Women who have had abnormal Pap smears are at an increased risk of developing vulvar cancer.
- Chronic immunosuppression. Women who have had long-term suppression of their immune system caused by disease (such as certain cancers) or medication (such as those taken after organ transplantation) have an increased risk of developing vulvar cancer.

The hallmark symptom of vulvar cancer is **itching** (pruritus), which is experienced by 90% of the women afflicted by this cancer. The cancerous lesion is readily visible. Unfortunately, because of embarrassment or denial, it is not uncommon for women to delay medical assessment of vulvar abnormalities. Any abnormalities should be reported to a gynecologist.

If squamous cell vulvar cancer is present, it may appear as a raised red, pink, or white bump (nodule). It is often accompanied by pain, bleeding, vaginal discharge, and painful urination. Malignant melanoma of the vulva usually appears as a pigmented, ulcerated growth. Other types of vulvar cancer may appear as a distinct mass of tissue, sore and scaly areas, or cauliflower-like growths that look like warts.

Diagnosis

A gynecological examination will be used to observe the suspected area. During this examination, the physician may use a special magnifying instrument called a colposcope to view the area better. Additionally, the area may be treated with a dilute solution of acetic acid, which causes some abnormal areas to turn white, making them easier to see. During this examination, if any area is suspected of being abnormal, a tissue sample (**biopsy**) will be taken. The biopsy can be performed in the doctor's office with the use of local anesthetic. A wedge-shaped piece of tissue, which contains the suspect lesion with some surrounding normal skin and the underlying skin layers and connective tissue, will be removed. Small lesions will be removed in their entirety (excisional biopsy). The diagnosis of cancer depends on a microscopic analysis of this tissue by a pathologist.

The diagnosis for vulvar cancer will determine how advanced the cancer is and how much it has spread. This is determined by the size of the tumor and how deep it has invaded the surrounding tissue and organs, such as the lymph nodes. It will also be determined if the cancer has metastasized, or spread to other organs. Tests used to determine the extent of the cancer include **x ray** and **computed tomography** scan (CT scan). Endoscopic examination of the bladder (**cystoscopy**) and/or rectum (proctoscopy) may be performed if it is suspected that the cancer has spread to these organs.

Treatment team

The treatment team for vulvar cancer may include a gynecologist, gynecologic oncologist, radiation oncologist, gynecologic nurse oncologist, sexual therapist, psychiatrist, psychological counselor, and social worker.

Clinical staging, treatments, and prognosis

Clinical staging

The International Federation of Gynecology and Obstetrics (FIGO) has adopted a surgical staging system for vulvar cancer. The stage of cancer is determined after surgery. The previous clinical staging system for vulvar cancer is no longer used. Vulvar cancer is categorized into five stages (0, I, II, III, and IV) which may be further subdivided (A and B) based on the depth or spread of cancerous tissue. The FIGO stages for vulvar cancer are:

- Stage 0. Vulvar intraepithelial neoplasia (precancerous cells).
- Stage I. Cancer is confined to the vulva and perineum. The lesion is less than 2 cm (about 0.8 in) in size.
- Stage II. Cancer is confined to the vulva and perineum. The lesion is larger than 2 cm (larger than 0.8 in) in size.
- Stage III. Cancer has spread to the vagina, urethra, anus, and/or the lymph nodes in the groin (inguinofemoral).
- Stage IV. Cancer has spread to the bladder, bowel, pelvic bone, pelvic lymph nodes, and/or other parts of the body.

Treatments

Treatment for vulvar cancer will depend on its stage and the patient's general state of health. Surgery is the mainstay of treatment for most cases of vulvar cancer.

SURGERY The primary treatment for stage I and stage II vulvar cancer is surgery to remove the cancerous lesion and possibly the inguinofemoral lymph nodes. Removal of the lesion may be done by laser, to burn off a minimal amount of tissue, or by scalpel (local excision), to remove more of the tissue. The choice will depend on the severity of the cancer. If a large area of the vulva is removed, it is called a vulvectomy. Radical vulvectomy removes the entire vulva. A vulvectomy may require skin grafts from other areas of the body to cover the wound and make an artificial vulva. Because of the significant morbidity and the psychosexual consequences of radical vulvectomy, there is a trend toward minimizing the extent of cancer excision. The specific inguinofemoral lymph node that would receive lymph fluid from the cancerous lesion, known as the sentinel node, may be

exposed for examination (**lymph node dissection**) or removed (lymphadenectomy), especially in cases in which the cancerous lesion has invaded to a depth of more than 1 mm. Surgery may also be followed by **chemotherapy** and/or **radiation therapy** to kill additional cancer cells.

Surgical treatment of stage III and stage IV vulvar cancer is much more complex. Extensive surgery would be necessary to completely remove the cancerous tissue. Surgery would involve excision of pelvic organs (pelvic **exenteration**), radical vulvectomy, and lymphadenectomy. Because this extensive surgery comes with a substantial risk of complications, it may be possible to treat advanced vulvar cancer with minimal surgery by using radiation therapy and/or chemotherapy as additional treatment (adjuvant therapy).

An intraoperative technique that is used to identify the sentinel node in **breast cancer** and melanoma is being applied to vulvar cancer. This technique, called lymphoscintigraphy, is performed during surgical treatment of vulvar cancer and allows the surgeon to immediately identify the sentinel node. A radioactive compound (technetium 99m sulfur colloid) is injected into the cancerous lesion approximately two hours prior to surgery. This injection causes little discomfort, so local anesthesia is not required. During surgery, a radioactivity detector is used to locate the sentinel node and any other nodes to which cancer has spread. Though still in the experimental stage, vulvar lymphoscintigraphy shows promise in reducing morbidity and hospital length of stay.

The most common complication of vulvectomy is the development of a tumor-like collection of clear liquid (wound seroma). Other surgical complications include urinary tract infection, wound infection, temporary nerve injury, fluid accumulation (edema) in the legs, urinary **incontinence**, falling or sinking of the genitals (genital prolapse), and blood clots (thrombus).

RADIATION THERAPY Radiation therapy uses high-energy radiation from x rays and gamma rays to kill the cancer cells. The skin in the treated area may become red and dry and may take as long as a year to return to normal. **Fatigue**, upset stomach, **diarrhea**, and nausea are also common complaints of women having radiation therapy. Radiation therapy in the pelvic area may cause the vagina to become narrow as scar tissue forms. This phenomenon, known as vaginal stenosis, makes intercourse painful.

CHEMOTHERAPY Chemotherapy uses anticancer drugs to kill the cancer cells. The drugs are given by mouth (orally) or intravenously. They enter the bloodstream and can travel to all parts of the body to kill cancer cells. Generally, a combination of drugs is given because it is more effective than a single drug in treating cancer. The side effects of chemotherapy are significant and include stomach upset, vomiting, appetite loss (anorexia), hair loss (alopecia), mouth or vaginal sores, fatigue, menstrual cycle changes, and premature menopause. There is also an increased chance of infections.

Prognosis

Factors that are correlated with disease outcome include the diameter and depth of the cancerous lesion, involvement of local lymph nodes, cell type, HPV status, and age of the patient. Vulvar cancers that are HPV positive have a better prognosis than those that are HPV negative. The 5-year survival rate is 98% for stage I vulvar cancer and 87% for stage II vulvar cancer. The survival rate drops steadily as the number of affected lymph nodes increases. The survival rate is 75% for patients with one or two, 36% for those with three or four, and 24% for those with five or six involved lymph nodes. The previous statistics were obtained from studies of patients who received surgical treatment only and cannot be used to determine survival rates when adjuvant therapy is employed.

Vulvar cancer can spread locally to encompass the anus, vagina, and urethra. Because of the anatomy of the vulva, it is not uncommon for the cancer to spread to the local lymph nodes. Advanced stages of vulvar cancer can affect the pelvic bone. The lungs are the most common site for vulvar cancer **metastasis**. Metastasis through the blood (hematogenous spread) is uncommon.

Alternative and complementary therapies

Although alternative and complementary therapies are used by many cancer patients, very few controlled studies on the effectiveness of such therapies exist. Mind-body techniques such as prayer, biofeedback, visualization, meditation, and yoga have not shown any effect in reducing cancer but can reduce stress and lessen some of the side effects of cancer treatments. Clinical studies of hydrazine sulfate found that it had no effect on cancer and even worsened the health and well- being of the study subjects. One clinical study of the drug amygdalin (Laetrile) found that it had no effect on cancer. Laetrile can be toxic and has caused death. Shark cartilage, although highly touted as an effective cancer treatment, is an improbable therapy that has not been the subject of clinical study.

The American Cancer Society has found that the ''metabolic diets'' pose serious risk to the patient. The effectiveness of the macrobiotic, Gerson, and Kelley diets and the Manner metabolic therapy has not been

scientifically proven. The FDA was unable to substantiate the anticancer claims made about the popular Cancell treatment.

There is no evidence for the effectiveness of most over-the-counter herbal cancer remedies. However, some herbals have shown an anticancer effect. As shown in clinical studies, Polysaccharide krestin, from the mushroom *Coriolus versicolor*, has significant effectiveness against cancer. In a small study, the green alga *Chlorella pyrenoidosa* has been shown to have anticancer activity. In a few small studies, evening primrose oil has shown some benefit in the treatment of cancer. Patients should discuss the use of any alternative or complementary therapies with their doctor.

For more comprehensive information, the patient should consult the book on complementary and alternative medicine published by the American Cancer Society listed in the Resources section.

Coping with cancer treatment

The patient should consult her treatment team regarding any side effects or complications of treatment. Vaginal stenosis can be prevented and treated by vaginal dilators, gentle douching, and sexual intercourse. A water-soluble lubricant may be used to make sexual intercourse more comfortable. Many of the side effects of chemotherapy can be relieved by medications. Women should consult a psychotherapist and/or join a support group to deal with the emotional consequences of cancer and vulvectomy.

Clinical trials

There are some active, long-term **clinical trials** for the diagnosis and treatment of vulvar cancer. Two of these trials are sponsored by the National Cancer Institute. One trial (protocol ID# GOG-173) is testing the effectiveness of a **sentinel lymph node mapping** technique which uses a visible dye. The sentinel node is identified and removed. This diagnostic and treatment study is open to patients with invasive squamous cell carcinoma of the vulva. The other trial (protocol ID# GOG-0185) is testing the effectiveness of the chemotherapeutic agent **cisplatin** in combination with radiation therapy. This treatment study is open to patients with stage I, II, or III squamous cell carcinoma of the vulva. Women should consult with their treatment team to determine if they are candidates for these or any other clinical studies.

Prevention

The risk of vulvar cancer can be decreased by avoiding risk factors, most of which involve lifestyle choices.

KEY TERMS

Adjuvant therapy—A treatment that is intended to aid primary treatment. Adjuvant treatments for vulvar cancer are radiation therapy and chemotherapy.

Biopsy—Removal of a small piece of tissue for microscopic examination. This is done under local anesthesia and removed by either using a scalpel or a punch, which removes a small cylindrical portion of tissue.

Colposcope—An instrument used for examination of the vagina and cervix. Part of the instrument includes a magnifying lens for better visualization.

Metastasis—The movement of cancer cells from one area of the body to another. This occurs through the blood vessels or the lymph vessels.

Pelvic exenteration—Surgical removal of the organs of the true pelvis which includes the uterus, vagina, and cervix.

Sentinel lymph node—The first lymph node to receive lymph fluid from a tumor. If the sentinel node is cancer-free, then it is likely that the cancerous cells have not metastasized.

Specifically, to reduce the risk of vulvar cancer, women should not smoke and should refrain from engaging in unsafe sexual behavior. Good hygiene of the genital area to prevent infection and inflammation may also reduce the risk of vulvar cancer.

Because vulvar cancer is highly curable in its early stages, women should consult a physician as soon as a vulvar abnormality is detected. Regular gynecological examinations are necessary to detect precancerous conditions that can be treated before the cancer becomes invasive. Because some vulvar cancer is a type of skin cancer, the American Cancer Society also recommends self-examination of the vulva using a mirror. If moles are present in the genital area, women should employ the ABCD rule:

- Asymmetry. A cancerous mole may have two halves of unequal size.
- Border irregularity. A cancerous mole may have ragged or notched edges.
- Color. A cancerous mole may have variations in color.
- Diameter. A cancerous mole may have a diameter wider than 6 mm (1/4 in).

QUESTIONS TO ASK THE DOCTOR

- What type of cancer do I have?
- What stage of cancer do I have?
- What is the five-year survival rate for women with this type and stage of cancer?
- Has the cancer spread?
- What are my treatment options?
- How much tissue will you be removing? Can you remove less tissue and complement my treatment with adjuvant therapy?
- What are the risks and side effects of these treatments?
- What medications can I take to relieve treatment side effects?
- Are there any clinical studies underway that would be appropriate for me?
- What effective alternative or complementary treatments are available for this type of cancer?
- How debilitating is the treatment? Will I be able to continue working?
- How will the treatment affect my sexuality?
- Are there any restrictions regarding sexual activity?
- How realistic will a vulvar reconstruction look?
- Are there any local support groups for vulvar cancer patients?
- What is the chance that the cancer will recur?
- Is there anything I can do to prevent recurrence?
- How often will I have follow-up examinations?

Special concerns

Surgical removal of the cancerous lesion may remove some or all of the vulva. Vulvectomy alters the appearance of the vulva and affects sexual function. **Depression**, due to the effects of surgery on appearance and **sexuality**, may occur. Short-term and long-term complications following extensive surgical treatment of vulvar cancer are not uncommon. Women of child-bearing age should discuss future fertility with their physician.

Waldenström's macroglobulinemia

Definition

Waldenström's macroglobulinemia is a rare, chronic cancer of the immune system that is characterized by hyperviscosity, or thickening, of the blood.

Description

Waldenström's (Waldenström, Waldenstroem's) macroglobulinemia (WM) is a lymphoma, or cancer of the lymphatic system. It was first identified in 1944, by the Swedish physician Jan Gosta Waldenström, in patients who had a thickening of the serum, or liquid part, of the blood. Their blood serum contained a great deal of a very large molecule called a globulin. Thus, the disorder is called macroglobulinemia.

Lymphomas are cancers that originate in tissues of the lymphatic system. All lymphomas other than **Hodgkin's disease**, including WM, are known collectively as **non-Hodgkin's lymphomas**. There are 13 major types of non-Hodgkin's lymphomas, and others that are very rare. Other names that are sometimes used for WM include: lymphoplasmacytic lymphoma, lymphoplasmacytic leukemia, macroglobulinemia of Waldenström, primary macroglobulinemia, Waldenström's syndrome, Waldenström's purpura, or hyperglobulinemic purpura. Purpura refers to purple spots on the skin, resulting from the frequent bleeding and bruising that can be a symptom of WM.

WM is classified as a low-grade or indolent form of lymphoma because it is a slow-growing cancer that produces fewer symptoms than other types of lymphomas. WM most often affects males over the age of 65. Frequently, this disease produces no symptoms and does not require treatment. It has not been studied as extensively as other types of lymphoma.

The lymphatic system

The lymphatic system is part of the body's immune system, for fighting disease, and part of the blood-producing system. It includes the lymph vessels and nodes, and the spleen, bone marrow, and thymus. The narrow lymphatic vessels carry lymphatic fluid from throughout the body. The lymph nodes are small, pea-shaped organs that filter the lymphatic fluid and trap foreign substances, including viruses, bacteria, and cancer cells. The spleen, in the upper left abdomen, removes old cells and debris from the blood. The bone marrow, the spongy tissue inside the bones, produces new blood cells.

B lymphocytes or B cells are white blood cells that recognize disease-causing organisms. They circulate throughout the body in the blood and lymphatic fluid. Each B lymphocyte recognizes a specific foreign substance, or antigen. When it encounters its specific antigen, the B cell begins to divide and multiply, producing large numbers of identical (monoclonal), mature plasma cells. These plasma cells produce large amounts of antibody that are specific for the antigen. Antibodies are large proteins called immunoglobulins (Igs) that bind to and remove the specific antigen.

A type of Ig, called IgM, is part of the early **immune response**. The IgM molecules form clusters in the bloodstream. When these IgM clusters encounter their specific antigen, usually a bacterium, they cover it so that it can be destroyed by other immune system cells.

Plasma cell neoplasm

WM is a type of plasma cell neoplasm or B-cell lymphoma. These are lymphomas in which certain plasma cells become abnormal, or cancerous, and begin to grow uncontrollably. In WM, the cancerous plasma cells overproduce large amounts of identical (monoclonal) IgM antibody. This IgM also is called M protein, for monoclonal or **myeloma** protein.

Macroglobulinemia refers to the accumulation of this M protein in the serum of the blood. This large amount of M protein can cause the blood to thicken, causing hyperviscosity. The malignant plasma cells of some WM patients also produce and secrete partial immunoglobulins called light chains, or Bence-Jones proteins. The malignant plasma cells can invade various tissues, including the bone marrow, lymph nodes, and spleen, causing these tissues to swell.

Demographics

WM accounts for about 1-2% of non-Hodgkin's lymphomas. It is estimated that it may affect about five out of every 100,000 people. It usually affects people over the age of 50, and most often develops after age 65. It is more common in men than in women. In the United States, WM is more common among Caucasians than among African Americans. The disease can run in families.

Causes and symptoms

The cause of WM is not known.

Many individuals with WM have no symptoms of the disease. This is known as asymptomatic macroglobulinemia. When symptoms of WM are present, they may vary greatly from one individual to the next.

Hyperviscosity syndrome

At least 50% of individuals with WM have hyperviscosity syndrome, an increased viscosity or thickening of the blood caused by the accumulation of IgM in the serum. Hyperviscosity can cause a slowing in the circulation through small blood vessels. This condition can lead to a variety of symptoms:

- **fatigue**
- weakness
- rash
- bruising
- nose bleeds
- gastrointestinal bleeding
- weight loss
- night sweats
- increased and recurrent infections
- poor blood circulation in the extremitiesPoor blood circulation, or Raynaud's phenomenon, can affect any part of the body, but particularly the fingers, toes, nose, and ears.

Cold weather can cause additional circulatory problems, by further thickening the blood and slowing down circulation. In some cases, the excess blood protein may precipitate out of the blood in the cold, creating particles that can block small blood vessels. This is called cryoglobulinemia. The extremities may turn white, or a patchy red and white. The hands, feet, fingers, toes, ears, and nose may feel cold, numb, or painful.

Hyperviscosity may affect the brain and nervous system, leading to additional symptoms. These symptoms include:

- peripheral **neuropathy**, caused by changes in the nerves, leading to pain or numbness in the extremities
- dizziness
- headaches
- vision problems or loss of vision
- mental confusion
- poor coordination
- temporary paralysis
- mental changes

Hyperviscosity can clog the tubules that form the filtering system of the kidneys, leading to kidney damage or kidney failure. Existing heart conditions can be aggravated by WM. In extreme cases, WM may result in heart failure. Late-stage WM also may lead to mental changes that can progress to coma.

Anemia

The accumulation of IgM in the blood causes an increase in the volume of the blood plasma. This effectively dilutes out the red blood cells and other blood components. The lowered concentration of red blood cells can lead to **anemia** and cause serious fatigue. Likewise, a deficiency in platelets (**thrombocytopenia**), which cause the blood to clot, can result in easy bleeding and bruising. As the cancer progresses, there may be abnormal bleeding from the gums, nose, mouth, and intestinal tract. There may be bluish discoloration of the skin. In the later stages of the disease, leukopenia, a deficiency in white blood cells, also can develop.

Organ involvement

In 5-10% of WM cases, the IgM may be deposited in tissues. Thus, some individuals with WM have enlargement of the lymph nodes, the spleen, and/or the liver.

If Bence-Jones proteins are produced by the malignant plasma cells, they may be deposited in the kidneys. There they can plug up the tiny tubules that form the filtering system of the kidneys. This can lead to kidney damage and kidney failure.

Diagnosis

Since many individuals with WM have no symptoms, the initial diagnosis may result from blood tests that are performed for some other purpose. Blood cell counts may reveal low red blood cell and platelet levels. A physical examination may indicate enlargement of the lymph nodes, spleen, and/or liver. A retinal eye examination with an ophthalmoscope may show retinal veins that are enlarged or bleeding.

Blood and urine tests

Serum **protein electrophoresis** is used to measure proteins in the blood. In this laboratory procedure, serum proteins are separated in an electrical field, based on the size and electrical charge of the proteins. Serum **immunoelectrophoresis** uses a second antibody that reacts with IgM. A spike in the Ig fraction indicates a large amount of identical or monoclonal IgM in individuals with WM.

Normal serum contains 0.7-1.6 gm per deciliter (g/dl) of Ig, with no monoclonal Ig present. At serum IgM concentrations of 3-5 g/dl, symptoms of hyperviscosity often are present. However some individuals remain asymptomatic with IgM levels as high as 9 g/dl.

Urinalysis may indicate protein in the urine. A urine Bence-Jones protein test may indicate the presence of these small, partial Igs.

Bone marrow

Abnormal blood tests usually are followed by a bone marrow **biopsy**. In this procedure, a needle is inserted into a bone and a small amount of marrow is removed. Microscopic examination of the marrow may reveal elevated levels of lymphocytes and plasma cells. However, less than 5% of patients with WM have lytic bone lesions, caused by cancerous plasma cells in the bone marrow that are destroying healthy cells. Bone lesions can be detected with x rays.

Treatment team

WM usually is diagnosed and treated by a hematologist/oncologist, a specialist in diseases of the blood. Asymptomatic macroglobulinemia is followed closely by the patient's physician for the development of symptoms.

Clinical staging, treatments, and prognosis

Clinical staging, to define how far a cancer has spread through the body, is the common method for choosing a cancer treatment. However, there is no generally accepted staging system for WM.

There also is no generally accepted course of treatment for WM. Treatment may not be necessary for asymptomatic macroglobulinemia. However, if IgM serum levels are very high, treatment may be initiated even in the absence of symptoms. If symptoms are present, treatment is directed at relieving symptoms and retarding the disease's development. Of major concern is the prevention or alleviation of blood hyperviscosity. Therefore, the initial treatment depends on the viscosity of the blood at diagnosis.

Hyperviscosity

Plasmapheresis, or plasma exchange transfusion, is a procedure for thinning the blood. In this treatment, blood is removed and passed through a cell separator that removes the plasma, containing the IgM, from the red and white blood cells and platelets. The blood cells are transfused back into the patient, along with a plasma substitute or donated plasma. Plasmapheresis relieves many of the acute symptoms of WM. Individuals with WM may be given fluid to counter the effects of hyperviscous blood.

Low blood cell counts

Treatments for low blood cell levels include:

- the drug Procrit to treat anemia
- transfusions with packed red blood cells to treat anemia in later stages of the disease
- antibiotics to treat infections caused by a deficiency in white blood cells
- transfusions with blood platelets

Chemotherapy

Chemotherapy, the use of anti-cancer drugs, helps to slow the abnormal development of plasma cells, but does not cure WM. It can reduce the amount of IgM in the bone marrow. In particular, chemotherapy is used to treat severe hyperviscosity and anemia that are caused by WM.

Chlorambucil (Leukeran), possibly in combination with prednisone, is the typical chemotherapy choice for WM. This treatment is effective in 57% of cases. These drugs are taken by mouth. Prednisone is a corticosteroid that affects many body systems. It has anti-cancer and anti-inflammatory effects and is an immune system suppressant. Other drug combinations that are used to treat WM include **cyclophosphamide** (Cytoxan), **vincristine**, and prednisone, with or without **doxorubicin**. Fludarabine, 2-chlorodeoxyadenosine, and **corticosteroids** also may be used.

KEY TERMS

Anemia—Any condition in which the red blood cell count is below normal.

Antibody—Immunoglobulin produced by immune system cells that recognizes and binds to a specific foreign substance (antigen).

Antigen—Foreign substance that is recognized by a specific antibody.

Autosomal dominant—Genetic trait that is expressed when present on only one of a pair of non-sex-linked chromosomes.

B cell (B lymphocyte)—Type of white blood cell that produces antibodies.

Bence-Jones protein—Light chain of an immunoglobulin that may be overproduced in Waldenström's macroglobulinemia; it is excreted in the urine.

Biopsy—Removal of a small sample of tissue for examination under a microscope; used in the diagnosis of cancer.

Cryoglobulinemia—Condition in which protein in the blood forms particles in the cold, blocking blood vessels and leading to pain and numbness of the extremities.

Hyperviscosity—Thick, viscous blood, caused by the accumulation of large proteins, such as immunoglobulins, in the serum.

Immunoelectrophoresis—Use of an electrical field to separate proteins in a mixture (such as blood or urine), on the basis of the size and electrical charge of the proteins; followed by the detection of an antigen (such as IgM), using a specific antibody.

Immunoglobulin (Ig)—Antibody such as IgM; large protein produced by B cells that recognizes and binds to a specific antigen.

Interferon alpha—Potent immune-defense protein; used as an anti-cancer drug.

Lymphatic system—The vessels, lymph nodes, and organs, including the bone marrow, spleen, and thymus, that produce and carry white blood cells to fight disease.

Lymphoma—Cancer that originates in lymphatic tissue.

M protein—Monoclonal or myeloma protein; IgM that is overproduced in Waldenström's macroglobulinemia and accumulates in the blood and urine.

Monoclonal—Identical cells or proteins; cells (clones) derived from a single, genetically distinct cell, or proteins produced by these cells.

Plasma cell—Type of white blood cell that produces antibodies; derived from an antigen-specific B cell.

Plasmapheresis—Plasma exchange transfusion; the separation of serum from blood cells to treat hyperviscosity of the blood.

Platelet—Cell that is involved in blood clotting.

Stem cell—Undifferentiated cell that retains the ability to develop into any one of numerous cell types.

Side effects of chemotherapy may include:

- Mouth sores
- Nausea and indigestion
- Hair loss (alopecia)
- Increased appetite
- Nervousness
- Insomnia These side effects disappear after the chemotherapy is discontinued.

The long-term management of WM usually is accomplished through a combination of plasmapheresis and chemotherapy.

Alternative and complementary therapies

Biological therapy or immunotherapy, with the potent, immune system protein interferon alpha, is used to relieve the symptoms of WM. Interferon alpha works by boosting the body's immune response. Interferon can cause flu-like symptoms, such as **fever**, chills, and fatigue. It also can cause digestive problems and may affect blood pressure.

The drug **rituximab**, an antibody that is active against antibody-producing cells, is effective in about 30% of individuals with WM. Rituximab is a monoclonal antibody produced in the laboratory. Monoclonal antibody treatment may cause a an allergic reaction in some people.

Prognosis

There is no cure for WM. In general, patients go into partial or complete remission following initial treatments. However the disease is not cured and follow-up treatment may be necessary.

QUESTIONS TO ASK THE DOCTOR

- Why have you diagnosed Waldenström's macroglobulinemia?
- Is my disease likely to progress?
- Do you recommend treatment, and if so, why?
- What are my treatment options?
- What is my prognosis?

The prognosis for this cancer depends on an individual's age, general health, and genetic (hereditary) makeup. Males, individuals over age 60, and those with severe anemia have the lowest survival rates. The Revised European American Lymphoma (REAL) classification system gives WM a good prognosis following treatment, with an average five-year survival rate of 50-70%. However, many people with WM live much longer, some without developing any symptoms of the disease. About 16-23% of individuals with WM die of unrelated causes.

Clinical trials

Clinical studies for the treatment of WM are ongoing. These studies are focusing on new anti-cancer drugs, new combinations of drugs for chemotherapy, and new biological therapies to boost the immune system. The drug **thalidomide** is a promising new treatment for WM. Its mode of action is unclear; the drug appears to have various effects on the immune system and may inhibit cancerous plasma cells, both directly and indirectly. If thalidomide is taken during pregnancy, it can cause severe birth defects or death of the fetus.

Biological therapies in clinical trial include **monoclonal antibodies** that contain radioactive substances (radioimmunotherapy), in combination with autologous peripheral blood stem cell rescue or transplantation (PBSCT). With PBSCT, the patient's peripheral blood stem cells (immature bone marrow cells found in the blood) are collected and frozen prior to radioimmunotherapy, which destroys bone marrow cells. A procedure called apheresis is used to collect the stem cells. Following the therapy, the stem cells are reinjected into the individual. The procedure is autologous because it utilizes the individual's own cells. A similar procedure that utilizes chemotherapy with PBSCT also is being tested.

Prevention

There is no known prevention for WM.

Special concerns

WM is a rare disorder and many physicians and even hematologists may not have had experience with it. Furthermore, there is not a clear consensus among professionals as to what constitutes a diagnosis of WM; nor is there a defined course of treatment or accurate prognosis. Thus, it is important that the patient obtain all available information, including seeking second opinions and additional consultations.

Warfarin

Definition

Wafarin is a vitamin K antagonist that belongs to the family of drugs called anticoagulants (''blood thinners,'' although it does not actually thin the blood). The brand name of warfarin in the U.S. is Coumadin.

Purpose

Wafarin is used to decrease the clotting ability of the blood and to help prevent harmful clots from forming in the blood vessels. It is also used for the long-term treatment of thromboembolic disease, a common side effect of cancer.

One of the most common hematological complications is disordered coagulation. Approximately 15% of all cancer patients are affected by thromboembolic disease, and it is the second leading cause of death for cancer patients. However, thromboembolic disease may represent only one of many complications in end-stage patients. Thromboembolic disease includes superficial and deep vein thrombosis, pulmonary embolism, thrombosis of venous access devices, arterial thrombosis, and embolism. The cancer itself or cancer treatments may induce coagulation. For example, **tamoxifen**, a drug prescribed to treat **breast cancer**, increases the chance of developing pulmonary embolism or deep vein thrombosis.

Cancer and its treatment can affect all three causes of thromboembolic disease including the alteration of blood flow, damage to the cells in blood vessels (endothelial cells), and enhancing procoagulants (precursors, such as fibrinogen or prothrombin, that mediate coagulation). Cancer can affect blood flow by mechanically affecting blood vessels close to a tumor. In addition, tumors cause angiogenesis, which may create complexes of blood vessels with a disordered appearance and flow (varying in magnitude and direction). **Chemotherapy** or tumors may directly damage endothelial cells. Procoagulants may be secreted into the blood stream by cancer cells or can be increased on the surface of cancer cells.

Description

Warfarin will not dissolve an existing blood clot, but it may prevent it from getting larger. When warfarin is taken orally, it is absorbed quickly from the gastrointestinal tract. It reaches a maximal plasma concentration in 90 minutes and stays in the bloodstream (i.e. its half-life) 36–42 hours. Warfarin circulates in the bloodstream attached to plasma proteins—in particular, a protein called albumin. The response or effects of a warfarin dose vary from person to person.

Whether anticoagulants like wafarin may also improve cancer survival rates independent of their effect on thromboembolism has been investigated. There is suggestive evidence that warfarin may actually enhance cancer survival rates. Animal studies show that warfarin and other agents such as **heparin**, fibrinolytics, and even antiplatelet agents inhibit tumor growth and **metastasis**.

Recommended dosage

A doctor may prescribe a dosage based on laboratory blood tests that determine a patient's clotting time. This blood test (called prothrombin time) is conducted usually weekly or monthly as suggested by a physician and should always be done at the same time of day. Based on the clotting time, the doctor determines the dose and/or whether the dose should be adjusted. Warfarin is normally prescribed to be taken once a day, and it should be taken at the same time every day.

Precautions

Following certain precautions when taking warfarin may reduce the risk of side effects and improve the effectiveness of the medication. The rate of blood clotting is affected by illness, diet, medication changes, and physical activities. If an individual has other medical problems, this may affect the use of warfarin. Of particular importance are bleeding ulcers, heavy menstrual periods, infections, high blood pressure, and liver or kidney problems. The doctor should be informed of any changes in these conditions so dose alterations can be made, if necessary. If a patient using warfarin is scheduled for surgery or dental work, the doctor or dentist should be informed that the patient is taking this medication. Warfarin should not be prescribed if an allergic reaction has occurred in the past, during pregnancy or while breastfeeding, or if pregnancy is planned. Anyone taking warfarin should exercise extra care not to cut him/herself

and not to sustain injuries that can result in bruising or bleeding.

In addition, patients taking warfarin should watch their intake of vitamin K, since too much vitamin K may alter the way in which warfarin works. The amount of foods high in vitamin K (such as broccoli, spinach, and turnip greens) eaten each week should be kept stable. Grapefruit juice should be avoided because it may intensify the effects of this medication. Alcohol should also be avoided while taking warfarin because it interferes with warfarin's effectiveness.

In order to determine a safe and effective dose, regular blood tests to check prothrombin time should be done while taking this medicine. Individuals taking warfarin frequently require dose adjustments.

Side effects

The most common complication of long-term warfarin therapy is bleeding. The intensity of anticoagulant therapy, age, kidney function, and unidentified diseases of the gastrointestinal and genitourinary tracts all directly influence the risk of bleeding. Patients taking warfarin should be aware of the signs and symptoms that may indicate a bleeding problem. These signs and symptoms include:

- bleeding from the gums or nose
- red or black bowel movements
- coughing up blood (hemoptysis)
- heavy bleeding from cuts or wounds that will not stop
- unusually heavy menstrual bleeding
- blood in the urine
- easy bruising or purple spots on the skin
- severe headache

The patient should inform his/her doctor immediately if any of these symptoms is present.

Other side effects that may occur with warfarin treatment include:

- mild stomach cramps
- upset stomach
- hair loss (alopecia)
- poor appetite (anorexia)
- cough or hoarseness
- fever or chills
- skin rash, hive, or itching
- painful or difficult urination

KEY TERMS

Angiogenesis—The formation of new blood vessels that occurs naturally under certain circumstances, for example, in the healing of a cut.

Anticoagulant—A medication that prevents the formation of new blood clots and keeps existing blood clots from growing larger.

Arterial thrombosis—A condition characterized by a blood clot in an artery.

Blood clot—A clump of blood that forms in or around a vessel as a result of coagulation. The formation of blood clots when the body has been cut is essential because without blood clots to stop the bleeding, a person would bleed to death from a relatively small wound.

Coagulation—The blood's natural tendency to clump and stick.

Embolism—An obstruction in a blood vessel due to a blood clot or other foreign matter that gets stuck while traveling through the bloodstream.

Embolus—A blood clot, gas bubble, piece of tumor tissue, or other foreign matter that moves through the bloodstream from its site of origin to obstruct a blood vessel.

Endothelial cells—The cells lining the inside of blood vessels.

Fibrinolytics—Agents that decompose fibrin, a protein produced in the clotting process.

Pulmonary embolism—A blockage of the pulmonary artery by foreign matter such as a blood clot.

Thromboembolic disease—A condition in which a blood vessel is obstructed by an embolus carried in the bloodstream from the site of formation.

Thrombosis—A condition in which a clot develops in a blood vessel.

Vein thrombosis—A condition characterized by a blood clot in a vein.

The occurrence of any of these side effects should also be reported to the doctor.

Interactions

Some medications should not be combined. The patient should check with the doctor monitoring the warfarin treatment before taking any new medication, including over-the-counter medication or medication prescribed by another doctor.

Among the medications and dietary supplements that may alter the way warfarin works are:

- other prescription medications
- nonprescription medications such as aspirin or nonsteroidal anti-inflammatory drugs (i.e. ibuprofen)
- cough or cold remedies
- herbal products and nutritional supplements
- products containing vitamin K

Studies have shown that Warfarin along with cranberry juice can be big trouble. The volume of the case studies included glasses of cranberry juice daily, not gallons. This drug-food interaction was shown to cause an increased risk of bleeding. This risk prompted the UK's Committee on Safety of Medicines and the Medicines and Healthcare Products Regulatory Agency to warn patients of warfarin to limit consumption of cranberry juice or avoid it altogether. According to Dr. Jacci Bainbrigde of the University of Colorado, Denver, "A cranberry juice/warfarin interaction is biologically plausible. Warfarin is metabolized chiefly by cytochrome P-450 in the liver, and the antioxidant flavonoids contained in the juice are known to inhibit the enzyme pathway." However, limited consumption is advised.

Weight loss

Definition

Weight loss is a reduction in body mass characterized by a loss of adipose tissue (body fat) and skeletal muscle.

Description

Unintentional weight loss is the most common symptom of cancer and often a side effect of cancer treatments. A poor response to cancer treatments, reduced quality of life, and shorter survival time may result from substantial weight loss. The body may become weaker and less able to tolerate cancer therapies. As body weight decreases, body functionality declines and may lead to malnutrition, illness, infection, and perhaps death.

Most cancer patients in the United States expect to suffer weight loss during treatment for their disease; a study of 938 patients from 17 communities in upstate New York reported in 2004 that weight loss was the fourth most commonly expected side effect of cancer therapy, after fatigue, nausea, and sleep disturbances.

Severe malnutrition is typically defined in two ways: functionally (increased risk of morbidity and/or mortality) and by degree of weight loss (greater than 2% per week, 5% per month, 7.5% per 3 months, and 10% per 6 months). Without considering a specific time course, grading is as follows:

- Grade 0 = less than 5.0% weight loss
- Grade 1 = 5.0% to 9.9%
- Grade 2 = 10.0% to 19.9%
- Grade 3 = greater than 20.0%
- Grade 4 (life-threatening) is not specifically defined. Paying attention to weight loss at an early stage is necessary to prevent deterioration of weight, body composition, and performance status.

Causes

There are many reasons for weight loss in cancer patients, including appetite loss because of the effect of cancer treatments (**chemotherapy**, **radiation therapy**, or biological therapy) or psychological factors such as **depression**. Patients may suffer from **anorexia** and lose desire to eat, and thus consume less energy. When inadequate calories are consumed, it can lead to "wasting" of body stores (muscle and adipose tissue). Weight loss may be temporary or may continue at a life-threatening pace.

Weight loss may be also be a consequence of an increased requirement for calories (energy) due to infection, **fever**, or the effects of the tumor or cancer treatments. If infection or fever is present, it is necessary to consider that there is an increased caloric need of approximately 10% to 13% per degree above 98.6°F (37°C). Therefore, energy intake has to be increased to account for this rise in body temperature.

Weight loss may be a result of a common problem in cancer called cachexia. Approximately half of all cancer patients experience cachexia, a wasting syndrome that induces metabolic changes leading to a loss of muscle and fat. It has been proposed that cachexia may be due to the effects of the tumor, but this is debatable considering some patients with very large tumors do not experience cachexia, while others do even though tumors are less than 0.01% of body mass. Cachexia is most common in patients with pancreatic and gastric cancer. Approximately 83% to 87% of these patients experience weight loss. Cachexia is characterized by such symptoms as decreased appetite, **fatigue**, and poor performance sta-

tus. It can occur in individuals who consume enough food, but due to disease complications, cannot absorb enough nutrients (i.e. fat malabsorption). Although energy expenditure is sometimes increased, cachexia can occur even with normal energy expenditure. Cachexia is multifactorial in nature and associated with mechanical factors, psychological factors, changes in taste, and cytokines. It should be distinguished from anorexia, in which there is a loss of desire to eat, resulting in weight loss. Cachexia is a serious complication in cancer patients, thought to be responsible for as many as 20% of all deaths from cancer.

Special concerns

In order to allow normal tissue repair following aggressive cancer therapies, patients require adequate calories and macronutrients in the form of protein, carbohydrates, and fat. Inadequate consumption of food and/or poor nutrition may impair the ability of a patient to tolerate a specific therapy. If a low tolerance to therapy necessitates a decrease in dose, the therapy's effectiveness could be compromised. Wound healing may also be impaired with poor nutrition and inadequate energy intake.

Research has demonstrated that men often experience significantly more weight loss than women over the course of the disease and lose weight much faster. On average, survival time for men is shorter than for women. Significant predictors of patient survival are stage of disease, initial weight-loss rate, and gender.

Treatments

Nutritional problems related to side effects should be addressed to ensure adequate nutrition and prevent weight loss. In particular, cancer patients should maintain an adequate intake of calories and protein to prevent protein-calorie malnutrition. The patient's caloric requirements can be calculated by a dietitian or doctor since nutrient requirements vary considerably from patient to patient. Moreover, patient education about nutrition is vitally important; several recent studies have shown that almost half of all cancer patients in the United States receive no nutritional information from health care professionals, including the 18% who experience significant weight loss.

The following dietary tips may help patients to reduce weight loss:

- Eat more when feeling the hungriest.
- Eat foods that are enjoyed the most.
- Eat several small meals and snacks instead of three large meals. A regular meal schedule should be kept so meals are not missed.
- Have ready-to-eat snacks on hand such as cheese and crackers, granola bars, muffins, nuts and seeds, canned puddings, ice cream, yogurt, and hard boiled eggs.
- Eat high-calorie foods and high-protein foods.
- Take a small meal as to enjoy the satisfaction of finishing a meal. Have seconds if still hungry.
- Eat in a pleasant atmosphere with family and friends if desired.
- Make sure to consume at least eight to 10 glasses of water per day to maintain fluid balance.
- Consider commercial liquid meal replacements such as Ensure, Boost, Carnation, and Sustacal.

An appetite stimulant may be given in order to prevent further weight loss such as **megestrol acetate** or **dexamethasone**. In **clinical trials**, both these medications appear to have similar and effective appetite stimulating effects with megestrol acetate having a slightly better toxicity profile. **Fluoxymesterone** has shown inferior efficacy and an unfavorable toxicity profile.

As of 2004, researchers at the Medical College of Virginia are studying a group of compounds known as cannabinoids for the treatment of cachexia and vomiting associated with cancer treatment. The best-known natural cannabinoids are derived from marijuana.

Further research is needed in order to devise an effective treatment for the loss of muscle tissue in cachexia. As of 2004, there are no medications, nutritional supplements, or other treatments that are even moderately successful in reversing the wasting of muscle tissue in cachexia.

Alternative and complementary therapies

Depression may affect approximately 15%–25% of cancer patients, particularly if the prognosis for recovery is poor. If anorexia is due to depression, there are antidepressant choices available through a physician. Counseling may be also be sought through a psychologist or psychiatrist to cope with depression.

It is important to check with a dietitian or doctor before taking nutritional supplements or alternative therapies because they may interfere with cancer medications or treatments. St. John's Wort has been used as a herbal remedy for treatment of depression, but it and prescription antidepressants is a dangerous combination that may cause symptoms such as nausea, weakness, and may cause one to become incoherent.

See also Taste alteration.

KEY TERMS

Anorexia—A condition frequently observed in cancer patients characterized by a loss of appetite or desire to eat.

Cachexia—A condition in which the body weight "wastes" away, characterized by a constant loss of weight, muscle, and fat.

Cancer—A group of diseases in which abnormal cells divide without control. Cancer cells can invade nearby tissues and can spread through the bloodstream and lymphatic system to other parts of the body.

Chemotherapy—Chemotherapy kills cancer cells using drugs taken orally or by needle in a vein or muscle. It is referred to as a systemic treatment due to fact that it travels through the bloodstream and kills cancer cells outside the small intestine.

Enteral nutrition—Feedings administered through a nose tube (or surgically placed tubes) for patients with eating difficulties.

Parenteral nutrition—Feeding administered most often by an infusion into a vein. It can be used if the gut is not functioning properly or due to other reasons that prevent normal or enteral feeding.

Protein-calorie malnutrition—A lack of sufficient protein and calories to sustain the body's composition, resulting in weight loss and muscle wasting.

Radiation therapy—Also called radiotherapy; uses high-energy rays to kill cancer cells.

Wasting—When inadequate calories are consumed, it can lead to depletion of body mass. Wasting results in weight loss in tissues such as skeletal muscle and adipose tissue (fat).

Wilms' tumor

Definition

Wilms' tumor is a cancerous tumor of the kidney that usually occurs in young children. It is named for Max Wilms, a German surgeon (1867–1918) and is also known as a nephroblastoma.

Description

When an unborn baby is developing, the kidneys are formed from primitive cells. Over time, these cells

become more specialized. The cells mature and organize into the normal kidney structure. Sometimes, clumps of these cells remain in their original, primitive form. If these cells begin to multiply after birth, they may ultimately form a large mass of abnormal cells. This is known as a Wilms' tumor.

Wilms' tumor is a type of malignant tumor. This means that it is made up of cells that are significantly immature and abnormal. These cells are also capable of invading nearby structures within the kidney and traveling out of the kidney into other structures. Malignant cells can even travel through the body to invade other organ systems, most commonly the lungs and brain. These features of Wilms' tumor make it a type of cancer that, without treatment, would eventually cause death. However, advances in medicine during the last 20 years have made Wilms' tumor a very treatable form of cancer.

Wilms' tumor occurs almost exclusively in young children. The average patient is about three years old, although cases have also been reported in infants younger than six months and adults in their early twenties. Females are only slightly more likely than males to develop Wilms' tumors. In the United States, Wilms' tumor occurs in 8.3 individuals per million in white children under the age of 15 years. The rate is higher among African-Americans and lower among Asian-Americans. Wilms' tumors are found more commonly in patients with other types of congenital conditions. These conditions include:

- absence of the colored part (the iris) of the eye (aniridia)
- enlargement of one arm, one leg, or half of the face (hemihypertrophy)
- certain birth defects of the urinary system or genitals
- certain genetic syndromes (WAGR syndrome, Denys-Drash syndrome, and Beckwith-Wiedemann syndrome)

Causes and symptoms

The cause of Wilms' tumor is not completely understood. Because 15% of all patients with this type of tumor have other heritable defects, it seems clear that at least some cases of Wilms' tumor are due to an inherited alteration. A genetic defect known as WT1, the Wilms' tumor suppressor gene, has been identified in some patients on chromosome 11. It appears that the tendency to develop a Wilms' tumor can run in families. In fact, about 1.5% of all children with a Wilms' tumor have family members who have also had a Wilms' tumor. The genetic mechanisms associated with the disease are unusually complex; it is thought as of 2004 that the tumor develops because the defective WT1 gene fails to stop its growth. Other genes that have been linked to Wilms' tumor are located on chromosomes 16q, 7p15, and 17q12.

Some patients with Wilms' tumor experience abdominal pain, nausea and vomiting, high blood pressure, or blood in the urine. However, the parents of many children with this type of tumor are the first to notice a firm, rounded mass in their child's abdomen. This discovery is often made while bathing or dressing the child and frequently occurs before any other symptoms appear. Rarely, a Wilms' tumor is diagnosed after there has been bleeding into the tumor, resulting in sudden swelling of the abdomen and a low red blood cell count (**anemia**).

About 4–5% of Wilms' tumor cases involve both kidneys during the initial evaluation. The tumor appears on either side equally. When pathologists look at these tumor cells under the microscope, they see great diversity in the types of cells. Some types of cells are associated with a more favorable outcome in the patient than others. In about 15% of cases, physicians find some degree of cancer spread (**metastasis**). The most common sites in the body where metastasis occurs are the liver and lungs.

Researchers have found evidence that certain types of lesions occur before the development of the Wilms' tumor. These lesions usually appear in the form of stromal, tubule, or blastemal cells.

Diagnosis

Children with Wilms' tumor generally first present to physicians with a swollen abdomen or with an obvious abdominal mass. The physician may also find that the child has **fever**, bloody urine, or abdominal pain. The physician will order a variety of tests before imaging is performed. These tests mostly involve blood analysis in the form of a white blood cell count, complete blood count, platelet count, and serum calcium evaluation. Liver and kidney function testing will also be performed as well as a urinalysis.

Initial diagnosis of Wilms' tumor is made by looking at the tumor using various imaging techniques. Ultrasound and **computed tomography** scans (CT scans) are helpful in diagnosing Wilms' tumor. Intravenous pyelography, where a dye injected into a vein helps show the structures of the kidney, can also be used in diagnosing this type of tumor. Final diagnosis, however, depends on obtaining a tissue sample from the mass (**biopsy**), and examining it under a microscope in order

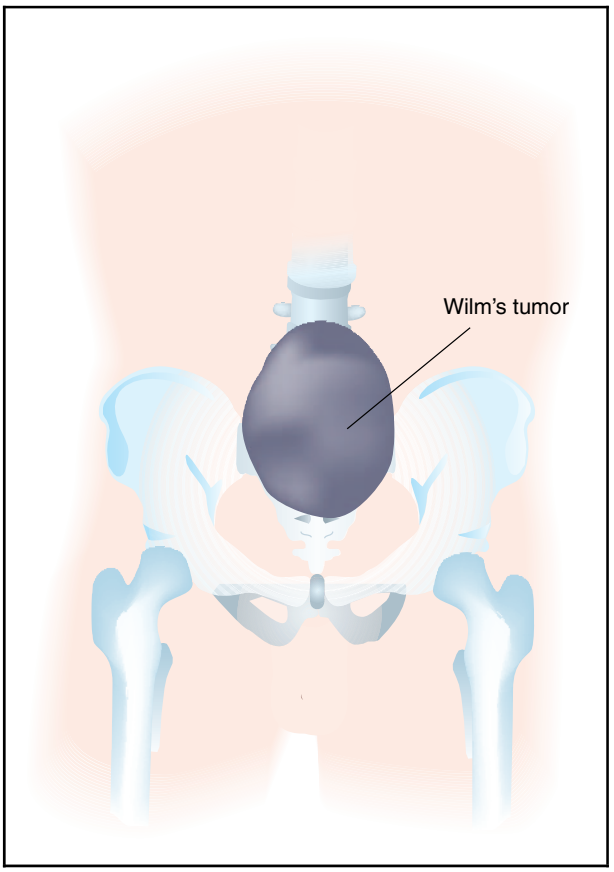
to verify that it has the characteristics of a Wilms' tumor. This biopsy is usually done during surgery to remove or decrease the size of the tumor. Other studies (chest x rays, CT scan of the lungs, bone marrow biopsy) may also be done in order to see if the tumor has spread to other locations.

Treatment

In the United States, treatment for Wilms' tumor almost always begins with surgery to remove or decrease the size of the kidney tumor. Except in patients who have tumors in both kidneys, this surgery usually will require complete removal of the affected kidney. During surgery, the surrounding lymph nodes, the area around the kidneys, and the entire abdomen will also be examined. While the tumor can spread to these surrounding areas, it is less likely to do so compared to other types of cancer. In cases where the tumor affects both kidneys, surgeons will try to preserve the kidney with the smaller tumor by removing only a portion of the kidney, if possible. Additional biopsies of these areas may be done to see if the cancer has spread. The next treatment steps depend on whether/where the cancer has spread. Samples of the tumor are also examined under a microscope to determine particular characteristics of the cells making up the tumor.

Information about the tumor cell type and the spread of the tumor is used to decide the best kind of treatment for a particular patient. Treatment is usually a combination of surgery, medications used to kill cancer cells (**chemotherapy**), and x rays or other high-energy rays used to kill cancer cells (**radiation therapy**). These therapies are called adjuvant therapies, and this type of combination therapy has been shown to substantially improve outcome in patients with Wilms' tumor. It has long been known that Wilms' tumors respond to radiation therapy. Likewise, some types of chemotherapy have been found to be effective in treating Wilms' tumor. These effective drugs include **dactinomycin**, **doxorubicin**, **vincristine**, and **cyclophosphamide**. In rare cases, **bone marrow transplantation** may be used.

The National Wilms' Tumor Study Group (NWTSG) has developed a staging system to describe Wilms' tumors. All of the stages assume that surgical removal of the tumor has occurred. Stage I involves "favorable" Wilms' tumor cells and is usually treated successfully with combination chemotherapy involving dactinomycin and vincristine and without abdominal radiation therapy. Stage II tumors involving a favorable histology (cell characteristics) are usually treated with the same therapy as Stage I. Stage III tumors with favorable histology are usually treated with a combination chemotherapy with doxorubicin, dactinomycin, and vincristine along with radiation therapy to the abdomen. Stage IV disease with a favorable histology is generally treated with combination chemotherapy with dactinomycin, doxorubicin, and vincristine. These patients usually receive abdominal radiation therapy and lung radiation therapy if the tumor has spread to the lungs.



(Illustration by Argosy Publishing. Reproduced by permission of The Gale Group.)

In the case of Stage II through IV tumors with unfavorable, or anaplastic, cells, then the previously mentioned combination chemotherapy is used along with the drug cyclophosphamide. These patients also receive lung radiation therapy if the tumor has spread to the lungs. Another type of tumor cell can be present in Stages I through IV. This cell type is called clear cell sarcoma of the kidney. If this type of cell is present, then patients receive combination therapy with vincristine, doxorubicin, and dactinomycin. All of these patients receive abdominal radiation therapy and

KEY TERMS

Biopsy—A procedure in which a small sample of tissue is removed, prepared, and examined with a microscope to determine the characteristics of the tissue's cells.

Blastemal—An immature material from which cells and tissues develop.

Cancer—A process where abnormal cells within the body begin to grow out of control, acquire the ability to invade nearby structures, and travel through the bloodstream in order to invade distant structures.

Congenital—Present at birth.

Malignant—Refers to cancer or cancer cells.

Sarcoma—A type of cancer that originates from connective tissue such as bone or muscle.

Stromal—A type of tissue that is associated with the support of an organ.

Tubule—Tissues and cells associated with the structures that connect the renal pelvis to the glomeruli.

lung radiation therapy if the tumor has spread to the lungs.

As of 2004, there are significant differences between the treatment protocols of the NWTSG and its European counterpart, the Société Internationale d'Oncologie Pédiatrique (SIOP). Whereas American practice favors surgery followed by chemotherapy, European oncologists use preoperative chemotherapy and stage the tumor at the time of surgery rather than at the point of initial imaging studies.

Prognosis

The prognosis for patients with Wilms' tumor is quite good, compared to the prognosis for most types of cancer. One German study reported the overall five-year survival rate to be 89.5%. The patients who have the best prognosis are usually those who have a small-sized tumor, a favorable cell type, are young (especially under two years old), and have an early stage of cancer that has not spread. Modern treatments have been especially effective in the treatment of this cancer. Patients with the favorable type of cell have a long-term survival rate of 93%, whereas those with anaplasia have a long-term survival rate of 43% and those with the sarcoma form have a survival rate of 36%.

Prevention

There are no known ways to prevent Wilms' tumor, although it is important that children with congenital conditions associated with Wilms' tumor be carefully monitored.

X

X rays

Definition

X rays are a type of radiation used in imaging and therapy that uses short wavelength energy beams capable of penetrating most substances except heavy metals.

Purpose

Diagnostic x rays are some of the most powerful medical imaging tools available. Other imaging techniques that do not use x rays include **magnetic resonance imaging** (MRI), ultrasonography, and radionucleotide imaging. Based on the symptoms presented by the patient, the physician can request specific x rays (such as chest x rays) that help diagnose many types of cancers, including **sarcomas**, lymphomas, and lung cancers. X rays allow the physician to visualize certain internal body conditions with little or no invasive procedures. Conditions may be visualized on photographic film, or for more complex and detailed information, **computed tomography** (CT scan), fluroscopy, or **angiography** might be used.

Precautions

Before consenting to any x-ray procedure, the patient should consider the impact of existing medical conditions or medications. Sensitivities to contrast dyes may produce allergic reactions. Pregnant women or those who suspect they might be pregnant should consult a physician prior to x-ray treatments to avoid injury to the fetus. Nursing mothers may be required to store enough milk to last for 48 hours following certain procedures. Patient age should always be taken into consideration when choosing the type and intensity of x ray. Patients should be aware that some prescribed cancer medications act as radiosensitizers and amplify the effect of x rays. Any patient with a suppressed immune system or diabetes may require special x-ray procedures.

Description

X-ray procedures are administered in a hospital or clinical setting. Most procedures may be conducted on an outpatient basis. The time required for the procedure may vary from a few minutes to more than an hour. There is little or no discomfort associated with diagnostic x rays. The general procedure for diagnostic x rays include:

- proper positioning and shielding of the patient
- administering contrast dyes, if necessary
- administering radiation
- review of the films by a technician to insure proper imaging
- Scheduling a time to review the films with the radiologist. However, if fluoroscopy or angiography is used, the procedure is dynamic (in motion), and the radiologist is present during the x ray administration.
- dismissal of the patient

Preparation

Diagnostic x rays require little preparation. The patient may be required to abstain from food and liquids for a certain period prior to the x ray. For some x rays, enemas may be necessary or a contrast agent may be administered immediately prior to or during the procedure.

Aftercare

For non-invasive diagnostic x-ray procedures, the patient is dismissed immediately after the films have been reviewed, and little or no aftercare is necessary.

Risks

A general rule for x rays suggests that the beneficial effects of x rays far exceed the risks involved. As a result of certified training and strict guideline compliance,

Chest x ray of patient with Hodgkin's disease. *(Custom Medical Stock Photo. Reproduced by permission.)*

risks from technical application are essentially nonexistent. However, for any x-ray procedure, radiation exposure is always a concern, and although uncommon, the risk of infection during invasive techniques can not be discounted.

Normal results

Diagnostic x rays provide detailed information that the physician can use to determine the best approach to correct or control a medical problem. Normal results would indicate no existing abnormalities.

Abnormal results

Abnormal results would indicate irregularities such as a tumor, an enlarged lymph node, or **pleural effusion**. Although highly unlikely, diagnostic x-ray films can be misread and the wrong diagnosis made.

KEY TERMS

Angiography—A radiographic technique in which an opaque contrast material is injected into a blood vessel for the purpose of identifying its anatomy on x ray.

Computed tomography (CT)—A special radiographic technique that uses a computer to convert multiple x-ray images into a two dimensional cross-sectional image.

Contrast dye—A radiopaque dye that allows enhancement of the anatomy demonstrable with conventional x ray.

Fluoroscopy—X-ray imaging of moving anatomic structures.

Gene therapy—The delivery of normal genes or genetically altered cells to the site of a tumor.

Interventional radiography—Diagnostic and therapeutic x-ray procedures that are invasive or surgical in nature but do not require the use of general anesthesia.

Pleural effusion—The accumulation of fluid in the pleural space, the region between the outer surface of each lung.

Radiologist—A physician specially trained in the use of x-rays for diagnostic and therapy purposes.

QUESTIONS TO ASK THE DOCTOR

- What type of x-ray procedure is best to diagnosis my condition?
- Will the procedure or treatment hurt?
- How long will it take each time and how many treatments are required?
- What are my chances for a complete recovery?
- Are these procedures covered by insurance?

KEY TERMS

Oral cavity—The collective term for several structures in the mouth: the lips, teeth, gums, tongue, pharynx, and salivary glands.

Sialogogue—A medication given to increase the flow of saliva.

Xerostomia—The medical term for dry mouth.

Xerostomia

Description

Xerostomia, also known as dry mouth, is marked by a significant reduction in the secretion of saliva. Signs and symptoms of xerostomia include:

- dryness of the mouth
- cracked lips, cuts, or cracks at the corners of the mouth
- taste changes
- a burning sensation of the tongue
- changes in the surface of the tongue
- difficulty wearing dental appliances (like dentures)
- difficulty swallowing fluids accompanied by an increase in thirst Xerostomia makes the mouth less able to neutralize acid, clean the teeth and gums, and protect itself from infection. This can lead to the development of gum disease and cavities.

Saliva is necessary for carrying out the normal functions of the oral cavity, such as taste, speech, and swallowing. Saliva provides calcium and phosphate, minerals that protect the teeth against softening. It also contains substances inhibiting the production of bacteria that cause tooth decay. In addition, saliva buffers the acids produced when leftover food particles are broken down by bacteria.

Xerostomia causes the following mouth changes that can contribute to discomfort for the patient, and an increased risk for oral lesions:

- Saliva becomes thick and is less able to lubricate the mouth.
- Acids in the mouth cannot be neutralized, leading to mineral loss from the teeth.
- There is an increased risk for cavities because the mouth is less able to control bacteria.
- Plaque becomes thicker and heavier because of the patient's difficulty in maintaining good oral hygiene.
- The acid produced after eating or drinking sugary foods leads to further mineral loss from the teeth, causing even more tooth decay.

Causes

Xerostomia in cancer patients is primarily caused by the effects of **radiation therapy** on the salivary glands, usually the result of radiation to the head and neck area. These changes may occur rapidly and cannot normally be reversed, especially if the salivary glands themselves are irradiated. Within one week of starting radiation treatment, the production of saliva drops and continues to decrease as treatment continues. The severity of xerostomia is dependent upon the radiation dose and how many salivary glands are irradiated. Typically, the salivary glands inside the upper back cheeks (the parotid glands) are more affected than others. Salivary glands that are not irradiated may become more active as a way of compensating for the loss of saliva from the destroyed glands.

A number of medications can cause xerostomia, including many drugs used in the management of cancer or cancer treatment side effects. Some of these are: atropine, **amitriptyline**, **carbamazepine**, **diphenhydramine**, **gabapentin**, haloperidol, loperamide, **lorazepam**, **meperidine**, and **scopolamine**, among several others.

Xerostomia may develop in patients with HIV infection, as the virus often damages the salivary glands.

Lastly, xerostomia often accompanies the normal aging process; between 25 and 50% of people over the age of 65 complain of increasing dryness of mouth.

Treatments

A number of **clinical trials** are investigating drugs called radioprotectors, which are given at the time of

radiation therapy in an attempt to prevent xerostomia. If xerostomia has already developed, there are a number of measures that may help to both alleviate the symptoms of dry mouth and prevent cavities and gum disease. These measures include:

- cleaning the mouth well at least four times per day (after every meal and at bedtime)
- rinsing the mouth immediately after every meal
- using fluoride toothpaste to brush the teeth
- sipping water frequently
- rinsing the mouth with a salt and baking soda solution four to six times per day (1/2 tsp. salt, 1/2 tsp. baking soda, and 8 oz of water)
- avoiding foods and liquids containing large amounts of sugar
- avoiding mouthwashes containing alcohol
- using moisturizer on the lips
- using saliva substitutes to help relieve discomfort
- using a sialogogue such as **pilocarpine** (Salagen), which can stimulate saliva secretion from the remaining salivary glands
- applying a prescription-strength fluoride gel daily at bedtime to clean the teeth

Xerostomia usually cannot be reversed when the cause is the destruction of the salivary glands by radiation treatments. It may be reversible if related to a medication. All of the treatment measures serve to increase the level of comfort, decrease the chance for oral lesions, and reduce the occurrence of gum disease and cavities.

Zoledronate

Definition

Zoledronate, which is also known as zoledronic acid, is a treatment for **hypercalcemia** (high levels of calcium in the blood) caused by tumors. It is sold under the brand name Zometa. New laboratory evidence suggests that, in addition, zoledronate may have direct anticancer effects.

Purpose

Tumor-induced hypercalcemia is also known as hypercalcemia of malignancy. Tumor-induced hypercalcemia may be caused by a tumor spreading to and causing breakdown of bone, or by chemicals released from some tumors. The result is high levels of calcium in the blood. High levels of calcium may cause changes in mental status, constipation, and kidney damage.

Zoledronate was approved by the Food and Drug Administration (FDA) in 2002 as a treatment for multiple myeloma and bone metastases. Bone metastases may develop if cells from breast, lung, or other cancers are transplanted to bone by the disease process. Bone **metastasis** may cause pain, compression of the nerves of the spine, and bone fractures.

Other drugs in the same class as zoledronate are used to prevent pain or fractures in people with bone metastases. Zoledronate appears to be effective for this use as well, particularly in men being treated for prostate cancer. In addition, these drugs (the class of **bisphosphonates**) are being studied to see if they prevent the development of bone metastases in the first place.

Description

Zoledronate is one of a group of medicines known as bisphosphonates. Bisphosphonates prevent bone destruction by inhibiting the action of osteoclasts, cells that break down bone. As of 2004 zoledronate is one of the most potent bisphosphonates approved for use in the United States.

KEY TERMS

Bisphosphonates—A class of drugs that inhibit the action of osteoclasts—the cells that dissolve or break down bone.

Bone metastases—The spread of tumor cells from the primary site of origin to bone. Bone metastases from breast cancer, for example, represent breast cancer cells that have invaded bone. They are not the same as bone cancer cells that originate in bone.

Hypercalcemia of malignancy—Also called tumor-induced hypercalcemia; high levels of calcium in the blood from the dissolving of bone, either directly by cancer cells or indirectly by chemicals released from cancer cells.

Recommended dosage

As of 2002 the recommended dosage of zoledronate is 4 mg, given intravenously over a 15-minute period. This short infusion period gives zoledronate an advantage over other drugs in the bisphosphonate class; one study done in Australia found that patients preferred zoledronate to other intravenous bisphosphonates for this reason. The frequency of administration of zoledronate for hypercalcemia depends on the patient's calcium blood level.

Side effects

The most common side effects due to zoledronate that have been reported to date are **fever**, low blood concentration of phosphate, and low blood calcium (not low enough to cause symptoms). Overall, the drug appears to be well tolerated and safe for long-term use in cancer patients.

Zollinger-Ellison syndrome

Definition

In Zollinger-Ellison syndrome (ZES), a tumor (a gastrinoma) secretes the hormone gastrin, which stimulates the secretion of gastric acid. This leads to the development of ulcers in the stomach and duodenum (the first part of the small intestine).

Description

In normal individuals, the stomach secretes the hormone gastrin after food enters the stomach. Gastrin is carried by the bloodstream to other parts of stomach. The main effect of gastrin is to stimulate the parietal cells of the stomach. Parietal cells are stomach cells that secrete gastric acid to aid in digestion. This acid plays a vital role in the digestion of food. This process is highly regulated so that the stomach produces gastrin in significant amounts only when necessary, as when there is food in the stomach.

The underlying entity of ZES is a tumor called a gastrinoma which secretes gastrin inappropriately. Marked overproduction of gastrin leads to hypersecretion of gastric acid by the parietal cells. The end result is severe ulcers of the stomach and duodenum that are more difficult to treat than common ulcers.

Gastrinomas are generally small tumors located in the pancreas or duodenum. They often occur in multiples in the same patient. More than half of all gastrinomas are malignant, with the potential to spread to nearby lymph nodes and also spread to the liver and other organs by way of **metastasis**. The malignant potential of gastrinoma is ultimately more life-threatening than the associated ulcers.

The ulcers in ZES are frequently located further down the gastrointestinal tract than common ulcers, and they may be multiple.

About 25% of patients with ZES also demonstrate other tumors of the endocrine system in a syndrome called Multiple Endocrine Neoplasia syndrome.

Demographics

ZES occurs slightly more frequently in males than females. The average age of onset is between 30 and 50 years of age. It is difficult to determine the prevalence of ZES, but it is not a common syndrome.

Causes and symptoms

The symptoms of ZES are chiefly related to the ulcer disease. The main symptom is abdominal pain, present in the vast majority of patients. Ulcers can also cause nausea, vomiting, and heartburn. Compared with patients with common ulcers, patients with ZES generally have more severe and persistent symptoms that are more difficult to control. In some cases, the ulcers can bleed or actually perforate completely through the walls of the stomach or duodenum.

Many patients also suffer **diarrhea** in addition to ulcer pain. In fact, diarrhea is the only symptom in a small fraction of patients, and the diarrhea may precede the development of ulcers in the stomach and duodenum.

Diagnosis

A number of clinical circumstances suggest that a patient's ulcer disease may be due to ZES:

- ulcer disease resistant to conventional medical treatment
- recurrent ulcers after surgery intended to cure the ulcer disease
- ulcer disease in the absence of the usual risk factors for ulcers
- ulcers located in abnormal locations in the gastrointestinal tract
- multiple ulcers
- ulcers accompanied by diarrhea
- strong family history of ulcer disease

Diagnosis of ZES must be confirmed by observing abnormally high levels of gastrin in the blood. This is the hallmark of the disease. But it must be mentioned that the gastrinoma of ZES is not the only cause of hypersecretion of gastrin. ZES is distinguished from these other conditions by the presence of appropriate symptoms and high levels of gastrin and gastric acid. In cases where the diagnosis is not clear, several provocative tests can help determine if the patient has ZES. In the intravenous secretin injection test, a standard dose of the hormone secretin is injected intravenously. If the blood levels of gastrin respond by increasing a certain amount, the diagnosis is ZES. Similarly, in the intravenous calcium infusion test, a dose of calcium is injected and gastrin levels are measured. A substantial increase in the gastrin level points to ZES. A newer test measures the response in gastrin level to the ingestion of a standard meal. For example, the standard meal might be one slice of bread, one boiled egg, 200 mL of milk, and 50 gm of cheese.

Treatment team

The surgeon and gastroenterologists are the chief members of the treatment team. Radiologists play a vital role in the localization of the gastrinoma before surgery. Oncologists may be involved after surgery or if surgery is not indicated.

Clinical staging, treatments, and prognosis

The goal of treatment for ZES is the elimination of excess gastrin production, acid hypersecretion, ulcer disease, and malignant potential. This is achieved only by complete surgical removal of all gastrinomas. An attempt at surgical cure is offered to most patients, with the exception of those who already have widespread metastasis to the liver or who are too ill to undergo surgery. It is important to locate the gastrinoma(s) and any possible areas of metastasis before surgery. This can be accomplished with tests such as **computed tomography** (CT), ultrasound, **magnetic resonance imaging** (MRI), **angiography**, scintigraphy, and endoscopy. But as gastrinomas may be small, multiple, and hidden in atypical positions, finding the exact locations of all cancerous tissue can be challenging and sometimes impossible. In that case, surgeons will still proceed and attempt to find the tumor(s) at the time of operation. All identified gastrinoma should be removed if possible, including involved lymph nodes. Metastatic lesions in the liver can sometimes be safely removed, but only when they are isolated to one part of the liver.

Chemotherapy is sometimes able to reduce tumor size, which may relieve some symptoms due to local invasion or massive growth of the tumor. But it has not been shown to consistently prolong survival.

KEY TERMS

Angiography—Radiographic examination of blood vessels after injection with a special dye

Computed tomography—A radiology test by which images of cross-sectional planes of the body are obtained

Duodenum—The first portion of the small intestine in continuity with the stomach

Endoscopy—Examination of the interior of a hollow part of the body by means of a special, lighted instrument

Gastric—Of or relating to the stomach

Gastrin—Hormone normally secreted by the stomach that stimulates secretion of gastric acid

Gastrinoma—Tumor that secretes the hormone gastrin

Magnetic resonance imaging—A radiology test that reconstructs images of the body based on magnetic fields

Malignant—In reference to cancer, having the ability to invade local tissues and spread to distant tissues by metastasis

Metastasis—The spread of tumor cells from one part of the body to another

Parietal cells—Stomach cells that secrete gastric acid to aid in digestion

Scintigraphy—A radiology test that involves injection and detection of radioactive substances to create images of body parts

Ultrasound—A radiology test utilizing high frequency sound waves

Medical therapy plays a vital role in the treatment of ZES. A group of drugs known as proton pump inhibitors, which includes omeprazole (a drug used to treat common ulcers), is effective in decreasing acid secretion and promoting ulcer healing in patients with ZES. Omeprazole acts by blocking the last biochemical step in acid production. Omeprazole should be prescribed immediately after diagnosis. If surgery is not attempted, or ultimately unsuccessful, omeprazole is also useful for long-term treatment. For reasons that are not fully known, sometimes patients still require omeprazole after successful surgery. Another drug called octreotide is also effective in reducing acid secretion.

The prognosis for ZES depends primarily on whether or not the gastrinoma can be completely removed. If the cancer has spread diffusely to the liver, surgical cure is nearly impossible. The gastrinoma tissue is completely removed in about 40% of patients, resulting in reduced acid secretion and resolution of ulcer disease or diarrhea. These patients should expect a normal life expectancy, although they should undergo regular testing thereafter and may also require long-term omeprazole treatment. The prognosis is poor for patients in whom all the gastrinoma cannot be removed.

Clinical trials

In 2001, five **clinical trials** were recruiting patients with Zollinger-Ellison syndrome. These trials were studying various aspects of treatment for the syndrome, including the use of Omeprazole, interferon therapy, and combination chemotherapy. For further information about ongoing clinical trials, patients may consult the National Institutes of Health clinical trials site listed below.

Zolpidem

Definition

Zolpidem is a medicine that helps a person get to sleep and stay asleep. The brand name of zolpidem in the U.S. is Ambien.

Purpose

Zolpidem is a sleep medication. It is intended for the short-term treatment of insomnia. Zolpidem may be particularly useful for people who have trouble falling asleep.

Description

Sleep medications are called sedatives or hypnotics. Zolpidem affects brain chemicals, resulting in sleep. It is somewhat similar in its actions on sleep to the group of drugs known as benzodiazepines. Zolpidem is only intended for short term use (seven–10 days). Although there is some information published about effectiveness with longer use, some side effects may increase with longer use.

Recommended dosage

The usual dose is 10 mg before bedtime in adults and 5 mg before bedtime in the elderly and in people with liver disease. The onset of effect occurs within about 30 minutes and the effects on sleep last for 6–8 hours.

Precautions

It is suggested that zolpidem not be discontinued abruptly after regular use (that is daily use for even as short a time as one week). Instead, the drug should be gradually tapered. The tapering is recommended to avoid the possibility of a withdrawal syndrome as well as to avoid the possibility of a rebound worsening of insomnia.

Side effects

The most common side effects of zolpidem include drowsiness, dizziness, and headache. Drowsiness, of course, is desirable when it occurs at bedtime. Daytime drowsiness that is left over from the night before would be considered a side effect. Other side effects include **diarrhea**, nausea and vomiting, and muscle aches. Rarely, amnesia, confusion, falls, and tremor are seen. Falls probably result from the drowsiness or dizziness. There was also a reported study of a patient sleepwalking when taking Zolpidemalong with valproic acid. It is possible that the interactions between the two might have resulted in sleepwalking.

Interactions

Increased effects of zolpidem (eg. more drowsiness, confusion) may be seen with **alcohol consumption** and with other drugs known to cause drowsiness.

APPENDIX I: NCI-DESIGNATED COMPREHENSIVE CANCER CENTERS

Comprehensive Cancer Centers have been designated as such by the National Cancer Institute. They are required to have basic laboratory research in several fields; to be able to transfer research findings into clinical practice; to conduct clinical studies and trials; to research cancer prevention and control; to offer information about cancer to patients, the public, and health care professionals; and to provide community service related to cancer control.

U.S. Food and Drug Administration
5600 Fishers Lane
Rockville, MD 20857-0001
Tel: (888) INFO-FDA
Web: <http://www.fda.gov/cder/cancer/index.htm>
Contains an Oncology Tools section with information on cancer and approved cancer drugs, oncology reference tools, and other resources.

INDEX

Individual volume references are listed before colons; numbers following a colon refer to specific page numbers within that particular volume. **Boldface** page numbers indicate main topical essays. *Italicized* page numbers indicate an illustration or a photographic image. A lowercase *t* following a page number indicates a table on that page.
