Strict sterile technique should be used when preparing to do an exchange to prevent infection. Dialysate should be warmed to 98.6°F (37°C) to provide comfort to the patient; this also is the optimal temperature for clearance of uremic metabolites. The catheter tubing should be flushed so that air does not enter the abdominal cavity.

Aftercare

When not in use, the dialysis catheter can be clamped and tucked under clothing for concealment. If a method of peritoneal dialysis is chosen with dwell times during the day, the patient may have to wear larger, loose-fitting clothes to account for the additional fluid in the abdominal cavity.

Complications

The major complication that can be encountered by peritoneal dialysis patients is peritonitis, an infection of the peritoneum. Symptoms of peritonitis include **fever**, rebound tenderness, nausea, malaise, and cloudy dialysate output. Peritonitis is treated with **antibiotics** placed in the dialysate or taken orally. To avoid peritonitis, patients must be taught to handle the catheter and other dialysis equipment with sterile technique.

Other complications associated with peritoneal dialysis are problems with the catheter such as obstruction, as well as bowel and bladder perforations caused by the insertion of the catheter. Dialysis-related complications include fluid and electrolyte imbalances, hypotension, **pain**, hyperglycemia (high blood glucose levels), and respiratory difficulties due to the presence of the dialysate fluid and the pressure it puts on the diaphragm.

Results

When the proper type of peritoneal dialysis is prescribed, and the patient complies with the regimen, peritoneal dialysis can be very successful in maintaining the fluid and **electrolyte balance** and removing waste when the kidneys are unable to perform these tasks. Peritoneal dialysis allows patients to live full and productive lives by providing flexibility of time and place in dialysis treatment.

KEY TERMS

Automated peritoneal dialysis (APD)—A type of peritoneal dialysis that requires a cyclic machine to complete exchanges.

Continuous ambulatory peritoneal dialysis (CAPD)—A type of peritoneal dialysis that uses gravity to infuse and empty dialysate instead of a machine.

Dialysate—The solution that is used during peritoneal dialysis.

Dialysis—The process of removing fluid and waste products from the body through artificial means.

Dwell time—Stage of a dialysis exchange when the dialysate is inside the abdominal cavity, which is when the filtration takes place.

Exchange—A complete dialysis cycle, starting with infusing the dialysate and ending with the emptying out of the used dialysate solution.

Hypercatabolism—A state in which the body is metabolizing proteins at an exaggerated rate.

Peritoneal dialysis—A removal system for waste products and excess fluid in patients whose kidneys are failing. This system uses the abdominal lining or peritoneal membrane as a filter.

Peritonitis—An infection of the peritoneum.

Uremic toxins—Waste products carried in the blood stream that are usually excreted by the kidneys.

Health care team roles

Peritoneal dialysis is primarily performed at home by patients and their family members. It is the responsibility of health care providers to educate patients in the proper use of peritoneal dialysis so that the patient complies with the regimen and avoids complications. **Patient education** must include instruction on aseptic measures to prevent infection, timing and number of exchanges to be performed, appropriate dwell times, use of the cycler if automated dialysis is chosen, obtaining the proper dialysate solutions, and storage of solutions and equipment.

Personality disorders

Definition

Personality disorders are a group of personality flaws defined by the fourth (1994) edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* as “enduring pattern[s] of inner experience and behavior” that are sufficiently rigid and deep-seated to bring a person into repeated conflicts with his or her social and occupational environment. *DSM-IV* specifies that these dysfunctional patterns must be regarded as non-conforming or deviant by the person’s culture, and cause significant emotional **pain** and/or difficulties in relationships and occupational performance. In addition, the patient usually sees the disorder as being consistent with his or her self-image (ego-syntonic) and may blame others.

Description

To meet the diagnosis of personality disorder, which is sometimes called character disorder, the patient’s problematic behaviors must appear in two or more of the following areas:

- perception and interpretation of the self and other people
- intensity and duration of feelings and their appropriateness to situations
- relationships with others
- ability to control impulses

Personality disorders have their onset in late adolescence or early adulthood. Doctors rarely give a diagnosis of personality disorder to children on the grounds that

children’s personalities are still in the process of formation and may change considerably by the time they are in their late teens. But, in retrospect, many individuals with personality disorders could be judged to have shown evidence of the problems in childhood.

It is difficult to accurately estimate the percentage of the population that suffer from personality disorders. Patients with certain personality disorders, including antisocial and borderline disorders, are more likely to get into trouble with the law or otherwise attract attention than are patients whose disorders chiefly affect their capacity for intimacy. On the other hand, some patients, such as those with narcissistic or obsessive-compulsive personality disorders, may be outwardly successful because their symptoms are useful within their particular occupations. It has, however, been estimated that about 15% of the general population of the United States suffers from personality disorders, with higher rates in poor or troubled neighborhoods. The rate of personality disorders among patients in psychiatric treatment is between 30% and 50%. It is possible for patients to have a so-called dual diagnosis; for example, they may have more than one personality disorder, or a personality disorder together with a substance-abuse problem.

DSM-IV classifies personality disorders into three clusters based on symptom similarities:

- Cluster A (paranoid, schizoid, schizotypal): Patients appear odd or eccentric to others.
- Cluster B (antisocial, borderline, histrionic, narcissistic): Patients appear overly emotional, unstable, or self-dramatizing to others.
- Cluster C (avoidant, dependent, obsessive-compulsive): Patients appear tense and anxiety-ridden to others.

The *DSM-IV* clustering system does not mean that all patients can be fitted neatly into one of the three clusters. It is possible for patients to have symptoms of more than one personality disorder or to have symptoms from different clusters.

Since the criteria for personality disorders include friction or conflict between the patient and his or her social environment, these syndromes are open to redefinition as societies change. Successive editions of *DSM* have tried to be sensitive to cultural differences, including changes over time, when defining personality disorders. One category that had been proposed for *DSM-III-R*, self-defeating personality disorder, was excluded from *DSM-IV* on the grounds that its definition reflected prejudice against women. *DSM-IV* recommends that doctors take a patient’s background, especially recent immigration, into account before deciding that he or she has a personality disorder. One criticism that has been made of the

general category of personality disorder is that it is based on Western notions of individual uniqueness. Its applicability to people from other cultures is thus open to question. Furthermore, even within a culture, it can be difficult to define the limits of “normalcy.”

The personality disorders defined by *DSM-IV* are described below. Certain personality disorders, such as paranoid, schizoid, and schizotypal, should not be confused with psychotic disorders with the same or similar names. Psychotic disorders are characterized by more seriously disordered thinking, frequently involving hallucinations (seeing things that aren't present or hearing voices) and delusions (having unrealistic beliefs, such as thinking one has god-like powers), with an inability to distinguish reality from fantasy.

Paranoid

Patients with paranoid personality disorder are characterized by suspiciousness and a belief that others are out to harm or cheat them. They have problems with intimacy and may join cults or groups with paranoid belief systems. Some are litigious, bringing lawsuits against those they believe have wronged them. Although not ordinarily delusional, these patients may develop psychotic symptoms under severe **stress**. It is estimated that 0.5–2.5% of the general population meet the criteria for paranoid personality disorder.

Schizoid

Schizoid patients are perceived by others as “loners” without close family relationships or social contacts. Indeed, they are aloof and really do prefer to be alone. They may appear cold to others because they rarely display strong emotions. They may, however, be successful in occupations that do not require personal interaction. About 2% of the general population has this disorder. It is slightly more common in men than in women.

Schizotypal

Patients diagnosed as schizotypal are often considered odd or eccentric because they pay little attention to their clothing and sometimes have peculiar speech mannerisms. They are socially isolated and uncomfortable in parties or other social gatherings. In addition, people with schizotypal personality disorder often have oddities of thought, including “magical” beliefs or peculiar ideas (for example, a belief in telepathy) that are outside of their cultural norms. It is thought that 3% of the general population has schizotypal personality disorder. It is slightly more common in males. There is some evidence that schizotypal personality disorder and the psychotic disorder, **schizophrenia**, are genetically related.

Antisocial

Patients with antisocial personality disorder are sometimes referred to as sociopaths or psychopaths. They are characterized by lying, manipulateness, and a selfish disregard for the rights of others; some may act impulsively. People with antisocial personality disorder are frequently chemically dependent and sexually promiscuous. It is estimated that 3% of males in the general population and 1% of females have antisocial personality disorder.

Borderline

Patients with borderline personality disorder (BPD) are highly unstable, with wide mood swings, a history of intense but stormy relationships, impulsive behavior, and confusion about career goals, personal values, or sexual orientation. These often highly conflicting ideas may correspond to an even deeper confusion about their sense of self (identity). People with BPD frequently cut or burn themselves, or threaten or attempt suicide. Many of these patients have histories of severe childhood abuse or neglect. About 2% of the general population have BPD; 75% of these patients are female.

Histrionic

Patients diagnosed with this disorder impress others as overly emotional, overly dramatic, and hungry for attention. They may be flirtatious or seductive as a way of drawing attention to themselves, yet they are emotionally shallow. Histrionic patients often live in a romantic fantasy world and are easily bored with routine. About 2–3% of the population is thought to have this disorder. Although historically, in clinical settings, the disorder has been more associated with women, there may be bias toward diagnosing women with this personality disorder.

Narcissistic

Narcissistic patients are characterized by a sense of self-importance, a craving for admiration, and exploitative attitudes toward others. They have unrealistically inflated views of their talents and accomplishments, and may become extremely angry if they are criticized or outshone by others. Narcissists may be professionally successful but rarely have long-lasting intimate relationships. Fewer than 1% of the population has this disorder; about 75% of those diagnosed with it are male.

Avoidant

Patients with avoidant personality disorder are fearful of rejection and shy away from situations or occupations that might expose their supposed inadequacy. They

may reject opportunities to develop close relationships because of their fears of criticism or humiliation. Patients with this personality disorder are often diagnosed with dependent personality disorder as well. Many also fit the criteria for social phobia. Between 0.5–1.0% of the population have avoidant personality disorder.

Dependent

Dependent patients are afraid of being on their own and typically develop submissive or compliant behaviors in order to avoid displeasing people. They are afraid to question authority and often ask others for guidance or direction. Dependent personality disorder is diagnosed more often in women, but it has been suggested that this finding reflects social pressures on women to conform to gender stereotyping or bias on the part of clinicians.

Obsessive-compulsive

Patients diagnosed with this disorder are preoccupied with keeping order, attaining perfection, and maintaining mental and interpersonal control. They may spend a great deal of time adhering to plans, schedules, or rules from which they will not deviate, even at the expense of openness, flexibility, and efficiency. These patients are often unable to relax and may become “workaholics.” They may have problems in employment as well as in intimate relationships because they are very “stiff” and formal, and insist on doing everything their way. About 1% of the population has obsessive-compulsive personality disorder; the male/female ratio is about 2:1.

Causes and symptoms

Personality disorders are thought to be a disparity between a child’s temperament or character and his or her family or social relationships. Temperament can be defined as a person’s innate or biologically shaped basic disposition. Human infants vary in their sensitivity to light or noise, their level of physical activity, their adaptability to schedules, and other aspects. Even traits such as “shyness” and “novelty-seeking” may be, at least in part, determined by the biology of the **brain** and the genes one inherits.

Character is defined as the set of attitudes and behavior patterns that the individual acquires or learns over time. It includes such personal qualities as work and study habits, moral convictions, neatness or cleanliness, and consideration of others. Since children must learn to adapt to their specific families, they may develop personality disorders in the course of struggling to survive psychologically in disturbed or stressful families. For

example, nervous or high-strung parents might be unhappy with a baby who is very active and try to restrain him or her at every opportunity. The child might then develop an avoidant personality disorder as the outcome of coping with constant frustration and parental disapproval. As another example, **child abuse** is believed to play a role in shaping borderline personality disorder. One reason that some therapists use the term developmental damage instead of personality disorder is that it takes the presumed source of the person’s problems into account.

Some patients with personality disorders come from families that appear to be stable and healthy. It has been suggested that these patients are biologically hypersensitive to normal family stress levels. Levels of the brain chemical (neurotransmitter) dopamine may influence a person’s level of novelty-seeking, and serotonin levels may influence aggression.

Diagnosis

Diagnosis of personality disorders is complicated by the fact that persons suffering from them rarely seek help until they are in serious trouble or until their families (or the law) pressure them to get treatment. The reason for this slowness is that the problematic traits are so deeply entrenched that they seem normal (ego-syntonic) to the patient. Diagnosis of a personality disorder depends in part on the patient’s age. Although personality disorders originate during the childhood years, they are considered to be adult disorders. Some patients, in fact, are not diagnosed until late in life because their symptoms had been modified by the demands of their job or by marriage. After retirement or the spouse’s death, however, these patients’ personality disorders become fully apparent. In general, however, if the onset of the patient’s problem is in mid- or late-life, the doctor will rule out substance abuse or personality change caused by medical or neurological problems before considering the diagnosis of a personality disorder. It is unusual for people to develop personality disorders “out of the blue” in mid-life.

There are no tests that can provide a definitive diagnosis of personality disorder. Most doctors will evaluate a patient on the basis of several sources of information collected over a period of time in order to determine how long the patient has been having difficulties, how many areas of life are affected, and how severe the dysfunction is. These sources of information may include:

Interviews

The doctor may schedule two or three interviews with the patient, spaced over several weeks or months, in order to rule out an adjustment disorder caused by job

loss, bereavement, or a similar problem. An office interview allows the doctor to form an impression of the patient's overall personality as well as obtain information about his or her occupation and family. During the interview, the doctor will note the patient's appearance, tone of voice, body language, eye contact, and other important non-verbal signals, as well as the content of the conversation. In some cases, the doctor may contact other people (family members, employers, close friends) who know the patient well in order to assess the accuracy of the patient's perception of his or her difficulties. It is quite common for people with personality disorders to have distorted views of their situations, or to be unaware of the impact of their behavior on others.

Psychological testing

Doctors use psychological testing to help in the diagnosis of a personality disorder. Most of these tests require interpretation by a professional with specialized training. Doctors usually refer patients to a clinical psychologist for this type of test.

PERSONALITY INVENTORIES. Personality inventories are tests with true/false or yes/no answers that can be used to compare the patient's scores with those of people with known personality distortions. The single most commonly used test of this type is the Minnesota Multiphasic Personality Inventory, or MMPI. Another test that is often used is the Millon Clinical Multiaxial Inventory, or MCMI.

PROJECTIVE TESTS. Projective tests are unstructured, meaning that instead of giving one-word answers to questions, the patient is asked to talk at some length about a picture that the psychologist presents, or to supply an ending for the beginning of a story. Projective tests allow the clinician to assess the patient's patterns of thinking, fantasies, worries or anxieties, moral concerns, values, and habits. Common projective tests include the Rorschach, in which the patient responds to a set of 10 inkblots; and the Thematic Apperception Test (TAT), in which the patient is shown drawings of people in different situations and then tells a story about the picture.

Prognosis

At one time psychiatrists thought that personality disorders did not respond very well to treatment. This opinion was derived from the notion that human personality is fixed for life once it has been molded in childhood, and from the belief among people with personality disorders that their own views and behaviors are correct, and that others are the ones at fault. More recently, how-

KEY TERMS

Character—An individual's set of emotional, cognitive, and behavioral patterns learned and accumulated over time.

Character disorder—Another name for personality disorder.

Developmental damage—A term that some therapists prefer to personality disorder, on the grounds that it is more respectful of the patient's capacity for growth and change.

Ego-syntonic—Consistent with one's sense of self, as opposed to ego-alien or dystonic (foreign to one's sense of self). Ego-syntonic traits typify patients with personality disorders.

Neuroleptic—Another name for older antipsychotic medications, such as haloperidol. The term does not apply to newer "atypical" agents, such as clozapine (Clozaril).

Personality—The organized pattern of behaviors and attitudes that makes a human being distinctive. Personality is formed by the ongoing interaction of temperament, character, and environment.

Projective tests—Psychological tests that probe into personality by obtaining open-ended responses to such materials as pictures or stories. Projective tests are often used to evaluate patients with personality disorders.

Rorschach—A well-known projective test that requires the patient to describe what he or she sees in each of 10 inkblots. It is named for the Swiss psychiatrist who invented it.

SSRI medications—A group of antidepressants known as selective serotonin reuptake inhibitors.

Temperament—A person's natural or genetically determined disposition.

ever, doctors have recognized that humans can continue to grow and change throughout life. Most patients with personality disorders are now considered to be treatable, although the degree of improvement may vary. The type of treatment recommended depends on the personality characteristics associated with the specific disorder.

Treatment

A number of treatments are available for patients with personality disorders. One of the newer treatments

is the use of certain antidepressant medications such as the SSRI (selective serotonin reuptake inhibitors) antidepressants.

Hospitalization

Inpatient treatment is rarely required for patients with personality disorders, with two major exceptions: borderline patients who are threatening suicide or suffering from drug or alcohol withdrawal; and patients with paranoid personality disorder who are having psychotic symptoms.

Psychotherapy

Psychoanalytic **psychotherapy** is suggested for patients who can benefit from insight-oriented treatment. These patients typically include those with dependent, obsessive-compulsive, and avoidant personality disorders. Doctors usually recommend individual psychotherapy for narcissistic and borderline patients, but often refer these patients to therapists with specialized training in these disorders. Psychotherapeutic treatment for personality disorders may take as long as three to five years.

Insight-oriented approaches are not recommended for patients with paranoid or antisocial personality disorders. These patients are likely to resent the therapist and see him or her as trying to control or dominate them.

Supportive therapy is regarded as the most helpful form of psychotherapy for patients with schizoid personality disorder.

Cognitive-behavioral therapy

Cognitive-behavioral approaches are often recommended for patients with avoidant or dependent personality disorders. Patients in these groups typically have mistaken beliefs about their competence or likableness. These assumptions can be successfully challenged by cognitive-behavioral methods.

Group therapy

Group therapy is frequently useful for patients with schizoid or avoidant personality disorders because it helps them to break out of their social isolation. It has also been recommended for patients with histrionic and antisocial personality disorders. These patients tend to act out, and pressure from peers in group treatment can motivate them to change. Because patients with antisocial personality disorder can destabilize groups that include people with other disorders, it is usually best if these people meet exclusively with others with the same disorder (in "homogeneous" groups).

Family therapy

Family therapy may be suggested for patients whose personality disorders cause serious problems for members of their families. It is also sometimes recommended for borderline patients from overinvolved or possessive families.

Medications

Medications may be prescribed for patients with specific personality disorders. The type of medication depends on the disorder.

ANTIPSYCHOTIC DRUGS. **Antipsychotic drugs**, such as haloperidol (Haldol), may be given to patients with paranoid personality disorder if they are having brief psychotic episodes. Patients with borderline or schizotypal personality disorder are sometimes given antipsychotic drugs in low doses; however, the efficacy of these drugs in treating personality disorder is less clear than in schizophrenia.

MOOD STABILIZERS. Carbamazepine (Tegretol) is a drug that is commonly used to treat seizures, but is also helpful for borderline patients with rage outbursts and similar behavioral problems. Lithium and valproate may also be used as mood stabilizers, especially among people with borderline personality disorder.

ANTIDEPRESSANTS AND ANTI-ANXIETY MEDICATIONS. Medications in these categories are sometimes prescribed for patients with schizoid personality disorder to help them manage **anxiety** symptoms while they are in psychotherapy. Antidepressants are also commonly used to treat people with borderline personality disorder.

Treatment with medications is not recommended for patients with avoidant, histrionic, dependent, or narcissistic personality disorders. The use of potentially addictive medications should be avoided in people with borderline or antisocial personality disorders. However, some avoidant patients who also have social phobia may benefit from monoamine oxidase inhibitors (MAO inhibitors), a particular class of antidepressant.

Prognosis

The prognosis for recovery depends in part on the specific disorder and the existence of a mood disorder or coexisting psychiatric diagnosis. Although some patients improve as they grow older and have positive experiences in life, personality disorders are generally life-long disturbances with periods of worsening (exacerbations) and periods of improvement (remissions). Others, particularly schizoid patients, have better prognoses if they are given appropriate treatment. Patients with paranoid per-

sonality disorder are at some risk for developing delusional disorders or schizophrenia. The personality disorders with the poorest prognoses are the antisocial and the borderline. Borderline patients are at high risk for developing substance abuse disorders or bulimia. About 80% of hospitalized borderline patients attempt suicide at some point during treatment, and about 5% succeed in committing suicide.

Health care team roles

Nursing staff and allied health professionals can assist in the treatment of personality disorders by being aware of the symptoms of each cluster. Since personality disorders often present as relationship difficulties, nursing staff and allied health professionals may recognize personality disorders in particularly problematic patients.

During the treatment phase, nursing staff and allied health professionals can help patients by providing them with appropriate educational materials and referrals for ongoing psychotherapy or group therapy, if applicable.

Prevention

The most effective preventive strategy for personality disorders is early identification and treatment of children and adults who are at risk. High-risk groups include abused children, children from troubled families, children with close relatives diagnosed with personality disorders, children of substance abusers, and children who grow up in cults or political extremist groups.

Pharmacology

Definition

Pharmacology is the study of how drugs act on biological systems.

Description

Pharmacology is the science of understanding how drugs act on the body and conversely, how the body acts on drugs. This is not to be confused with pharmacy, which deals with the preparation and dispensing of drugs. Drugs can be defined as chemical compounds with a specific therapeutic function, such as aspirin. Pharmacology focuses on how a drug gets into the body, where in the body the drug acts, and how the body gets rid of a drug. In addition, a pharmacologist will also study the therapeutic potential of a drug, the interaction of a drug with other drugs, and analyze adverse drug reactions, otherwise known as toxicities. There are several subdivisions and sub-disciplines of pharmacology which use the basic principles of pharmacology in different ways.

Pharmacology can be divided into subdivisions based on the body organ being studied. These include, but are not limited to, neuropharmacology, cardiovascular pharmacology, endocrine pharmacology, and **chemotherapy**. Neuropharmacology deals with the effect of drugs on the nervous system, which includes the **brain, spinal cord**, and nerves. Neuropharmacology includes the study of drugs of abuse such as heroin and also drugs used to treat nervous system disorders such as L-dopa, which is given to **Parkinson's disease** patients. Cardiovascular pharmacology focuses on drugs that modify the **heart** and vascular system. **Blood pressure** medications would be studied under this category. Endocrine pharmacology focuses on the interaction of drugs with various hormones or hormonal systems. Birth control pills would fall under the division of endocrine pharmacology. Lastly, the division of chemotherapy studies the pharmacology of drugs used to treat **cancer** such as tamoxifen used in **breast cancer**.

In addition to dividing the field of pharmacology on the basis of the targeted organ system, pharmacology can also be divided into sub-disciplines. These sub-disciplines include, but are not limited to, molecular pharmacology, behavioral pharmacology, and clinical pharmacology. Molecular pharmacology studies the interaction of drugs at the cellular level. This includes studies on the interaction of drugs with protein receptors expressed on the surface of the cell. For example, the **asthma** drug, albuterol, interacts with beta receptors in the lung to increase airflow. The effect of drugs on behavior is the

KEY TERMS

Efficacy—The effectiveness of a drug in treating a disease or condition.

Pharmacodynamics—The way a drug acts on tissues and cells in the body.

Pharmacokinetics—The route and rate at which a drug gets in and out of the body.

basis for the behavioral pharmacology discipline. Behavioral pharmacology includes addiction research which tries to understand why people become addicted to drugs like alcohol. The field of clinical pharmacology focuses more on the therapeutic use of drugs, the interactions of drugs with one another in the body, and the nature of adverse drug reactions.

The various subdivisions and disciplines of pharmacology pursue the discovery and understanding of drugs for the purpose of treating a disease or condition, such as high **blood** pressure. The basic principles of pharmacokinetics, pharmacodynamics, and efficacy are universal across the various areas of pharmacology. A significant amount of pharmacology research is spent on identifying new drugs to treat disease. In addition, it is important to predict drug toxicities or adverse reactions. This is accomplished by studying the pharmacokinetics of a drug. Pharmacokinetics is basically how drugs get into the body and how they get out. It describes the relationships between drug dosage and drug blood levels, which can be influenced by individual differences in drug absorption, distribution, **metabolism**, and elimination. This is important because if a drug is eliminated by the **kidneys** and a patient has damaged kidneys, then the drug could accumulate in the patient to fatal levels. Pharmacokinetic calculations can be used to determine the dose needed to give safe and effective blood levels in this situation. A significant amount of pharmacology research is also spent on understanding how drugs act on the body. This is important to understanding adverse reactions, **drug interactions**, and also for the design of better drugs. This area is known more specifically as pharmacodynamics. Pharmacodynamics is basically how drugs interact with the body. Many drugs bind to protein receptors on the surface of a cell. Pharmacodynamics strives to understand how tightly a drug binds to its receptor and what happens inside the cell upon drug binding. Lastly, the overall outcome of drugs on the human condition is studied and this is known as efficacy. Efficacy deals with analyzing how well a drug may correct a condition such as arthritis. All three principles,

pharmacodynamics, pharmacokinetics, and efficacy, play a pivotal role in pharmacology research.

Work settings

Many pharmacologists work in a laboratory research setting conducting experiments with various drugs. These experiments may be done in animal models of disease or at the biochemical level. Pharmacologists are employed by universities, commercial companies such as a pharmaceutical company, or by the government. University settings are often associated with medical centers and pharmacology research projects are largely funded by grants from outside resources. Many pharmacologists in academic settings study very focused areas in which they are interested. Academic labs are headed by a Ph.D. scientist who will lead a team of technicians and students. Academic pharmacology projects tend to focus on how different drugs work and why. Pharmaceutical settings usually have a basic pharmacology research division, a clinical trials division, a production area, and a quality assurance team. A pharmaceutical company may hire a pharmacologist to discover new drugs or to study existing ones for adverse reactions. Pharmaceutical companies conduct very detailed clinical trials in order to have drugs approved by the FDA (U.S. Department of Health and Human Services Food and Drug Administration). Pharmaceutical companies spend a significant amount of money and employ many scientists in order to prove that a drug is safe and useful in treating a particular disease or condition. A pharmacologist may also be hired by a government agency such as the FDA to conduct research on drugs or to review drug approval applications. The FDA is also responsible for monitoring the safety of already approved drugs and therefore hires pharmacologists to monitor approved drugs as well as establish guidelines. All three settings, academic, commercial, and government, provide viable and exciting opportunities for a pharmacologist.

A typical workday for a pharmacologist depends on the sub-discipline the pharmacologist works in. A molecular pharmacologist may spend a significant portion of the day at the lab bench conducting experiments in test tubes. A behavioral pharmacologist may spend the day observing animals treated with certain drugs. A clinical pharmacologist is more likely to spend time evaluating data from patients taking certain medications. These workdays are typical of traditional research pharmacologists. Pharmacologists in more non-traditional careers may be involved in the business or legal side of science. In other words, pharmacologists are not limited to just experimental research in a laboratory setting.

Education and training

In order to become a pharmacologist, a college degree is required. High school students should take biology, chemistry, and math classes. Several undergraduate institutions now offer a bachelor of science degree in pharmacology. College level courses in biology, biochemistry, anatomy, and physiology are required. The field of pharmacology also requires the use of statistics and laboratory mathematics, and students should complete a statistics course. Undergraduate pharmacology majors should also take chemistry courses, including basic chemistry and organic chemistry. The undergraduate science courses should have a practical laboratory component to prepare students for careers in a laboratory research setting. Students should also pursue undergraduate research projects and look for internship opportunities at pharmaceutical or biotechnology companies. Research associate positions in industry are available for pharmacology college majors, but experience in a laboratory research setting is a must for many of these job opportunities. Universities also hire lab technicians with a college level pharmacology background.

Advanced education and training

Most pharmacologists have advanced degrees at the masters or Ph.D. level. Many universities offer graduate degree programs in pharmacology. Students pursuing a graduate degree should have a baccalaureate degree in biology, chemistry, or related field. Ph.D. students take in depth courses in physiology and pharmacology. In addition, a major requirement for a Ph.D. is a dissertation research project that is conducted over several years. The Ph.D. student is required to publish novel findings in peer-reviewed scientific journals. After completing a Ph.D. in pharmacology, many graduates go on to postdoctoral research training. Postdoctoral training may be in an academic or commercial setting. This training period has an indefinite time length. Many pharmacologists will then go on to become professors at universities or enter the commercial workforce as research scientists.

Future outlook

The field of pharmacology is experiencing rapid growth and prospects for pharmacologists continue to look good. The mapping of the human genome will provide new insights into designing better drugs and will create a need for more pharmacologists to make use of this new information. Many pharmaceutical companies are hiring pharmacologists for their drug discovery research projects. The pharmaceutical industry is a \$300

billion dollar a year industry and this rapid growth is expected to continue.

Pharmacy technician

Definition

Pharmacy technicians assist licensed pharmacists in preparing medications for patients.

Description

Pharmacy technicians, who may also be called pharmacy assistants or pharmacy aides, assist licensed pharmacists in preparing medication for patients. Depending on the work setting and the laws of the individual state, this may involve a number of different tasks.

The primary responsibility of most technicians is to fill orders or prescriptions under the direction and supervision of a pharmacist. The extent of this involvement is often subject to state law, which limits certain activities to performance by a licensed pharmacist. The following discussion will vary with the specific location.

When a medication order or prescription is received, it is reviewed by the pharmacist. This review assures that the order is properly written, and is for a safe and effective dose considering the patient's medical condition and the other drugs being taken. Once the order has been reviewed, the technician locates the medication, counts the required number of doses, prepares a label, and performs other required tasks such as pricing the prescription. This work is subject to review by the pharmacist, who is also responsible for giving the medication to the

KEY TERMS

Dispensing—The act of providing medication to a patient or their representative. This includes providing consultation on the way in which the medication should be taken or administered.

Licensed pharmacist—A pharmacist who has completed the full program of education, and has passed a state licensing examination. Also termed “registered pharmacist.”

Pharmacology—The study of the actions and uses of drugs.

Prescription—A written or verbal order for a medication, from a professional practitioners, such as a physician, dentist, nurse practitioner, podiatrist, or other health care provider.

Protocols—Detailed instructions for performing a task.

patient and for providing information about the proper way in which the medication should be taken.

Preparing medication for dispensing may take varying forms, depending on the work setting. In some hospitals, technicians, following written protocols, prepare injections. This requires familiarity with **infection control** procedures and specialized machinery. Extreme care in measuring and technical proficiency in the use of equipment are also required. Technicians may also prepare ointments, solutions, or fill capsules.

Technicians may be expected to do stock work. This may require taking inventories of drugs, checking inventories for expiration dates, preparing orders, and checking in deliveries.

Technicians may be responsible for maintaining patient medication profiles. These are records of a patient’s prescriptions or drug orders, and are used by the pharmacist to review all the drugs a patient is taking. After the order has been reviewed, the technician may transcribe the information onto the profile, either by hand or using a computer. This task requires familiarity with drugs names and doses, as well as knowledge of common medical abbreviations and terminology. The technician must be extremely diligent and precise.

Technicians commonly prepare insurance claim forms. This requires the same familiarity with terminology as preparing medication profiles, plus familiarity with insurance claims procedures.

Technicians routinely clean and maintain equipment, including computers and dispensing machinery. Because the cleaning process prevents medication from becoming contaminated by other drugs, this task requires extreme thoroughness.

In some work locations, the technician may be expected to serve as a cashier. This requires knowledge of cash register operation and additional diligence.

Work settings

Pharmacy technicians work in a pharmacy. Seventy percent work in retail pharmacies, either independent stores or those that are part of chains. The stores may be drug stores or supermarkets that contain a pharmacy. Most other pharmacy technicians work in hospitals, although a small percentage may find employment with wholesale pharmacies, clinics, or in other settings.

Pharmacy technicians normally work as part of a team, under the direction of one licensed pharmacist, with another technician or other unlicensed person. Most states limit the ratio of technicians or other unlicensed personnel who can be supervised by a single pharmacist. The most common ratio is two unlicensed people to one pharmacist, but this may vary. Other possible team members include cashiers, pharmacy interns, graduates of a college of pharmacy who have not yet been licensed, and pharmacy aides, who may do some of the stock and inventory work but do not prepare medication orders.

Hours are variable, and may include evenings, nights, week-ends, and holidays.

The physical work-load depends on circumstances, and may be very light, or may require heavy lifting.

Education and training

Training varies by state, with many states having no requirements for pharmacy technician training. California requires a formal 240-hour training program with at least 120 hours devoted to lecture, rather than on-the-job training, and a letter certifying completion of the program. Louisiana requires that all pharmacy technicians pass an examination given by the State, but does not specify how training is to be provided.

Some technical and community colleges offer courses leading to a career as a pharmacy technician, and in other places, labor unions have developed educational programs for their members. A typical program, such as the one described by the Indiana State Board of Pharmacy “includes **medical terminology** specific to the pharmacy, reading and interpreting prescriptions and defining drugs by brand name. Students receive a **phar-**

macology overview and learn dosage calculations, I.V. flow rates, drug compounding and dose conversions. Dispensing of prescriptions, inventory control, billing and reimbursement also are covered.”

A number of on-line programs and books are also available for technician training.

Although there are no formal education requirements, the Pharmacy Technician Certification Board (PTCB) administers a national certification examination. Admission to the certification examination requires a high school diploma or equivalent. Certification is not required for employment, but many employers prefer to hire certified technicians, and some states may require certification for employment in the future. Maintenance of certification requires participation in 10 hours each year of continuing education, at least one hour of which must be in the area of pharmacy law.

Advanced education and training

Pharmacy technicians may continue their studies and become pharmacists.

Future outlook

There are currently an estimated 170,000 to 200,000 pharmacy technicians in the United States, of which about 50,000 are certified. Although it has been estimated that the growth of this occupation will be no greater than average for all occupations, the current and projected shortage of licensed pharmacists may lead to increased job opportunities for trained technicians. This shortage, combined with an aging population and increased use of drug therapy, has led to recommendations that the ratio of technicians to pharmacists be increased.

Phlebography

Definition

Phlebography is an x-ray test that provides an image of the leg veins after a contrast dye is injected into a vein in the patient’s foot.

Purpose

Phlebography is primarily performed to diagnose deep vein thrombosis—a condition in which clots form in the veins of the leg that can lead to pulmonary embolism in which those clots break off, travel to the **lungs** and pulmonary artery. Phlebography can also be used to distinguish **blood** clots from obstructions in the veins, to evaluate congenital vein problems, to assess the function of the deep leg vein valves, and to identify a vein for arterial bypass grafting. Ultrasound has replaced phlebography in many cases; but phlebography is the “gold standard” or the best test by which others are judged, but not used as a standard practice.

Precautions

Phlebography is usually not performed in patients with kidney (renal) problems.

Description

Phlebography, also called venography, ascending contrast phlebography, or contrast phlebography, is an invasive diagnostic test that provides a constant image of leg veins on a **fluoroscope** screen. Phlebography identifies the location, extent, and degree of attachment of blood clots, and enables the condition of the deep leg veins to be assessed. It is especially useful when there is a strong suspicion of deep vein thrombosis, after noninvasive tests have failed to identify the disease.

Phlebography is the most accurate test for detecting deep vein thrombosis. It is nearly 100% sensitive and specific in making this diagnosis (pulmonary embolism is diagnosed in other ways). Accuracy is crucial since deep vein thrombosis can lead to pulmonary embolism, a condition that can be fatal.

A phlebography can show problems such as varicose veins. (Science Photo Library/Custom Medical Stock Photo. Reproduced by permission.)

Phlebography is not used often, however, because it is painful, expensive, exposes the patient to a fairly high dose of radiation, and can cause complications. In about 5% of cases, there are technical problems in conducting the test. In addition, the test is less accurate in diagnosing problems below the knee.

Phlebography takes between 30 to 45 minutes and can be done in a physician's office, a laboratory, or a hospital. During the procedure, the patient lies on a tilting x-ray table. The area where the catheter will be inserted is sometimes shaved, if necessary, and cleaned. Sometimes a local anesthetic is injected to numb the skin at the site of the insertion. A small incision may be required to make a point for insertion. The catheter is inserted and the contrast solution (or dye) is slowly injected. Injection of the dye causes a warm, flushing feeling in the leg that may spread through the body. The contrast solution may also cause slight nausea. About 18% of patients experience discomfort from the contrast solution.

In order to fill the deep venous system with dye, a tight band (tourniquet) may be tied around the ankle or below the knee of the side into which the dye is injected, or the lower extremities may be tilted. The patient is asked to keep the leg still. The doctor also observes the movement of the solution through the vein with a fluoroscope. At the same time, a series of x rays is taken. When the test is finished, fluid is injected to clear the dye from the veins, the catheter is removed, and a bandage is applied over the site of the injection.

Preparation

Fasting or drinking only clear liquids is necessary for four hours before the test, although the test may be done in an emergency even if the patient has eaten. The contrast solution contains iodine, to which some people are allergic. Patients who have **allergies** or hay **fever**, or have had a bad reaction to a contrast solution, should tell their doctor.

Aftercare

Patients should drink large amounts of fluids to flush the remaining contrast solution from their bodies. The area around the incision will be sore for a few days. If there is swelling, redness, **pain**, or fever, the doctor should be notified. Pain medication may be needed. In most cases, the patient can resume normal activities the next day.

Complications

Phlebography can cause complications such as phlebitis, tissue damage, and the formation of deep vein thrombosis in a healthy leg. A rare side effect in up to 8% of cases is a severe allergic reaction to the dye. This usually happens within 30 minutes after injection of the dye and requires medical attention.

Results

Normal phlebography results show proper blood flow through the leg veins.

Abnormal phlebography results show well-defined filling defects in veins. Findings include:

- blood clots
- consistent filling defects
- an abrupt end of a test dye column
- major deep veins that are unfilled
- dye flow that is diverted (These results confirm a diagnosis of deep vein thrombosis.)

KEY TERMS

Contrast solution—A liquid dye injected into the body that allows veins to be seen by x rays. Without the dye, the veins could not be seen on x rays.

Deep vein thrombosis—The development or presence of a blood clot in a vein deep within the leg. Deep vein thrombosis can lead to pulmonary embolism.

Invasive—A diagnostic test that invades healthy tissue; in the case of phlebography, through an incision in a healthy vein.

Pulmonary embolism—An obstruction of a blood vessel in the lungs, usually due to a blood clot that blocks a pulmonary artery. Pulmonary embolism can be very serious and in some cases is fatal.

Health care team roles

A phlebography is generally performed in a hospital, or in an outpatient or freestanding facility. A qualified x-ray lab technician, nurse, or doctor might perform the test, with a radiologist reading or interpreting the results that are presented to the patient either directly, or through the primary care physician. Because the patient will be asked to lie on the x-ray table and a vein is punctured in order for the test to be taken, an attending nurse or other medical assistant in addition to the person performing the test should be present to assist when necessary. A professional will be prepared to handle any possible complication, especially if a patient experiences an allergic reaction to the test medium.

Phosphorus

Description

Phosphorus (chemical symbol P) is a mineral discovered by the German alchemist Henig Brand in 1699. It plays an essential part in multiple biochemical reactions for both plants and animals and is essential to all life. Phosphorus is found in living things, in soil and rock, mostly as chemical compounds known as phosphates. Rock and soil phosphorus are mined extensively throughout the world, but especially in the Peoples' Republic of China and the United States.

Phosphorus extracted from rock is classified as either white, red or black. White (also called yellow or common) phosphorus is a wax-like substance created by heating phosphate rock until it vaporizes and the condensation solidifies. One of this form's characteristics has given the English language the adjective *phosphorescent*, from white phosphorus's capacity to glow in the dark when exposed to air.

White phosphorus is highly toxic, causes **burns** if it comes in contact with skin, and is so combustible that it has to be stored underwater for safety. Red phosphorus is a rust-colored powder created by heating white phosphorus and exposing it to sunlight. It is not as combustible as the white form. Black phosphorus is made by heating white phosphorus under extremely high pressure until it resembles graphite.

In plants, phosphorus is necessary for photosynthesis to take place. In the human body, phosphorus works in tandem with another element, **calcium**, in much the same way that two other electrolyte components, sodium

KEY TERMS

Anorexia nervosa—A serious and sometimes fatal eating disorder characterized by intense fear of being fat and severe weight loss. It primarily affects teenage and young adult females. Sufferers have a distorted body image wherein they see themselves as being fat even when they are at normal weight or even emaciated.

Bulimia—An eating disorder characterized by bouts of gross overeating usually followed by self-induced vomiting.

Calcitonin—A hormone produced by the thyroid gland that controls the calcium level in the blood. It does this by slowing the rate that calcium is lost from bone.

Deciliter—A fluid measurement that is equal to one-tenth of a liter, or 100 cubic centimeters (27 fluid drams or teaspoons).

Diabetic ketoacidosis—A potentially serious condition in which ketones become present in the blood stream because of the metabolism of fats burned in lieu of carbohydrates that would normally be used. This occurs because there is insufficient insulin available to cause carbohydrates to be used as fuel.

Electrolyte—Substances that split into ions, or elec-

trically-charged particles, within the body to regulate many important bodily processes. Examples of electrolytes would be sodium, potassium, hydrogen, magnesium, calcium, bicarbonate, phosphates, and chlorides.

Multiple endocrine neoplasia—Tumor formation characterized by a progressive, abnormal multiplication of cells that are not necessarily malignant in any of the glands that secrete chemicals directly into the blood stream, such as the thyroid gland, adrenal glands, or ovaries.

Osteomalacia—Softening, weakening, and removal of the minerals from bone in adults caused by vitamin D deficiency.

Osteoporosis—Loss of formative protein tissue from bone, causing it to become brittle and easily fractured. It is considered to be a normal part of aging, but does have hormonal causes that make it much more common in women than men.

Sarcoidosis—A rare disease of currently unknown cause that occurs mostly in young adults. Inflammation occurs in the lymph nodes and other tissues throughout the body, usually including the lungs, liver, skin, and eyes.

and potassium, do. Though phosphorus is found in every cell of the human body and accounts for 1% of the body's total weight, its primary function is working in conjunction with calcium to form teeth and bones.

Eighty-five percent of the phosphorus found in the body is located in these structures. In a delicately balanced chemical reaction, substances known as PTH (parathyroid hormone), calcitonin, and 25-dihydroxy **vitamin D** regulate the absorption of both calcium and phosphorus from the intestinal tract, thus making it available for the production of bones and teeth. If an excessive amount of phosphorus is absorbed, this will result in the phosphorus combining with all available calcium and preventing the calcium's efficient use in making and maintaining bones and teeth.

PTH balances the proportions of calcium and phosphorus in the body by increasing the release of calcium and phosphate from bone and the loss of phosphorus via the **kidneys** while limiting the excretion of calcium. PTH also increases the activity of the 25-dihydroxy vitamin D,

which, in contrast, increases the absorption of both phosphorus and calcium from the intestinal tract.

General use

White phosphorus is a component of fertilizers, detergents and water softeners. It is also used in the manufacture of steel, plastics, insecticides, medical drugs, and animal feeds. Both white and red phosphorus are used in the making of safety matches and pesticides, including rat poison.

But the 15% of this element found in the **blood** stream and in other soft tissue also has a highly significant part to play in a variety of other body functions. Working with vitamin B, phosphorus is involved in the **metabolism of fats and carbohydrates**, in both the repair of damaged cells and tissues and the routine maintenance of healthy ones. Phosphorus is necessary for the regularity of the heartbeat, and aids in the contraction of all other muscles throughout the body. Phosphorus is needed for the functioning of the kidneys and plays a part in the conduction of impulses along the network that makes up the nervous system.

Preparations

According to the American Dietetic Association, phosphorus intake in the United States is generally above what is needed, and in recent years has actually increased. Therefore, under normal circumstances with normal food intake, there is seldom if ever a need to supplement intake of phosphorus. Persons suffering from eating disorders such as anorexia and bulimia can be deficient in phosphorus intake as well as other nutrients. As the best source of phosphorus is in protein foods such as meat, eggs, and milk products. Some vegetarians may also need to evaluate their intake of this element. Excess consumption of processed foods, and inadequate intake of whole foods, plus fertilizers and pesticides are some of the causes for excess phosphorus.

Beside high-protein foods, phosphorus is also found in decreasing quantities in whole grain breads and cereals, especially unprocessed ones, and in minute amounts in fruits and vegetables. The phosphorus present in whole grain breads and cereals, however, exists as a substance called phytin. Phytin combines with calcium to create a salt that the human body is incapable of absorbing, thus making unprocessed, unenriched grains a negligible source of phosphorus. But both commercially prepared cereals and breads may provide this element as they are frequently enriched with it. Phosphates can also be taken by mouth as a tablet.

Precautions

White phosphorus is poisonous. Red phosphorus is not. As noted, white phosphorus is a highly toxic, flammable substance capable of burning the skin if it makes contact, and of igniting at room temperature. It should be handled with extreme care. Accidental phosphorus **poisoning** can happen from both fertilizers and pesticides. Phosphates sometimes are leached into water systems through sewage and can drastically alter the chemical makeup of lakes and rivers. In sufficient quantities, they can lead to the death of nearly all forms of aquatic life.

A normal blood serum level of phosphorus is 2.4–4.1 mg per deciliter of blood. An abnormal serum phosphorus level should be evaluated by a physician.

Phosphorus levels higher than normal can indicate a diet that includes an excessive phosphorus intake, inadequate intake of calcium, or lack of PTH (parathyroid hormone) in the system. It can be related to bone metastasis associated with **cancer, liver** or kidney disease, or sarcoidosis.

Serum phosphorus levels that are below normal can be related to insufficient phosphorus or vitamin D in one's diet leading to rickets in children and osteomalacia in adults. Disorders of the parathyroid gland, causing it to secrete excessive quantities of PTH, or of the **pancreas**, causing it to secrete too much insulin, also affect blood levels of phosphorus. Diabetic ketoacidosis or too much calcium are other possible causes. Multiple endocrine neoplasia (MEN) is yet another condition that often is associated with lower than normal levels of phosphorus.

Side effects

Phosphorus preparations taken to supplement low phosphorus levels in the body can cause **diarrhea**.

Interactions

Antacids can decrease the absorption of phosphorus. **Laxatives** and **enemas** that contain the chemical compound sodium phosphate and excessive intake of vitamin D can increase phosphorus levels in the body. Administration of intravenous glucose solutions will cause phosphorus to combine with the glucose that is being absorbed by the cells.

Phototherapy

Definition

Phototherapy, or light therapy, is the administration of doses of bright light in order to treat a variety of disorders. It is most commonly used to re-regulate the body's internal clock and/or relieve depression.

Origins

Light, both natural and artificial, has been prescribed throughout the ages for healing purposes. Sunlight has been used medicinally since the time of the ancient Greeks; Hippocrates, the father of modern medicine, prescribed exposure to sunlight for a number of illnesses. In the late nineteenth and early twentieth centuries, bright light and fresh air were frequently prescribed for a number of mood and **stress** related disorders. In fact, prior to World War II, hospitals were regularly built with solariums, or sun rooms, in which patients could spend time recuperating in the sunlight.

In the 1980s, phototherapy began to make an appearance in the medical literature as a treatment for seasonal affective disorder, or SAD. Today, it is widely recognized as a front-line treatment for the disorder.

Benefits

Phototherapy is most often prescribed to treat seasonal affective disorder, a form of depression most often associated with shortened daylight hours in northern latitudes from the late fall to the early spring. It is also occasionally employed to treat sleep-related disorders such as insomnia and jet lag.

When used for SAD treatment, phototherapy has several advantages over prescription antidepressants. Phototherapy tends to work faster than medications, alleviating depressive symptoms within two to 14 days after beginning phototherapy as opposed to an average of four to six weeks with medication. And unlike antidepressants, which can cause a variety of side effects from nausea to concentration problems, phototherapy is extremely well tolerated. Some side effects are possible with light but are generally not serious enough to cause discontinuation of the therapy.

There are several other different applications for phototherapy, including:

- Full-spectrum/UV phototherapy for disorders of the skin. A subtype of phototherapy that is often prescribed to treat skin diseases, rashes, and jaundice.

- Cold laser therapy. The treatment involves focusing very low-intensity beams of laser light on the skin, and is used in laser acupuncture to treat a myriad of symptoms and illnesses, including **pain**, stress, and tendinitis.
- Colored phototherapy. In colored phototherapy, different colored filters are applied over a light source to achieve specific therapeutic effects. The colored light is then focused on the patient, either with a floodlight which covers the patient with the colored light, or with a beam of light that is focused on the area of the illness.
- Back of knee phototherapy. A 1998 report published in the journal *Science* reported that the area behind the human knee known as the popliteal region contains photoreceptors which can help adjust the body's circadian rhythms. The authors of the study found that they could manipulate circadian rhythms by focusing a bright light on the popliteal region. Further studies are needed to determine the efficacy of this treatment on disorders such as SAD and jet lag.

Description

Phototherapy is generally administered at home. The most commonly used phototherapy equipment is a portable lighting device known as a light box. The light box may be a full spectrum box, in which the lighting element contains all wavelengths of light found in natural light (including UV rays), or it may be a bright light box, in which the lighting element emits non-UV white light. The box may be mounted upright to a wall, or slanted downwards towards a table.

The patient sits in front of the box for a prescribed period of time (anywhere from 15 minutes to several hours). For patients just starting on the therapy, initial sessions are usually only 10–15 minutes in length. Some patients with SAD undergo phototherapy session two or three times a day, others only once. The time of day and number of times treatment is administered depends on the physical needs and lifestyle of the individual patient. If phototherapy has been prescribed for the treatment of SAD, it typically begins in the fall months as the days begin to shorten, and continues throughout the winter and possibly the early spring. Patients with a long-standing history of SAD are usually able to establish a time-table or pattern to their depressive symptoms, and can initiate treatment accordingly before symptoms begin.

The light from a slanted light box is designed to focus on the table it sits upon, so patients may look down to read or do other sedentary activities during therapy. Patients using an upright light box must face the light source, and should glance toward the light

A seasonal affective disorder sufferer sits next to full-spectrum light box. (A/P Wide World Photos. Reproduced by permission.)

source occasionally without staring directly into the light. The light sources in these light boxes typically range from 2,500–10,000 lux (in contrast, average indoor lighting is 300–500 lux; a sunny summer day is about 100,000 lux).

Light boxes can be purchased for between \$200 and \$500. Some health care providers and healthcare supply companies also rent the fixtures. This gives a patient the opportunity to have a trial run of the therapy before making the investment in a light box. Recently, several new light box products have become available. Dawn simulators are lighting devices or fixtures that are programmed to gradually turn on, from dim to bright light, to simulate the sunrise. They are sometimes prescribed for individuals who have difficulty getting up in the morning due to SAD symptoms. Another device, known as a light visor, was designed to give an individual more mobility during treatment. The visor is a lighting apparatus that is worn like a sun visor around the crown of the head. Patients with any history of eye problems should consult their health care professional before attempting to use a light visor.

Preparations

Full-spectrum light boxes do emit UV rays, so patients with sun-sensitive skin should apply a sun screen before sitting in front of the box for an extended period of time.

Precautions

Patients with eye problems should see an ophthalmologist regularly both before and during phototherapy. Because UV rays are emitted by the light box, patients taking photosensitizing medications should consult with their healthcare provider before beginning treatment. In addition, patients with medical conditions that make them sensitive to UV rays should also be seen by a healthcare professional before starting phototherapy.

Patients beginning phototherapy for SAD may need to adjust the length, frequency, and timing of their phototherapy sessions in order to achieve the maximum benefits. Patients should keep their healthcare provider informed of their progress and the status of their depressive symptoms. Occasionally, additional treatment measures for depression (i.e., antidepressants, herbal reme-

KEY TERMS

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Seasonal affective disorder—SAD is a mood disorder characterized by depression during the winter months. An estimated 4–6% of the U.S. population suffers from SAD.

dies, **psychotherapy**) may be recommended as an adjunct, or companion treatment, to phototherapy.

Side effects

Some patients undergoing phototherapy treatments report side effects of eyestrain, headaches, insomnia, fatigue, sunburn, and dry eyes and nose. Most of these effects can be managed by adjusting the timing and duration of the phototherapy sessions. A strong sun block and eye and nose drops can alleviate the others. Long-term studies have shown no negative effects to eye function of individuals undergoing phototherapy treatment.

A small percentage of phototherapy patients may experience hypomania, a feeling of exaggerated, hyper-elevated mood. Again, adjusting the length and frequency of treatment sessions can usually manage this side effect.

Research and general acceptance

Phototherapy is widely accepted by both traditional and complementary medicine as an effective treatment for SAD. The exact mechanisms by which the treatment works are not known, but the bright light employed in phototherapy may act to readjust the body's circadian rhythms, or internal clock. Other popular theories are that light triggers the production of serotonin, a neurotransmitter believed to be related to **depressive disorders**, or that it influences the body's production of melatonin, a hormone that may be related to circadian rhythms.

Wide spectrum UV light treatment for skin disorders such as psoriasis is also considered a standard treatment option in clinical practice. However, other light-related treatments such as cold laser therapy and colored phototherapy are not generally accepted, since few or no scientific studies exist on the techniques.

Training and certification

Psychiatrists, psychologists, and other mental health-care professional prescribe phototherapy treatment for

SAD. Holistic health care professionals and light therapists who specialize in this treatment are also available; in some states, these professionals require a license, so individuals should check with their state board of health to ensure their practitioner has the proper credentials. Phototherapy for skin disorders should be prescribed by a dermatologist or other healthcare professional with expertise in skin diseases and phototherapy treatment.

Physical development in children see
Human growth and development

Physical examination

Definition

A physical examination is the evaluation of a body to determine its state of health. The techniques of inspection, palpation (feeling with the hands), percussion (tapping with the fingers), auscultation (listening), and **smell** are used. A complete health assessment also includes gathering information about a person's medical history and lifestyle, conducting laboratory tests, and screening for disease. These elements constitute the data on which a diagnosis is made and a plan of treatment is developed.

Purpose

The term annual physical examination has been replaced in most health care circles by periodic health examination. The frequency with which it is conducted depends on factors such as the age, gender, and the presence of risk factors for disease in the person being examined. Health care professionals often use guidelines that have been developed by organizations such as the United States Preventative Services Task Force. Organizations such as the American Cancer Society or American Heart Association, which promote detection and prevention of specific diseases, generally recommend more intensive or frequent examinations or that examinations be focused on particular organ systems of the body.

Comprehensive physical examinations provide opportunities for health care professionals to obtain baseline information about individuals that may be useful in the future. They also allow health care providers to establish relationships before problems occur. Physical examinations are appropriate times to answer questions and teach good health practices. Detecting and addressing problems in their early stages can have beneficial long-term results.

Precautions

The individual being examined should be comfortable and treated with respect throughout the examination. As the examination continues, the examiner should explain what they are doing and share any relevant findings. Using language appropriate to the person being examined improves the effectiveness of communications and ultimately fosters better relations between examiners and examinees.

Description

A complete physical examination usually starts at the head and proceeds all the way to the toes. However, the exact procedure will vary according to the needs of the person being examined and the preferences of the examiner. An average examination takes about 30 minutes. The cost of an examination will depend on the charge for the professional's time and any tests that are included. Most health plans cover routine physical examinations including some tests.

The examination

Before examiners even speak, they will observe a person's overall appearance, general health, and behavior. Measurements of height and weight are made. **Vital**

A doctor examines the abdomen of a young man. (*Science Source/Photo Researchers. Reproduced by permission.*)

signs such as pulse, breathing rate, body temperature, and **blood pressure** are recorded.

With the person being examined in a sitting position, the following systems are reviewed:

- **Skin.** The exposed areas of the skin are observed. The size and shape of any lesions are noted.
- **Head.** The hair, scalp, **skull**, and face are examined.
- **Eyes.** The external structures are observed. The internal structures can be observed using an ophthalmoscope (a lighted instrument) in a darkened room.
- **Ears.** The external structures are inspected. A lighted instrument called an **otoscope** may be used to inspect internal structures.
- **Nose and sinuses.** The external nose is examined. The nasal mucosa and internal structures can be observed with the use of a penlight and a nasal speculum.
- **Mouth and pharynx.** The lips, gums, teeth, roof of the mouth, tongue, and pharynx are inspected.

Measuring infant head circumference. (Delmar Publishers, Inc. Reproduced by permission.)

- Neck. The lymph nodes on both sides of the neck and the **thyroid gland** are palpated (examined by feeling with the fingers).
- Back. The spine and muscles of the back are palpated and checked for tenderness. The upper back, where the **lungs** are located, is palpated on the right and left sides and a **stethoscope** is used to listen for breath sounds.
- Breasts and armpits. A woman's breasts are inspected with the arms relaxed and then raised. In both men and women, the lymph nodes in the armpits are felt with the examiner's hands. While the person is still sitting, movement of the joints in the hands, arms, shoulders, neck, and jaw can be checked.

While the person is lying down on the examining table, the examination includes:

- Breasts. The breasts are palpated and inspected for masses.
- Front of chest and lungs. The area is inspected with the fingers, using palpation and percussion. A stethoscope is used to listen to internal breath sounds.

The head should be slightly raised for:

- Heart. A stethoscope is used to listen to the heart's rate and rhythm. The **blood vessels** in the neck are observed and palpated.

The person being examined should lie flat for:

- Abdomen. Light and deep palpation is used on the abdomen to feel the outlines of internal organs includ-

ing the **liver**, spleen, **kidneys**, and aorta, a large **blood vessel**.

- Rectum and anus. With the person lying on the left side, the outside areas are observed. An internal digital examination (using a gloved finger), is usually done for persons over 40 years old. In men, the prostate gland is also palpated.
- Reproductive organs. The external sex organs are inspected and the area is examined for hernias. In men, the scrotum and testicles are palpated. In women, a pelvic examination is completed using a speculum and a Papanicolaou test (Pap test) may be taken.
- Legs. While lying flat, the legs are inspected for swelling, and pulses in the knee, thigh, and foot area are found. The groin area is palpated for the presence of lymph nodes. The joints and muscles are observed.
- Musculoskeletal system. With the person standing, the straightness of the spine and the alignment of the legs and feet is noted.
- Blood vessels. The presence of any abnormally enlarged veins (varicose), usually in the legs, is noted.

In addition to evaluating a person's alertness and mental ability during the initial conversation, additional inspection of the nervous system may be conducted:

- Neurologic screen. The person's ability to take a few steps, hop, and do deep knee bends is observed. The strength of the hand grip is felt. While sitting in an upright position, the **reflexes** in the knees and feet can be tested with a small hammer. The sense of touch in the hands and feet can be evaluated by testing reaction to **pain** and vibration.
- Sometimes additional time is spent examining the 12 nerves in the head (cranial) that are connected directly to the **brain**. They control the senses of smell and **taste**, strength of muscles in the head, reflexes in the eye, facial movements, gag reflex, **vision**, **hearing**, and muscles in the jaw. General muscle tone and coordination, and the reaction of the abdominal area to stimulants like pain, temperature, and touch may also be evaluated.

Preparation

Before visiting a health care professional, individuals should write down important facts and dates about their own medical history, as well as those of family members. There should be a complete listing of all medications and their dosages. This list should include over-the-counter preparations, **vitamins**, and herbal supplements. Some people bring their bottles of medications

with them. Any questions or concerns about medications should be written down.

Before the physical examination begins, the bladder should be emptied. A urine specimen is usually collected in a small container at this time. The urine is tested for the presence of glucose (sugar), protein, and blood cells. For some blood tests, individuals may be told ahead of time not to eat or drink after midnight.

Individuals being examined usually remove all clothing and put on a loose-fitting hospital gown. An additional sheet is provided to keep persons covered and comfortable during the examination.

Aftercare

Once a physical examination has been completed, the person being examined and the examiner should review what laboratory tests have been ordered, why they have been selected, and how the results will be shared with the patient. A health professional should discuss any recommendations for treatment and follow-up visits. Special instructions should be put in writing. This is also an opportunity for persons to ask any remaining questions about their own health concerns.

Complications

Complications with the process of a physical examination are unusual. Occasionally, a useful piece of information or data may be overlooked. More commonly, results of associated laboratory tests compel physicians to recheck an individual or to re-examine portions of the body already reviewed. In a sense, complications may arise from the findings of a physical examination. These usually trigger further investigations or initiate treatment. They are really more beneficial than negative as they often begin a process of treatment and recovery.

Results

Normal results of a physical examination correspond to the healthy appearance and normal functioning of the body. For example, appropriate reflexes will be present, no suspicious lumps or lesions will be found, and vital signs will be normal.

Abnormal results of a physical examination include any findings that indicate the presence of a disorder, disease, or underlying condition. For example, the presence of lumps or lesions, **fever**, muscle weakness or lack of tone, poor reflex response, heart arrhythmia, or swelling of lymph nodes will indicate possible health problems.

KEY TERMS

Auscultation—The process of listening to sounds that are produced in the body. Direct auscultation uses the ear alone, such as when listening to the grating of a moving joint. Indirect auscultation involves the use of a stethoscope to amplify sounds from within the body, such as those coming from the heart or intestines.

Hernia—The bulging of an organ, or part of an organ, through the tissues normally containing it; also called a rupture.

Inspection—The visual examination of the body using the eyes and a lighted instrument if needed. The sense of smell may also be used.

Ophthalmoscope—Lighted device for studying the interior of the eyeball.

Otoscope—An instrument with a light for examining the internal ear.

Palpation—The examination of the body using the sense of touch. There are two types: light and deep.

Percussion—An assessment method in which the surface of the body is struck with the fingertips to obtain sounds that can be heard or vibrations that can be felt. It can determine the position, size, and consistency of an internal organ. It is performed over the chest to determine the presence of normal air content in the lungs, and over the abdomen to evaluate air in the loops of the intestine.

Reflex—An automatic response to a stimulus.

Speculum—An instrument for enlarging the opening of any canal or cavity in order to facilitate inspection of its interior.

Stethoscope—A Y-shaped instrument that amplifies body sounds such as heartbeat, breathing, and air in the intestine. Used in auscultation.

Varicose veins—The permanent enlargement and twisting of veins, usually in the legs. They are most often seen in people working in occupations requiring long periods of standing, and in pregnant women.

Health care team roles

When considering a physical examination, the leader of a health care team is usually an examining physician,

although **advanced practice nurses** and physician assistants also perform the procedures. This individual has the responsibility for coordinating and interpreting the results of any needed laboratory tests and managing any post-examination activities or treatment. A physician assistant may perform some components of a routine physical examination. A nurse may assist in aspects of many examinations. Laboratory technicians collect and analyze bodily samples such as blood, urine, sputum and tissue. They supply data to an examining physician for analysis and interpretation.

Physical therapy

Definition

Physical therapists provide services to restore function, improve mobility, relieve **pain**, and prevent or limit permanent physical disabilities among those suffering from injuries, disabilities, or disease.

Description

Organized physical therapy began during World War I with 800 reconstruction aides. Today there are more

than 80,000 licensed physical therapists in the United States.

Physical therapists treat patients with a variety of health conditions and diseases including accident victims and individuals with disabling conditions such as low back pain, arthritis, **heart** disease, **fractures**, head injuries, and **cerebral palsy**.

In an effort to restore, maintain, and promote overall fitness and health, physical therapists examine patients' medical histories, as well as test and measure patients' strength, range of motion, balance, coordination, posture, muscle performance, respiration, and motor function. Physical therapists determine patients' ability to be independent and reintegrate into the community or workplace. Based on a patient's medical history and test results, physical therapists develop treatment plans that describe treatment strategy, purpose, and anticipated outcome.

A physical therapist's treatment often includes **exercise** for patients who have been immobilized or who lack flexibility, strength, or endurance. As part of the treatment, physical therapists encourage patients to improve flexibility, range of motion, strength, balance, coordination, and endurance. The goal is to improve an individual's function at work and home.

Physical therapists may use electrical stimulation, hot packs, cold compresses, or ultrasound to relieve pain and reduce swelling. They may use traction or deep-tissue massage to relieve pain. Therapists also teach patients to use assistive and adaptive devices including crutches, prostheses, and wheelchairs. They may also show patients how to perform exercises to do at home.

During treatment, physical therapists document the patient's progress, conduct periodic examinations, and modify treatments when necessary. Physical therapists rely on this documentation to track the patient's progress and identify areas requiring more or less attention.

Physical therapists often consult and practice with physicians, dentists, nurses, educators, social workers, occupational therapists, speech-language pathologists, and audiologists.

Some physical therapists treat a wide range of ailments while others specialize in areas such as pediatrics, geriatrics, orthopedics, sports medicine, neurology, and cardiopulmonary physical therapy.

Physical therapist assistants and aides

Physical therapist assistants, under the direction and supervision of a physical therapist, may be involved in implementing patient treatment plans. For example, physical therapist assistants perform treatment proce-

A patient on a physical therapy machine. (UPI/Corbis Bettmann. Reproduced by permission.)

dures including exercises, massages, electrical stimulation, paraffin baths, hot and cold packs, traction, and ultrasound. Physical therapist assistants record patients' treatment responses and report these responses to the physical therapist.

Physical therapist aides work under the direct supervision of a physical therapist or a physical therapist assistant. Aides help make therapy sessions productive and are often responsible for keeping the treatment area clean and organized, preparing for each patient's therapy, and assisting patients who need help in moving to or from a treatment area. Because they are not licensed, aides are only able to perform a limited range of tasks.

Physical therapist aides' duties include clerical tasks such as ordering supplies, answering the phone, filling out insurance forms, and other paperwork. The extent of an assistant's or an aide's clerical responsibilities depend on the size and location of the facility.

Work settings

Physical therapists practice in hospitals, clinics, and private offices. They may also treat patients in the patient's home or at school.

Most physical therapists work a 40-hour week, which may include some evenings and weekends depending on their patients' schedules. The job can be physically demanding, because therapists often have to stoop, kneel, crouch, lift, or stand for long periods of time. In addition, physical therapists move heavy equipment, lift patients, or help them turn, stand, or walk.

In 1998, approximately 75% of the physical therapists employed in approximately 120,000 jobs worked full time. Approximately 10% of physical therapists held more than one job.

Over two-thirds of physical therapists are employed in either hospitals or physical therapists' offices. Other work settings include home health agencies, outpatient rehabilitation centers, physicians' offices and clinics, and **nursing homes**. Some physical therapists maintain a private practice and provide services to individual patients or contract to provide services in hospitals, rehabilitation centers, nursing homes, home health agencies, adult day-care programs, or schools. They may be engaged in individual practice or be part of a consulting group. Some physical therapists teach in academic institutions and conduct research.

Physical therapist assistants and aides

Physical therapist assistants and aides work varying schedules, depending on the facility and whether they are full or part-time employees. To accommodate patients' schedules, many outpatient physical therapy offices and clinics remain open during evenings and weekends.

Physical therapist assistants and aides are required to have a moderate degree of strength due to the physical exertion needed in assisting patients with their treatment. In some cases, for example, assistants and aides help lift patients. In addition, these jobs typically require a good deal of kneeling, stooping, and standing for long periods.

Physical therapist assistants and aides held 82,000 jobs in 1998. Although they work alongside physical therapists in a variety of settings, over two-thirds of all assistants and aides work in hospitals or physical therapists' offices. Other assistants and aides work in nursing and personal care facilities, outpatient rehabilitation centers, physicians' offices and clinics, and home health agencies.

Education and training

Before they can practice, physical therapists are required to pass a licensure exam after graduating from an accredited physical therapist educational program.

According to the American Physical Therapy Association, in 1999 there were 189 accredited physical therapist programs. Of the accredited programs, 24 offered bachelor's degrees, 157 offered master's degrees, and eight offered doctoral degrees. By 2002, the Commission on Accreditation in Physical Therapy Education will require all physical therapist programs seeking accreditation to offer degrees at the post-baccalaureate level.

Physical therapist programs start with basic science courses such as biology, chemistry, and physics, followed by specialized courses such as biomechanics, neuroanatomy, **human growth and development**, manifestations of disease, examination techniques, and therapeutic procedures. Besides classroom and laboratory instruction, students receive supervised clinical experience.

Admission to physical therapist education programs is very competitive. Interested students may improve their admission potential by attaining superior grades, especially in science courses. Interested students should take courses such as anatomy, biology, chemistry, social science, mathematics, and physics. Before granting admission, many programs require that the student at least have experience as a volunteer in a hospital or clinic physical therapy department.

Physical therapists need strong interpersonal skills to successfully educate patients about their physical therapy treatments and to interact with the patient's family. Therapists should also be compassionate and possess a desire to help patients.

Physical therapists are expected to remain current in their professional development by participating in continuing education courses and workshops. A number of states require continuing education to maintain licensure.

In 1998, physical therapists earned a median annual income of \$56,600. The lowest 10% earned less than \$35,700 while the highest 10% earned in excess of \$90,870 a year. Those in the middle 50% earned between \$44,460 and \$77,810 a year. In 1997, physical therapists' median annual earnings in the industries employing the largest number of physical therapists included home health care services, \$65,600; nursing and personal care facilities, \$60,400; health care practitioner offices, \$56,600; physicians' offices and clinics, \$55,100; and hospitals, \$50,100.

Physical therapist assistants and aides

Physical therapist assistants typically have earned an associate's degree from an accredited physical therapist assistant program. As of January 1997, 44 states and Puerto Rico regulated assistants. Physical therapist assistants are also required to have certifications in **CPR** and other **first aid**, along with a specified minimum number of hours of clinical experience. Physical therapist aides are also trained on the job.

In 1999, according to the American Physical Therapy Association, there were 274 accredited physical therapist assistant programs in the United States. Accredited physical therapist assistant programs are designed to last two years or four semesters. Those who successfully complete the program are awarded an associate's degree. Admission into physical therapist assistant programs is competitive. Programs are divided into academic study and hands-on clinical experience. Academic coursework includes algebra, anatomy, physiology, biology, chemistry, and psychology. Before students begin their clinical field experience, many programs require that they complete a semester of anatomy and physiology and have certifications in CPR and other first aid. Employers and educators view clinical experience as essential to ensuring that students understand the responsibilities of a physical therapist assistant.

Employers typically require physical therapist aides to have a high school diploma, strong interpersonal skills, and a desire to assist people in need. Most employers provide clinical on-the-job training.

Future outlook

Employment for physical therapists is expected to grow by 21–35% through 2008. For a variety of reasons, the demand for physical therapists should continue to rise. As the baby boom generation ages, the number of individuals with disabilities requiring therapy services should increase, as well as patients who will require cardiac and physical rehabilitation after a heart attack or stroke. In addition, the need for physical therapy will be increased as technological advances save the lives of a larger number of newborns with severe birth defects.

Future medical developments will also increase trauma victims' survival rate, thereby creating additional demand for rehabilitative care. Growth may also result from advances in medical technology which permit treatment of more disabling conditions.

Widespread interest in health promotion may also increase demand for physical therapy services. A growing number of employers are seeking the services of physical therapists to evaluate worksites, develop exercise programs, and teach safe work habits to employees in the hope of reducing injuries.

Physical therapist assistants and aides

Employment for physical therapist assistants and aides is expected to increase by at least 36% through the year 2008. As with the future outlook for physical therapists, the demand for physical therapist assistants and aides will continue to rise to keep pace with the increase in the number of individuals with disabilities and the rapidly growing elderly population, many of whom are particularly vulnerable to chronic and debilitating conditions that require therapeutic services. These patients often need additional assistance in their treatment, making the roles of assistants and aides vital. As the large baby-boom generation reaches the prime age for heart attacks and strokes, the demand for cardiac and physical rehabilitation will also increase. In addition, future medical developments should permit an increased percentage of trauma victims to survive, creating an additional demand for therapy services.

In 1998, physical therapist assistants and aides earned a median annual income of \$21,870. The lowest 10% earned less than \$13,760 while the highest 10% earned more than \$39,730 a year. The middle 50% earned between \$16,700 and \$31,260 a year. In 1997, the median annual income earned by physical therapist assistants and aides working in the industries employing the largest number of physical therapist assistants and aides included hospitals, \$21,200; health care practitioners offices,

\$20,700; and nursing and personal care facilities, \$19,200.

Physical therapy assisting

Definition

The professional field consists of skilled health care providers who work under the direction or supervision of a physical therapist or physical therapists. Their role is to facilitate care and treatment of patients with injuries, diseases, or disabilities that involve mobility or other basic physical functioning. Duties include patient instruction and monitoring, reporting progress and problems to the therapist, and providing or assisting in various forms of treatment.

Description

Physical therapy assisting is an adjunct to the profession of physical therapy and comprises workers with at least a two-year education and clinical experience. Physical therapist assistants (PTAs) are in the role of supporting the physical therapist by providing different types of patient treatment and education, and tracking patient progress. Some kinds of treatment PTAs can provide or assist with include massage, heat and cold therapy, traction, ultrasound, electrical stimulation, and helping patients learn and perform various therapeutic exercises. PTAs may also work with patients who need to

Physical therapy assistants help with many aspects of a patient's therapy under the supervision or direction of a physical therapist. (M. Goldstein/Custom Medical Stock Photo. Reproduced by permission.)

learn to use corrective equipment, such as braces or prostheses, wheelchairs or crutches, or other supportive devices. Other PTA responsibilities include organization and maintenance of treatment areas and equipment, and occasional performance of clerical tasks.

Patients with whom PTAs work may include children, the elderly, athletes, accident victims, and those with diseases like low back **pain**, arthritis, **cerebral palsy**, as well as people who have sustained **fractures** and head injuries. PTAs also assist people who need help managing pain and restoring, acquiring, or maintaining mobility and other functions. Coworkers may include physical therapists, other health care and rehabilitation professionals. Physical therapy aides also work with PTAs; aides perform a more limited range of functions, albeit similar, along with clerical, maintenance, and other supportive duties. Aides usually receive their training on the job.

Work settings

Physical therapy assistants may work in hospitals, private physical therapy offices, **nursing homes**, rehabilitation centers, sports facilities, schools, and other institutions. Some degree of bodily strength and endurance is necessary because of the physical handling of patients with limited mobility.

Education and training

A two-year associate's degree, usually from a community or junior college, is generally required. More than half of the states in the United States require licensure, registration, or an American Physical Therapy Association (APTA) certification. **Cardiopulmonary resuscitation** and **first aid** certification and clinical experience hours are also required, although the amount of hours varies by state.

Advanced education and training

Some PTAs may choose to complement their education by obtaining a baccalaureate degree in a related health field (APTA). The PTA curriculum does not meet the prerequisites for a physical therapy degree. PTAs, therefore, cannot directly advance to the status of physical therapist through supplementary education. There are programs, however, that help PTAs earn a master's degree in physical therapy while remaining employed as PTAs. PTAs who would like to participate in the clinical education of PTA students can also earn a Clinical Instructor Credentialing Certificate from the APTA.

Future outlook

According to the *Occupational Outlook Handbook (OOH)*, employment opportunities for PTAs (and physical therapy aides) are expected to grow faster than average through 2008, with the majority of the growth in the latter part of the period. Some of the reasons for expected growth are an increasing elderly population, the aging of the baby boom generation, and increased survival potential of trauma victims. In California, for example, physical therapy assistants and aides are in the Top Fifty Fastest Growth Occupations, as noted by California's Employment Development Department.

Pituitary gland

Definition

The pituitary gland is located at the base of the **brain** and is part of the **endocrine system**. It is sometimes called the hypophysis, from two Greek words that mean “to grow beneath.” The pituitary is responsible for the hormonal regulation of several body processes, including water retention, breast milk synthesis and release, human growth, and **thyroid gland** secretions.

Description

The pituitary is one of the most extensively researched glands in the endocrine system. In humans, it is located at the base of the brain just beneath the hypothalamus. There are three separate lobes (or sections) of the pituitary: the anterior lobe, the posterior lobe and the intermediate lobe. Therefore, it is sometimes considered as three different glands. In addition, there is a small stem called the pituitary stalk that connects the pituitary to the hypothalamus.

The pituitary gland is formed during early **fetal development**. An understanding of its formation explains its position in the endocrine system as well as its neurological importance. Early in the development of the fetus, a small sac of cells forms at the top of the oral cavity and moves upward. These cells are known as Rathke’s

pouch. At the same time, a small fold of neural tissue extends downward from the hypothalamus. During fetal development, the two structures continue to move toward each other; they meet and fuse to form the anterior (originally Rathke’s pouch) and posterior (from the hypothalamus) lobes of the pituitary.

The hypothalamus, which is located just above the pituitary gland, is a region in the forebrain that is responsible for regulating all lobes of the pituitary. The pituitary releases, but does not necessarily synthesize, nine different hormones. Neurohormones are synthesized by the hypothalamus and transported to the posterior pituitary. The release of hormones from each lobe of the pituitary is regulated differently.

Anterior pituitary

The anterior pituitary is sometimes called the adenohypophysis. It constitutes about 80% of the pituitary by weight. The cells of the anterior pituitary act like true endocrine cells. Instead of containing **neurons**, the anterior pituitary receives chemical signals through the **blood** and releases hormones in response. It has a direct connection with the hypothalamus through **blood vessels**. Various cells in the anterior pituitary release the following hormones:

- Gonadotrophs release luteinizing hormone (LH) and follicle-stimulating hormone (FSH).
- Lactotrophs release prolactin (PRL).
- Corticotrophs release adrenocorticotrophic hormone (ACTH).
- Somatotrophs release growth hormone (GH).
- Thyrotrophs release thyroid-stimulating hormone (TSH).

Posterior pituitary

The posterior pituitary is sometimes referred to as the neurohypophysis because it acts like an extension of the nervous system. As opposed to the anterior pituitary, which is connected to the hypothalamus via the circulatory system, the posterior pituitary receives nerve impulses from the same nerve cells that innervate the hypothalamus. The posterior pituitary releases oxytocin and antidiuretic hormone (ADH, or vasopressin).

Intermediate pituitary

The intermediate lobe is not a complete “lobe” in humans. Instead it is a simple structure comprised of just a few cells. The intermediate pituitary is an important structure in many lower vertebrates, but it has very little significance in humans. In lower vertebrates, the inter-

KEY TERMS

Acromegaly—Abnormal enlargement of such parts of the body as the hands, face, head, and feet.

Adenohypophysis—Another name for the anterior lobe of the pituitary.

Antidiuretic hormone (ADH)—A hormone released by the posterior lobe of the pituitary gland that increases the absorption of water by the kidneys. It is also known as vasopressin.

Diabetes insipidus—A disorder characterized by increased urine production resulting from inadequate levels of ADH.

Gonadotropins—Hormones that affect the development or activity of the ovaries or testes.

Hypophysis—Another name for the pituitary gland.

Hypopituitarism—A condition produced by deficient activity of the anterior lobe of the pituitary gland. It is characterized by obesity, incomplete sexual maturation, and in extreme cases, dwarfism.

Hypothalamus—A region in the forebrain that regulates the functions of the autonomic nervous system by vascular communication. The hypothalamus governs the functions of both lobes of the pituitary gland.

Neurohypophysis—Another name for the posterior lobe of the pituitary.

Oxytocin—A hormone produced by the posterior pituitary that stimulates the movement of breast milk from the sacs in which the milk is produced to the larger ducts from which the milk is ejected.

Peptide—A compound containing two or more amino acids, in which the carboxyl group of one acid is linked to the amino group of the other.

Vasopressin—Another name for ADH.

mediate pituitary releases melanocyto-stimulating hormone. This hormone stimulates the growth of melanocytes, which are cells that produce a dark pigment called melanin.

Function

The pituitary gland is an organ that is part of the endocrine system, along with many other glands and

organs. It is regulated by the hypothalamus, and it in turn regulates the secretion of many different hormones that are essential to human health.

Role in human health

Hormones released from the anterior and posterior pituitary have far-reaching effects on many different organ systems and physiological processes.

Hormones of the anterior pituitary

Luteinizing hormone and follicle stimulating hormone are called gonadotropins. As the name suggests, the target tissues of these hormones are the gonads (ovaries and testes). They have two main functions. The first is to promote the development and maturation of sperm and eggs. Second, they stimulate the production and release of such sex steroid hormones as estradiol and testosterone in women and men respectively.

Prolactin is responsible for stimulating cells in the female breast to produce milk. Therefore, lactotrophs located in the anterior pituitary of women that are breastfeeding are large and numerous, indicating an increased amount of prolactin production. These lactotrophs comprise about 30% of the cells in the anterior pituitary. The pituitary in women doubles in size during **pregnancy** because of the increase in size and number of lactotrophs.

The target tissue of adrenocorticotrophic hormone is the adrenal cortex (part of the adrenal gland that is located above the kidney). ACTH stimulates the production of cortisol and also causes the cells of the adrenal gland to grow. Cortisol has many effects on **metabolism** in various tissues.

Growth hormones have many different target tissues and promote the growth of each of them. For this reason human growth hormone (GH) is considered an anabolic hormone, indicating that it is responsible for building tissue **proteins**. For example, GH directly increases protein synthesis in muscles and the **liver**; and it decreases the size of adipose tissue. It also has an indirect effect by stimulating other hormones. Growth hormones indirectly affect the bones by increasing protein synthesis, collagen synthesis and cell proliferation. In many other tissues, the indirect effects of growth hormone are responsible for protein, RNA and DNA synthesis. The overall effect of growth hormone is to promote skeletal growth and a lean body mass.

As its name implies, thyroid-stimulating hormone (TSH) promotes cell growth in the thyroid gland. TSH also triggers the secretion of thyroid hormones that affect many metabolic processes in the body.

Hormones of the posterior pituitary

Both oxytocin and antidiuretic hormone (ADH) are peptide hormones that are synthesized in the cell bodies of the nerves originating in the hypothalamus and then delivered through the axons to the posterior pituitary. Thus, they are good examples of neuroendocrine hormones.

The primary target organ of ADH is the kidney. ADH is responsible for increasing water retention by the kidney, resulting in an increase in extracellular fluid and a decrease in urine volume. Receptors in the hypothalamus called osmoreceptors can sense the concentration of water in the extracellular fluid through changes in extracellular fluid osmolarity. The osmoreceptors in turn determine the release of ADH by the posterior pituitary. The consumption of alcohol decreases the amount of ADH released. As a result, more fluid is lost through urination, resulting in excessive water loss and thirst.

The primary site of action of oxytocin is female breast tissue. Oxytocin stimulates the contraction of smooth muscle cells in the breast, transferring milk from the place of synthesis to the larger ducts of the breast. Oxytocin is secreted by the stimulation of touch sensors when an infant is suckling. Other psychological factors, such as the sound of a baby crying, can stimulate the release and action of oxytocin. The role of oxytocin in the onset of labor contractions is not fully clear. There is no known stimulus for the secretion of oxytocin in the human male.

Common diseases and disorders

Hypopituitarism

Disorders of the pituitary gland can have severe effects on normal growth and sexual maturation. A general condition known as **hypopituitarism**, also known as pituitary dwarfism, is characterized by a decrease in one or more of the hormones produced by the anterior pituitary. Sexual immaturity and metabolic dysfunction leading to **obesity** are symptoms of this syndrome. When hypopituitarism occurs in childhood, growth is slowed. Tumors are often the cause of hypopituitarism; however, sometimes there is no identifiable cause. If there is a decrease in the levels of hormones released from the hypothalamus, then hypopituitarism results. The symptoms vary according to the number and amount of hormones that are deficient. The most effective treatment is the administration of replacement hormones.

Hyperpituitarism

The overproduction of growth hormone during childhood produces a condition known as gigantism or

acromegaly. Excessive secretion of anterior pituitary hormones is known as hyperpituitarism. Growth hormone influences the overgrowth of the skeleton and all other tissues. A person may grow to 8 ft (2.4 m) or more in height. It is still unclear, but researchers think that overproduction of growth hormone may be caused by an adenoma (tumor) on the anterior pituitary. Sometimes, this condition occurs in more than one member of the family, suggesting that there is a genetic component. Gigantism is treated by removing the tumor and administering medications (bromocriptine and octreotide) that inhibit the production of growth hormone.

Diabetes insipidus

A disorder related to both the hypothalamus and the posterior lobe of the pituitary is diabetes insipidus, not to be confused with **diabetes mellitus**. Diabetes insipidus, or DI, is caused by a deficiency of antidiuretic hormone (ADH). As a result, water is rapidly released from the body through large volumes of urine (3–30 quarts per day). DI may result from an inherited trait; from damage to the hypothalamus, which synthesizes ADH; or from damage to the posterior pituitary, which stores the ADH. Diabetes insipidus occurs more frequently in men than in women. In mild cases, no treatment is necessary other than water replacement. In extreme cases, the patient can be treated by hormone replacement therapy.

Pituitary hormone tests

Definition

Pituitary hormones include growth hormone, adrenocorticotropic hormone, thyroid stimulating hormone, follicle stimulating hormone, luteinizing hormone, prolactin, antidiuretic hormone, and oxytocin. The first six of these are made in the anterior **pituitary gland**, under the control of the hypothalamus. The last two are made during transport to the posterior pituitary from precursor peptides produced by the hypothalamus. This cluster of hormones has a vast and complex impact on the growth, fertility, and function of the human body via the effect of the hormones on their target organs.

Growth hormone (hGH), or somatotropin, is responsible for normal body growth and development, and regulates carbohydrate and protein **metabolism**. Adrenocorticotropic hormone (ACTH) regulates cortisol release from the **adrenal glands**. Thyroid stimulating hormone (TSH) regulates the synthesis and release of thyroid hormones. Follicle stimulating hormone (FSH) controls the maturation of the ovarian follicle in females and the development of the seminiferous tubules and sperm production in males. In females, luteinizing hormone (LH) causes release of the ovum from the ovary and supports the corpus luteum after ovulation. In males, LH supports testosterone production. Both FSH and LH are found at highest concentrations in plasma immediately before a woman ovulates. Prolactin promotes **lactation**, or milk production, after **childbirth**. Antidiuretic hormone (ADH), also called vasopressin, acts on the **kidneys** (collecting tubules) to increase the reabsorption of water. Oxytocin is released during labor and breastfeeding. It causes smooth muscle contractions needed for delivery and promotes the release of breast milk.

Purpose

Measurement of several pituitary hormones may be requested to investigate pituitary dysfunction in general. The entire gland may cease to function normally due to a hypothalamic disease, surgery, pituitary tumor, or trauma (e.g., Sheehan's syndrome, pituitary failure caused by hemorrhage into the gland after obstetric delivery). Alternatively, one or more specific hormones may be measured to investigate dysfunction of a target organ. For example, LH, FSH, and prolactin are commonly measured along with estrogen (estradiol) and progesterone to investigate ovarian failure. ACTH is needed to investigate the cause of adrenocortical excess or insufficiency. TSH is specifically used to diagnose thyroid under- or overactivity. Growth hormone is used to test for growth

impairment or acromegaly. ADH testing is used to investigate disturbances in electrolytes (sodium and potassium) that will be abnormal when either too much or too little water is reabsorbed by the kidneys. Oxytocin is rarely measured, but may be used to identify ectopic production by tumor cells (e.g., lung carcinoma) that secrete the hormone.

Precautions

Each of these hormones is involved in intricate relationships with other organ systems. Levels may vary markedly depending on time of sampling (hGH, ACTH, prolactin), phase of the menstrual or reproductive cycle (FSH, LH), age, sex, physical activity, and a variety of psychological and nutritional factors. A thorough history of the patient's physical activities and medications is very helpful in interpreting **blood** test results. Pituitary hormones may be measured on plasma or urine. The nurse or phlebotomist collecting the sample should observe **universal precautions** for the prevention of transmission of bloodborne pathogens.

Many drugs are known to affect the level of pituitary hormones. For example, TSH test results may be influenced by such medications as lithium, potassium iodide, aspirin, dopamine, heparin, and **corticosteroids**. In addition, small fibrin clots and heterophile antibodies (HAMA) have been known to cause erroneous results with some immunoassays.

Description

Growth hormone

Human growth hormone (hGH), or somatotropin, is a protein made up of 191 amino acids. It is secreted by the anterior pituitary gland and coordinates normal growth and development. Human growth is characterized by two spurts, one at birth and the other at **puberty**. hGH plays an important role at both of these times. Receptors that respond to hGH exist on cells and tissues throughout the body. The most pronounced effect of hGH is on linear skeletal development, but hGH also greatly increases lean muscle mass. Humans have two forms of hGH, and the functional difference between the two is unclear. hGH is produced in the anterior portion of the pituitary gland by somatotrophs under the control of hormonal peptides from the hypothalamus. The primary hypothalamic hormone regulating hGH is growth hormone-releasing hormone (GHRH). When blood glucose levels fall, GHRH triggers the secretion of stored hGH. As blood glucose levels rise, GHRH release is turned off. Increases in blood protein levels trigger a similar response. GHRH is opposed by growth hormone-inhibiting hormone

(GHIH), which is a neuropeptide causing decreased release of hGH and TSH and which inhibits gastrin, secretin, and insulin. As a result of this hypothalamic feedback loop, hGH levels fluctuate throughout the day.

Because of its critical role in producing hGH and other hormones, an aberrant pituitary gland will often yield altered growth. Dwarfism (very small stature) can be caused by underproduction of hGH or insulin-like growth factor I (IGF-I), or by a flaw in the target tissue response to either of these. Overproduction of hGH or IGF-I, or an exaggerated response to these hormones, can lead to gigantism or acromegaly, both of which are characterized by a very large stature. Gigantism is the result of hGH overproduction in early childhood, leading to a skeletal height up to 8 feet (2.4 m) or more. In this condition, the epiphyseal plates of the long bones do not close, and they remain responsive to hGH. Acromegaly results when hGH is overproduced after the onset of puberty. This disorder is characterized by an enlarged **skull**, hands and feet, nose, neck, and tongue owing to proliferation of connective tissue.

Growth hormone in plasma or urine is usually measured by radioimmunoassay (RIA). Some fluorescent and chemiluminescent enzyme immunoassays are available, as well. In children, hGH in plasma is often too low to detect or permit differentiation of normal and deficient levels. A child below average in height who has normal pituitary function may have a low level of growth hormone as a result of normal physiological variation. Diagnosis is made either by a provocative test or measurement of IGF-I. A deficiency of IGF-I occurs in both hGH deficiency and protein malnutrition. Provocative testing for hGH deficiency involves administration of a drug known to stimulate release of growth hormone, or vigorous **exercise**, which does the same. Drugs used include arginine, insulin, glucagon, and propranolol. In the exercise test, a blood sample is measured for hGH immediately following exercise performed vigorously for 20 minutes. A level greater than 6 nanograms per mL rules out growth hormone deficiency. A lower response is suggestive and is followed by a drug stimulation test. Growth hormone is increased in approximately 90% of persons with acromegaly. Acromegaly is caused by an adenoma in the pituitary that produces hGH. For suspected cases that do not demonstrate an elevated plasma level, a glucose suppression test is needed for diagnosis. The test is performed by giving 100 grams of glucose orally, and collecting a blood sample one hour later. The glucose should suppress hGH to below 1 ng/mL. Failure to do so is evidence of acromegaly.

Adrenocorticotrophic hormone

ACTH production is controlled by the production of corticotropin-releasing hormone (CRH) by the hypothalamus. The release of this neuropeptide is inhibited by plasma cortisol via negative feedback. When plasma cortisol is elevated, CRH is inhibited and less ACTH is produced. As a result the adrenal cortex produces less cortisol and ACTH levels return to normal. Conversely, if cortisol levels fall, CRH is released, causing increased secretion of ACTH by the pituitary. ACTH levels rise in response to **stress**, emotions, injury, **infection**, **burns**, surgery, and decreased **blood pressure**.

Cushing's disease is caused by an abnormally high level of circulating cortisol (hydrocortisone). The high level may be the result of an adrenal gland tumor; enlargement of both adrenal glands due to a pituitary tumor; production of ACTH by a tumor outside the pituitary gland (ectopic production); or excessive administration of corticosteroid drugs. Corticosteroid drugs are widely used for reducing inflammation in such disorders as rheumatoid arthritis, inflammatory bowel disease, and **asthma**.

Addison's disease is a rare disorder in which symptoms are caused by a deficiency of cortisol and aldosterone. The most common cause of this disease is an autoimmune disorder. Addison's disease generally progresses slowly, with symptoms developing gradually over months or years. However, acute episodes, called Addisonian crises, are brought on by infection, injury, or other stresses.

ACTH is measured by RIA or fluorescent and chemiluminescent enzyme immunoassay. ACTH in plasma is measured in order to help differentiate the cause of Cushing's disease. Approximately half of persons with Cushing's disease (pituitary Cushing's) have a normal ACTH level and half will have an elevated level. Most persons with adrenal tumors will have low (less than 10 picograms/L) or undetectable ACTH in the plasma owing to suppression by cortisol. Most persons with ectopic ACTH secreting tumors will have elevated levels in excess of 200 pg/L. Persons with primary Addison's disease will usually have high ACTH levels (greater than 150 picograms/L) caused by negative feedback (low cortisol) while those with secondary Addison's disease will have low or normal ACTH levels owing to pituitary failure or hypothalamic suppression.

Thyroid stimulating hormone

Thyroid stimulating hormone is released by the anterior pituitary in response to thyroid releasing hormone (TRH) from the hypothalamus. It results in synthesis, storage, and release of T3 and T4, the thyroid hormones.

Elevated levels of free T3 and T4 exert negative feedback on the hypothalamus inhibiting the release of TRH which reduces TSH. Thyroid hormones have pronounced effects on the body's rate of metabolism. Decreased levels are responsible for myxedema, which produces a constellation of such symptoms as **edema**, low **heart** rate, intolerance to cold, hyperlipidemia, and anemia. The most common cause of myxedema is Hashimoto's disease, an autoimmune condition causing chronic hypothyroidism. Increased levels of the thyroid hormones (hyperthyroidism) causes a condition called thyrotoxicosis. It is characterized by exophthalmia (protruding eyeballs), tachycardia, insomnia, and weight loss. The most common cause of hyperthyroidism is Graves' disease.

TSH is commonly measured by enzyme immunoassay, and is the best screening test for diagnosis of both hypothyroidism and hyperthyroidism. In primary hypothyroidism, the plasma level of free T4 will be low and TSH will be elevated. In primary hyperthyroidism, the plasma level of free T3 will be high and TSH will be low. In thyroid disease caused by pituitary failure, the TSH and thyroid hormones will move in the same direction. For example, in secondary hypothyroidism, both free T4 and TSH will be low.

Follicle stimulating hormone and luteinizing hormone

Both FSH and LH are regulated by the hypothalamic release of gonadotropin-releasing hormone. In males, both hormones are inhibited via negative feedback by testosterone. In females, both hormones are inhibited via negative feedback by estrogen and progesterone. Levels of these hormones show pulse variation; this is especially true of LH and for this reason, 24-hour urine levels are preferred by some clinicians over plasma measurements. FSH and LH are performed when a person exhibits abnormal reproductive function. In women such conditions as precocious puberty, polycystic ovaries, failure to ovulate, dysmenorrhea, and the onset of **menopause** are the primary reasons for measuring these hormones. In males, these hormones are measured along with testosterone to diagnose and differentiate the cause of gonadal failure.

Levels of FSH and LH are somewhat constant prior to puberty. At puberty, both hormone levels increase significantly. In women the levels of both hormones varies with the phase of the menstrual cycle. Both FSH and LH peak in the midcycle just prior to ovulation. Prior to this peak levels are somewhat higher than they are after ovulation. The midcycle peak has been used to identify the best opportunity to conceive. A urine LH detection kit is available for use at home. This test is sometimes called

an "ovulation test" and is similar to a home **pregnancy test**. A sample of the woman's first morning urine is tested with the materials provided in the kit. These home tests may be used by women who want to become pregnant. By monitoring levels of LH and watching for the surge signaling ovulation, a couple can time sexual intercourse to increase the chance that the egg will be fertilized.

LH and FSH are measured mainly by enzyme or chemiluminescent immunoassays. In males, testosterone RIA is used along with FSH and LH to differentiate the cause of gonadal failure. A low testosterone with low LH or FSH points to a hypothalamic-pituitary cause. A low testosterone with an increased LH and/or FSH indicates primary testicular failure. In females, LH and FSH are measured along with estrogen, progesterone, and prolactin to investigate the cause of abnormal gonadal function. In menopause, the midcycle peaks for both LH and FSH are usually higher than in normal menstruating females. Prior to menopause, the LH peak is greater in magnitude than FSH. However, in menopause, this pattern reverses. In females, low plasma estrogen and progesterone seen with elevated serum or urinary levels of LH and FSH signal primary ovarian failure. Conversely, low estrogen and progesterone in association with low levels of LH and FSH indicate pituitary (secondary) hypogonadism. Prolactin levels should also be performed when evaluating hypogonadism in females. High plasma prolactin caused by pituitary adenoma causes inhibition of LH and FSH by negative feedback. Therefore, prolactinoma may be responsible for ovarian failure.

Prolactin

Prolactin is also known as the lactogenic hormone or lactogen. It is essential for enlargement of the mammary glands during **pregnancy**, and for stimulating and maintaining lactation after childbirth. Like hGH, prolactin acts directly on tissues, and levels rise in response to sleep and to physical or emotional stress. During sleep, prolactin levels in nonpregnant females can reach as high as those seen in pregnant women (as high as ten to twenty times the normal level). Prolactin secretion is controlled by prolactin-releasing and prolactin-inhibiting factors secreted by the hypothalamus. In addition, TRH can also stimulate prolactin secretion.

Prolactin deficiency is rare, and like hGH it cannot be diagnosed without a provocative test because low and normal levels overlap. As with hGH, a normal or elevated level will rule out a deficiency. Documentation of prolactin deficiency requires the use of the TRH stimulation test and demonstration of a subnormal response. Elevated prolactin is the most common pituitary abnormality.

Microadenomas of the pituitary that produce prolactin are the most common pituitary tumors. Depending on the type of cell involved, these tumors are also called prolactin-secreting pituitary acidophilic or chromophobic adenomas. However, there are several other conditions that increase plasma prolactin including pregnancy, drugs, hypothyroidism, and renal failure. Prolactinoma is typically associated with a plasma prolactin level greater than 200 nanograms per mL. Because about half of microadenomas are too small to see by imaging tests such as **CT scans**, plasma prolactin levels above 200 ng/mL, together with the absence of other known causes, are used to diagnose prolactinoma.

Pituitary neoplasia

Pituitary tumors are often responsible for increases in one or more pituitary hormones. About 30% of pituitary adenomas produce prolactin and about 20% of produce FSH. Ectopic hormones may also be produced, for example, ACTH by squamous cell carcinoma of the lung. In addition, the pituitary gland is often involved in multiple endocrine neoplasia, type 1 (MEN-1). This condition is inherited as an autosomal dominant disorder. It involves enlargement of at least two endocrine glands, which may be the result of hyperplasia, adenoma, or adenocarcinoma. One or more pituitary hormones will be secreted when the gland is involved. Therefore, plasma levels of pituitary hormones are sometimes measured to diagnose and to monitor various malignant diseases.

Posterior pituitary hormones

The purpose of ADH is to control the amount of water reabsorbed by the kidneys. Water is continually being taken into the body in food and drink, as well as being produced by chemical reactions in cells. Water is also continually lost in urine, sweat, feces, and in the breath as water vapor. ADH acts to keep blood and extracellular fluid volumes constant under conditions of constantly changing water and solute intake. Under normal conditions, the blood volume expands when excess water is absorbed. This reduces the plasma osmolality, which inhibits the release of ADH, causing water to be lost in the urine. Under conditions of water deprivation, plasma osmolality increases. This stimulates the osmoreceptors in the carotid sinus and ADH is released. The distal collecting tubule of the kidney reabsorbs more water, causing the osmolality to fall until blood volume is restored. Various factors can affect ADH production, thereby disturbing the body's water balance. Physical stress, surgery, and high levels of **anxiety** can stimulate ADH release. Alcohol consumption reduces ADH production by direct action on the **brain**, resulting in a temporarily increased production of urine. Abnormal water balance

occurs in diabetes insipidus, when the pituitary gland produces insufficient ADH; and in chronic renal disease, when the kidneys fail to respond to ADH. The reverse effect, water retention, can result from temporarily increased ADH production after a major operation or accident. Water retention may also be caused by the secretion of ADH by some tumors, especially of the brain and lung. Any condition other than the thirst response that causes increased release of ADH is referred to as the syndrome of inappropriate ADH release (SIADH). Ectopic ADH production by tumors is the most common cause.

Antidiuretic hormone is measured by RIA. It is used in conjunction with serum and urine osmolality or sodium measurements to differentiate SIADH from psychogenic polydipsia and other causes of low electrolytes and to differentiate neurogenic (pituitary) diabetes insipidus from nephrogenic (renal) diabetes insipidus.

Oxytocin is released by the posterior pituitary to cause strong uterine contractions in labor and delivery, and it also acts on muscle cells in lactating breast tissue to aid in the release of milk. Oxytocin levels are rarely measured, but oxytocin is often used in the hospital setting to induce or reinforce uterine contractions in labor. It is also useful in its natural or commercial form for helping the uterus to stay small and contracted after delivery, minimizing blood loss. Oxytocin is produced by males as well, and its function is thought to be related to sperm transportation.

Preparation

Pituitary hormones demonstrate both diurnal and pulse variation, and it is important to note the time of day that the sample is collected. Samples for both ACTH and ADH should be drawn in the fasting state. Blood for ACTH is usually drawn early in the morning, when ACTH is anticipated to be at its peak; and is also assessed in the evening, when it is expected to be at its lowest level. ACTH is very labile and should be collected in EDTA, using plastic tubes. The blood should be centrifuged immediately (preferably in the cold) and the plasma removed and frozen until the time of assay. FSH and LH vary greatly depending upon the time of collection. For this reason, results should be evaluated with regard to the time of sampling. Since levels vary greatly during the menstrual cycle, the levels must be evaluated with regard to the menstrual phase. Some clinicians prefer to pool plasma specimens collected across the menstrual cycle for a single measurement, or to use 24-hour urine samples for measurement. Growth hormone specimens should be collected using heparin or EDTA from a fasting patient. The various tests used to investigate

human growth hormone are highly influenced by the fasting or non-fasting state, as well as the presence or absence of recent exercise. Prolactin levels should be drawn in the morning at least two hours after the patient wakes (samples drawn earlier may show sleep-induced peak levels). No specific preparation is necessary for drawing TSH levels, but illness and stress can affect results significantly.

Aftercare

No special care is necessary after collection of blood or urine for pituitary hormone assessment. Patients should return to normal eating and exercise, and resume routine medications. Following venipuncture for blood plasma hormone tests, the laboratory technologist, nurse, or phlebotomist drawing the sample should inspect the venipuncture site to make sure that the wound has closed and no bleeding is present. The site should be covered with an adhesive bandage. There is no notable aftercare for patients undergoing 24-hour urine hormone tests. Patients should be reminded to resume foods and medications that were restricted prior to testing.

Complications

Complications from drawing blood are minimal and may include slight bleeding from the venipuncture site, fainting, or lightheadedness after the blood sample is drawn. Blood may accumulate under the puncture site (hematoma) if pressure is not applied to the site immediately after drawing blood. There are no complications for the urine test. Some of the test protocols for growth hormone assessment involve administering drugs, such that nausea, sleepiness, sweating and/or nervousness may occur. Severe hypoglycemia could theoretically occur with insulin, but this is unlikely if the patient is closely monitored and treated appropriately.

Results

The normal ranges for pituitary hormone tests are highly method-dependent, resulting in significant laboratory variation. Also, age, sex, and sampling time must be taken into consideration when interpreting results.

Generally, hGH ranges from undetectable to 5ng/mL for adult men, up to 10 ng/mL for adult women, and as high as 16 ng/mL in children over six years. Arginine (an amino acid), insulin, and other substances are sometimes used to try to elicit higher levels of hGH to investigate a possible deficiency. Decreased levels are seen in hGH deficiency, dwarfism, hyperglycemia, failure to thrive, and delayed sexual maturity. Excess hGH is responsible for the syndromes of gigantism and acromegaly. Excess

secretion is stimulated by anorexia nervosa, stress, hypoglycemia, and exercise.

Representative normal values for ACTH range from 8-100 pg/mL between 4 and 8 AM, and less than 50 pg/mL between 8 and 10 PM. High levels of ACTH may be caused by ACTH-producing tumors. These tumors may be either in the pituitary or in another area (such as tumors from **lung cancer** or **ovarian cancer**). In Addison's disease, the adrenal glands fail, and the pituitary gland secretes very high levels of ACTH in an attempt to restore normal adrenal hormone. Low levels of ACTH may occur because of decreased pituitary function. Low ACTH levels may result from adrenal adenoma which causes high levels of cortisol. The cortisol causes negative feedback to the pituitary.

Representative adult normal values for TSH are 0.2 to 4.7 microunits per mL (uU/mL). Higher values may be caused by congenital hypothyroidism (cretinism) or primary hypothyroidism (**thyroid gland** failure). Low values may be due to hyperthyroidism such as in Graves' disease or thyroiditis, or secondary hypothyroidism (hypothalamic or pituitary failure).

FSH test results vary according to age and sexual maturity. The phase of a woman's menstrual cycle or use of birth-control pills also affects test results. For an adult male, normal results range from 4-25 U/L. For a premenopausal woman, normal values range from 4-30 U/L. In a pregnant woman, FSH levels are too low to measure. After menopause, normal values range from 40-250 U/L. FSH levels fluctuate during premenopause. If no other symptoms are present, an elevated FSH level should not be interpreted as proof that menopause has begun. Anorexia nervosa and disorders of the hypothalamus or pituitary gland can result in abnormally low FSH levels. Abnormal levels can also indicate precocious puberty, **hypopituitarism** (diffuse failure of the pituitary to make hormones), Klinefelter's syndrome (in men), Turner syndrome, testicular failure, and polycystic ovarian syndrome.

The normal range for LH in males is 1-8 mU/mL and in children is 1-5 mU/mL. Levels in females vary dramatically based upon the phase of the menstrual cycle. In the follicular phase, levels are normally in the range of 1.7-15 mU/mL; in the midcycle peak they are normally between 16-104 mU/mL; and in the luteal phase they normally range from 0.6-16 mU/mL. LH in postmenopausal women is normally in the range of 16-66 mU/mL. Abnormally high levels may be found in primary gonadal dysfunction, polycystic ovarian syndrome, and pituitary adenoma. Abnormally low levels can be seen with delayed puberty, congenital adrenal hyperplasia.

sia, stress, malnutrition and diffuse pituitary or hypothalamic problems.

Reference ranges for prolactin vary from laboratory to laboratory, but are generally between 3-15 ng/mL for adult males and 3.8-23 ng/mL for nonpregnant adult females. Prolactin levels in pregnancy vary greatly with the time of gestation. Normal values in the third trimester are 95-475 ng/mL. Increased prolactin levels are found in galactorrhea, amenorrhea, hypothyroidism, prolactin-secreting pituitary tumors, infiltrative diseases of the hypothalamus, and metastatic cancer of the pituitary gland. Higher levels than normal are also seen in stress, which may be produced by anorexia nervosa, surgery, strenuous exercise, trauma, and in renal (kidney) failure. Decreased prolactin levels are seen in pituitary failure.

ADH normal ranges are also laboratory-specific but can range from 1-5 pg/mL or 1-5 ng/L (SI units). Patients who are dehydrated; who have a decreased amount of blood in the body (hypovolemia); or who are undergoing severe physical stress (e.g., trauma, **pain** or prolonged mechanical ventilation) may exhibit increased ADH levels as a normal response to the needs of the body. Similarly, patients who are overly hydrated may have decreased ADH levels. Abnormal conditions that cause increased levels (SIADH) include **central nervous system** tumors, ectopic tumors, and infection. ADH deficiency is called diabetes insipidus, and results in severe water losses from the body. It is easily treated with nasally administered vasopressin.

Health care team roles

A physician will order pituitary tests and will interpret the results often with the aid of an endocrinologist. A nurse or phlebotomist will draw blood samples and give instructions for 24-hour urine collection if needed. Nurses are also responsible for accurate history-taking in order to document medications, stressors, or exercise that may influence test results. Clinical laboratory scientists/medical technologists perform the various hormone assays. Tests for hGH, ACTH, and ADH are usually performed by reference laboratories.

KEY TERMS

Adrenal glands—A pair of endocrine glands that lie on top of the kidneys, which produce natural steroid-based hormones.

Anovulatory bleeding—Bleeding without release of an egg from an ovary.

Klinefelter's syndrome—Inheritance of an extra X chromosome that results in small testes and male infertility.

Polycystic ovarian syndrome—A condition in which a woman has little or no menstruation, is infertile, has excessive body hair, and is usually obese. The ovaries may contain several cysts.

Pivot joint

Definition

A pivot joint is a synovial joint in which the ends of two bones meet—one end being a central bony cylinder, the other end being a ring (or ring-like structure) made of bone and ligament. In some joints, the cylinder rotates inside the ring. In other joints, the ring rotates around the cylinder. The rotation of the **skull** is made possible by a pivot joint. (A synovial joint is the living material that holds two or more bones together but also permits these bones to move relative to each other.)

A more precise rendering of the international Latin anatomical term for pivot joint would be “wheel joint.” A wheel rotates around an axis or pivot (for example, the axle around which automobile tires rotate). The Latin term (itself borrowed from Greek) refers directly to the

KEY TERMS

Articulation—A synonym of “joint.”

Carpals—The eight small bones that form the wrist and are joined to the metacarpals of the hand and to the bones of the forearm.

Humerus—The bone of the upper part of the arm.

Neoplasm—New and abnormal growth of tissue, which may be non-cancerous (benign) or cancerous (malignant).

Pronation—Motion of the forearm and hand by which, after one bends the elbow, the palm is turned downward.

Radius—One of the two bones of the forearm. A pivot joint joins it to the ulna near the elbow. A second pivot joint joins the other end of the radius to the other end of the ulna near the wrist.

Supination—Motion by which, after one bends one’s elbow, a palm is turned upward.

Synovial fluid—A transparent, sticky fluid that lubricates joints and nourishes the cartilage in a joint. (It is also found in tendons, sheaths, and bursae.)

Ulna—One of the two bones of the forearm. Two pivot joints join it to the radius, one near the elbow, one near the wrist.

ring made of bone and ligament. The English term refers directly to the cylindrical end of the bone.

Description

Pivot joints hold the two bones of the forearm together. That is, a pivot joint, located near the elbow, joins the bones of the forearm (called the ulna and the radius) to each other. These two bones are also joined to each other near the wrist by another pivot joint. A different pivot joint, located at the base of the skull, joins the first vertebra of the spine to the second vertebra and thus permits the head to rotate (since the first vertebra is joined to the skull).

If the bony surfaces of two bones that meet at a joint actually touched each other, then motion would cause friction, which would soon produce wear and tear on the touching ends of the bones. An engineer designing a mechanical counterpart would arrange for lubricating oil to prevent such wear and tear and facilitate smooth movement between the two metal “bones.” A joint thus

holds bones together (it is called a “joint” because it “joins” them) but also keeps them slightly separated to prevent their damaging each other in motion.

A kind of cartilage special to joints covers the ends of the bones being joined. A membrane hermetically seals two (or more) bone-ends with their cartilage, enclosing them in a kind of living capsule. For the sake of simplicity, the following example discusses a joint with only two bones. Inside this membrane capsule, there is a short distance between the cartilage of one bone and the cartilage of the other, because even cartilage rubbing directly against cartilage would produce wear and tear. But the gap between the cartilage surfaces is not a vacuum and is not filled with air. It is filled with synovial fluid. This fluid is in a sense the equivalent of the motor oil that lubricates moving parts of an automobile engine.

The interior of a synovial joint has negative pressure in relation to air pressure. For this reason, air pressure pushes the bones together tightly into the membrane capsule while the fluid keeps them from actually touching. The hermetically sealed membrane capsule in this paradoxical fashion aids the tight joining while it ensures the slight separation.

This negative pressure in the joint continues to work even after death. Of course, the two bones are kept together in a living body not only by the membrane capsule and the synovial fluid, but also by the tissues around the bones. If, while dissecting a corpse, one removes the tissues leaving only the membrane capsule, the pair of bones will remain tightly joined. But if one pierces the capsule and allows air to rush inside, one then has normal atmospheric pressure inside the capsule instead of the negative pressure of the interior of the living joint when it is hermetically sealed by the capsule, and now the bones come easily apart.

Synovial fluid has another important quality. Most bodily tissues are nourished by **blood vessels**, but the cartilage on bone-ends in joints does not have **blood vessels**. Synovial fluid provides the **nutrition** for the cartilage that keeps it alive, strong, and healthy. The wall of the membrane capsule has two layers. The outer layer is fibrous. The inner layer produces the synovial fluid, and hence is called the synovial layer.

Function

A pivot joint allows movement in one plane, such as rotation about an axis. Pivot joints, for example, permit one, after bending the elbow, to turn the palm of one’s hand upward or downward by rotating the forearm. The two bones of the forearm (the ulna and the radius) twist around each other using a pivot joint.

Role in human health

The role of pivot joints in human health (the same as that played by the other types of synovial joints) is to allow freedom of movement and thus provide flexibility to the skeleton.

Common diseases and disorders

The pivot joints (and the other joints) can be affected by such conditions as the following:

- **Ankylosis:** The fusion of bones across a joint. It is often a complication of arthritis.
- **Ankylosing spondylitis:** A type of inflammatory arthritis that progresses to ankylosis. It occurs chiefly in young men.
- **Capsulitis:** Inflammation of the membrane capsule that produces and encloses the synovial fluid.
- **Dislocation:** The displacing of a bone from its normal position, causing tendons to stretch and strain.
- **Neoplasms:** Abnormal growths (neoplasms) involving the pivot joints are rare. Such growths as do occur usually involve non-cancerous (benign) growths of cartilage or of tendons and their sheaths. Synovial sarcoma is a cancerous (malignant) growth of cells resembling those of the synovial layer of the membrane capsule. It is found at the contact surfaces of bones in a joint, usually in the larger joints of young adults.
- **Rheumatoid arthritis:** A common form of chronic inflammation of the joints. It causes swelling, **pain**, stiffness, elevated temperature, and redness of the joints. It is a disease of connective tissue and leads to the destruction of bone, cartilage, and ligaments in the joints.

Placenta previa

Definition

Placenta previa is an abnormal condition of **pregnancy** in which the placenta is attached to the lower section of the uterus, partially or completely covering the cervix. It occurs in about 0.5% of pregnancies.

Description

The placenta is a hormone-producing fetal organ, rich in **blood vessels**, that connects the baby to the mother via the umbilical cord. It begins to develop along with the embryo right after conception. The placenta normally implants high on the uterine wall and securely attaches into the wall through finger-like projections. The umbilical cord is created by the interweaving of two arteries and one vein that connect the placenta to the fetus. The nutrients and oxygen from the mother pass through the placenta and into the fetus. Carbon dioxide and waste products excreted by the fetus pass through the placenta and into the mother's circulation for removal. The placenta functions as a lifeline for the fetus.

In placenta previa, the placenta has attached itself towards the bottom of the uterus, near or on the cervix. Its usual implantation site is high up on the uterine wall. During a vaginal birth the cervix thins and opens sufficiently for the fetus to pass through the cervix, into the birth canal, and out the mother's vagina. As the cervix begins to dilate during labor, the force on the low-lying placenta causes tearing and subsequent bleeding. Excessive bleeding, or hemorrhage, can be dangerous for both the mother and fetus. If the placenta tears, the fetus is deprived of nutrients and oxygen and can suffer **brain damage** or even death.

In some pregnancies, the low placement may not provide a sufficiently large area for good exchange of nutrients and gases. This lack may impede fetal growth. In most cases of placenta previa, the condition becomes a concern towards the end of the pregnancy, often around 30 weeks gestation. At this point the uterus starts to undergo changes in preparation for labor and delivery. It is when these changes occur that the placenta may begin to tear and bleed. Infants born to mothers with placenta previa also have a greater risk of **respiratory distress syndrome**. In a study published in October of 2000, researchers found that mothers carrying a male fetus are at greater risk of placenta previa than those carrying a female fetus.

There are four degrees of placenta previa:

KEY TERMS

Cervix—The cervix, or cervical os, is the opening between the vagina and the uterus. During labor the cervix thins and dilates, allowing the fetus to pass through, entering the birth canal and leaving through the vagina.

Cesarean birth—The terms cesarean section, birth, or delivery may be used interchangeably. This procedure to deliver a baby involves an abdominal incision made through the abdominal wall and into the uterus to extract the baby.

Hemorrhage—Hemorrhage refers to an excessive amount of blood lost within a very short time period. With massive blood loss the mother may have a rapid, weak pulse, drop in blood pressure, dizziness, pallor, clammy skin and appear disoriented. Hemorrhage is an emergency situation.

Placental abruption—This condition of pregnancy, also called abruptio placentae, is characterized by sharp pain, a hard, rigid abdomen, and vaginal bleeding due to the detachment of the placenta from the uterine wall, placing the mother and fetus at great risk.

- Low-lying implantation. The placenta lies abnormally low on the uterine wall, but is not yet approximating the cervix.
- Marginal implantation. The placenta is within 2 centimeters of the internal cervical os.
- Partial previa. The placenta covers part of the cervix. The distinction between partial and complete previa is somewhat unclear while the cervix is still closed.
- Total previa. The placenta completely covers the cervical os.

Causes and symptoms

The exact cause of placenta previa is unknown. However, contributing factors include:

- uterine shape abnormality
- increased parity, i.e. the mother has been pregnant before
- previous cesarean births
- older maternal age (Women over the age of 35 have an increased risk of placenta previa by 4.7 times. When the mother is over 40, the risk rises to 9 times.)
- previous dilation and curettage of the uterus

- multiple gestation (twins, triplets, etc.)
- previous placenta previa
- cigarette smoking

Placenta previa is characterized by painless vaginal bleeding that often starts abruptly. The bleeding may continue, or it may stop as abruptly as it started. By the time the woman is seen by her obstetrical provider, there may be some spotting, or perhaps no bleeding at all. Even if the bleeding has stopped, placenta previa is an emergency situation and the mother needs to be seen right away. Bleeding indicates that the placenta has begun to tear. The mother is now at risk of hemorrhage if no intervention is made. The fetus may be compromised, as the level of oxygen available to it has changed.

Diagnosis

Most pregnant women undergo at least one routine ultrasound during their pregnancy. During the ultrasound the placement and position of the placenta is identified. When a low-lying placenta is detected, the degree to which the placenta covers the cervical os is described in percentages. For example, a complete placenta previa is 100%. Once placenta previa has been diagnosed, the pregnancy is considered high-risk. However, the position of the placenta can change as the uterus grows, and so periodic ultrasounds may be ordered. A transvaginal ultrasound may be ordered following an **abdominal ultrasound** to more accurately assess how low the placenta is lying. There is a false-negative and false-positive risk of 7% with abdominal ultrasound. For this condition, transvaginal ultrasound appears to be far more reliable. In addition, the placenta is able to creep upwards over time.

If a woman experiences sudden, painless, bright red bleeding at any point in the pregnancy, she should be seen right away, even if the bleeding has stopped. An ultrasound will usually be done in order to reassess the position of the placenta, and to evaluate the fetus. A manual examination of the cervix is not done, as this could disturb the placenta.

Treatment

The treatment plan will depend on the gestational age, the severity of the bleeding, and the risks to mother and fetus. If the fetus is sufficiently mature and the pregnancy is near term, immediate cesarean birth may be suggested. If it is too early for the fetus to survive outside the womb, and the mother's condition is stable, the mother may be placed on bed rest in the hospital with medications to prevent uterine contractions. Close monitoring of the fetus and mother will continue. If there has been no bleeding for a few days, the mother may be sent home, and may

be prescribed medication to improve the fetus' lung maturity so that if a preterm birth is necessary, the fetus has a better chance for healthy survival. The position of the placenta will determine if a vaginal birth is possible, or if the safest delivery will be by cesarean section.

Prognosis

Prognosis for mother and fetus have significantly improved with accurate imaging technology that identifies the condition in advance and allows for proper high-risk management of the pregnancy. A planned cesarean birth rather than unexpected, profuse bleeding at the time of labor is a part of placenta previa management. The prognosis for the fetus depends on how well developed it is at the time of delivery, and whether the bleeding caused any significant oxygen deprivation. The mother has an excellent prognosis unless hemorrhage occurs and is not well managed.

Health care team roles

The radiologic technologist usually performs the ultrasound, but the obstetrical provider may choose to do it if bleeding has begun. Any reassuring signs should be mentioned to the mother. Bleeding during pregnancy is frightening, and speaking in a calm voice and providing a comfortable environment can allow the mother the opportunity to relax somewhat. The nurse places the woman on her side to ensure better **blood** flow once she arrives at the health care facility, and obtains baseline **vital signs**, particularly **blood pressure** and pulse rate. Questions to ask the mother include:

- How far along is the pregnancy?
- When did the bleeding begin?
- What color was the bleeding? Bright red indicates fresh, or ongoing bleeding.
- Was there **pain** with the bleeding?
- How many sanitary pads have you used since the bleeding started? This question is to estimate amount of blood loss.
- Did you use anything to stop the blood flow, such as a tampon? Tampons will absorb the blood, and the true amount of bleeding may be masked.
- Is this the first episode of bleeding in this pregnancy? If not, obtain details about previous episodes.

The woman should be closely monitored for any signs of hemorrhage. The health of the fetus is monitored externally. Once bleeding has stopped and the mother must wait for the delivery, she can be at risk of perceiving the pregnancy as failed. This could result in her tak-

ing less care of herself, and thereby putting the fetus at risk. Continued reassurance for the mother helps prevent this from happening.

Prevention

Placenta previa is not preventable, as it is not possible to affect where the placenta will implant. However, once diagnosed, the mother may be instructed to avoid intercourse, get enough rest, and telephone the provider if any bleeding occurs.

Placental abruption

Definition

Placental abruption is a condition in **pregnancy** in which the placenta prematurely separates from the uterine wall while the fetus is still *in utero*. While it is seen most often during the third trimester of pregnancy, especially during the labor process, the term can be applied from 20 weeks gestation through term. Severe bleeding, even hemorrhage, can result, putting both the mother and fetus at significant risk. It is also known as placenta abruptio and abruptio placentae.

Description

In most cases placental abruption occurs in a normally implanted placenta, one that is located high on the uterine wall. However, it can occur in tandem with **placenta previa**. In a normal vaginal delivery, the delivery of the placenta follows that of the neonate within about 30 minutes. Because the neonate has been born and is now breathing on his or her own, the separation of the placenta from the uterine wall causes no distress. In placental abruption, however, the premature separation of the placenta deprives the fetus of the oxygen, nutrients, and **gas exchange** taking place at the site of the separation. The cost to the fetus depends on the degree and size of the separation. The risk to the mother depends on the amount of **blood** lost, and the change in circulating blood volume and its accompanying decreased tissue perfusion.

Placental abruption occurs in about one in 120 deliveries. Severe abruption leading to fetal death occurs in about one in 420 deliveries. Cocaine use increases the risk of abruption by increasing vasoconstriction, and about 10% of mothers using cocaine in the third trimester succumb to placental abruption.

Causes and symptoms

The causes of abruption are not fully understood, but it appears that it may be the end result of a series of fetal-maternal vascular abnormalities. Impaired blood vessel integrity and suppressed immune function may lie at the core of the development of abruption. Some of the factors leading to placental abruption include:

- Trauma. An abdominal blow, such as that incurred during an automobile accident, may cause abruption. Mothers experiencing a severe blow to the abdomen, with subsequent uterine contractions, should be monitored for about 24 hours, even in the absence of vaginal bleeding. This is because there could be a delay in symptoms. Observation of the mother should also include fetal monitoring to assure fetal well-being.
- Maternal **hypertension**. Mothers who have either chronic high **blood pressure** or hypertension induced by pregnancy are at increased risk of abruption.
- Maternal age. Placental abruption is seen more often in older women. However, it is unclear whether the advanced age or the increased likelihood of previous gestations is the primary factor.
- Uterine and umbilical cord abnormalities, such as a short cord or a uterine myoma at the placental implantation site.
- Placental abnormalities resulting in poor implantation.

- Cigarette smoking. As the number of cigarettes per day increases, so does the risk of abruption. This higher risk may be because of the harmful effect of nicotine on blood vessel integrity.
- Previous placental abruption. The risk of recurrence may be almost 17%.

The classic symptoms of abruption include sharp abdominal **pain**, rigid abdomen, vaginal bleeding, uterine contractions, and uterine tenderness. However, these signs are not always present. About 10% of women may have no vaginal bleeding. This is because the blood is pooling behind the placenta that has detached in the center. If the abruption occurred in tandem with labor contraction, and if the abruption is mild or moderate, the pain of labor contractions may mask the underlying abdominal pain and uterine tenderness of the abruption. This variability of symptoms emphasizes the need for careful diagnosis.

Diagnosis

Diagnosis of placental abruption, especially when mild or moderate, can be elusive. A thorough maternal history can play a significant role in identifying mothers at increased risk. Severity of abruption cannot be determined only from the volume of visible blood lost, as concealed hemorrhage may be taking place. Pain may be primarily in the back instead of abdominal. It may be sharp and severe, or dull and intermittent. It may be accompanied by nausea and vomiting. The uterine contraction pattern tends to be low in amplitude but high in frequency. If the uterus and abdomen are rigid, external monitoring or contractions may be inaccurate. Uterine tenderness may be localized to the site of detachment, but may also present as generalized. Unfortunately, ultrasound is not very reliable in establishing the presence of placental abruption. Blood work may be done to check on the presence of an abnormal clotting process. Diagnosis may become the piecing together of a puzzle of symptoms, with the experienced practitioner being more likely to solve the puzzle.

Placental abruption is categorized into four degrees of separation. These are:

- Grade 0. Abruption was diagnosed after delivery, upon inspection of the placenta. The placenta will show a small area of clotting on the side of maternal attachment. No other visible maternal or fetal signs of abruption were present.
- Grade 1. Some separation occurred with some vaginal bleeding and changes in maternal **vital signs**. No fetal distress was noted.

- Grade 2. Moderate separation, fetal distress, uterus is tender to touch.
- Grade 3. Extreme separation; without emergency intervention mother and fetus are at risk of **shock**, hemorrhage, or death.

Separation may be partial, with vaginal bleeding; partial without vaginal bleeding (known as concealed hemorrhage); complete separation, with vaginal bleeding (likely hemorrhage); or complete separation with concealed hemorrhage. Concealed bleeding is very dangerous because the lack of vaginal bleeding masks the true severity of the condition. Then, if the mother goes into shock, it may be unexpected and result in a poor outcome. If the placenta detached in the center, concealed bleeding is more likely to occur. Blood may seep into the uterine wall and result in a condition called *couvellaire uterus*, which is characterized by a hard uterus, no bleeding, and no signs of impending maternal shock. Shock results from the blood loss into the uterine tissue.

Treatment

A mother with suspected placental abruption needs to be admitted to the hospital. As complete a history as possible should be taken. If the mother is in crisis, family or friends may be able to assist with the history. Blood work to check for clotting disorders is done, as placental abruption may be accompanied by disseminated intravascular coagulation (DIC) which can lead to massive hemorrhage. Intravenous (IV) fluids and blood transfusions may be necessary to replace blood lost. Oxygen may be administered. Continuous fetal monitoring is done to assess for signs of fetal distress. Decreased maternal urine output indicates a compromised blood volume with poor tissue perfusion. The severity of the abruption determines the course of treatment. If a small separation has occurred, the pregnancy may be maintained as long as the mother is stable and the fetus does not show signs of distress. If the separation is a grade 0 or 1, and the fetus is near term, a vaginal delivery may be attempted. A separation of grade 3 or 4 necessitates delivery even if the fetus is not sufficiently mature, as the separation has compromised adequate nutrients and oxygen from reaching the fetus, and the accompanying blood loss has put the mother's well-being at risk. If DIC has begun, prompt evacuation of the uterus of the fetus and the placenta can allow for a positive prognosis for the mother. However, surgery poses great risk to the mother because of her compromised ability to clot. Severe hemorrhage, organ failure, and death could occur.

KEY TERMS

Disseminated intravascular coagulation—DIC is a serious medical complication in which the mother's blood no longer clots in the usual manner because of extreme loss of blood. Bruising is visible on the skin, and blood can seep from sites of IV insertion. This is a medical emergency, as it can quickly lead to massive hemorrhage.

Gestation—The age of the fetus in weeks since conception.

Myoma—A benign fibroid tumor of the uterine muscle.

Placenta previa—Placenta previa is a condition of pregnancy in which the placenta, which normally is implanted high on the uterine wall, is instead implanted near the cervical opening. As the uterus begins to change in preparation for labor and delivery, the force exerted on the placenta can cause it to tear, depriving the fetus of nutrition and oxygen, and putting the mother at risk of hemorrhage.

Prognosis

Prognosis is dependent on many factors, such as the frequent monitoring of vital signs, the degree of separation, amount of blood lost, such preexisting fetal complications as growth retardation and congenital abnormalities, gestational age of the fetus, any permanent organ damage to the mother, and degree of oxygen deprivation. Prompt diagnosis enhances chances for a successful outcome.

Health care team roles

Nurses play a significant role in obtaining a full and accurate patient history. Questions should include maternal symptoms, time elapsed since symptoms began, presence and quality of pain (sharp, dull, constant, intermittent), bleeding (amount and color), and any actions taken, such as medication for pain or use of tampons.

Prevention

While most factors contributing to abruption are not preventable, cigarette smoking, cocaine use, and seat belt use with proper placement are important areas on which to focus during **prenatal care**. Identifying a mother at high risk and having a management plan in place can expedite diagnosis, especially if the mother arrives

through the emergency department in crisis; and result in a more successful outcome for both mother and baby.

Plasma protein tests

Definition

Plasma protein tests are laboratory tests used to evaluate the levels of specific **proteins** in the blood. A decrease or increase in the concentration of the protein is associated with one or more clinical conditions. Prior to measuring a specific protein, a comprehensive metabolic profile is usually performed. This profile includes tests for the total protein and albumin. If either of these tests is abnormal, serum protein electrophoresis may be performed in order to determine the cause. Abnormalities seen on the **protein electrophoresis test** as well as other clinical information are used to determine the necessity for specific protein tests. The most frequently measured plasma proteins include alpha-1 antitrypsin (AAT), ceruloplasmin (CER), C3 and C4 (complement proteins), C-reactive protein (CRP), haptoglobin (Hp, HAP), immunoglobulins (IgG, IgA, IgM), transferrin (TRF), and transthyretin (TTR).

Purpose

Plasma protein tests are used to determine whether a specific protein or proteins have increased or decreased in concentration. An abnormal level of total protein or of a specific protein indicates particular diseases or conditions associated with the respective change. Some protein tests are useful for establishing a diagnosis, while others are useful in determining the extent of a condition such as **dehydration** or inflammation.

Precautions

A nurse or phlebotomist who collects the sample for a plasma protein test should follow standard precautions for the prevention of transmission of bloodborne pathogens. Total protein and albumin concentrations are approximately 10% higher in ambulatory persons. Plasma total protein is approximately 0.2 - 0.4 g/dL higher than serum. Some drugs, especially estrogens and **corticosteroids**, may increase the concentration of specific proteins.

Description

Proteins are vital to the proper functioning of the body. There are more than 3,000 proteins found in a single human cell. Some proteins, such as enzymes, hormones, coagulation factors, lipoproteins, and hemoglobin, are measured routinely and are described in other topics. The proteins considered here are those which are sufficient in concentration to affect results of the total protein or protein electrophoresis tests or are measured by immunonephelometry. Each of the proteins described below, with the exception of total protein and albumin, are measured by this method. In immunonephelometry, plasma or serum is added to a buffer containing an excess of a specific antibody (e.g., anti-haptoglobin). The antibodies will bind to the haptoglobin molecules (antigen), forming small soluble immune complexes. Monochromatic light (usually 450-550 nm) passing through the reaction tube will be scattered by the immune complexes as they form. Forward-angle light scatter is measured by a light detector (photomultiplier tube) placed at an angle (usually 70 degrees) to the incident light. The combination of antibody and antigen molecules occurs rapidly, and the photodetector current increases with time until a peak signal is reached. This peak is proportional to antigen concentration. To insure that the antibody molecules are in excess, an addition of reagent antigen is injected into the reaction mixture after the peak rate is obtained. This addition will produce an increase in light scattering

provided that sufficient antibody remains. The clinical significance of each protein test is described below.

Total protein: The total protein of plasma or serum is measured by a colorimetric reaction called the biuret method. The sample is added to an alkaline solution of **copper II** sulfate. The copper ions form coordinate bonds with the carbonyl and imine groups of the protein. This causes the reagent to change from a sky blue to a purple color. The absorbance of the solution at 540 nm is proportional to protein concentration.

Total protein is increased in conditions causing dehydration. They includes vomiting, **diarrhea**, diabetes insipidus, **diabetes mellitus**, and Addison's disease. Total protein is increased in conditions that cause inflammation. These include **cancer**, autoimmune diseases, and chronic or severe infections. Total protein is also increased by monoclonal immunoglobulin production caused by benign or malignant proliferation of antibody-secreting cells (plasma cells) such as multiple myeloma. Low total protein can result from protein loss, as occurs in hemorrhage, glomerulonephritis, nephrosis, protein-losing gastroenteropathy, and **burns**; excessive hydration as occurs in salt retention syndromes and the syndrome of inappropriate antidiuretic hormone (SIADH); or decreased synthesis resulting from starvation and chronic **liver** disease.

Albumin: The albumin in plasma comprises 50-65% of the total protein. In addition to holding water in the vascular bed (maintenance of oncotic pressure) albumin is primarily a transport protein and is responsible for the protein binding of most drugs. It is measured by a dye-binding method using either bromocresol green (BCG) or bromocresol purple (BCP). These dyes selectively bind to albumin, forming a colored complex. The color formed is proportional to albumin concentration. Plasma albumin is increased by dehydration or intravenous infusion of albumin as a **blood** volume expander. It is decreased in hemorrhage, renal disease, salt retention, SIADH, liver disease, starvation, inflammation, malignancy, and **infection**.

Alpha-1 antitrypsin: ATT is a glycoprotein (molecular weight 52,000) made by the liver. ATT is an inhibitor of the enzyme trypsin as well as of other proteolytic enzymes (serine proteases) that are released from phagocytic white blood cells during inflammation. ATT reduces the damage to tissues caused by the **immune response**, and plasma levels increase up to two-fold in acute and chronic inflammatory conditions. Proteins such as ATT that are increased in response to inflammation are called acute phase proteins. They are sensitive markers for tissue injury, **myocardial infarction**, infection, malignancy, and autoimmune diseases.

A deficiency of AAT results in excessive inflammation in tissues that are exposed to **bacteria** and other foreign cells, commonly the **lungs** and gastrointestinal organs. AAT deficiency is usually inherited. Expression of the genes for AAT is codominant. The most common normal phenotype is MM. The phenotype ZZ (homozygous for the Z variant) produces only about 10% of normal activity and is most commonly associated with immunological damage. The most frequent complications involve the lungs (**emphysema**) and the hepatobiliary tract (hepatitis and cirrhosis). A deficiency of AAT is suspected when the alpha-1 band of serum protein electrophoresis is absent or below 1% of the total protein. The AAT concentration is measured by immunonephelometry and the variant proteins can be identified by high-resolution gel electrophoresis.

Ceruloplasmin: CER is a protein (molecular weight 120,000) produced by the liver. It is an acute phase protein, and increased CER may contribute slightly to the size of the alpha-2 band on electrophoresis. Ceruloplasmin is measured as an aid to the diagnosis of Wilson's disease. Wilson's disease is an autosomal recessive disease in which the binding of copper by CER and the excretion of copper into the bile are impaired. Copper accumulates in the tissues, principally the liver, **central nervous system**, and eyes. Deposition in the eyes produces Kayser-Fleischer rings (green to brown rings around the edge of the cornea), a classic sign on physical exam. Copper deposition damages tissues, causing cirrhosis of the liver and damage to the lenticular area of the **brain** (hepatolenticular degeneration). It may also cause **osteoporosis**, renal, joint, cardiac, and other damage. Plasma levels below half the lower limit of normal and low plasma copper are suggestive but are not conclusive in the absence of clinical signs. CER is measured by immunonephelometry.

C3 and C4: C3 and C4 are glycoproteins that act along with other complement proteins to facilitate lysis of antibody-coated cells. The complement system consists of nine proteins in the classical pathway and an additional five that act in the alternative pathway. Deficiencies of 10 complement proteins have been described. A deficiency of C3 or C4 is associated with systemic lupus erythematosus (SLE) and other autoimmune diseases. The deficiency of either complement component may be responsible in part for the development of the disease by preventing the effective removal of immune complexes. C3 and C4 deficiency are also associated with severe recurrent infections. In active SLE, glomerulonephritis, cirrhosis, and sepsis C3, C4 and complement activity may be reduced due to consumption by immune complex formation. In rheumatoid arthritis, rheumatic **fever**, and some chronic dermatolog-

KEY TERMS

Edematous—The state of having swelling (edema) caused by the collection of excess fluid within tissues.

Hematoma—Swelling and subsequent bruising when blood leaks from a vein into local tissues; can be caused by improper venipuncture when the needle has gone through a vein or when the needle has been inserted incorrectly.

Hemolytic—Destructive to red blood cells.

Venipuncture—Puncture of a vein with a needle for the purpose of withdrawing a blood sample for analysis.

Wilson's disease—A genetic disorder that leads to excessive amounts of copper in the body. Patients often have damaging deposits of copper in the brain, liver, and other organs, and a green discoloration from copper around the iris of the eyes. This disease is also called hepatolenticular degeneration.

ic diseases, C3 and C4 levels are elevated owing to increased complement activation.

C-reactive protein (CRP): C-reactive protein is a protein consisting of five subunits (molecular weight 120,000) produced mainly in the liver. Its name is derived from the fact that it binds to the C-polysaccharide of the capsule of *Streptococcus pneumoniae*. Increased levels are seen in patients with pneumococcal **pneumonia** as well as other acute infections and inflammatory conditions. In the absence of inflammation, CRP levels in plasma are very low (< 4 mg/L). Levels in inflammation can reach several hundred-fold above normal, causing a small but distinct band in the gamma zone on electrophoresis. Recent studies have shown that a CRP near the upper limit of normal (5-10 mg/L) in persons with a history of chronic inflammation is a risk factor for **coronary artery disease**. A new test, called high-sensitivity CRP, can measure CRP levels below 1 mg/L; and is being used by some cardiologists to predict the risk of coronary artery disease in persons with normal total cholesterol who have no history of angina or **heart** disease. CRP is measured by immunonephelometry or enzyme immunoassay.

Haptoglobin: Hp is a glycoprotein (molecular weight 85,000-100,000) made by the liver. Hp binds to free plasma hemoglobin, transporting it to the liver,

where the complex is removed by the reticuloendothelial cells. Low levels are seen in persons with intravascular hemolysis (e.g., following an intravascular transfusion reaction). Haptoglobin is also an acute phase protein. Hp and alpha-2 macroglobulin are responsible for the increased density of the alpha-2 band on electrophoresis seen in acute and chronic inflammatory states. Hp is measured by immunonephelometry.

Immunoglobulins G, A and M (IgG, IgA, and IgM): Immunoglobulins are antibodies produced by B lymphocytes and secreted by plasma cells. They will be increased in response to infections, malignancy, and autoimmune diseases—all of which produce a polyclonal response (i.e., a general increase in all three immunoglobulin classes). This response causes a diffuse increase in the density of the gamma zone on electrophoresis. In malignant or benign plasma cell disorders, proliferation of a single clone of plasma cells results in the accumulation of identical antibody molecules called a monoclonal gammopathy. This result may be recognized on electrophoresis as an area of restricted mobility in the gamma zone. Decreased plasma concentration of one or more immunoglobulin classes may be associated with immunologic impairment and result in both recurrent and opportunistic infections. Both increases and decreases of each immunoglobulin class can be detected by immunonephelometry, using antibodies specific for each. For example, rabbit anti-human IgG can be used to measure the plasma concentration of IgG.

Transferrin: TRF is a glycoprotein (molecular weight 77,000) made by the liver. It is responsible for transport of **iron** from the gut to the bone marrow. The concentration of transferrin in the plasma is directly related to the total iron binding capacity (TIBC). In iron deficiency, the transferrin level is increased, causing an increase in the density of the beta globulin band on electrophoresis. Transferrin levels are decreased in nephrosis, liver disease, starvation, and chronic illness. Like albumin, transferrin is reduced in acute and chronic inflammation and is referred to as a negative acute phase protein.

Transthyretin: Transthyretin or prealbumin is a glycoprotein (molecular weight 54,000) made in the liver. TTR has a very short half-life, making it a useful marker for protein calorie malnutrition. In persons with deficient protein intake, the plasma level of TTR decreases before those of most other proteins. The level of TTR can be monitored to assess the efficacy of dietary intervention in malnourished persons. TTR is measured by immunonephelometry.

Preparation

Prior to performing the venipuncture, the nurse or other health care professional should document any medications the patient is currently taking, and any medical conditions that could influence the protein tests. For example, oral contraceptives, estrogen-containing drugs, or **pregnancy** can increase the level of ceruloplasmin.

Aftercare

The patient may feel discomfort when blood is drawn from a vein. Bruising may occur at the puncture site, or the person may feel dizzy or faint. Pressure should be applied to the puncture site until the bleeding stops, to reduce bruising. Warm packs can also be placed over the puncture site to relieve discomfort.

Complications

In normal circumstances, a blood draw for protein tests takes only a few minutes, and the patient experiences only minor discomfort from the puncture.

Results

The physician will carefully consider the results from the specific protein test within the context of the patient's current health status to make decisions on further testing, diagnosis, and treatment. The protein test results must be interpreted by comparison with standard reference ranges provided by the laboratory that has performed the test. The normal ranges shown below are frequently cited for the methods described previously.

- total protein: 6.0-8.0 g/dL nonambulatory; 6.5-8.5 g/dL ambulatory
- albumin: 3.0-5.0 g/dL nonambulatory; 3.5-5.5 g/dL ambulatory
- alpha-1 antitrypsin: 90-200 mg/dL
- ceruloplasmin: 20-60 mg/dL
- C-reactive protein: 0.7-8.2 mg/L
- Hs-CPR: 0.08-3.1 mg/L
- C3: 90-180 mg/dL
- C4: 10-40 mg/dL
- haptoglobin: 30 - 200 mg/dL
- immunoglobulins: IgG: 700-1600 mg/dL; IgA: 70-400 mg/dL; IgM: 40-230 mg/dL
- transferrin: 200-360 mg/dL
- transthyretin: 20-40 mg/dL

Health care team roles

In accordance with the physician's orders, the nurse, phlebotomist, or laboratory professional usually prepares the patient, performs the blood draw, and readies the specimen for transport to the laboratory for analysis. A clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or clinical laboratory technician CLT(NCA)/medical laboratory technician MLT(ASCP) performs the testing. Results are interpreted by a physician.

Plasma renin activity

Definition

Renin is an enzyme released by the kidneys to help control the body's sodium-potassium balance, fluid volume, and **blood pressure**. Renin splits angiotensinogen

in plasma, forming angiotensin I. This compound is acted upon by plasma-converting enzymes produced in the **lungs** to form antiotensin II or III. These powerful vasoconstrictors increase **blood** pressure and stimulate aldosterone release by the adrenal cortex.

Purpose

Plasma renin activity (PRA), also called plasma renin assay, is used to investigate the cause of **hypertension**. PRA is increased in persons with hypertension of renal origin. It is used to classify persons with essential hypertension. A PRA test, along with a measurement of the plasma aldosterone level, is used for the differential diagnosis of primary and secondary aldosteronism. The latter condition is caused by increased renin release by the kidney(s), and therefore, elevated PRA. Patients with primary hyperaldosteronism (caused by an adrenal tumor that overproduces aldosterone) will have an increased aldosterone level with decreased renin activity.

Precautions

Patients taking diuretics, antihypertensives, vasodilators, oral contraceptives, and licorice should discontinue use of these substances for two to four weeks before the test. It should be noted that renin activity is increased in **pregnancy** and in diets with reduced salt intake. Also, since renin is affected by body position, as well as by diurnal variation, blood samples should be drawn in the morning, and the position of the patient (sitting or lying down) should be noted.

The nurse or phlebotomist performing the venipuncture should follow **universal precautions** for the prevention of transmission of bloodborne pathogens. Blood should be collected in EDTA in a chilled syringe, and the sample immediately placed on ice. The plasma should be separated from the cells immediately and then frozen until assay.

Description

The **kidneys** normally release renin in response to decreased blood volume, low plasma sodium, and high plasma potassium levels. The release of renin is the first step in the renin-angiotensin-aldosterone cycle. Renin is produced and secreted by specialized cells called juxtaglomerular cells, located at the junction where the distal tubule meets the afferent and efferent arterioles. These cells secrete renin in response to a decreased flow of blood through the afferent arteriole. Renin is a proteolytic enzyme; it splits angiotensinogen in the plasma forming angiotensin I, which in turn is converted to angiotensin II or III by a converting enzyme produced by

the lungs. Angiotensins II and III are powerful blood vessel constrictors. In addition, they stimulate the release of aldosterone from the cortex of the **adrenal glands**. Aldosterone causes increased sodium reabsorption by the kidneys. As sodium is reabsorbed, the osmotic pressure (osmolality) of the plasma rises, and this rise stimulates osmoreceptors in the **central nervous system**. These cause secretion of antidiuretic hormone (vasopressin) from the posterior **pituitary gland**. Vasopressin causes more water to be reabsorbed by the kidney. Reabsorption increases blood volume and restores the blood pressure in the afferent arterioles reducing renin release. Together, angiotensin and aldosterone increase the blood volume, the blood pressure, and the blood sodium to re-establish the body's sodium-potassium and fluid volume balance.

High blood pressure affects about 20 million people in the United States and is a major risk factor for cardiovascular disease and stroke. More than 90% of hypertension is due to essential (primary) hypertension. This form of high blood pressure is genetic and its causes are unknown. Essential hypertension is aggravated by excess sodium intake, and affected individuals vary in their response to treatment. Plasma renin activity can be used to classify persons with essential hypertension into groups (high, normal, or low PRA) that respond differently to treatment. For instance, low PRA-type essential hypertension results from excessive aldosterone secretion (primary aldosteronism), and is effectively treated by diuretic therapy.

Measurement

Renin itself is not actually measured in the PRA test. There are two forms of this test. The classic test is called the plasma renin activity (PRA) test, and the newer form is called the plasma renin concentration (PRC) test. Both tests measure the conversion of angiotensinogen to angiotensin I by renin. The difference between the two is that the former uses endogenous (i.e., the patient's own) plasma angiotensinogen as the substrate, while the latter uses excess angiotensinogen from an exogenous source such as sheep plasma. To perform the activity test, the plasma is thawed and a small measured amount is added to a buffered solution at pH 6 that contains phenylmethyl sulfonyl fluoride to inhibit plasma angiotensinases that also split angiotensinogen. The mixture is incubated for one hour at 37°C and then refrigerated to stop the enzyme activity. Following this, the angiotensin I produced is measured by radioimmunoassay (RIA). To correct for the endogenous angiotensin I present beforehand, an equal amount of the thawed sample is kept at 4°C and then measured for angiotensin I activity by RIA. This value is subtracted from the test result obtained from the 37°C incubation. The plasma renin concentration test is per-

formed as described above, except that the test plasma is first treated with an acid buffer to destroy the endogenous angiotensinogen. A measured volume of the treated plasma is added to a buffered solution containing an excess amount of exogenous angiotensinogen. The amount of angiotensin I produced following the incubation is equivalent to the maximum rate of enzyme activity, and is a more accurate reflection of renin concentration because it is independent of the plasma angiotensinogen.

Both the PRA and the PRC are extremely difficult to perform. Not only is renin itself unstable, but the patient's body position and the time the specimen is collected affect the results. Also, the sample must be collected properly: drawn into a chilled syringe and collection tube, placed on ice, and sent to the laboratory immediately. Even when all these procedures are followed, results can vary significantly. An alternative method is the measurement of plasma renin mass by double antibody sandwich immunoassay. This assay uses two monoclonal antibodies, one that binds to the prorenin molecule and a second that binds to renin. This assay detects only active renin because the inactive enzyme is not bound by the second antibody. The mass unit assay is independent of angiotensinogen and therefore not as subject to procedural errors related to temperature inactivation of the enzyme.

Renin stimulation tests

A renin stimulation test is performed to help diagnose and distinguish primary from secondary aldosteronism. The test protocol involves either stimulating salt loss by administration of furosemide, a diuretic; or restricting the patient's salt intake for three to five days. A low sodium level and standing posture stimulate renin release in normal persons, resulting in a two to three fold increase in PRA. Persons with secondary aldosteronism (renin-mediated aldosteronism) typically show a five-fold increase in PRA. Persons with primary aldosteronism show no increase in PRA over the baseline.

One example of a stimulation test is performed as follows. With the patient having been on a low-salt diet and lying down for the test, a blood sample for PRA is obtained. The PRA is repeated with the patient still on the low-salt diet, but now standing upright for two or more hours. In cases of primary hyperaldosteronism, the blood volume is greatly expanded, and a change in position or reduced salt intake does not result in decreased renal blood flow or decreased blood sodium. As a result, renin levels do not increase. However, in secondary hyperaldosteronism, blood sodium levels decrease with a lowered salt intake, and when the patient is standing upright,

KEY TERMS

Aldosteronism—A disorder caused by excessive production of the hormone aldosterone, which is produced by a part of the adrenal glands called the adrenal cortex. Causes include a tumor of the adrenal gland (Conn's syndrome), or a disorder reducing the blood flow through the kidney. This leads to overproduction of renin and angiotensin, and in turn causes excessive aldosterone production. Symptoms include hypertension, impaired kidney function, thirst, and muscle weakness.

Conn's syndrome—A disorder caused by excessive aldosterone secretion by a benign tumor of one of the adrenal glands. This hypersecretion results in malfunction of the body's salt and water balance and subsequently causes hypertension. Symptoms include thirst, muscle weakness, and excessive urination.

the renal blood flow decreases as well. Consequently, renin levels will increase.

Captopril suppression test

The captopril test is a screening test for renovascular hypertension. This is a common form of secondary aldosteronism. For this test, a baseline PRA test is measured; then the patient receives an oral dose of captopril, an angiotensin-converting enzyme (ACE) inhibitor. Blood pressure measurements are taken at this time and again at 60 minutes, when another PRA test is done. Patients with kidney-based hypertension demonstrate greater falls in blood pressure and increases in PRA after captopril administration than do those with essential hypertension. Consequently, the captopril test is an excellent screening procedure to determine the need for a more invasive radiographic evaluation such as renal arteriography.

Preparation

This test requires a blood sample. For the PRA, the patient should maintain a normal diet with a normal amount of sodium (approximately 3 g per day) for three days before the test, unless specified otherwise as for a stimulation test. It is recommended that the patient be fasting (nothing to eat or drink) from midnight on the day of the test.

Aftercare

Discomfort or bruising may occur at the puncture site. Applying pressure to the puncture site until the bleeding stops helps to reduce bruising; warm packs

relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test.

Results

Reference values for the PRA test are laboratory-specific, and depend upon the patient's diet (sodium restricted or normal), the age of the patient, and the patient's posture at the time of the test. Values are also affected if renin has been stimulated or if the patient has received an ACE inhibitor like captopril. A representative normal range for the PRA test in adults on a normal diet is 0.2-3.3 nanograms angiotensin I per mL per hour. For the monoclonal double antibody sandwich assay (direct renin assay), the normal range is 7-76 U/mL for persons not lying down.

Increased PRA levels are seen in up to 15% of persons with essential hypertension (associated with renal injury or vascular disease), malignant hypertension, and kidney-based (renovascular) hypertension. Renin-producing renal and other tumors, while rare, can also cause elevated levels; as can cirrhosis, low blood volume due to hemorrhage, and diminished adrenal function (Addison's disease). Decreased renin levels may indicate increased blood volume due to a high-sodium diet, salt-retaining steroids, primary aldosteronism, or licorice ingestion syndrome. About 25% of persons with essential hypertension will have low renin levels.

Health care team roles

Physicians order PRA tests and interpret the results. A nurse or phlebotomist usually collects the blood and is responsible for icing the sample and transporting to the laboratory. Clinical laboratory scientists/medical technologists perform the renin (and angiotensin I) tests.

Platelet aggregation test

Definition

Platelets (thrombocytes) are small anucleate (i.e. without a nucleus) disk-shaped **blood** cells that play a major role in the blood-clotting process. When a blood vessel wall is cut or injured, platelets adhere to the damaged site and aggregate (clump) together to form a barrier to the escape of blood. The platelet aggregation test is a measure of the platelet clumping function.

Purpose

The platelet aggregation test aids in the evaluation of **bleeding disorders** by measuring the rate and degree to which platelets aggregate after the addition of a chemical, an agonist, that stimulates platelet clumping. The test can be used to differentiate between several inherited and acquired disorders of platelet function.

Precautions

There are many medications that can affect the results of the platelet aggregation test. The patient should discontinue as many of these as possible beforehand. Some of the drugs that can decrease platelet aggregation include aspirin, some **antibiotics**, beta-blockers, dextran (Macrodex), alcohol, heparin (Lipo-Hepin), **non-steroidal anti-inflammatory drugs** (NSAIDs), tricyclic antidepressants, and warfarin (Coumadin).

Description

There are many factors involved in blood clotting (coagulation). One of the first steps in the process involves small cells in the bloodstream called platelets, which are produced in the bone marrow. Platelets gather at the site of an injury, adhere to the damaged vessel wall, and aggregate together forming a plug that helps to limit the loss of blood and promote healing. Normal aggregation depends upon the release of platelet granules, normal membrane receptors on the platelets, and a normal level of plasma fibrinogen.

A defect in platelet aggregation will result in a prolonged bleeding time. Abnormal platelet aggregation may be caused by an inherited bleeding disorder (e.g., von Willebrand's disease); certain acquired bleeding disorders that occur as a consequence of another disease or condition (e.g. connective tissue or collagen disorders, kidney or **liver** failure, leukemia, myeloma); or by certain medications (e.g., aspirin, heparin, and NSAIDs).

The platelet aggregation test uses an instrument called an aggregometer to measure the optical density (turbidity) of platelet-rich plasma. The plasma should stand at room temperature for 30 minutes prior to the assay, but the tests should be performed within three hours of sample collection. Several different substances called agonists are used in the test. These agonists include adenosine diphosphate (ADP), epinephrine, thrombin, collagen, arachidonic acid, and ristocetin. The addition of an agonist to a plasma sample causes the platelets to aggregate, making the fluid more transparent. The aggregometer then measures the increased light transmission through the specimen. Some aggregometers measure platelet aggregation of whole blood. These instruments use two electrodes that measure impedance (resistance to current flow). When platelet aggregation occurs, the platelets collect at the electrode surface, increasing the impedance at the electrode.

Some inherited platelet disorders that can be differentiated by the aggregation response to different agonists include Glanzmann's thrombasthenia, von Willebrand's disease, and Bernard-Soulier disease. Glanzmann's thrombasthenia is an autosomal dominant condition. The platelet count is normal, but the bleeding time is prolonged. Aggregation is normal with ristocetin, but is abnormal with all the other agonists. Von Willebrand's disease is the most common inherited bleeding disorder. It is associated with an increased bleeding and clotting time and is caused by a deficiency of two coagulation factors, factor VIII and von Willebrand factor. The platelet count may be normal or low. It may be inherited as autosomal dominant or autosomal recessive forms. The aggregation profile in von Willebrand's disease is the reverse of that seen in Glanzmann's thrombasthenia. The aggregation with ADP, collagen, thrombin, epinephrine, and arachidonic acid is normal, but is abnormal with ristocetin. Bernard-Soulier disease is an autosomal recessive condition associated with large platelets and an abnormal bleeding time. The platelet count may be normal or low. It produces the same profile as von Willebrand's disease, but the abnormal aggregation with ristocetin cannot be reversed by addition of von Willebrand factor.

Preparation

The test requires a blood sample collected in sodium citrate. The patient should either avoid food and drink altogether for eight hours before the test, or eat only non-fat foods. High levels of fatty substances in the blood can affect test results.

Because the use of aspirin and/or aspirin compounds can directly affect test results, the patient should avoid

KEY TERMS

Aggregation—The blood cell clumping process that is measured in the platelet aggregation test.

Agonist—A chemical that is added to the blood sample in the platelet aggregation test to stimulate the clumping process.

Platelets—Small, round, anucleate disk-shaped blood cells that are involved in clot formation. The platelet aggregation test measures the clumping ability of platelets.

Turbidity—The cloudiness or lack of transparency of a solution.

von Willebrand's disease (vWD)—An autosomal dominant inherited lifelong bleeding disorder caused by a defective gene. The gene defect results in a decreased blood concentration of a substance called von Willebrand factor (vWF). Tests for vWF (and coagulation Factor VIII) are used along with platelet aggregation tests to diagnose this disorder.

these medications for at least one week before the test. The test should be completed within three hours of specimen collection. Specimens that sit at room temperature for four hours or more may lose the ability to aggregate.

Aftercare

Because the platelet aggregation test is ordered when some type of bleeding problem is suspected, the patient should be cautioned to watch the puncture site for signs of additional bleeding.

Complications

Risks for this test are minimal in normal individuals. Patients with bleeding disorders, however, may have prolonged bleeding from the puncture wound; or the formation of a bruise (ecchymosis) or blood clot (hematoma) in or under the skin where the blood was withdrawn.

Results

The platelet aggregation test produces a graph in which the x-axis is time and the y-axis is percent transmission. The platelet aggregation curve will vary depending upon the reaction conditions (e.g., pH of the platelet-rich plasma), agonist used, and agonist concentration. The typical aggregation curve is biphasic. It is

characterized by an initial increase in light transmission (primary wave) followed by a plateau and a second steeper increase in light transmission (secondary wave) caused by irreversible platelet clumping. An exception to this pattern is aggregation with collagen, which produces a single steep increase in light transmission preceded by a lag phase. An abnormal response can be a decreased or absent primary wave, secondary wave, or both.

Abnormal platelet aggregation can be found in such inherited disorders as von Willebrand's disease, as well as in some connective tissue disorders. Abnormal aggregation can also occur in leukemia or myeloma; with medications taken during recent heart/lung bypass or **kidney dialysis**; and after taking certain other drugs.

Health care team roles

The physician orders the test. The specimen will be drawn by a nurse or phlebotomist, and transported to the laboratory. The clinical laboratory scientist/medical technologist will perform the test. The results are interpreted by a hematopathologist.

Pneumonia

Definition

Pneumonia is a serious **infection** of the lung that impairs breathing. Small air sacs in the lung (alveoli) become filled with pus, mucus or other fluid, and cannot supply oxygen to circulating **blood**. Lobar pneumonia affects one section, or lobe, of the lung; bronchial pneu-

monia, or bronchopneumonia, affects scattered areas of either lung.

Description

Pneumonia is not just one disease. Although it is commonly caused by *Streptococcus pneumoniae*, several different microorganisms—as well as toxic chemicals—or choking on food or vomit, can cause the disease.

An estimated four million Americans become ill with pneumonia each year, accounting for one million hospital admissions and over ten million hospital bed days. In the United States, pneumonia is the sixth most common disease leading to death. It is also the most common fatal infection acquired by already hospitalized patients. In developing countries, pneumonia ties with **diarrhea** as the most common cause of death.

Pneumonia is one of the most ancient known diseases. Although the incidence of pneumonia has declined because of the use of **antibiotics**, it has become a more serious health risk among elderly people. From 1980 to 1992, the overall death rate due to pneumonia increased by 20%. Nine out of every ten deaths due to pneumonia occurred among people aged 65 years and over.

Causes and symptoms

Pneumonia can have more than 30 different causes, but the five main causes are:

- **bacteria**
- **viruses**
- mycoplasmas
- other infectious pathogens, like **fungi** (including *Pneumocystis*)
- some chemicals

Common symptoms of pneumonia vary according to its cause, but may include:

- Cough. In bacterial pneumonia, the cough produces a rust-colored or greenish mucus. Pneumonia due to mycoplasmas produces only sparse whitish mucus, while viral pneumonia is generally characterized by a dry cough that worsens over time and ultimately produces a small amount of mucus that is *purulent*, or obviously infected.
- **Fever** (as high as 105°F, or 40.5°C) and chills.
- Localized **pain** in the area of the chest at the location of the lung infection; pain may be severe.
- Shortness of breath (SOB). (Severe pneumonia may cause **cyanosis**, or a bluish tinge to the skin, especially

around the lips and nailbeds, due to lack of oxygen in the blood.)

- Chattering teeth.
- Profuse sweating.
- Rapid breathing and pulse.
- Confused mental state.
- Muscle pain and weakness.

Anatomy of the lung

To better understand pneumonia, it is important to be familiar with the basic anatomic features of the **respiratory system**. The human respiratory system begins at the nose and mouth, where air is breathed in (inspired) and out (expired). The air tube extending from the nose is the nasopharynx. The tube carrying air breathed in through the mouth is the oropharynx. The nasopharynx and the oropharynx merge into the larynx. The oropharynx also carries swallowed substances, including food, water, and salivary secretion, which must pass into the esophagus and then the **stomach**. The larynx is protected by a trap door called the epiglottis, which prevents substances that have been swallowed, as well as substances that have been regurgitated (thrown up), from heading down into the larynx and toward the **lungs**.

The larynx flows into the trachea, which is the broadest part of the respiratory tree. The trachea divides into two tree limbs, the right and left bronchi. Each one of these branches off into multiple smaller bronchi, which penetrate the lung tissue. Each bronchus divides into tubes of smaller and smaller diameter, finally ending in the terminal bronchioles. The air sacs of the lung, in which oxygen-carbon dioxide exchange actually takes place, are clustered at the ends of the bronchioles like the leaves of a tree. They are called alveoli.

The tissue of the lung, which serves only in a supportive role for the bronchi, bronchioles, and alveoli, is known as lung parenchyma.

Function of the respiratory system

The main function of the respiratory system is to provide oxygen, the most important energy source for the body's cells. Inspired air (the air that is breathed in) contains oxygen and travels down the respiratory tree to the alveoli. The oxygen moves out of the alveoli and is sent into circulation throughout the body as part of the red blood cells. The oxygen in the inspired air is exchanged within the alveoli for carbon dioxide, the waste product of the human metabolic process. The air that is breathed out contains the gas carbon dioxide. During expiration,

carbon dioxide leaves the alveoli. As one breathes in oxygen, one breathes out carbon dioxide.

Respiratory system defenses

Bacteria and viruses do not normally reside in significant numbers inside the lung, part of the upper respiratory system. This absence is in contrast to parts of the gastrointestinal system, where bacteria dwell even in a healthy state. There are multiple safeguards along the path of the respiratory system. These are designed to keep organisms from invading and leading to infection.

The first line of defense against infection includes the hairs in the nostrils, which serve as a filter for larger particles. The epiglottis is a "trap door," designed to prevent food and other swallowed substances from entering the larynx and the trachea. Sneezing and coughing, both provoked by the presence of irritants within the respiratory system, help to clear such irritants from the respiratory tract.

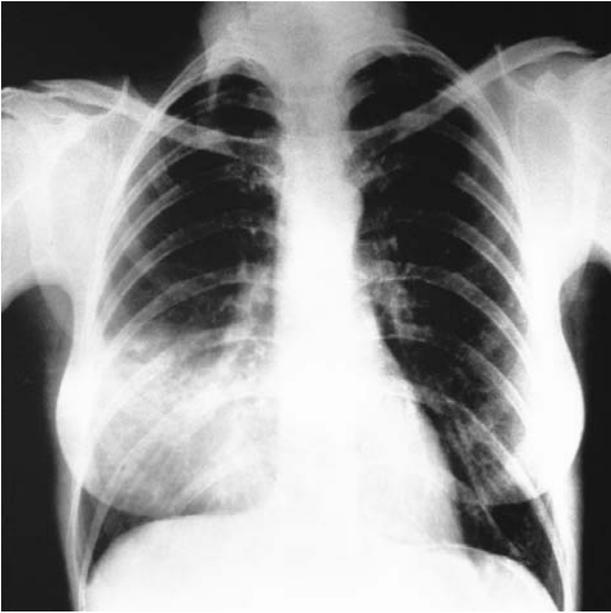

Mucus, produced through the respiratory system, also serves to trap dust and infectious organisms. Tiny hair-like projections (cilia) from cells line the respiratory tract and beat constantly, moving debris trapped by mucus upwards and out of the respiratory tract. This mechanism of protection is called the "mucociliary escalator."

The cells that line the respiratory tract produce several types of immune substances that protect against various organisms. Other cells (macrophages) along the respiratory tract actually ingest and kill invading organisms.

Thus, the organisms that cause pneumonia are usually carefully kept from entering the lungs by virtue of these host defenses. However, when an individual encounters a large number of organisms at once, the usual defenses may be overwhelmed and infection may occur. This may occur either when contaminated air droplets are inhaled, or when aspiration of organisms that inhabit the upper airways takes place.

Conditions predisposing to pneumonia

In addition to exposure to sufficient quantities of causative organisms, certain conditions may make an individual more likely to become sick with pneumonia. Certainly, the lack of normal anatomical structure could result in an increased risk of pneumonia. There are certain inherited defects of cilia that can result in less effective protection. Cigarette smoke, inhaled directly by a smoker or secondhand by an innocent bystander, interferes significantly with ciliary function; and inhibits macrophage (a large white blood cell [WBC] that ingests particles and infectious microorganisms) function.

X ray showing pneumonia in the right lung. (National Aududon Society Collection/Photo Researchers, Inc. Reproduced by permission.)

Stroke, seizures, alcohol, and various drugs interfere with the function of the epiglottis. This interference can lead to a leaky seal on this “trap door,” with possible contamination by swallowed substances and/or regurgitated stomach contents. Alcohol and some drugs may also interfere with the normal cough reflex. An inadequate cough reflex further decreases the success of clearing unwanted debris from the respiratory tract.

Viruses or such other microorganism invaders as bacteria, may interfere with ciliary function and lead to access to the lower respiratory tract. One of the most invasive viruses is HIV (human **immunodeficiency** virus), the causative virus in **AIDS** (acquired immunodeficiency syndrome). In recent years, this virus has resulted in a significant increase in the incidence of pneumonia. Because AIDS results in a general decreased efficiency of many protective mechanisms of the host’s **immune system**, a patient with AIDS may be susceptible to all kinds of pneumonia. This vulnerability includes some parasitic types considered rare prior to the emergence of AIDS in the 1980s. These rare parasites are incapable of causing illness in an individual with a normal immune system.

The elderly have a less effective mucociliary escalator, as well as changes in their immune system that compromise their ability to fight infection. These factors cause this age group to be at greater risk for the development of pneumonia.

Various chronic conditions predispose a person to infection with pneumonia. These conditions include **asthma**, **cystic fibrosis**, and neuromuscular diseases, which may interfere with the seal of the epiglottis. Esophageal disorders may result in stomach contents passing upwards into the esophagus. This increases the risk of aspiration into the lungs of stomach contents (with their normally resident bacteria). Diabetes, sickle cell anemia, lymphoma, leukemia, and **emphysema** also predispose a person to pneumonia.

Pneumonia is one of the most frequent infectious complications of all types of surgery. Many drugs used during and after surgery may increase the risk of aspiration, impair the cough reflex, and cause a patient to underfill his or her lungs with air. Pain after surgery also discourages a patient from breathing deeply enough, and from coughing effectively.

The number of organisms that can cause pneumonia is very large, and includes nearly every class of infectious organism, including viruses, bacteria, bacteria-like organisms, fungi, and parasites (including certain worms). Different organisms are more frequently encountered by different age groups. Further, other characteristics of an individual may place him or her at greater risk for infection by particular types of organisms:

- Viruses cause the majority of pneumonias in young children (especially respiratory syncytial virus [RSV]), parainfluenza, **influenza** viruses, and adenovirus).
- Adults are more frequently infected with bacteria (such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*), but the numbers of both adults and children are increasing globally, and both groups are being infected with *Pneumococcus*, a common bacterium.
- Pneumonia in older children and young adults is often caused by the bacteria-like *Mycoplasma pneumoniae*, the cause of what is often referred to as “walking” pneumonia.
- *Pneumocystis carinii* is an extremely important cause of pneumonia in patients with immune problems (such as patients being treated for **cancer** with **chemotherapy**, or patients with AIDS). Classically considered a parasite, *Pneumocystis* appears to be more related to fungi.
- People who come into contact with bird droppings, such as poultry workers, are at risk for pneumonia caused by the organism *Chlamydia psittaci*.
- A very large serious outbreak of pneumonia occurred in 1976, when many people attending an American Legion convention were infected by a previously unknown organism. Subsequently named *Legionella*

pneumophila, it causes what is now called “Legionnaire’s Disease.” The organism was traced to air conditioning units in the convention’s hotel.

Pneumonia is suspected in the patient who is febrile, has a cough, chest pain, SOB, and an increased rate of respiration (number of breaths per minute). Fever with a shaking chill is even more suspicious. Many patients cough up clumps of sputum—commonly known as “spit.” These secretions are produced in the alveoli during an infection or other inflammatory condition. They may appear streaked with pus or blood.

Severe pneumonia results in the signs of oxygen deprivation. These include a blue appearance of the nail beds or lips (cyanosis). The invading organism causes symptoms in part by provoking an overly strong **immune response** in the lungs. Thus, the immune system, which should help fight off infections, kicks into such high gear and damages the lung tissue, making it more susceptible to infection. The small **blood vessels** in the lungs (capillaries) become leaky, and protein-rich fluid seeps into the alveoli. This seepage results in less functional area for oxygen-carbon dioxide exchange. The patient becomes relatively oxygen-deprived while retaining potentially damaging carbon dioxide. The patient breathes faster and faster in an effort to inhale more oxygen and exhale more carbon dioxide.

Mucus production is increased, and the leaky capillaries may tinge the mucus with blood. Mucus plugs actually further decrease the efficiency of **gas exchange** in the lung. The alveoli fill further with fluid and debris from the large number of white blood cells (WBCs) being produced to fight the infection.

Consolidation, a feature of bacterial pneumonia, occurs when the alveoli—normally hollow air spaces within the lung—become solid due to quantities of fluid and debris.

Viral pneumonia and mycoplasma pneumonia do not result in consolidation. These types of pneumonia primarily infect the walls of the alveoli and the parenchyma of the lung.

X-ray examination of the chest may reveal certain abnormal changes associated with pneumonia. Localized shadows obscuring areas of the lung may indicate a bacterial pneumonia, while streaky- or patchy-appearing changes in the x-ray picture may indicate viral or mycoplasma pneumonia.

Diagnosis

Diagnosis is based on the patient’s symptoms and **physical examination** of the chest. When the physician listens with a **stethoscope**, abnormal sounds are

revealed. Tapping on the patient’s back, which should produce a resonant sound as a result of air filling the alveoli, may yield a dull thump if the alveoli are filled with fluid and debris.

Diagnosis of some bacterial pneumonias can be made with the results of specific laboratory tests. By staining sputum with special chemicals and examining it under a **microscope**, the technician can identify specific types of bacteria. Identification may require culturing the sputum, a procedure in which the sputum sample is used to grow greater numbers of itself (the bacteria) in a lab (petri) dish.

Treatment

Prior to the discovery of penicillin and other antibiotics, bacterial pneumonia was almost always fatal. As of 2001, when antibiotics are given early in the course of the disease, they are very effective against bacterial causes of pneumonia. Both erythromycin (E-Mycin, ERYC) and tetracycline (achromycin, sumycin) improve recovery time for symptoms of mycoplasma pneumonia. They do not, however, eradicate the organisms. Amantadine (Symmetrel) and acyclovir (Zovirax) may be helpful against certain viral pneumonias.

Prognosis

Prognosis varies according to the type of organism causing the infection. Recovery following pneumonia with *Mycoplasma pneumoniae* is nearly 100%. *Staphylococcus pneumoniae* has a death rate of 30–40%. Similarly, infections with a number of gram-negative bacteria (such as those in the gastrointestinal tract, which can cause infection following aspiration) have a high death rate—25–50%. *Streptococcus pneumoniae*, the most common organism causing pneumonia, produces a death rate of about 5%. More complications occur in the very young, or in elderly individuals who may have infections in multiple areas of the lung simultaneously. Individuals with other chronic illnesses—such as cirrhosis of the **liver**, congestive **heart** failure—or those without a functioning spleen or those who have other diseases that result in a weakened immune system—may experience complications. Patients with immune disorders, various types of cancer, transplanted organ(s) or tissue(s) transplants, or AIDS also may experience complications.

Health care team roles

In most cases, a diagnosis of pneumonia is made in a physician’s office, a general medical clinic, or emergency room by a primary care practitioner. Children and adolescents with pneumonia are most likely to be diagnosed by their primary care physician or pediatrician.

KEY TERMS

Alveoli—The little air sacs clustered at the ends of the bronchioles, in which oxygen-carbon dioxide exchange takes place.

Aspiration—A situation in which solids or liquids that should be swallowed into the stomach are instead breathed into the respiratory system.

Cilia—Hair-like projections from certain types of cells.

Cyanosis—A bluish tinge to the skin that can occur when the blood oxygen level drops too low.

Parenchyma—A term used to describe the supportive tissue surrounding a particular structure. An example is the tissue that surrounds and supports the actually functional lung tissue.

Sputum—Material produced within the alveoli in response to an infectious or inflammatory process.

Both registered nurses (RNs) and licensed practical nurses (LPNs) must complete a prescribed course in nursing and pass a state examination. RNs typically have a degree in nursing. Both RNs and LPNs are often the specialists who deal the most with pneumonia patients, both in general hospitals, homes, or other health care facilities. Good nursing care and observation are primary requirements. These include monitoring **vital signs**, including oxygen saturation (the amount of oxygen circulating in the blood), encouraging the patient to move, breathe deeply, cough, and get out of bed with assistance (if indicated) to facilitate good lung expansion. The nurse should also provide education to the patient about the importance of coughing, breathing deeply, and taking in adequate fluid.

Clinical laboratory scientists have specialized training and must pass a state examination. These are the staff who analyze blood samples or test urine/sputum specimens that reflect the presence of pneumonia at the outset, and as it resolves. These tests are typically ordered by physicians to diagnose and assess the progress of the infection.

Radiologic technologists have specialized training and must pass a state examination. Their responsibility is to take chest x rays to visualize and monitor the course of the pneumonia.

Prevention

Because many bacterial pneumonias occur in patients who are first infected with the influenza virus (the flu), yearly **vaccination** against influenza can

decrease the risk of pneumonia in certain patients. This is particularly true of the elderly and those afflicted with such chronic diseases as asthma, cystic fibrosis, other lung or heart diseases, **sickle cell disease**, diabetes, kidney disease, and some cancers.

A specific vaccine against *Streptococcus pneumoniae* and another vaccine developed in the early 2000s against *Pneumococcus* are very protective, and should also be administered to people over 65 years of age as well as to patients with chronic illnesses.

Poisoning

Definition

Poisoning is the state produced by the introduction of toxic substances; that is, any substance that produces an injurious or fatal effect, into the body.

Description

Poisoning commonly involves the introduction of poisonous elements from outside the body. The term also can apply to noxious material produced within the body that, because of a disease condition such as kidney or **liver** failure, cannot be removed; or toxins produced by **bacteria**, as in the case of **food poisoning**. Poisons can enter the body from multiple external sources. They can be swallowed; inhaled, as in the case of carbon monoxide or aerosol compounds; or they can enter via the skin, as in snake or insect bites; and even via radiation from the sun that we call *sun poisoning*. Some question exists regarding whether electro-magnetic fields (EMFs) also produce damaging effects within the body.

Poisoning is a common occurrence. An estimated 10 million cases of poisoning occur in the United States each year. 2.24 million exposures to poisonous substances were reported to United States Poison Control Centers in 1998. In 50% of the cases, the victim is a child under the age of five. The most common toxic substances taken in are cosmetics and personal care products, followed by home cleaning products, medications and plants. Most poisonings, nearly 89%, occur in the home, and are accidental.

About 50 children die each year in the United States from poisoning. Curiosity, inability to read warning labels, a desire to imitate adults, and inadequate supervision lead to childhood poisonings. The elderly are the second most likely group to be poisoned. Mental confusion, poor eyesight, and the use of multiple drugs are the leading reasons why this group has a high rate of accidental poisoning. A substantial number—approximately eleven percent of all poisonings—also occur as suicide attempts.

Poisons taken internally are common in the home and workplace. There are basically two major types. One group consists of products that were never meant to be ingested or inhaled, such as shampoo, paint thinner, pesticides, houseplant leaves, and carbon monoxide. The other group contains products that can be safely ingested in small quantities, but which are harmful if taken in large amounts. These include pharmaceuticals, medicinal herbs, or alcohol. Other types of poisons include the bacterial toxins that cause food poisoning, such as *Escherichia coli*; heavy metals, such as the lead found in the paint on older houses; and the venom found in the **bites and stings** of some animals and insects. The staff at a poison control center and emergency room doctors have the most experience diagnosing and treating poisoning cases.

Causes and symptoms

The effects of poisons are as varied as the poisons themselves. The exact mechanisms of only a few are understood. Some poisons interfere with the **metabolism**. Others destroy the liver or **kidneys**, such as heavy metals and some **pain** relief medications, including acetaminophen (Tylenol) and **nonsteroidal anti-inflammatory drugs** (Advil, Ibuprofen). A poison may severely depress the **central nervous system**, leading to **coma** and eventual respiratory and circulatory failure. Potential poisons in this category include anesthetics (e.g. ether and chloroform); opiates (e.g. morphine and codeine); and barbiturates. Some poisons directly affect the respiratory and circulatory systems. Carbon monoxide causes death by binding with hemoglobin that would normally transport oxygen throughout the body. Certain corrosive vapors trigger the body to flood the **lungs** with fluids, effectively drowning the person. Cyanide interferes with respiration at the cellular level. Another group of poisons interferes with the electrochemical impulses that travel between **neurons** in the nervous system. Another group, including cocaine, ergot, strychnine, and some snake venoms, causes potentially fatal seizures.

Severity of poisoning symptoms can range from headache and nausea to convulsions and death. The type of poison; the amount and time of exposure; and the age, size, and health of the victim are all factors that determine the severity of symptoms and the chances for recovery.

Plant poisoning

There are more than 700 species of poisonous plants in the United States. Plants are second only to medicines in causing serious poisoning in children under age five. The appearance of a plant offers no determination of its poison. Some plants, such as the yew shrub, are almost entirely toxic: needles, bark, seeds, and berries. In other plants, only certain parts are poisonous. The bulb of the hyacinth and daffodil are toxic, but the flowers are not. It is the flowers of the jasmine plant that are the poisonous part. Some plants are confusing because portions of them are eaten as food while other parts are poisonous. For example, the fleshy stem (tuber) of the potato plant is nutritious; however, its roots, sprouts, and vines are poisonous. The leaves of tomatoes are poisonous, while the fruit is not. Rhubarb stalks are good to eat, but the leaves are poisonous. Apricots, cherries, peaches, and apples all produce healthful fruit, but their seeds contain a form of cyanide that can kill a child if chewed in sufficient quantities. One hundred milligrams (mg) of moist, crushed apricot seeds can produce 217 milligrams of cyanide.

Common houseplants that contain some poisonous parts include:

COMMON HOUSEHOLD, INDUSTRIAL, AND AGRICULTURAL PRODUCTS CONTAINING TOXIC SUBSTANCES

Alcohol (rubbing)	Fuel
Antifreeze	Floor/furniture polish
Arsenic	Gasoline
Art and craft supplies	Glues/adhesives
Automotive fluids	Hemlock
Batteries, automotive	Kerosene
Batteries, household	Mercury
Building products	Metal primers
Cleaning products	Metalworking materials
Cosmetics/personal care products	Mothballs
Cyanide	Oven cleaners
Daffodil bulbs	Paint strippers/thinners
<i>Dieffenbachia</i>	Paints, oil-based or alkyds
Disinfectants/air fresheners	Paints, water-based or latex
Drain openers	Pesticides, flea collars, insect repellents
English nightshade	Stains/finishes
Ethanol (found in alcoholic beverages)	Strychnine
Foxglove	Wood preservatives

(Illustration by Standley Publishing. Courtesy of Gale Group.)

- aloe
- amaryllis
- Boston ivy
- caladium
- cyclamen
- dumb cane (also called *Dieffenbachia*)
- philodendron

Common outdoor plants that contain some poisonous part include:

- azalea
- bird-of-paradise flower
- black cherry
- buttercup
- calla lilly
- castor bean
- chinaberry tree
- caffodil
- delphinium
- English ivy
- eucalyptus
- foxglove
- holly
- horse chestnut
- hydrangea
- iris
- jack-in-the-pulpit
- jimson weed (also called thornapple)
- larkspur
- lily-of-the-valley
- morning glory
- nightshade (several varieties)
- oleander
- potato
- rhododendron
- rhubarb
- sweet pea
- tomato
- wisteria
- yew

Symptoms of plant poisoning range from irritation of the skin or mucous membranes of the mouth and throat to nausea, vomiting, convulsions, irregular heartbeat, and even death. It is often difficult to tell if a person has eaten

a poisonous plant because there are no telltale empty containers and no unusual lesions or odors around the mouth.

Household chemicals

Many products used daily in the home are poisonous if swallowed. These products often contain strong acids or strong bases (alkalis). Toxic household cleaning products include:

- ammonia
- bleach
- dishwashing liquids
- drain openers
- floor waxes and furniture polishes
- laundry detergents, spot cleaners, and fabric softeners
- mildew removers
- oven cleaners
- toilet bowl cleaners

Personal care products found in the home can also be poisonous. These include:

- deodorant
- hair spray
- hair straighteners
- nail polish and polish remover
- perfume
- shampoo

Signs that a person has swallowed one of these substances include evidence of an empty container nearby, nausea or vomiting, and **burns** on the lips and skin around the mouth if the substance is a strong acid or alkali. The chemicals in some of these products may leave a distinctive odor on the breath.

Pharmaceuticals

Both over-the-counter and prescription medicines can help the body heal if taken as directed. When taken in large quantities, or with other drugs where there may be an adverse interaction, they can subsequently act as poisons. Drug overdoses, both accidental and intentional, are the leading cause of poisoning in adults. Medicinal herbs should be treated like pharmaceuticals and taken only in designated quantities under the supervision of a knowledgeable person. Herbs that have healing qualities when taken in small doses can be toxic in larger doses.

Diagnosis

Initially, poisoning is suspected if the victim shows changes in behavior and the signs or symptoms previously described. Evidence of an empty container or information from the victim are helpful in determining exactly what substance has caused the poisoning. Some acids and alkalis leave burns on the mouth. Petroleum products, such as lighter fluid or kerosene, leave a distinctive odor on the breath. Vomitus may be tested to determine the exact composition of the poison. Once hospitalized, **blood** and urine tests may be done on the patient to determine his metabolic condition.

Treatment

Treatment for poisoning depends on the poison swallowed or inhaled. Contacting a poison control center or hospital emergency room is the first step in getting proper treatment. The poison control center's telephone number is often listed with emergency numbers on the inside cover of the telephone book, or can be reached by dialing 911 or the operator. The poison control center will ask for specific information about the victim and the poison, then give appropriate **first aid** instructions. If the patient is to be taken to a hospital, a sample of vomitus and the poison container should be taken along, if they are available.

Most cases of plant poisoning are treated by inducing vomiting, if the person is fully conscious. Vomiting can be induced by taking syrup of **ipecac**, an over-the-counter product available at any pharmacy.

For acid, alkali, or petroleum product poisonings, the patient should not be made to vomit. Acids and alkalis can burn the esophagus if they are vomited, and petroleum products can be inhaled into the lungs during vomiting, resulting in aspiration **pneumonia**.

Once under medical care, doctors have the option of treating the patient with a specific remedy to counteract the poison (antidote) or with activated charcoal to absorb the substance inside the patient's **digestive system**. In some instances, pumping the **stomach** may be required. Medical personnel will also provide supportive care as needed, such as intravenous fluids or mechanical ventilation.

Prognosis

The outcome of poisoning varies from complete recovery to death, and depends on the type and amount of the poison, the health of the victim, and the speed with which medical care is obtained.

KEY TERMS

Acid—A chemical substance that contains the element hydrogen and has a pH above seven, which is considered neutral. Acids are generally described as sour or biting in character.

Alkali—A chemical substance that has the ability to neutralize acid. It has a pH below seven, which is considered neutral, and is generally described as caustic in nature.

Aspiration pneumonia—Fluid entering the lungs through choking or vomiting, and leading to infection of the lung.

Gastric lavage—Insertion of a tube into the stomach for the purpose of washing out and removing toxic material.

Ipecac—A medication made from the dried root of a plant native to Brazil, often used to induce vomiting.

Health care team roles

In most cases, a poisoning victim will initially be discovered by a family member or friend. Once the health care staff has been engaged at the request of those involved, it can include:

- Staff at local poison control centers. These are people specially trained regarding the properties and treatment of poisons. Staff may include physicians and nurses who are especially skilled at obtaining necessary information regarding the poison and providing the needed facts in regard to treatment.
- **Emergency medical technicians (EMTs)**, are specially trained in providing emergency care to people outside of hospitals. Often under the supervision of an emergency room physician, EMTs are frequently the first to provide medical intervention. They work from ambulances, providing the initial care often in the home, or place where the poisoning took place.
- If the poisoning victim is transported to a hospital emergency room, a licensed physician trained in emergency medicine will either begin or take further measures to negate the effect of the poison.
- Both registered nurses (RNs), and licensed practical nurses (LPNs) work in hospital emergency rooms, and are often located in poison control centers. In emergency rooms, both RNs and LPNs will be responsible for monitoring **vital signs**, obtaining specimens of vomitus, administering such medications as activated

charcoal or ipecac, or providing assistance in carrying out such procedures as gastric lavage (pumping the stomach). Providing reassurance to frightened patients and families, and offering information regarding poisons, especially to the families of children that have been poisoned, are both critical elements of care.

- Clinical laboratory scientists have specialized training and must pass a state examination. They draw blood samples or test urine to do toxic screens for various drugs, or other tests that determine what toxic substance has been ingested.
- Radiologic technologists have specialized training and must pass a state examination. They may be called upon to take a **chest x ray** to ensure that the person has not aspirated (had foreign material such as vomit enter the lungs), causing aspiration pneumonia.

Prevention

Most accidental poisonings are preventable. The number of deaths of children from poisoning in the United States has declined from about 450 per year in the 1960s to about 50 each year in the 1990s. This decline has occurred primarily due to better packaging of toxic materials, and to better public education.

Actions to prevent poisonings include:

- removing plants that are poisonous
- keeping medicines and household chemicals locked and in a place inaccessible to children
- keeping medications in child-resistant containers
- never referring to medicine as “candy”
- keeping cleaners and other poisons in their original containers
- disposing of outdated prescription medicines

Polyneuropathies

Definition

Polyneuropathies encompass a wide range of disorders in which the nerves outside of the **brain** and spinal cord—peripheral to the central nervous system—have been damaged. Polyneuropathy is also referred to as peripheral neuritis or polyneuritis.

Description

Polyneuropathy is a common disorder with many underlying causes. Some of these causes occur frequently, such as diabetes, and others are extremely rare, such as acrylamide **poisoning** and certain inherited disorders. The most common worldwide cause of polyneuropathy is leprosy. Leprosy is caused by the bacterium *Mycobacterium leprae*, which attacks the peripheral nerves. According to statistical data from the World Health Organization, an estimated 1.15 million people suffer from leprosy worldwide.

Leprosy is extremely rare in the United States, where diabetes is the most commonly known cause of polyneuropathy. It has been estimated that more than 17 million people in the United States and Europe suffer from diabetes-related polyneuropathy. Many neuropathies are idiopathic, meaning that no known cause can be found. The most common inherited polyneuropathy in the United States is Charcot-Marie-Tooth disease, which affects approximately 125,000 persons.

Another of the better known polyneuropathies is Guillain-Barré syndrome (GBS, acute idiopathic demyelinating polyneuropathy); it is a complication of such viral illnesses, as cytomegalovirus, Epstein-Barr

virus, and human **immunodeficiency** virus (HIV) or bacterial **infection**, including *Campylobacter jejuni* and Lyme disease. The worldwide incidence rate is approximately 1.7 cases per 100,000 people annually. Other well-known causes of polyneuropathies include chronic **alcoholism**, infection, varicella-zoster virus, botulism, and poliomyelitis. Polyneuropathy may develop as a primary symptom, or it may be due to another disease. For example, polyneuropathy is only one symptom of such diseases as amyloid neuropathy, certain cancers, or inherited neurologic disorders. Such diseases may affect the peripheral nervous system (PNS) and the **central nervous system** (CNS), as well as other body tissues.

To understand polyneuropathy and its underlying causes, it may be helpful to review the structures and arrangement of the PNS.

Nerve cells and nerves

Nerve cells are the basic building block of the nervous system. In the PNS, nerve cells can be threadlike—their width is microscopic, but their length may be measured in feet. The long, spidery extensions of nerve cells are called axons. When a nerve cell is stimulated—by touch or **pain**, for example—the message is carried along the axon, and neurotransmitters are released within the cells. Neurotransmitters are chemicals within the nervous system that direct nerve-cell communication.

Certain nerve cell axons, such as those in the PNS, are covered with a substance called myelin. This myelin sheath may be compared to the plastic insulation coating electrical wires—it both protects the cells and prevents interference with the signals being transmitted. Protection is also given by Schwann cells, special cells within the nervous system that wrap around both myelinated and unmyelinated axons.

Nerve cell axons leading to the same areas of the body may be bundled together into nerves. Continuing the comparison to electrical wires, nerves may be compared to an electrical cord—the individual components being coated in their own sheaths and then encased together inside a larger protective sheath.

The nervous system is classified into two parts: the CNS and the PNS. The CNS is the brain and the **spinal cord**, and the PNS is composed of the nerves that lead to or branch off from the CNS.

Peripheral nervous system

The peripheral nerves handle a diverse array of functions in the body. This diversity is reflected in the major divisions of the PNS—the afferent and the efferent divisions. The afferent division conveys sensory information

Chronic alcoholism may lead to such signs as alcoholic neuropathy and ulcers on the feet. (Ansary/Custom Medical Stock Photo. Reproduced by permission.)

from the body to the CNS. When afferent nerve cell endings, called receptors, are stimulated, they release neurotransmitters. These neurotransmitters relay a signal to the brain, which interprets it and reacts by releasing other neurotransmitters.

Some of the neurotransmitters released by the brain are directed at the efferent division of the PNS. The efferent nerves control voluntary movements, such as moving the arms and legs; and involuntary movements, such as making the **heart pump blood**. The nerves controlling voluntary movements are called motor nerves, and the nerves controlling involuntary actions are referred to as autonomic nerves. The afferent and efferent divisions continually interact with one another.

Neuropathy

NERVE DAMAGE. When a patient suffers from a polyneuropathy, nerves of the PNS have been damaged. Nerve damage can arise from a number of causes, such as disease, physical injury, poisoning, or malnutrition. These agents may affect either afferent or efferent nerves. Depending upon the cause of damage, the nerve cell axon, its protective myelin sheath, or both may be injured or destroyed.

CLASSIFICATION. There are hundreds of polyneuropathies. Reflecting the scope of PNS activity, symptoms may involve sensory, motor, or autonomic functions. To aid in diagnosis and treatment, symptoms are classified into principal neuropathic syndromes, based on the type of affected nerves and how long symptoms have been developing. Acute development refers to symptoms that have appeared within days, and subacute refers to those that have evolved over a number of weeks. Early chronic symptoms are those that take from months to a

few years to develop, and late chronic symptoms are those that have been present for several years.

The classification system is composed of six principal neuropathic syndromes, which are subdivided into more specific categories. By narrowing the possible diagnoses in this way, specific medical tests can be used more efficiently and effectively. The six syndromes and a few associated causes are:

- Acute motor **paralysis** accompanied by variable problems with sensory and autonomic functions: Neuropathies associated with this syndrome are mainly accompanied by motor nerve problems, but the sensory and autonomic nerves may also be involved. Associated disorders include Guillain-Barré syndrome, diphtheritic polyneuropathy, and porphyritic neuropathy.
- Subacute sensorimotor paralysis: The term sensorimotor refers to neuropathies that are mainly characterized by sensory symptoms but also have a minor component of motor nerve problems. Poisoning with heavy metals (e.g., lead, mercury, and arsenic), chemicals, or drugs are linked to this syndrome. Diabetes, Lyme disease, and malnutrition are also possible causes.
- Chronic sensorimotor paralysis: Physical symptoms may resemble those in the above syndrome but the time frame for symptom development is prolonged. This syndrome encompasses neuropathies arising from cancers, diabetes, leprosy, inherited neurologic and metabolic disorders, and hypothyroidism.
- Neuropathy associated with mitochondrial diseases: Mitochondria are organelles (structures within cells) responsible for handling a cell's energy requirements. When mitochondria are damaged or destroyed, the cell's energy requirements are not met and it can die.
- Recurrent or relapsing polyneuropathy: This syndrome covers neuropathies that affect several nerves and may come and go, such as Guillain-Barré syndrome, porphyria, and chronic inflammatory demyelinating polyneuropathy.
- Mononeuropathy or plexopathy: Nerve damage associated with this syndrome is limited to a single nerve or a few closely associated nerves. Neuropathies related to physical injury to the nerve, such as **carpal tunnel syndrome** and **sciatica**, are included in this syndrome.

Causes and symptoms

Typical symptoms of neuropathy relate to the type of affected nerve. If a sensory nerve is damaged, common symptoms include numbness, tingling in the area, a prickling sensation, or pain. Pain associated with neuropathy can be quite intense and may be described as cut-

ting, stabbing, crushing, or burning. In some cases a normally nonpainful stimulus may be perceived as excruciating, or pain may be felt even in the absence of a stimulus. Damage to a motor nerve is usually indicated by weakness in the affected area. If the problem with the motor nerve has persisted, then atrophy (muscle wasting) or lack of muscle tone may be noticeable. Autonomic nerve damage is most noticeable when a patient stands upright and experiences such problems as light-headedness or changes in **blood pressure**. Other indicators of autonomic nerve damage are lack of sweat, tears, and saliva; constipation; urinary retention; and impotence. In some cases heart rhythm irregularities and respiratory problems may develop.

Symptoms may appear over days, weeks, months, or years. Their duration and the ultimate outcome of the neuropathy are linked to the cause of the nerve damage. Potential causes include diseases, physical injuries, poisoning, and malnutrition or alcohol abuse. In some cases neuropathy is not the primary disorder but a symptom of an underlying disease.

Disease

Diseases that cause polyneuropathies may be acquired or inherited; in some cases it is difficult to make the distinction. The diabetes-polyneuropathy link has been well established. A typical pattern of diabetes-associated neuropathic symptoms includes sensory effects that first begin in the feet. The associated pain or pins-and-needles, burning, crawling, or prickling sensations, form a typical “stocking” distribution in the feet and lower legs. Other diabetic neuropathies affect the autonomic nerves and have potentially fatal cardiovascular complications.

Several other metabolic diseases have a strong association with polyneuropathy. Uremia (**chronic kidney failure**) carries a 10%-90% risk of eventually developing neuropathy, and there may be an association between **liver** failure and polyneuropathy. Atherosclerosis (accumulation of **lipids** inside **blood vessels**) can impair blood supply to certain peripheral nerves. Without oxygen and nutrients the nerves slowly die. Mild polyneuropathy may develop in patients with hypothyroidism (low thyroid hormone levels). Individuals with acromegaly (abnormally enlarged skeletal extremities caused by an excess of growth hormone) may also develop mild polyneuropathy.

Neuropathy can also result from vasculitis, a group of disorders in which blood vessels are inflamed. When the blood vessels are inflamed or damaged, blood supply to the nerve can be affected, injuring the nerve.

Both viral and bacterial infections have been implicated in polyneuropathy. Leprosy is caused by the **bacterium** *M. leprae*, which directly attacks sensory nerves. Other bacterial illnesses may set the stage for an immune-mediated attack on the nerves. For example, one theory about Guillain-Barré syndrome involves complications following infection with *Campylobacter jejuni*, a bacterium commonly associated with **food poisoning**. This bacterium carries a protein that closely resembles components of myelin. The **immune system** launches an attack against the bacteria; but, according to the theory, the immune system confuses the myelin with the bacteria in some cases and attacks the myelin sheath as well. The underlying cause of neuropathy associated with Lyme disease is unknown; the bacteria may either precipitate an immune-mediated attack on the nerve or inflict damage directly.

Infection with certain **viruses** is associated with extremely painful sensory neuropathies. Shingles is an example of such a neuropathy. After a case of chickenpox the causative virus, varicella-zoster virus, becomes inactive or latent in sensory nerves. Years later the virus may be reactivated and, once reactivated, attacks and destroys axons. Infection with HIV is also associated with polyneuropathy, but the type of neuropathy that develops can vary. Some HIV-linked neuropathies are noted for myelin destruction rather than axonal degradation. Also, HIV infection is frequently accompanied by other infections, both bacterial and viral, that are associated with neuropathy.

Several types of polyneuropathies are associated with inherited disorders. These inherited disorders may primarily involve the nervous system, or the effects on the nervous system may be secondary to an inherited metabolic disorder. Inherited neuropathies fall into several of the principal syndromes because symptoms may be sensory, motor, or autonomic. The inheritance patterns also vary depending upon the specific disorder. The development of inherited disorders is typically prolonged over several years and may herald a degenerative condition—that is, a condition that becomes progressively worse over time. Even among specific disorders there may be a degree of variability in inheritance patterns and symptoms. For example, Charcot-Marie-Tooth disease is usually inherited as an autosomal dominant disorder; however, it can be autosomal recessive or, in rare cases, linked to the X chromosome. Its estimated frequency is approximately one in 2,500 people. Age of onset and sensory nerve involvement can vary between cases. The main symptom is a degeneration of the motor nerves in legs and arms with resultant muscle atrophy. Other inherited neuropathies have a distinctly metabolic component. For example, in familial amyloid polyneuropathies, pro-

tein components that make up the myelin are constructed and deposited incorrectly.

Physical injury

Accidental injuries during sports and recreational activities are common causes of polyneuropathy. The common types of injuries in these situations occur from placing too much pressure on the nerve, exceeding the nerve's capacity to stretch, blocking adequate blood supply of oxygen and nutrients to the nerve, and tearing the nerve. Pain may not always be immediately noticeable, and obvious signs of damage may take a while to develop.

These injuries usually affect one nerve or a group of closely associated nerves. For example, a common injury encountered in contact sports such as football is the "burner," or "stinger," syndrome. Typically, a stinger is caused by overstretching the main nerves that span from the neck into the arm. Immediate symptoms are numbness, tingling, and pain that travels down the arm, lasting only a minute or two. A single incident of a stinger is not dangerous, but recurrences can eventually cause permanent motor and sensory loss.

Poisoning

The poisons, or toxins, that cause polyneuropathy include drugs, industrial chemicals, and environmental toxins. Neuropathy that is caused by drugs usually involves sensory nerves on both sides of the body, particularly in the hands and feet; and pain is a common symptom. Neuropathy is a rare side effect of prescription medications. A few drugs that have been linked with polyneuropathy include metronidazole, an antibiotic; phenytoin, an anticonvulsant; and simvastatin, a cholesterol-lowering medication.

Certain industrial chemicals are neurotoxic (poisonous to nerves) following work-related exposures. Such chemicals as acrylamide, allyl chloride, and carbon disulfide have been strongly linked to development of polyneuropathy. Organic compounds, such as N-hexane and toluene, are also encountered in work-related settings, as well as in glue-sniffing and solvent abuse. Either route of exposure can produce severe sensorimotor neuropathy that develops rapidly.

Heavy metals are the third group of toxins that cause polyneuropathy. Lead, arsenic, thallium, and mercury usually are not toxic in their elemental form, but rather as components in organic or inorganic compounds. The types of metal-induced neuropathies vary widely. Arsenic poisoning may mimic Guillain-Barré syndrome; lead affects motor nerves more than sensory nerves; thallium produces painful sensorimotor neuropathy; and the effects of mercury are seen in both the CNS and PNS.

Malnutrition and alcohol abuse

Burning, stabbing pains and numbness in the feet, and sometimes in the hands, are distinguishing features of alcoholic neuropathy. The level of alcohol consumption associated with this variety of polyneuropathy has been estimated as approximately 3 liters of beer or 300 milliliters of liquor daily for three years. However, it is unclear whether alcohol alone is responsible for the neuropathic symptoms, because chronic alcoholism is strongly associated with malnutrition.

Malnutrition refers to an extreme lack of nutrients in the diet. It is unknown precisely which nutrient deficiencies cause polyneuropathies in alcoholics and famine and starvation victims, but it is suspected that the **B vitamins** have a significant role. For example, **thiamine** (vitamin B₁) deficiency is the cause of beriberi, a neuropathic disease characterized by **heart failure** and painful polyneuropathy of sensory nerves. **Vitamin E** deficiency seems to have a role in both CNS and PNS neuropathy.

Diagnosis

Clinical symptoms can indicate polyneuropathy, but an exact diagnosis requires a combination of medical history, medical tests, and possibly a process of exclusion. Certain symptoms may suggest a diagnosis, but more information is commonly needed. For example, painful, burning feet may be a symptom of alcohol abuse, diabetes, HIV infection, or an underlying malignant tumor, among other causes. Without further details effective treatment would be difficult.

During the history and **physical examination**, the physician obtains detailed information about the location, nature, and duration of symptoms to exclude some causes or even pinpoint the actual problem. The patient's medical history may also provide clues as to the cause, because certain diseases and medications are linked to specific polyneuropathies. A medical history should also include information about diseases that run in the family, because some polyneuropathies are genetically linked. Information about hobbies, recreational activities, alcohol consumption, and workplace activities can uncover possible injuries or exposures to poisonous substances.

The evaluation of a patient with polyneuropathy also includes laboratory tests, such as blood levels of glucose and creatinine, to detect diabetes and kidney problems, respectively. A **complete blood count** (CBC) is also done to determine levels of different blood cell types. **Iron, vitamin B₁₂, folic acid**, and other factors may be measured to rule out malnutrition. More specific tests, such as an assay for heavy metals or poisonous substances, or tests to detect vasculitis, are not typically per-

KEY TERMS

Afferent—Refers to peripheral nerves that transmit signals to the spinal cord and the brain. These nerves carry out sensory function.

Autonomic—Refers to peripheral nerves that carry signals from the brain and control such involuntary actions in the body as the beating of the heart.

Autosomal dominant or autosomal recessive—Refers to the inheritance pattern of a gene on a chromosome other than X or Y. Genes are inherited in pairs—one gene from each parent. However, the inheritance may not be equal, and one gene may overshadow the other in determining the final form of the encoded characteristic. The gene that overshadows the other is called the dominant gene; the overshadowed gene is the recessive one.

Axon—A long, threadlike projection that is part of a nerve cell.

Central nervous system (CNS)—The part of the nervous system that includes the brain and the spinal cord.

Efferent—Refers to peripheral nerves that carry signals away from the brain and spinal cord. These nerves carry out motor and autonomic functions.

Electromyography—A medical test that assesses nerve signals and muscle reactions. It can deter-

mine if there is a disorder with the nerve or if the muscle is not capable of responding.

Inheritance pattern—Refers to dominant or recessive inheritance.

Motor—Refers to peripheral nerves that control such voluntary movements as moving the arms and legs.

Myelin—The protective coating on axons.

Nerve biopsy—A medical test in which a small portion of a damaged nerve is surgically removed and examined under a microscope.

Nerve conduction—The speed and strength of a signal being transmitted by nerve cells. Testing these factors can reveal the nature of nerve injury, such as damage to nerve cells or to the protective myelin sheath.

Neurotransmitter—Chemicals within the nervous system that transmit information from or between nerve cells.

Peripheral nervous system (PNS)—Nerves that are outside of the brain and spinal cord.

Sensory—Refers to peripheral nerves that transmit information from the senses to the brain.

formed unless there is reason to suspect a particular cause. Routine and specialized blood tests are generally performed by a laboratory technologist.

An individual with neuropathy may be referred to a neurologist (physician specializing in nervous system disorders). By considering the results of the physical examination and observing information supplied by the referring primary care physician, the neurologist may be able to narrow down the possible diagnoses. Additional tests, such as nerve conduction studies and **electromyography**, which tests muscle reactions, can confirm that nerve damage has occurred and may also be able to indicate the nature of the damage. For example, if the neuropathy is caused by destruction of the myelin, damage is shown by slowed nerve conduction. If the axon itself has suffered damage, the nerve conduction may be slowed but will also be diminished in strength. Electromyography (performed by technologists often known as electromyographers or EMG technicians) adds further information by measuring nerve conduction and muscle response, which

determine whether the symptoms are due to a neuropathy or a muscle disorder.

In approximately 10% of polyneuropathy cases a nerve biopsy may be helpful. In this test the physician surgically removes a small part of the nerve for examination under a **microscope**. This procedure is usually performed to confirm a suspected diagnosis rather than as an initial diagnostic procedure.

Treatment

Treat the cause

Attacking the underlying cause of the neuropathy can prevent further nerve damage and may allow for better recovery. For example, in cases of such bacterial infections as leprosy or Lyme disease, **antibiotics** may be given to destroy the infectious bacteria. Viral infections are more difficult to treat because antibiotics are not effective against them. Neuropathies associated with drugs, chemicals, and toxins are treated in part by stop-

ping exposure to the damaging agent. Such chemicals as ethylenediaminetetraacetic acid (EDTA) are used to help the body concentrate and excrete some toxins. Diabetic neuropathies may be treated by gaining better control of blood sugar levels, but chronic kidney failure may require dialysis or even kidney transplant to prevent or reduce nerve damage. In some cases, such as compression injury or tumors, surgery may be considered to relieve pressure on a nerve.

In a crisis situation, as in the onset of Guillain-Barré syndrome, plasma exchange, intravenous immunoglobulin, and steroids may be prescribed. Intubation and mechanical ventilation may be required to support the **respiratory system**. Treatment may focus more on symptom management than on combating the underlying cause, at least until a definitive diagnosis has been made.

Supportive care and long-term therapy

Some polyneuropathies cannot be resolved; or may require considerable time for resolution. In these cases long-term monitoring and supportive care are necessary. Medical tests may be repeated to chart the progress of the neuropathy. If autonomic nerve involvement is a concern, regular monitoring of the **cardiovascular system** may be performed.

Because pain is associated with many neuropathies, **pain management** is an important aspect of treatment, especially if the pain becomes chronic. As in any chronic disease, narcotics are best avoided. Agents that may relieve neuropathic pain include amitriptyline, carbamazepine, and capsaicin cream. **Physical therapy** and physician-directed exercises can help maintain or improve function. When motor nerves are affected, braces and other supportive equipment can aid patients' ability to move about.

Prognosis

The outcome for polyneuropathy depends heavily upon the underlying cause. Polyneuropathy ranges from a reversible problem to a potentially fatal complication. In the best cases a damaged nerve regenerates. Though nerve cells cannot be replaced if they are killed, they are capable of recovering from damage. The extent of recovery depends upon the extent of the damage and the patient's age and general health status. Recovery can take weeks to years because **neurons** grow very slowly. Full recovery may not be possible, and it may not be possible to determine the prognosis at the outset.

If the neuropathy is a degenerative condition, such as Charcot-Marie-Tooth disease, then the patient's condition will worsen although there may be periods when the

disease seems to plateau. Cures have not yet been discovered for many degenerative diseases. For patients with incurable neuropathies, continued symptoms with a potential to worsening to disabilities, are to be expected.

A few polyneuropathies are eventually fatal. Fatalities from polyneuropathies have been associated with some cases of diphtheria, botulism, and other causes. Some diseases associated with neuropathy may also be fatal, but the ultimate cause of death is not necessarily related to the neuropathy—such as with **cancer**.

Health care team roles

The composition of the health care team treating patients with polyneuropathies will necessarily vary depending upon the underlying cause of the condition. For example, patients suffering from diabetes may be managed by physicians specializing in internal medicine and/or endocrinology. Cancer patients are often managed by oncologists, and patients with degenerative neurological disorders are treated by neurologists. Nearly all patients will also be cared for by laboratory technologists, radiological technologists, and nurses—the latter providing education about the disorder and management of the patient at home, and home safety assessments.

Patients requiring rehabilitation services may be seen by physiatrists (physician specialists in physical medicine), as well as physical and occupational therapists. Patients with diabetes and other metabolic or endocrine disorders also may receive counseling from registered dietitians and nutritionists to assist them to better manage these chronic diseases.

Prevention

Polyneuropathies are preventable only to the extent that the underlying causes are preventable. Primary prevention includes vaccines against diseases that cause neuropathy, such as polio and diphtheria. Timely treatment for physical injuries may help prevent permanent or worsening damage to nerves. Precautions when using certain chemicals and drugs are well advised in order to prevent exposure to neurotoxic agents. Control of such chronic diseases as diabetes may also reduce the risk of developing polyneuropathy.

Although not a preventive measure, genetic screening can serve as an early warning for potential problems. Genetic screening is available for some inherited conditions, but not all. In some cases presence of a particular gene does not necessarily mean the person will develop the disease because environmental and other components may be involved.

Polysomnography

Definition

Polysomnography is a set of tests performed while a patient sleeps. It is done to diagnose and evaluate **sleep disorders**, and examines at a minimum **brain** wave patterns, the movements of both eyes, and the tone of at least one skeletal muscle.

Purpose

Polysomnography is used to diagnose and evaluate many types of sleeping disorders, including disorders of initiating or maintaining sleep (dissomnias) and disorders during sleep (parasomnias), including medical, psychiatric, and dental disorders that have symptoms during sleep. A relatively common dissomnia is sleep apnea, a disorder most prevalent in middle-aged and elderly obese men, in which the muscles of the soft palate in the back of the throat relax and close off the airway during sleep. Sleep apnea may cause the patient to snore loudly and gasp for air at night, and to be excessively sleepy and doze off during the day.

Another dissomnia often evaluated by polysomnography is narcolepsy. Narcoleptics suffer from excessive daytime sleepiness, sudden attacks of muscle weakness (cataplexy), and hallucinations at sleep onset. Some parasomnias that can be detected using polysomnography include disorders of arousal or rapid-eye-movement (REM) sleep problems, such as nightmares. Medical conditions including sleep-related **asthma**, depression, and panic disorder can be evaluated. Teeth-grinding (**bruxism**) or such neurological problems as restless leg syndrome show up during polysomnography. Finally, the tests can also be used to detect or evaluate seizures of sleep-related epilepsy that occur in the middle of the night, when the patient and his or her family are unlikely to be aware of them.

Precautions

Polysomnography is completely safe, and no special precautions need to be taken.

Description

Polysomnography is done during an overnight stay in a sleep laboratory. While the patient sleeps, a wide variety of tests can be performed.

One form of monitoring is **electroencephalography** (EEG), in which electrodes are attached to the patient's scalp in order to record his or her brain wave activity. The electroencephalograph records brain wave activity from different parts of the brain and charts them on a graph. The EEG not only helps doctors establish what stage of sleep the patient is in, but may also detect seizures. Standard tests have at least one central electrode attached to the scalp and one reference electrode attached to the ear. Other electrodes can be added in order to pinpoint the area of the brain where abnormal activity is occurring.

Another form of monitoring is continuous electrooculography (EOG), which records eye movement and is useful in determining when the patient is going through a stage of REM sleep. Both EEG and EOG can be helpful in determining sleep latency (the time that transpires between lights out and the onset of sleep); total sleep time; the time spent in each sleep stage; and the number of arousals from sleep.

The air flow through the patient's nose and mouth is measured by heat-sensitive devices called thermistors. This measurement can help detect episodes of apnea (stopped breathing), or hypopnea (inadequate breathing). Another test, called pulse oximetry, measures the amount of oxygen in the **blood** and can be used to assess the

A polysomnograph collects data on the electrical activity of the heart and brain, and muscle activity in the face and neck of a sleeping subject. (Photograph by Philippe Plailly. Science Source/Photo Researchers. Reproduced by permission.)

degree of oxygen starvation during episodes of hypopnea or apnea.

The electrical activity of the patient's **heart** is also measured using **electrocardiography** (ECG or EKG). Electrodes are affixed to the patient's chest and pick up electrical activity from various areas of the heart. They help detect cardiac arrhythmias (abnormal heart rhythms), which may occur during periods of sleep apnea. **Blood pressure** is also measured as episodes of sleep apnea sometimes dangerously elevate blood pressure.

A final standard measurement is the tone of at least one skeletal muscle, often a muscle of the chin (mentalis or submental). This is done using **electromyography** (EMG), which involves placing an electrode on the muscle to record its contractions. If normal, measurements will indicate the general atonia present during REM sleep. Other EMG channels can be placed, particularly on the leg (anterior tibialis), to indicate movement during sleep.

Depending on the suspected disorder, polysomnography can also include sound monitoring to record snor-

ing; video monitoring to document body positions; core body temperature readings; incident light intensities; penile swelling (tumescence); and pressure and pH at various levels of the esophagus.

One test that is often performed in conjunction with polysomnography is a Multiple Sleep Latency Test (MSLT). This test is also performed in a sleep laboratory and involves the recording of the sleep of several naps during the day after the overnight test. The MSLT is particularly important for a complete diagnosis of narcolepsy.

Preparation

Patient preparation is necessary to ensure that the night or nights in the sleep laboratory are as close as possible to an unmediated night in the patient's own home. Patients should bring suitable sleepwear and make sure their hair is clean and free from gels or sprays that may interfere with electrode functioning. They should be advised to maintain usual awake-sleep cycles and avoid sleeping pills, alcohol, stimulants, and strenuous **exercise** before the test.

Aftercare

Once the test is over, the monitors are detached from the patient. No special measures need to be taken after polysomnography.

Complications

The greatest limitations to polysomnography are the differences between the recording conditions and those that are present in the patient's home. The differences between the sleep laboratory and home have the highest effect on the first night of testing. Detection and elimination of this "first night effect" can be accomplished by the rather costly step of recording for multiple nights. Multiple night recordings are also sometimes necessary to obtain information about problems that appear only sporadically.

Results

Standard analysis still involves the tedious and time-consuming review and scoring of either paper tracings or recordings projected on a computer monitor. However, automatic computer-based systems are becoming more and more common in clinical and research settings.

Results are interpreted in light of recorded overnight parameters such as the times of lights on/off, total time in bed, and total sleep time. The overnight recording is divided into time periods of approximately 30 seconds. The standard EEG, EMG, and EOG recordings are evaluated, and the predominant stage of sleep, according to the manual of Rechtschaffen and Kales, is assigned to the entire time period.

These data are used to calculate total time and relative proportion of the night spent in each of the six stages of sleep, including REM and non-REM. Latencies to REM and slow-wave sleep (SWS) are also recorded.

Special note is made of such neurophysiologic events as epileptic events, intrusion of alpha-type brain waves into sleep, or periodic activity of the tibialis anterior. Respiratory activities, including apneic or hypopneic episodes and oxygen saturation, are correlated with sleep stages. Other parameters that are being measured, such as body position, gastroesophageal reflux, bruxism, and penile tumescence, are recorded.

If a sleep apnea syndrome is diagnosed, primarily through a demonstration of periodic breathing stoppage and effects on the pulse and heart, a trial of continuous positive airway pressure or a trial of an oral appliance may be undertaken, either in a partial-night or second-night polysomnography recording.

KEY TERMS

Cataplexy—A condition characterized by sudden loss of muscle tone brought on by emotions, often associated with narcolepsy.

Electrocardiography (ECG)—Recording of the electrical activity from various regions of the heart muscle.

Electroencephalography (EEG)—Recording of the electrical activity from various regions of the brain.

Electrooculography (EOG)—Recording of the electrical activity of the muscles that control eye movement.

Narcolepsy—A sleep disorder characterized by attacks of sleep, cataplexy, sleep paralysis, or hallucinations with the onset of sleep.

Sleep apnea—A sleep disorder characterized by lapses in breathing during sleep.

Sleep latency—The time it takes to fall asleep once the lights are out.

Health care team roles

Polysomnography is often performed by a specially trained technician called a polysomnographic technologist. Training programs for this position can involve one- to two-year programs in training as an electrodiagnostic technologist, with additional time for the polysomnography courses. Some typical courses in this area include:

- fundamentals of polysomnography
- sleep disorders
- infant and pediatric polysomnography
- polysomnography instrumentation
- polysomnography recording and monitoring
- polysomnography record scoring

Registration in polysomnography is available from the Board of Registered Polysomnography Technologists. The certification requires passing a written test.

Porphyrias

Definition

The porphyrias are a group of rare disorders that affect heme biosynthesis. Heme is an essential component of hemoglobin as well as of many enzymes throughout the body.

Description

Biosynthesis of heme is a multistep process that starts with simple molecules and ends with a large, complex heme molecule. Each step of the biosynthesis pathway is directed by its own enzyme (a task-specific protein). As a heme precursor molecule moves through each step, an enzyme modifies it in some way. If the precursor is not modified, it cannot proceed to the next step.

The main characteristic of the porphyrias is a defect in one of the enzymes of the heme biosynthesis pathway. The defect prevents protoporphyrins or porphyrin (heme precursors) from proceeding further along the pathway. Symptoms may be debilitating or life-threatening in some cases. Porphyria is an inherited condition, but it may be acquired after exposure to poisonous substances.

Heme

Heme is primarily synthesized in the **liver** and bone marrow. Heme synthesis for immature red **blood** cells, namely the erythroblasts and the reticulocytes, occurs in the bone marrow.

Although production is concentrated in the liver and bone marrow, heme is used in various capacities in virtually every tissue in the body. In most cells, it is a key building block in the construction of factors that oversee **metabolism** as well as transport of oxygen and energy. In immature red blood cells, heme is a featured component of hemoglobin. Hemoglobin is the red pigment that gives red blood cells the ability to transport oxygen as well as their characteristic color.

Heme biosynthesis

The heme molecule is composed of porphyrin and an **iron** atom. Much of the heme biosynthesis pathway is dedicated to constructing the porphyrin molecule. Porphyrin is a large molecule shaped like a four-leaf clover. An iron atom is placed at its center during the last step of heme biosynthesis.

The production of heme may be compared to a factory assembly line. The heme "assembly line" is an eight-step process, requiring eight different—and properly functioning—enzymes:

- step 1: delta-aminolevulinic acid synthase
- step 2: delta-aminolevulinic acid dehydratase
- step 3: porphobilogen deaminase
- step 4: uroporphyrinogen III cosynthase
- step 5: uroporphyrinogen decarboxylase
- step 6: coproporphyrinogen oxidase
- step 7: protoporphyrinogen oxidase
- step 8: ferrochelatase

The control of heme biosynthesis is complex. There are various chemical signals that can trigger increased or decreased production. These signals can affect the enzymes themselves or their production, starting at the genetic level.

Porphyrias

Under normal circumstances, when heme concentrations are at an appropriate level, precursor production decreases. However, a malfunction in the biosynthesis pathway—represented by a defective enzyme—means that heme biosynthesis does not reach completion. Because heme levels remain low, the synthesis pathway continues to churn out precursor molecules in an attempt to make up the deficit.

The net effect of this continued production is an abnormal accumulation of precursor molecules and development of some type of porphyria. Each type of porphyria corresponds to a specific enzyme defect and an accumulation of the associated precursor. Although there

are eight steps in heme biosynthesis, there are only seven types of porphyrias; a defect in ALA synthase activity does not have a corresponding porphyria.

The porphyrias are divided into two general categories, depending on the location of the deficient enzyme. Porphyrias that affect heme biosynthesis in the liver are called hepatic porphyrias. The porphyrias that affect heme biosynthesis in immature red blood cells are called erythropoietic porphyrias (erythropoiesis is the process through which red blood cells are produced).

Incidence of porphyria varies widely between types and occasionally by geographic location. Although certain porphyrias are more common than others, their greater frequency is only relative to other types; all porphyrias are considered rare disorders.

The hepatic porphyrias, and the heme biosynthesis steps at which enzyme defects occur, are:

- ALA dehydratase deficiency porphyria (step 2). This porphyria type is extraordinarily rare; only six cases have ever been reported in the medical literature. The inheritance pattern seems to be autosomal recessive, which means a defective enzyme gene must be inherited from both parents for the disorder to occur.
- Acute intermittent porphyria (step 3). Acute intermittent porphyria (AIP) is also known as Swedish porphyria, pyrraloporphyria, and intermittent acute porphyria. AIP is inherited as an autosomal dominant trait, which means only one copy of the defective gene needs to be present for the disorder to occur. However, simply inheriting this gene does not necessarily mean that a person will develop the disease. Approximately five to 10 per 100,000 persons in the United States carry the gene, but only 10% of carriers ever develop AIP symptoms.
- Porphyria cutanea tarda (step 5). Porphyria cutanea tarda (PCT) is also called symptomatic porphyria, porphyria cutanea symptomatica, and idiosyncratic porphyria. PCT may be acquired, typically as a result of disease (especially hepatitis C), drug or alcohol abuse, or exposure to certain poisons. PCT may also be inherited as an autosomal dominant disorder, but most people with the inherited form remain latent—that is, symptoms never develop. It is the most common of the porphyrias, but the incidence is not well defined.
- Hereditary coproporphyrinemia (step 6). Hereditary coproporphyrinemia (HCP) is inherited in an autosomal dominant manner. As with all porphyrias, it is an uncommon ailment. By 1977, only 111 cases were recorded; in Denmark, the estimated incidence is two in 1 million people.

- Variegate porphyria (step 7). Variegate porphyria (VP) is also known as porphyria variegata, protocoproporphyrinemia, South African genetic porphyria, and royal malady (supposedly King George III of England and Mary, Queen of Scots, suffered from VP). VP is inherited in an autosomal dominant manner and is especially prominent in South Africans of Dutch descent. Among that population, the incidence is approximately three in 1,000 persons, and it is estimated that there are 10,000 cases of VP in South Africa. Interestingly, it seems that the affected South Africans are descendants of two Dutch settlers who came to South Africa in 1680. Elsewhere, the incidence is estimated to be one to two cases per 100,000 persons.

The erythropoietic porphyrias, and the steps of heme biosynthesis at which they occur, are:

- Congenital erythropoietic porphyria (step 4). Congenital erythropoietic porphyria (CEP) is also called Günther's disease, erythropoietic porphyria, congenital porphyria, congenital hematoporphyria, and erythropoietic uroporphyrinemia. CEP is inherited in an autosomal recessive manner and occurs very rarely. Onset of symptoms usually occurs in infancy, but may be delayed until adulthood.
- Erythropoietic protoporphyria (step 8). Also known as protoporphyria and erythrohepatic protoporphyria, erythropoietic protoporphyria (EPP) is more common than CEP; more than 300 cases have been reported. In these cases, the onset of symptoms typically occurred in childhood.

In addition to the above types of porphyria, there is a very rare type, called hepatoerythropoietic porphyria (HEP), that affects heme biosynthesis in both the liver and the bone marrow. HEP results from a defect in uroporphyrinogen decarboxylase activity (step 5), but strongly resembles congenital erythropoietic porphyria. Only 20 cases of HEP have been reported worldwide; it seems to be inherited in an autosomal recessive manner.

Causes and symptoms

General characteristics

The underlying cause of all porphyrias is a defective enzyme somewhere along the heme biosynthesis pathway. In virtually all cases, the defective enzyme is a genetically linked factor. Therefore, porphyrias are inheritable conditions. However, an environmental trigger—such as diet, drugs, or sun exposure—may be necessary before any symptoms develop. In many cases, symptoms do not develop, and individuals may be completely unaware that they have a gene for porphyria.

KEY TERMS

Autosomal dominant—An inheritance pattern in which a trait is determined by one gene in a pair (genes are inherited in pairs; one copy from each parent).

Autosomal recessive—An inheritance pattern in which a trait is expressed only if both genes in a pair code for that particular characteristic (genes are inherited in pairs; one copy from each parent).

Enzyme—A protein molecule that catalyzes a chemical reaction.

Erythropoiesis—The process through which new red blood cells are created; it begins in the bone marrow.

Erythropoietic—Referring to the creation of new red blood cells.

Gene—A portion of DNA (deoxyribonucleic acid) that codes for a specific product, such as an enzyme.

Hematin—A drug that is administered intravenously to halt an acute porphyria attack. It inhibits heme biosynthesis, preventing the further accumulation of heme precursors.

Heme—A large complex molecule contained in hemoglobin and a number of important enzymes throughout the body. Through these factors, it plays a vital role in metabolism and oxygen and energy transport. Heme is composed of porphyrin and an iron atom.

Hemoglobin—A molecule composed of heme and protein that enables red blood cells to transport oxygen throughout the body. Hemoglobin gives red blood cells their characteristic color.

Hepatic—Referring to the liver.

Neuropathy—A condition characterized by nerve damage. Major symptoms can include weakness, numbness, paralysis, or pain in the affected area.

Porphyrin—A large molecule shaped somewhat like a four-leaf clover. Combined with an iron atom, it forms a heme molecule.

Protoporphyrin—A precursor molecule to the porphyrin molecule.

All of the hepatic porphyrias—except porphyria cutanea tarda—follow a pattern of acute attacks interspersed with periods of complete symptom remission.

For this reason, they are often referred to as the acute porphyrias. The erythropoietic porphyrias and porphyria cutanea tarda do not follow the same pattern and are considered chronic conditions.

The specific symptoms of each porphyria depend on the affected enzyme and whether it occurs in the liver or in the bone marrow. The severity of symptoms can vary widely, even within the same porphyria type. When the porphyria becomes symptomatic, the common factor between all types is an abnormal accumulation of protoporphyrins or porphyrin.

ALA dehydratase porphyria (ADP)

ADP is characterized by a deficiency of ALA dehydratase. Of the few cases on record, the prominent symptoms were vomiting; **pain** in the abdomen, arms, and legs; and neuropathy. (Neuropathy refers to nerve damage that can cause pain, numbness, or paralysis.) As a result of neuropathy, the arms and legs may be weak or paralyzed and breathing can be impaired.

Acute intermittent porphyria (AIP)

AIP is caused by a deficiency in porphobilogen deaminase, but symptoms usually do not occur unless an individual with the deficiency encounters a biological trigger. Triggers can include hormones (for example oral contraceptives, menstruation, **pregnancy**), drugs, and dietary factors. However, most people with the deficiency never develop symptoms.

Attacks occur after **puberty** and commonly feature severe abdominal pain, nausea and vomiting, and constipation. Muscle weakness and pain in the back, arms, and legs are also typical symptoms. During an attack, the urine takes on a deep reddish color. The **central nervous system** may also be involved, as demonstrated by hallucinations, confusion, seizures, and mood changes.

Congenital erythropoietic porphyria (CEP)

CEP arises from a deficiency in uroporphyrinogen III cosynthase. Symptoms are often apparent in infancy and include reddish urine and possibly an enlarged spleen. The skin is unusually sensitive to light and blisters easily if exposed to sunlight. (Sunlight induces changes in protoporphyrins in the plasma and skin. These altered molecules can damage the skin.) Increased hair growth is common. Damage from recurrent blistering and associated skin infections can be severe; in some cases facial features and fingers are lost to recurrent damage and **infection**. Deposits of protoporphyrins sometimes occur in the teeth and bones.

Porphyria cutanea tarda (PCT)

PCT is caused by deficient uroporphyrinogen decarboxylase; it may be an acquired or inherited condition. The acquired form usually does not appear until adulthood. The inherited form may appear in childhood, but often demonstrates no symptoms. Early symptoms include blistering on the hands, face, and arms following minor injuries or exposure to sunlight. Lightening or darkening of the skin may occur along with increased hair growth or loss of hair. Liver function is abnormal but the signs are mild.

Hepatoerythropoietic porphyria (HEP)

HEP is linked to a deficiency of uroporphyrinogen decarboxylase in both the liver and the bone marrow. The symptoms resemble those of CEP.

Hereditary coproporphyria (HCP)

HCP is similar to AIP, but the symptoms are typically milder; the disorder is caused by a deficiency in coproporphyrinogen oxidase. The greatest difference between HCP and AIP is that people with HCP may have some skin sensitivity to sunlight. However, extensive damage to the skin is rarely seen.

Variegate porphyria (VP)

VP is caused by deficient protoporphyrinogen oxidase, and, like AIP, symptoms only occur during attacks. Major symptoms of this type of porphyria involve neurologic problems and sensitivity to light. Areas of the skin that are exposed to sunlight are susceptible to burning, blistering, and scarring.

Erythropoietic protoporphyria (EPP)

Owing to deficient ferrochelatase, the last step in the heme biosynthesis pathway—the insertion of an iron atom into a porphyrin molecule—cannot be completed. The major symptoms of this disorder are related to sensitivity to light—including both artificial and natural light sources. Following exposure to light, a patient with EPP experiences burning, itching, swelling, and reddening of the skin. Blistering and scarring may occur but are neither common nor severe. EPP may result in the formation of gallstones as well as liver complications. Symptoms can appear in childhood and tend to be more severe during the summer when exposure to sunlight is more likely.

Diagnosis

Depending on the array of symptoms presented, the possibility of porphyria may not immediately come to the

physician's mind. In the absence of a family history of porphyria, some symptoms of porphyria, such as abdominal pain and vomiting, may be attributed to other disorders. Neurological symptoms, including confusion and hallucinations, may lead to an initial suspicion of psychiatric illness rather than a physical disorder. Diagnosis may be aided in cases in which these symptoms appear in combination with neuropathy, sensitivity to sunlight, or other factors. Certain symptoms, such as urine the color of port wine, are hallmarks of porphyria.

A common initial test measures protoporphyrins in the urine. However, if skin sensitivity to light is a symptom, a blood plasma test is indicated. If these tests reveal abnormal levels of protoporphyrins, further tests are performed to measure heme precursor levels in the stool and in red blood cells. The presence and estimated quantity of porphyrin and protoporphyrins are easily detected in biological samples using spectrofluorometric testing. This procedure involves the use of a laboratory instrument called a spectrofluorometer, which directs light of a specific strength at a fluid sample. Certain molecules in the sample—such as heme precursors—absorb the light energy and fluoresce. When molecules fluoresce, they emit light at a different strength from the absorbed light. The fluorescence can be detected and quantified by the spectrofluorometer. Not all molecules fluoresce, but among those that do, the intensity and quality of the fluorescence is an identifying characteristic. Diagnostic laboratory work, including analysis of blood, urine and stool samples is performed by laboratory technologists.

Heme precursors in the blood, urine, or stool give some indication of the type of porphyria, but more detailed biochemical testing is required to determine their exact identity. Making this determination yields a strong indicator of which enzyme in the heme biosynthesis pathway is defective, which in turn allows a diagnosis of the particular type of porphyria.

Biochemical tests rely on the color, chemical properties, and other unique features of each heme precursor. For example, a screening test for acute intermittent porphyria (AIP) is the Watson-Schwartz test. In this test, a special dye is added to a urine sample. If one of two heme precursors—porphobilinogen or urobilinogen—is present, the sample turns pink or red. Further testing is necessary to determine whether the precursor is porphobilinogen or urobilinogen—only porphobilinogen is indicative of AIP.

Other biochemical tests rely on the fact that heme precursors become less water-soluble (able to be dissolved in water) as they progress further through the heme biosynthesis pathway. For example, to determine

whether the Watson-Schwartz urine test is positive for porphobilinogen or urobilinogen, a measure of chloroform is added to the test tube. Chloroform is a water-insoluble substance, and even after vigorous mixing, the water and chloroform separate into two distinct layers. Whether the chloroform layer or the water layer becomes pink indicates which heme precursor is present. Porphobilinogen tends to be water-soluble, and urobilinogen is slightly water-insoluble. Since like mixes with like, porphobilinogen mixes more readily in the water than chloroform; therefore, if the water layer is pink, an AIP diagnosis is probable.

As a final test, measuring specific enzymes and their activities may be done for some types of porphyrias; however, such tests are not done for screening purposes. Certain enzymes, such as porphobilinogen deaminase (the defective enzyme in AIP), can be easily extracted from red blood cells; however, other enzymes are less readily collected or tested. Basically, an enzyme test involves adding a measure of the enzyme to a test tube containing the precursor it is supposed to modify. Both the production of modified precursor and the rate at which it appears are measured in the laboratory. If a modified precursor is produced, the test indicates that the enzyme is doing its job. The rate at which the modified precursor is produced can be compared to a standard to measure the enzyme's efficiency.

Treatment

Treatment for porphyria revolves around avoiding acute attacks, limiting potential effects, and treating symptoms. However, treatment options vary depending on the type of porphyria that has been diagnosed. Given the rarity of ALA dehydratase porphyria (six reported cases), definitive treatment guidelines have not been developed.

Acute intermittent porphyria, hereditary coproporphyria, and variegata porphyria

Treatment for acute intermittent porphyria, hereditary coproporphyria, and variegata porphyria follows the same basic regime. A patient diagnosed with one of these porphyrias can prevent most attacks by avoiding precipitating factors, such as certain drugs that have been identified as triggers for acute porphyria attacks. Individuals must maintain adequate **nutrition**, particularly in respect to **carbohydrates**. In some cases, an attack can be stopped by increasing carbohydrate consumption or by receiving carbohydrates intravenously.

When an attack occurs, medical attention is needed. Pain is usually severe, and narcotic **analgesics** are the best option for relief. Phenothiazines can be used to

counter nausea, vomiting, and **anxiety**; and chloral hydrate or diazepam is useful for sedation or to induce sleep. Intravenously administered hematin may be used to curtail an attack. This drug seems to work by signaling the heme biosynthesis pathway to slow production of precursors. Women, who tend to develop symptoms more frequently than men in response to hormonal fluctuations, may find hormone therapy that inhibits ovulation to be helpful.

Congenital erythropoietic porphyria

The key points of congenital erythropoietic porphyria treatment are avoiding exposure to sunlight, and preventing trauma to, and infections of the skin. Liberal use of sunscreens and taking beta-carotene supplements can provide some protection from sun-induced damage. Such medical treatments as removing the spleen or administering red blood cell transfusions can have short-term benefits, but do not offer a cure. Oral doses of activated charcoal may offer the potential of remission.

Porphyria cutanea tarda

As with other porphyrias, the first line of defense is the avoidance of precipitating factors, especially alcohol. Regular blood withdrawal is a proven therapy for pushing symptoms into remission. For patients who are anemic or cannot have blood drawn for other reasons, chloroquine therapy may be used.

Erythropoietic protoporphyria

Avoiding sunlight, using sunscreens, and taking beta-carotene supplements are typical treatment options for erythropoietic protoporphyria. The drug cholestyramine may reduce the skin's sensitivity to sunlight as well as the accumulated heme precursors in the liver. Liver transplantation has been used in cases of liver failure, but it has not effected a long-term cure of the porphyria.

Prognosis

Even in the presence of a genetic inheritance for a porphyria, symptom development depends on a variety of factors. In the majority of cases, an individual remains asymptomatic throughout life. Porphyria symptoms are rarely fatal with proper medical treatment, but they may be associated with temporarily debilitating or permanently disfiguring consequences. Measures to avoid these consequences are not always successful, regardless of how diligently they are pursued. Although pregnancy has

been known to trigger porphyria attacks, it is not as great a danger as was once thought.

Health care team roles

Patients diagnosed with porphyrias are cared for by an interdisciplinary treatment team that may include primary care physicians, hematologists, and dermatologists. Laboratory technologists are involved during the diagnostic process; and nurses, health educators and genetic counselors provide instruction about how to recognize triggers and prevent attacks or flares of the condition.

Prevention

For the most part, the porphyrias are attributable to inherited genes; such an inheritance cannot be prevented. However, symptoms can be prevented or limited by avoiding factors that trigger development.

When there is a family history of porphyria, individuals should consider testing to determine whether they carry the associated gene. Even if symptoms are absent, it is useful to know about the presence of the gene to assess the risks of developing the associated porphyria. This knowledge also reveals whether the individual's offspring may be at risk. Theoretically, it is possible to perform prenatal tests. However, these tests would not indicate whether the child would develop porphyria symptoms; only that they might have the genetic predisposition to develop symptoms.

Portable defibrillators see **Defibrillators, portable**

Positron emission tomography (PET)

Definition

Positron emission tomography (PET) is a non-invasive scanning technique that utilizes small amounts of radioactive positrons (positively charged particles) to visualize body function and **metabolism**.

Purpose

As of 2001, PET is the fastest growing nuclear medicine tool in terms of increasing acceptance and applications. It is useful in the diagnosis, staging, and treatment of **cancer** because it provides information that cannot be obtained by other techniques like computed tomography (CT) and **magnetic resonance imaging (MRI)**.

PET scans can be performed at medical centers equipped with a small cyclotron. Smaller cyclotrons and increasing availability of certain radiopharmaceuticals are making PET a more widely used imaging modality.

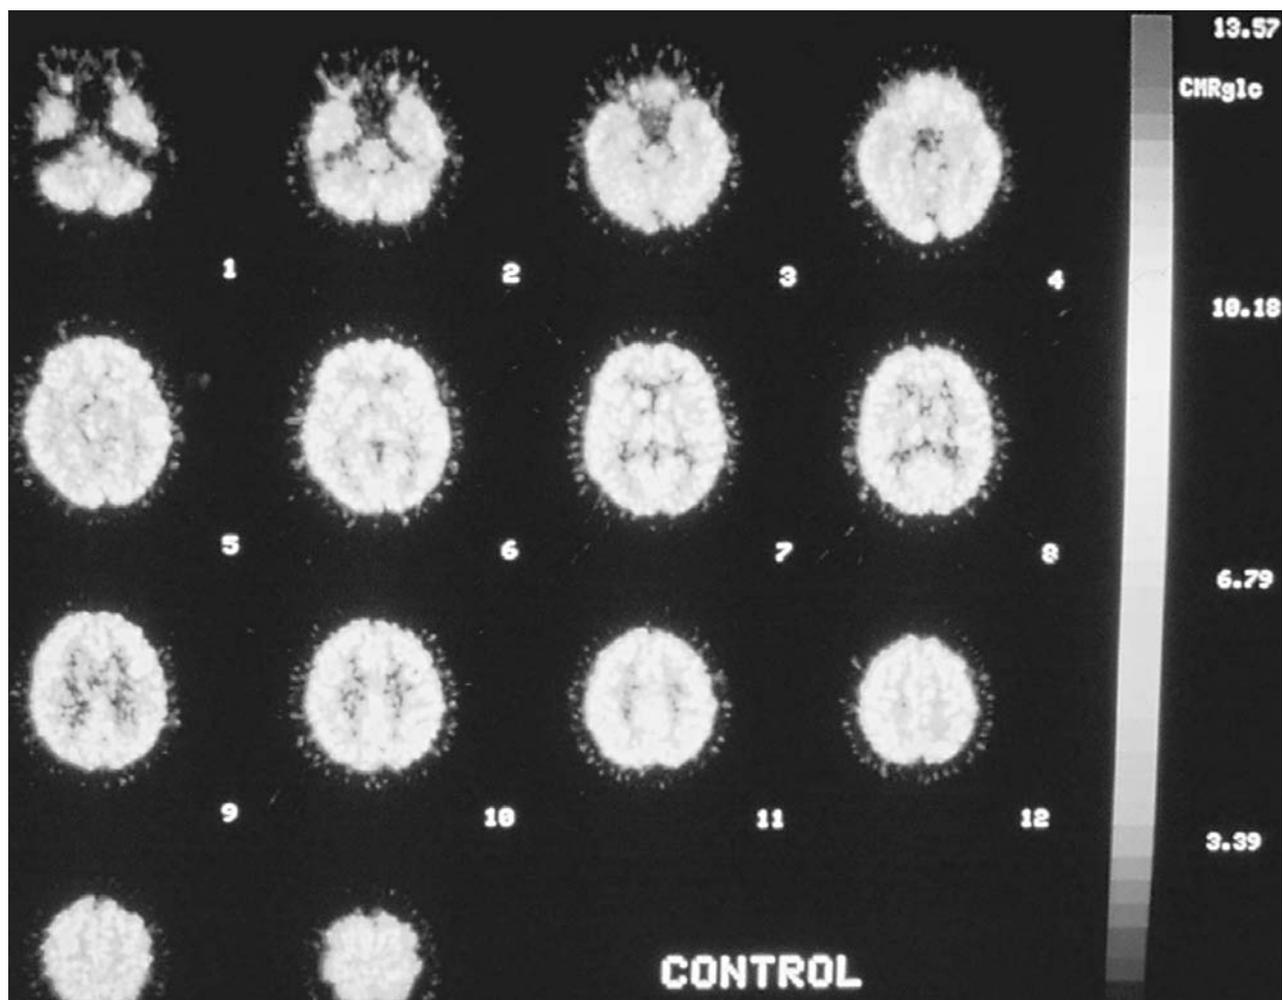

Physicians first used PET to obtain information about **brain** function and to study brain activity in various neurological diseases and disorders, including stroke, epilepsy, **Alzheimer's disease**, **Parkinson's disease**, and Huntington's disease; and in such psychiatric disorders as **schizophrenia**, depression, obsessive-compulsive disorder, attention-deficit/hyperactivity disorder, and Tourette syndrome. More and more, PET is being used to evaluate patients for head and neck, lymphoma, melanoma, lung, colorectal, and esophageal cancers. PET also is used to evaluate **heart** muscle function in patients with **coronary artery disease** or cardiomyopathy.

Precautions

There is always a slight risk when radioactive material is injected into the body. However, because the radioactive tracers used are short-lived and clear the body quickly, they are considered safe. The radiation dose received is only slightly more than that received in a **chest x ray**. Still, pregnant women should not have a PET scan.

Description

PET involves injecting a patient with a radiopharmaceutical similar to glucose. An hour after injection of this tracer, a PET scanner images a specific metabolic function by measuring the concentration and distribution of the tracer throughout the body.

Position emission tomography (PET) scan control study. (Photograph by Jon Meyer. Custom Medical Stock Photo. Reproduced by permission.)

When it enters the body, the tracer courses through the bloodstream to the target organ, where it emits positrons. The positively charged positrons collide with negatively charged electrons and gamma rays are produced. The gamma rays are detected by photomultiplier-scintillator combinations positioned on opposite sides of the patient. These signals are then processed by the computer and images are generated.

PET provides an advantage over CT and MRI because it can determine if a lesion is malignant. The two other modalities provide images of anatomical structures but often cannot provide a determination of malignancy. Recently, PET has been used in combination with CT and MRI to identify abnormalities with more precision and indicate areas of most active metabolism. This additional

information allows for more accurate evaluation of cancer treatment and management.

Health care team roles

Personnel for a PET facility should include a physicist for technical support, calibration, and software; a physician for medical interventions and reading; and administrative staff for scheduling, paperwork, and billing. A trained technologist performs the PET scans. A positron emission tomography technologist performs PET procedures on clinical and research subjects referred for neurologic, oncologic, cardiac, or other conditions. The technologist also ensures appropriate patient care, acquires data, and performs analysis according to protocols. A technologist needs training in nuclear medicine. State licensure is required as a nuclear medicine technologist.

KEY TERMS

Electron—One of the small particles that make up an atom. An electron has the same mass and amount of charge as a positron, but the electron has a negative charge.

Gamma ray—A high-energy photon emitted by radioactive substances.

Half-life—The time required for half of the atoms in a radioactive substance to disintegrate.

Photon—A light particle.

Positron—One of the small particles that make up an atom. A positron has the same mass and amount of charge as an electron, but the positron has a positive charge.

Dan Harvey

Positron emission tomography (PET) unit

Definition

The **positron emission tomography (PET)** unit is a device used to produce images of the body that reflect biochemical changes taking place in the body. Among the body imaging technologies used in medicine, the PET unit is characterized by its use of positron-emitting tracer substances. Because of its use of short-lived positron-emitting tracers, the PET unit can provide images of biochemical processes. This feature of PET technology distinguishes it from computer tomography (CT) and **magnetic resonance imaging (MRI)** technologies, which can provide only images of the structure of the body.

Purpose

The purpose of the PET unit is to provide images reflecting biochemical changes occurring within the body. The PET unit can also, when used in conjunction with mathematical models of organ systems, quantify biochemical activity (e.g. **blood** flow, metabolic activity in tissue).

Because the PET unit can provide information on biochemical function, it is particularly helpful in assessing tissue viability and biological processes related to tissue health. The PET unit is used for these purposes most often in the fields of neurology (study of the **brain**), cardiology (study of the **heart**), and oncology (**cancer**).

In neurology, the PET unit is used to diagnose and differentiate among different types of epilepsy, **dementia**, and cerebrovascular disease. Because the regions of the brain that are affected by these abnormalities have blood flow and glucose utilization patterns that are different from healthy parts of the brain, the PET unit can—by using tracers that follow cerebral blood flow, glucose pathways, and oxygen metabolism—identify areas of the brain that are affected. During epileptic seizures, blood flow and glucose use increase in the area of the epileptogenic focus (site originating the seizure). PET scans are used to identify these foci in patients with drug-resistant epilepsy so that surgical intervention can target these

seizure-prone areas. In dementia, the PET unit is used to distinguish **Alzheimer's disease** from other types of dementia, because each type of dementia has a characteristic glucose utilization pattern in the brain. The PET unit is also used to evaluate and monitor treatments for stroke patients by measuring cerebral blood flow, glucose **metabolism**, and oxygen levels.

In cardiology, the PET unit is used to assess the metabolism and function of myocardial tissue. Blood flow and fatty acid metabolism are measured by the PET unit, and areas that are affected by **coronary artery disease** are easily identified. The state of the myocardial tissue, as reflected in the PET scan, also helps the cardiologist determine the best intervention, e.g. an angiogram rather than a heart bypass.

In oncology, the PET unit has had a long history of being used for the diagnosis and localization of brain tumors. Because tumors have greater blood flow directed to them than normal brain cells, the PET scan can identify where the tumor is localized by pinpointing the area with abnormally high blood flow. More broadly, the PET unit can be used in many parts of the body to grade the severity of tumors and identify metastatic processes. Moreover, because PET identifies variations in metabolic activity, the scans are particularly useful in assessing the effectiveness of radiological treatment of cancer; unlike other types of imaging, PET scans can distinguish between (non-viable) scar tissue caused by the radiological treatment of tumors, and viable tumor cells that might have been missed by the treatment.

Description

Standard components

The components of the PET unit are best understood in the context of the procedures required for positron emission tomography.

The first step in the PET process is the creation of the radioisotope (radioactive version of a chemical element) that is to be used in the tracer compound. The creation of the radioisotope takes place in a device called the cyclotron. The cyclotron is a particle accelerator that speeds up a particle so quickly that it strips electrons from the particle. In most PET units, the particle used is hydrogen, and the resulting stripped particle is a proton (represented as H⁺). A beam of protons created in this way is then used to bombard a stable isotope (non-radioactive version of a chemical element). The bombardment of the stable version of a chemical element with H⁺ produces a radioactive version of the element.

The most common radionuclides created by a PET cyclotron are C-11 (carbon), N-13 (nitrogen), O-15 (oxy-

gen), and F-18 (flourine). These elements are popular because many of the compounds in the human body are based on these elements or on analogs of these elements, so that a biochemical compound that the body naturally uses can be created from these radionuclides. Note that, because these positron-emitting radionuclides decay in a short amount of time (depending on the element, 2-110 minutes), the radionuclide must be produced by a cyclotron within a short distance from the location of the other PET procedures.

Once the radionuclide is generated by the cyclotron, it enters the biosynthesizer unit, where it is used to create radioactive biochemical compounds. Examples of compounds synthesized are 15-C (to measure blood volume), 13-N-glutamine (to measure myocardial metabolism), 15-O₂ (to measure oxygen metabolism), and 18-F-deoxyglucose (to measure glucose metabolism).

The patient is then injected with or inhales the radioactive labeled tracer and is positioned in the gantry of the PET scanner. The scanner consists of a ring of detectors designed to find the location of and quantify the photon emissions from positron-electron reactions. Note that although the decaying radioactive compounds emit positrons, the positrons do not leave the body. Instead, the positrons emitted by the compounds go a short distance within the body before colliding with electrons. In the annihilation reaction that results from this positron-electron collision, high-energy photons are released; and it is these photons that pass through the body and are detected by the PET scanner. The two released photons, in an annihilation reaction, go in exactly opposite directions (180 degrees from each other), so that the PET scanner is able to reconstruct the three-dimensional spatial distribution of the compound by reconstructing the paths of photons and pinpointing the reaction site.

Since the photons released are not detectable visually, the detector ring in the scanner uses scintillation compounds (compounds that detect the photon flashes from the reaction) that convert the detected photon energy into visible forms. The scanner then uses sophisticated mathematical programs to construct coherent PET images from the visible data. When quantitative information is needed, a tracer kinetic model (mathematical model of tracer behavior) is used in conjunction with the PET data to quantify metabolic and functional processes.

The PET scanner is controlled by a computer monitor that allows for entry of text and commands. The images are previewed on an image monitor, which can be separate from or on the same screen as the control monitor. Because clinicians are often reluctant to diagnose using solely the image monitor, many PET systems allow for the conversion of these images to sheet film that can

then be viewed on a standard lightbox. Many systems also have an archival system that saves image data for future retrieval.

Variations of equipment

Because PET facilities differ in their imaging needs and financial resources, there may be variations in the features of cyclotrons and scanners among facilities. For radiotracer production, two different systems are often seen—the remote semiautomated system and the remote automated system. The remote semiautomated system allows the operator to determine the order and timing of the reactions and visually monitor the radionuclide synthesis. The semiautomated system is less expensive than the automated system, and is popular in research settings that do not have a standard set of radiotracers to be routinely produced. In clinical settings, where there is a regular flow of patients, the more costly automated system is used because automated synthesis requires less personnel time and production time, and there is less variation in the radionuclides required.

Cyclotrons are available as “Proton Only” devices or “Dual Particle” devices. Although “Proton Only” machines are cheaper, they restrict the chemical synthesis options through which particular radionuclides can be produced. Large quantities of O-15 used for brain research, for example, would be infeasible with “Proton Only” machines because of the prohibitive costs of the source materials required to synthesize O-15 with this type of machine. In general, institutions that have both clinical and research groups using the PET unit (and thus a broad range of radionuclide needs) use “Dual Particle” devices.

Some cyclotrons have what is called dual irradiation capacity, which allows them to produce two different radioisotopes at the same time. These cyclotrons can also, if both ion beams are used to produce the same type of radioisotope, produce large amounts of a single isotope. Dual irradiation cyclotrons are more expensive than single irradiation cyclotrons and are generally found in institutions with both clinical and research demands.

Although many PET scanners are single-ring scanners, multiple-ring scanners are emerging at advanced research and clinical institutions. These multiple-ring scanners allow for the simultaneous imaging of contiguous cross-sections. These types of scanners allow for faster scanning and more dynamic visualization of body processes.

Settings

Because of the high cost of the PET devices, the PET unit is used primarily in research institutions and

advanced clinical (tertiary care) settings. In 1992, Michel Ter-Pergossian, a prominent researcher in PET technology, noted that there were 50-80 PET centers internationally.

Operation

Partly because of radiation safety regulations strictly governing the use and disposal of radioactive materials, radiotracer production and cyclotron operation is mostly automated. The nuclear medicine technologist, typically through a menu-driven computer control unit, designates the specific radiotracer to be synthesized and selects the chemical processes desired. Because the cyclotron is shielded, either in a protected room with concrete walls or behind a shield accompanying the cyclotron unit, the technologist is exposed to very little radiation.

After the radiotracer is produced, quality control (QC) testing is conducted daily. The technologist transfers the materials (in a lead container) from the biosynthesizer unit to the radiochemistry area for QC testing. The compounds are tested for radiochemical purity, radionuclidic purity, correct pH, and sterility. As the pharmacist performs the spectrometry and chromatography tests, he or she stands behind lead shielding. A monitor in the QC testing area indicates the level of radiation exposure in the area to allow the pharmacist to gauge his/her exposure. Staff periodically check their gloves for radioactive contamination; and contaminated items (such as gloves, shoe covers, and syringes) are immediately placed in protected radioactive waste containers.

The scanner operator brings the patient to the scanning room and aligns the patient in a relatively immobile position on the gantry. In the radiochemistry room, he or she or another technologist measures the appropriate patient dose for the radiotracer, and the radiotracer is placed into a Lucite-shielded syringe. The syringe is placed in a lead container, and the technologist carries the lead container to the scanning room, where he or she administers the radiotracer to the patient.

In the control room—an attached room with a window through which the patient can be viewed throughout the entire scan—the technologist controls the scanning and image processing at the control computer. He or she selects the appropriate scanning procedure for the area of interest and enters parameters related to image processing. When all parameters have been verified and entered, the technologist enters the commands to execute the scan. Depending on the nature of the question that the scan seeks to answer, the scan may take 10-90 minutes. The technologist assesses the quality of the images, and should be able to identify artifacts from problems arising in the PET detector or image processor. If the PET

KEY TERMS

Annihilation reaction—Reaction between electron and positron in which both are destroyed and each particle's mass is converted into photon energy.

Electron—Negatively charged particle of an atom.

Gantry—Frame in which patient is placed, over which the PET scanner moves.

Photon—High-energy light waves.

Positron—Negatively charged electrons, often symbolized as H⁺.

Proton—Positively charged particle of an atom.

Radionuclide—A radioactive element.

Radiotracer—A tracer compound with a radioactive element.

Tracer—Substance that can be followed through the course of a biochemical process.

images are acceptable, they are stored for the physician or researcher to review at a later date.

Health care team roles

A typical team directly involved with using the PET unit consists of a radiochemist, a pharmacist, two nuclear medicine technologists (a scanner operator and a cyclotron operator), and a medical physicist. The radiochemist oversees the radiochemistry facility and supervises all radiotracer production. He or she is the primary cyclotron operator. The pharmacist performs quality control on the radiotracers. He or she can also operate the cyclotron and administer radiotracers to patients. Both nuclear medicine technologists assist in preparing patients for the PET scan. In addition, the scanner operator and cyclotron operator perform quality control on their respective devices. The medical physicist is the radiation safety officer of the facility. He or she ensures that the facility meets the legal safety requirements for dealing with radioactive materials, and makes sure that personnel are properly trained and monitored.

Nurses and nuclear medicine radiologists are also involved with the PET process. Nurses prepare the patients for the PET scan, monitor patients through the process, and may take blood samples as needed. Nuclear medicine radiologists are the physicians reviewing and interpreting the PET images in the course of patient work-up.

Training

Nuclear medicine technologists, researchers, and physicians who will be using the PET computer stations typically take a week-long course, offered by the makers of the PET unit, to learn how to operate the control computers. Technologists also require a more advanced course in the physics and instrumentation of PET; in radiation safety; and in quality control during image processing. Clinicians who interpret the scans require nuclear medicine training through fellowships or continuing education.

Genevieve Pham-Kanter

Post-traumatic stress disorder

Definition

Post-traumatic **stress** disorder (PTSD) is primarily caused by human reactions to events outside the realm of ordinary life experience. Domestic and criminal violence, natural disasters, and transportation accidents are major categories of incidents associated with PTSD. Once thought to be experienced primarily by war veterans, PTSD is now known to occur in survivors of sexual, physical or emotional abuse, and in persons who have witnessed a traumatic event.

PTSD may result from long-term experiences of trauma as well as from time-limited violent events. It is now recognized that repeated traumas or such traumas of long duration as **child abuse**, domestic violence, stalking, cult membership, and hostage situations may also produce the symptoms of PTSD in survivors.

Description

After a traumatic event, the person who suffered the trauma, as well as others who witnessed it or were

involved as emergency workers, may experience a range of symptoms. These may include physical **pain**; change in bowel function, such as **diarrhea** and/or constipation; change in sleep patterns, such as sleeping more or less than before the trauma; **heart** palpitations, sweating, being easily startled or becoming hypervigilant; becoming increasingly susceptible to illness.

As the individual struggles to cope with life after the event, ordinary events or situations that resemble the trauma in certain respects often trigger frightening, vivid memories or flashbacks. For example, one survivor of a plane crash would have flashbacks of the crash whenever he smelled something burning. A Vietnam veteran would have flashbacks whenever he heard a car backfire.

Causes and symptoms

Causes

While it is not clear why some people develop PTSD following a trauma and others do not, experts suspect that it may be influenced both by the severity of the event, by the person's personality and genetic make-up, and by whether or not the trauma was expected. In addition, occupational factors play a role; persons who work as fire fighters, police officers, emergency room staff, or in similar high-risk occupations have a higher rate of PTSD than the general population. Lastly, the nature of the trauma itself is a factor; as a rule, traumas resulting from intentional human behavior (rape, torture, genocide, domestic violence, etc.) are experienced as more stressful than traumas resulting from accidents, natural disasters, or animal attacks.

Symptoms

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), specifies six diagnostic criteria for PTSD:

- **Traumatic stressor:** The patient has been exposed to a catastrophic event involving actual or threatened death or injury, or a threat to the physical integrity of the self or others. During exposure to the trauma, the person's emotional response was marked by intense fear, feelings of helplessness, or horror.
- **Intrusive symptoms:** The patient experiences flashbacks, traumatic daydreams, or nightmares, in which he or she relives the trauma as if it were recurring in the present. Intrusive symptoms result from an abnormal process of **memory** formation.
- **Avoidant symptoms:** The patient attempts to reduce the possibility of exposure to anything that might trigger memories of the trauma, and to minimize his or her reactions to such memories. This cluster of symptoms

includes dissociative symptoms (derealization and depersonalization), psychic numbing, and avoidance of places, persons, or things associated with the trauma. Patients with PTSD are at increased risk of substance abuse as a form of self-medication to numb painful memories.

- **Hyperarousal:** Hyperarousal is a condition in which the patient's nervous system is always on "red alert" for the return of danger. This symptom cluster includes hypervigilance, insomnia, difficulty concentrating, general irritability, and an extreme startle response.
- **Duration of symptoms:** The symptoms must persist for at least one month.
- **Significance:** The patient suffers from significant social, interpersonal, or work-related problems as a result of the PTSD symptoms. A common social symptom of PTSD is a feeling of disconnection from other people (including loved ones); from the larger society; and from God or other sources of meaning.

The symptoms of PTSD usually begin within three months of the trauma, although sometimes PTSD does not develop until years after the initial trauma occurred. Once the symptoms begin, they may fade away again within six months. Others suffer with the symptoms for far longer; and in some cases, the problem may become chronic.

PTSD in children

PTSD in children may trigger the onset of learning disabilities, self-mutilation or other destructive behaviors, sleep terrors, and a variety of conduct disorders. Children may also develop abnormally close attachments to their primary caretakers or other dependency behaviors in their attempts to cope with the traumatic experience.

Treatment

A diagnosis of PTSD does not indicate personal weakness or mental illness. It is a perfectly natural and normal reaction to one or more abnormal events. Just like a perfectly healthy bone will break if placed under enough stress, a perfectly healthy person placed under sufficient stress can develop PTSD.

It is important to understand that not every person who experiences a traumatic event will experience PTSD. There is some evidence that an approach known as critical incident stress debriefing, or CISD, may lower the incidence of PTSD in survivors of a large-scale civilian disaster or war zone trauma. CISD should be offered to survivors within 48 hours of the traumatic event. In general, persons who are experiencing some of the symp-

KEY TERMS

Benzodiazepines—A class of drugs that have a hypnotic and sedative action, used mainly as tranquilizers to control symptoms of anxiety.

Cognitive-behavioral therapy—A type of psychotherapy used to treat anxiety disorders (including PTSD) that emphasizes behavioral change as well as alteration of negative thought patterns.

Dissociation—The splitting off of certain mental processes from conscious awareness. Many PTSD patients have dissociative symptoms.

Flashback—An abnormally vivid, often recurrent, recollection of a traumatic event.

Hyperarousal—A condition of abnormally intense nervous excitement. Some symptoms of PTSD are classified as symptoms of hyperarousal.

Hypervigilance—A condition of abnormally intense watchfulness or wariness. Hypervigilance is one of the most common symptoms of PTSD.

Selective serotonin reuptake inhibitors (SSRIs)—A class of antidepressants that work by blocking the reabsorption of serotonin in the brain, raising the levels of serotonin. SSRIs include Prozac, Zoloft, and Paxil.

toms of PTSD should consult a mental health professional. He or she will diagnose the condition if the symptoms of stress last for more than a month after a traumatic event. While a formal diagnosis of PTSD is made only in the wake of a severe trauma, it is possible to have a mild PTSD-like reaction following less severe stress.

Medication

The most helpful treatment of PTSD appears to be a combination of medication along with supportive and cognitive-behavioral therapies. Effective medications include anxiety-reducing medications and antidepressants, especially the selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac). Sleep problems can be lessened with brief treatment with an anti-anxiety drug, such as a benzodiazepine like alprazolam (Xanax), but long-term usage can lead to such disturbing side effects as increased anger.

Psychotherapy

Therapy can help reduce negative thought patterns and self-talk, in that many PTSD patients blame them-

selves for the traumatic event, their reactions to it, or both. Cognitive-behavioral therapy focuses on changing specific actions and thoughts with the help of **relaxation** training and breathing techniques. Group therapy with other PTSD sufferers and family therapy can also be helpful.

Alternative and complementary approaches

Patients diagnosed with PTSD may benefit from such complementary approaches as **meditation** and mindfulness training, which appear to be useful in reducing the number of flashbacks. **Yoga**, bodywork, and **massage therapy** help to reduce the muscle soreness and tension associated with PTSD. Lastly, some patients find martial arts training useful in restoring a sense of personal competence and safety.

Prognosis

The severity of PTSD depends in part on the predictability of the trauma; its severity; its duration and chronicity; the role of human intention in inflicting the trauma; and the patient's personality style, overall state of health, and genetic predisposition.

With appropriate medication, emotional support, and counseling, most people show significant improvement. On the other hand, prolonged exposure to severe trauma—such as experienced by victims of prolonged physical or sexual abuse and survivors of the Holocaust—may cause permanent psychological scars.

Health care team roles

It is essential for all treatment team members to know their roles and execute them properly throughout the treatment and recovery phases of this disorder. Depending on whether outpatient or inpatient treatment is being provided, the team leaders may include psychiatrists, psychologists, nursing staff, behavior specialists and other medical/behavioral staff. In some cases it may be appropriate to include the patient's religious or spiritual advisor as a member of the team, in that increasing numbers of clergy have taken advanced training in trauma therapy.

Regular meetings are important so that all persons involved can provide input. Family members involved in patient care should be reaffirmed as to their need to provide consistency and adherence to the plan of care. Psychological evaluations will provide a base for the rest of the team to compose and/or update the treatment plan.

During treatment planning phases, needs and strengths are assessed, as well as progress from prior

plans. The treatment team leader, normally a behavior specialist, a psychologist or a psychiatrist, will then compose a plan of care that will describe goals for the next phase of care, interventions and other information needed to initiate or continue care.

Postmortem care

Definition

Postmortem care is the care provided to a patient immediately after death.

Purpose

Postmortem care serves several purposes, including:

- preparing the patient for viewing by family
- ensuring proper identification of the patient prior to transportation to the morgue or funeral home
- providing appropriate disposition of patient's belongings
- maintaining vital organs, if donation is planned

Precautions

Government regulations at both state and federal level require hospitals to establish policies and procedures to certify death; to identify potential donors; and to care for a body after death. If organ donation is anticipated, respiratory and circulatory support must be maintained until vital organs can be harvested. It must be clearly communicated to the family that the devices used to maintain organ perfusion no longer keep the patient alive, but are merely supporting the organs in anticipation of transplant.

Vital organs requiring support are:

- heart
- liver
- lungs
- kidneys
- pancreas

KEY TERMS

Algor mortis—Reduction of body temperature with loss of skin elasticity.

Livor mortis—Discoloration of skin in dependent areas.

Rigor mortis—Stiffening of the body, developing within two to four hours of death.

Such non-vital tissues as the cornea, skin, long bones, and middle ear bones do not require support after death.

If the patient had an infectious disease, the body must be labeled in accordance with established policy.

Before rigor mortis develops, the nurse should position the body in a normal alignment and close the eyelids and mouth, inserting dentures if necessary. Because of the reduction in body temperature and loss of skin tone (algor mortis) after death, it is important to gently remove all tape and dressings to prevent tissue damage. The skin or body parts should never be pulled on. The head of the bed should be elevated to prevent purplish discoloration (livor mortis) of the face. The body must be stored in a cool place to slow bacterial formation after death.

Description

Equipment

A commercial morgue pack, if available, will contain gauze or string ties, chin straps, a shroud, and three identification tags. In addition to these items, the nurse should gather the following:

- gloves
- ABD pads
- cotton balls
- adhesive bandages to cover **wounds** or punctures
- plastic bag for belongings
- bath basin with water
- soap
- towels
- washcloths
- clean sheets
- stretcher or morgue cart

Preparation

Before placing the body in a supine position with arms at sides and head on a pillow, the nurse should put on clean gloves. The head of the bed should be slightly elevated. At this time, the nurse can insert the patient's dentures, if worn, and then close the mouth. By placing a fingertip on each eye, the nurse should gently close the patient's eyes. If the eyes will not remain closed, moistened cotton balls can be placed on the eyelids for several minutes, and then a repeated attempt to close the eyes can be made. A folded towel should be placed under the chin to keep the mouth closed. All catheters, tubes, and tape can be removed, but adhesive bandages should be applied to puncture sites.

At the time of death, the patient's survivors become the focus of concern, and the nurse must then be able to offer comfort and support to the living. All the patient's belongings can be gathered for the family to take. If a ring cannot be removed, the nurse can cover the ring with gauze, tape it securely, and tie the gauze to the wrist to prevent loss.

Before the family views the patient, the body is cleansed, using soap, water, and washcloths. To absorb any rectal drainage, one or more ABD pads is placed between the buttocks. The body is covered up to the chin in a clean sheet, with the arms placed outside of the sheet if possible. Then the room must be prepared for receiving the family and friends by removing all trash and providing lower light in the room. If there are unpleasant odors present in the room, a room deodorizer can be used before allowing the family to return.

The nurse can then offer family members the opportunity to view the body, but not force them, letting them know that either viewing or not viewing is acceptable. This is the time to ask family members if they prefer that any jewelry be left on the body. The nurse should clearly document whether personal items are remaining with the body, or to whom the items were given. The nurse can allow survivors privacy in viewing the body, but not leave them alone until it is ascertained that they are comfortable remaining with the body. The nurse can encourage the family to touch and talk as a way to say goodbye to the deceased.

When the family has left, the towel can be removed from under the chin, placing an ABD pad under the chin and wrapping chin straps under the chin, with the straps tied loosely on top of the head. Padding the wrists with an ABD pad prevents bruising, and then the nurse ties the wrists together with gauze or soft string ties; the ankles should be padded and tied in the same manner. It will be necessary to fill out three identification tags with the deceased's name, room and bed number; date and time of

death; and the physician's name. One tag will be tied to the big toe, hand, or foot. Another identification tag must be attached to the shrouded body, and the third identification tag attached to the personal belongings. The nurse must ensure that the patient's identification bracelet is not removed.

Aftercare

A family member should take all the patient's personal belongings. The body will be transported to the morgue or funeral home.

Complications

If organ donation is planned, failure to maintain support for vital organs will mean that organs cannot be harvested.

Results

The patient's family will have the opportunity to view the body, if they wish, in order to begin the grief process. Emotional support of the survivors will be provided by trained staff members.

Health care team roles

Physicians must certify the death. If the death occurred in unusual circumstances, an **autopsy** may be requested. Staff members, pastoral care, or other personnel should remain with the family during preparation of the patient's body for viewing. Nursing is responsible for coordination of all postmortem care. Trained staff members will provide information to the family regarding organ donation.

Postoperative care

Definition

Postoperative care is the management of a patient after surgery. This includes care given during the immediate postoperative period, both in the operating room and the postanesthesia care unit (PACU), as well as during the days following the surgery.

Purpose

The goal of postoperative care is to prevent such complications as **infection**, to promote healing of the surgical incision, and to return the patient to a state of health.

Precautions

Thorough postoperative care is crucial to ensuring positive outcomes for patients who have had surgery. There are no contraindications to providing this care. However, skill and careful monitoring are needed to prevent complications and to restore the patient to health as soon as possible.

Description

Postoperative care involves assessment, diagnosis, planning, intervention and outcome evaluation. The extent of postoperative care required by each patient depends on the original health status of the patient, type of surgery, and whether the surgery was performed in a day-surgery setting or in the hospital. Patients who have procedures done in a day-surgery center usually require only a few hours of care by health care professionals before they are discharged to go home. If postanesthesia or postoperative complications occur within these hours, the patient must be admitted to the hospital. Patients who are admitted to the hospital may require days or weeks of postoperative care by hospital staff before they are discharged.

Postanesthesia care unit (PACU)

After the surgical procedure, and anesthesia reversal and extubation if necessary, the patient is transferred to the PACU. The length of time the patient spends there depends on the length of surgery; the type of surgery; the status of regional anesthesia (for example, spinal anesthesia); and the patient's level of consciousness. Rather than being sent to the PACU, some patients may be transferred directly to the critical care unit instead. For example, patients who have had coronary artery bypass grafting (CABG) are sent directly to the critical care unit.

In the PACU, the anesthesiologist or the **nurse anesthetist** reports on the patient's condition; the type of surgery performed; the type of anesthesia given; estimated **blood** loss; and total input and output during the surgery. The receiving nurse should also be made aware of any complications during the surgery, including any variations in hemodynamic stability.

Assessment of the patient's airway patency, **vital signs**, and level of consciousness are the first priorities upon admission to the PACU. The following is a list of other assessment categories:

- surgical site (check that dressings are intact and there are no signs of overt bleeding)
- patency of drainage tubes/drains
- body temperature (hypothermia/hyperthermia)
- patency/rate of IV fluids
- circulation/sensation in extremities after vascular or orthopedic surgery
- level of sensation after regional anesthesia
- **pain** status
- nausea/vomiting

The patient is discharged from the PACU when they meet established criteria for discharge, as determined by use of a scale. An example is the Aldrete scale, which scores the patient on mobility, respiratory status, circulation, consciousness, and pulse oximetry. Depending on the type of surgery and the patient's condition, the patient may be admitted to either a general surgical floor or the intensive care unit. Since the patient may still be sedated from anesthesia, safety is a primary goal. The patient's call light should be in their hand and all side rails should be up. Patients in a day-surgery setting are either discharged from the PACU to the unit to their home, or are directly discharged home after they have voided, ambulated, and tolerated a small amount of oral intake.

First 24 hours

After the hospitalized patient transfers from the PACU, the receiving nurse should assess the patient again, using the same previously mentioned categories. If the patient reports "hearing" or feeling pain during surgery (under anesthesia) the observation should not be discounted. The anesthesiologist or nurse anesthetist should discuss the possibility of an episode of awareness under anesthesia with the patient. Vital signs, respiratory status, pain status, the incision, and any drainage tubes should be monitored every one to two hours for at least the first eight hours. Body temperature must be monitored, since patients are often hypothermic after surgery and may need a warming blanket or warmed IV fluids. Respiratory status should be assessed frequently, including auscultation of lung sounds, assessment of chest excursion, and presence of adequate cough. Fluid intake and urine output should be monitored every one to two hours. If the patient doesn't have a urinary catheter, the bladder should be assessed for distension and the patient monitored for inability to void. If they have not voided six to eight hours after surgery, the physician should be notified. If the patient had a vascular or neurological procedure performed, circulatory status or neurological status should be assessed as ordered by the surgeon, usually every one to two hours. The patient may require medication for nausea and/or vomiting, as well as for pain.

Patients with a patient-controlled analgesia (PCA) pump may need to be reminded how to use it. If the patient is too sedated immediately after the surgery, the nurse may push the button to deliver pain medication for them. The patient should be asked to rate their pain on a pain scale in order to determine their acceptable level of pain. Every attempt should be made by the nurse to keep the patient's pain under control. This often means that the nurse must offer pain medication every hour or two—many times before the patient requests it. Controlling pain is crucial so that the patient may perform coughing, deep breathing exercises, may be able to turn in bed, sit up, and, eventually, ambulate.

Effective preoperative teaching has a positive impact on the first 24 hours postoperatively. If patients understand that they must perform respiratory exercises to prevent **pneumonia**; and that movement is imperative for preventing blood clots, encouraging circulation to the extremities, and keeping the **lungs** clear; then they will be much more likely to perform these tasks. Understanding the need for movement and respiratory exercises also underscores the importance of keeping pain under control. Respiratory exercises (coughing, deep breathing and incentive spirometry) should be done

every two hours. The patient should be turned every two hours, and should at least be sitting on the edge of the bed by eight hours after surgery, unless contraindicated (for example, post-hip replacement). These patients will have sequential compression devices on their legs until they are able to ambulate. The sequential compression devices are stockings that inflate with air in order to simulate the effect of walking on the calf muscles and return blood to the **heart**. The patient should be encouraged to splint chest and abdominal incisions with a pillow to decrease the pain caused by coughing and moving. Patients should be kept NPO (nothing by mouth) if ordered by the surgeon, at least until their cough and gag **reflexes** have returned. Patients often have a dry mouth following surgery, which can be relieved with oral sponges dipped in ice water or by applying lemon ginger in mouth swabs.

Patients who are discharged home after a day-surgery procedure are given prescriptions for their pain medications and are responsible for their own pain control and respiratory exercises. Their families (or caregivers) should be included in preoperative teaching so that a caregiver can assist the patient at home. The patient should be reminded to call their physician if they have any complications or uncontrolled pain. These patients are often managed at home on a follow-up basis by a hospital-connected visiting nurse or **home care** service.

After 24 hours

After the initial 24 hours, vital signs can be monitored every four to eight hours if the patient is stable. The incision and dressing should be monitored for the amount of drainage and signs of infection; the surgeon may order the dressing to be changed during the first postoperative day. Postoperative dressing changes should be done using sterile technique. For home-care patients this technique must be emphasized. The hospitalized patient should be sitting up in a chair at the bedside and ambulating with assistance by this time period. Respiratory exercises should continue to be performed every two hours and incentive spirometry values should improve. Bowel sounds should be monitored and the patient's diet gradually increased as tolerated, depending on the type of surgery and the physician's orders.

The patient should be monitored for any evidence of potential complication, such as leg **edema**, redness, and pain (deep vein thrombosis); shortness of breath (pulmonary embolism); dehiscence (separation) of the incision; or ileus. If any of these occur, the surgeon should be notified immediately. If dehiscence occurs, sterile saline-soaked dressing packs should be placed on the wound. The patient and the family should be updated on the eval-

KEY TERMS

Deep vein thrombosis (DVT)—Potentially life-threatening blood clot in one of the deep veins of the body, and often in the legs secondary to immobility after surgery. Symptoms include pain, warmth, swelling, and redness.

Dehiscence—Separation of a surgical incision or rupture of a wound closure.

Ileus—Obstruction in or immobility of the intestines. Symptoms include nausea and vomiting, absent bowel sounds, abdominal pain, and abdominal distension.

Incentive spirometer—Device that is used postoperatively to prevent lung collapse and promote maximum inspiration. The patient inhales until a preset volume is reached, then sustains the volume by holding their breath for three to five seconds.

PACU—The post-anesthesia care unit, where the patient is cared for after surgery.

Patient-controlled analgesia pump (PCA pump)—A pump which the patient uses to self-administer medication to control pain.

Pulmonary embolism (PE)—Potentially life-threatening blockage of a pulmonary artery by fat, air, or a blood clot that originated elsewhere in the body. Symptoms include acute shortness of breath and sudden chest pain.

uation of the patient, the patient's condition, and any teaching as often as necessary.

Preparation

Postoperative care involves many procedures and teaching topics. Preparation for procedures includes having all needed supplies at the bedside. Pain medication should be offered prior to any procedure that is likely to cause discomfort. Preparation for teaching includes having resources available. Many hospitals have **patient education** materials such as handouts and video tapes that can be used to assist in teaching the patient what to expect during the postoperative time period.

Aftercare

Aftercare includes ensuring that patients are comfortable, either in bed or in a chair, and that they have their call lights accessible. After dressing changes, blood-

soaked dressings should be properly disposed of in a bio-hazard container. Again, pain medication should be offered before any procedure that might cause discomfort. After teaching a patient, or the caregiver, aftercare includes answering all of their questions; and, in some cases, having them demonstrate the techniques they will be using.

Complications

Postoperative care is indicated for all patients who have had an invasive procedure, regardless how minor. However, improper care can lead to complications. For example, changing a surgical dressing without sterile technique can lead to infection. Failure to monitor a patient closely, or failing to assist them with respiratory exercises and ambulation, can lead to pneumonia or deep vein thrombosis, and potentially pulmonary embolus. Patients who have not had thorough teaching on what to expect may resist attempts to assist them, leading to complications and anger on the part of the patient or family.

Results

The goal of postoperative care is to ensure that patients have good outcomes after surgical procedures. A good outcome includes recovery without complications and adequate **pain management**. Another objective of postoperative care is to assist patients in taking responsibility for regaining good health.

Health care team roles

Almost every member of the health care team has a role in postoperative care. The surgeon performs the surgery and manages the patient's postoperative care. The patient's primary care doctor often helps manage the care of hospitalized patients as well. Nurses are at the bedside 24 hours a day, so they monitor the patient for complications; assist the patient with respiratory exercises and regaining mobility; provide postoperative teaching; and generally care for the patient. Respiratory therapists also provide instruction and assistance with respiratory exercises, and monitor the patient's respiratory status. Radiology personnel take x-rays that are ordered by the physician, and laboratory personnel draw blood samples and perform blood tests. All team members must communicate with one another and with the patient to provide the best possible postoperative care.

Postpartum care

Definition

Postpartum care encompasses management of the mother, newborn, and infant during the postpartal period. This period usually is considered to be the first few days after delivery, but technically it includes the six-week period after **childbirth** up to the mother's postpartum checkup with her health care provider.

Purpose

Immediately following childbirth, a new mother experiences profound physical and emotional changes. She may stay in the hospital or birthing center a very short time, even as little as 24–48 hours after delivery. The physical and emotional care a woman receives during the postpartum period can influence her for the remainder of her life.

Precautions

During the postpartum period the mother is at risk for such problems as **infection**, hemorrhage, pregnancy-induced **hypertension**, **blood** clot formation, the opening up of incisions, breast problems, and **postpartum depression**.

Description

Postpartum care in the hospital

The initial phase of the postpartum period encompasses the first one to two hours after delivery. It takes place most often in the birthing room or in a recovery

room. Once this initial phase is over, the woman has passed through the most dangerous part of childbirth. Assessments of **pain**, the condition of the uterus, vaginal discharge, the condition of the perineum, and the presence/absence of bladder distension (followed by appropriate interventions) are part of the initial postpartum evaluation; and should be done every 15 minutes for the first hour, then generally every 30 minutes for the second hour, and every four to eight hours thereafter depending on facility policy.

PAIN/DISCOMFORT. The degree of pain and discomfort from incisions, lacerations, and uterine cramping (afterbirth pains) is assessed by hospital staff. The woman may also complain of muscle pain after a prolonged labor. If the level of pain warrants it, analgesic medications are given, usually orally. Women who have undergone cesarean births may have more pain than women who have given birth vaginally, and may need injectable **analgesics**. If a woman complains of pain in her calf, she should be evaluated for thrombophlebitis. Also, if a woman complains of a headache, her **blood pressure** should be checked to rule out the presence of pregnancy-induced hypertension. A woman who received epidural anesthesia during delivery may develop a “spinal headache.” A spinal headache is due to the loss of cerebrospinal fluid from the subarachnoid space that may occur during the administration of the spinal anesthesia. Spinal headaches should be treated by the anesthesiologist or nurse-anesthetist. Treatment for this type of headache typically includes keeping the patient flat in bed, encouraging increased fluid intake, and administering pain medication.

Breast engorgement is characterized by low-grade **fever** and the absence of systemic symptoms. It is usually bilateral; the breasts feel warm to the touch and appear shiny. Pain from breast engorgement can be minimized for the breastfeeding mother by mild analgesics, the application of warm packs, and frequent nursing. For the mother who is not breastfeeding, this pain can be minimized by mild analgesics and the application of cold packs. A nursing mother may find that the use of a lanolin-based preparation or a nipple shield (although controversial) provides relief for sore or cracked nipples. Changing positions for the nursing baby also can help in reducing irritation and minimizing stress on sore spots.

A plugged duct can also cause breast pain. Breast pain caused by a plugged duct is distinguished from breast engorgement by the fact that it is usually confined to one breast and the breast is not warm to the touch. This pain may be relieved by heat packs, gentle massage of the breast toward the nipple, and changing positions for nursing the baby.

FUNDUS. The condition of the uterus is assessed by evaluating the height and consistency of the fundus (the part of the uterus that can be palpated abdominally). Immediately after delivery, uterine contractions begin triggering involution. Involution is the process whereby the uterus and other reproductive organs return to their state prior to **pregnancy**. To properly palpate the uterus, the woman is positioned flat on her back (supine). The health care provider places one hand at the base of the uterus above the symphysis pubis (the interpubic joint of the pelvis) in a cupping manner (to support the lower uterine ligaments). Then, she presses in and downward with the other hand at the umbilicus until she makes contact with a hard, globular mass. If the uterus is not firm, light massaging usually results in tightening. Massaging of the uterus should not be so vigorous as to cause the mother pain. A mother who has had a cesarean delivery should be medicated, if possible, prior to assessment of the fundus; and the health care provider should use the minimal amount of pressure necessary to locate her fundus. The height of the fundus after the first hour following delivery is at the umbilicus or above it. Every day the fundal height decreases by approximately the width of one finger (one cm).

The fundal height may be palpated off of midline because of a distended bladder. If possible, the woman should be encouraged to empty her bladder prior to assessment of the fundus. A full bladder can prevent uterine involution.

A woman sometimes receives the medication oxytocin (Pitocin) after the delivery of the placenta. Oxytocin causes the uterus to contract and can decrease the amount of postpartum bleeding. The health care provider should assess the condition of the uterus frequently, and may need to massage the uterus gently to encourage its clamping down on itself, especially when oxytocin has not been given. If the uterus does not firm to gentle massage, then a clot may be present inside. Gentle pressure on the uterus following massage, and while simultaneously supporting the base of the uterus, may expel the clot.

If massaging the uterus does not result in a firming of the fundus, then the physician or nurse-midwife should be contacted immediately. The existence of severe atony or a retained fragment of placenta may result in excessive loss of blood.

VAGINAL DISCHARGE (LOCHIA). The color and amount of vaginal discharge (lochia) is assessed by frequently removing the perineal pad and checking the flow of lochia after delivery. An excessive amount could be a sign of a complication such as clot formation or a retained portion of the placenta. The vaginal discharge is

red for one to three days following delivery and is called *lochia rubra*. Between days two and 10, the discharge changes to a pink or brownish color and is called *lochia serosa*. The last phase occurs when the vaginal discharge turns white. This vaginal discharge is referred to as *lochia alba* and may occur from 10–14 days postpartum. The spotting can continue for another six weeks. It is common in mothers who breastfeed their babies. A constant trickling of blood or the soaking through of a perineal pad in an hour or less is not normal and should be further evaluated.

PERINEUM. The condition of the perineal area is assessed for an episiotomy or laceration repair. An episiotomy is the surgical procedure whereby the physician or nurse-midwife extends the vaginal outlet immediately prior to delivery of the baby. The incision is repaired with sutures after delivery.

Generally an episiotomy will be 1–2 inches (2.5–5 cm) in length. By 24 hours postpartum the edges of the episiotomy should be fused together. An episiotomy may be covered over with edematous tissue and not easily visible, so the examination must be done carefully. If the laceration or episiotomy is infected it appears red and swollen, and discharges pus. Treatment depends on the severity of the infection and may include sitz baths; application of an antibiotic cream to the wound; oral **antibiotics**; or opening the wound, cleansing the site, and resuturing it.

When the perineal area is examined, the patient should also be checked for the presence of a hematoma (a round area filled with blood) that is caused by the rupturing of small **blood vessels** on the surface of the perineum. After observing the perineum, the rectal area also is evaluated for hemorrhoids, making note of their size, character, and number.

The following measures are effective in providing relief of perineal discomfort:

- Application of cold packs to the perineum for the first 24 hours after delivery.
- Application of warm packs to the perineum after the first 24 hours.
- Rinsing of the perineal area with warm water after every void and/or bowel movement. (This is also helpful in preventing infection and in promoting healing.)
- Use of anesthetic sprays and creams. Cleaning the area with witch hazel pads (Tucks) is also soothing.
- Sitting in a sitz bath—a small basin that fits on top of the toilet through which warm water flows—three or four times a day. After discharge a woman may use her bathtub at home for this purpose.

BLADDER DISTENTION. In the first 48 hours after delivery it is normal to have an increase in the formation and secretion of urine (postpartum diuresis). A full bladder can cause the uterus to shift upwards and not contract effectively. An overdistended bladder can even cause injury to the **urinary system**. A woman should be encouraged to void within her first hour postpartum; and her bladder should be checked after voiding, since urinary retention can be a problem. If the woman had a cesarean section and has a Foley catheter in place in her bladder, then the output is checked every hour during the initial postpartum period. The Foley catheter is likely to be removed approximately eight hours after surgery. The health care provider needs to assess for voiding after removal of the Foley catheter.

Postpartum care after hospital discharge

Ideal postpartum care would include several home visits by health care providers in the one to two weeks following delivery to assess the status of the mother and her family. This rarely happens in the United States, but follow-up phone calls by health care providers during the first week and a visit by the mother and baby to her physician or nurse-midwife one to two weeks after the birth are desirable.

Several problems that may arise during the postpartum period do not typically develop until after the new mother is discharged from the hospital. These include **mastitis**, endometritis, and postpartum depression.

MASTITIS. Mastitis is an inflammation of the breast, usually caused by streptococcal or staphylococcal infection. It can develop any time a woman is breastfeeding, but usually does not occur before the tenth postpartum day. Symptoms of mastitis often mimic those of the flu, and include body aches and a fever of 101°F (38.6°C) or more. Mastitis is treated with a course of antibiotics, and women should begin to feel better within 24 hours of beginning the antibiotics. If this does not happen, the woman may need to be hospitalized for intravenous antibiotics.

Other measures that may help the mother feel better include bed rest for at least 24 hours, moist heat on the infected breast every two to three hours (when awake), acetaminophen for pain and fever relief, increased fluid intake, and going without a bra for several days. Mastitis does not contaminate the breast milk and the baby should continue to nurse from both breasts. If nursing from the affected breast is too painful, use of a breast pump or manual expression of milk may be needed to prevent engorgement and facilitate continued milk production.

ENDOMETRITIS. Endometritis is an inflammation of the endometrium, the mucous membrane lining the

uterus. It is usually caused by a bacterial infection. Symptoms of this infection include fever, abdominal pain, and foul-smelling vaginal discharge. **Physical examination** of the patient reveals a tender uterus. Endometritis is treated with a course of antibiotics and other care, including bed rest, acetaminophen for pain and fever relief, and increased fluid intake. Severe cases may require hospitalization.

POSTPARTUM DEPRESSION. Postpartum depression may appear at any time during the first year after a baby's birth. It ranges in severity from mild, postpartum "blues" that last only a few days shortly after birth, to intense, suicidal, depressive psychosis. Not only does postpartum depression cause distress for the new mother and her partner, but it can also interfere with the new mother's ability to bond with her baby and to relate to any other children she may have.

Symptoms of severe postpartum depression or psychosis include insomnia, hallucinations, agitation, and bizarre feelings or behavior. Any new mother exhibiting signs of postpartum depression should be referred to mental health professionals, support groups, and/or new mother groups. Psychotropic medication is often helpful, as is **psychotherapy**. About 10% of cases of postpartum depression are caused by postpartum thyroiditis, a temporary inflammation of the **thyroid gland** that usually clears up spontaneously in one to four months. Whenever postpartum depression occurs, thyroid function should be tested to rule out hyperthyroidism or hypothyroidism as the cause of symptoms.

Six-week postpartum check-up

Although this postpartum check-up is traditionally scheduled six weeks after delivery, it may be done any time between four weeks and eight weeks after delivery. It usually includes a breast examination, a pelvic examination, any necessary laboratory tests, and a health education component covering such areas as breastfeeding, birth control, weight reduction, etc. This checkup is also an opportunity to review the pregnancy and birth experience, to discuss problems and assess for depression, to provide emotional support, to answer questions, and to consider if any further referrals are necessary for the new mother.

Health care team roles

The new mother is given instruction in how to hygienically care for her perineal area. She is encouraged to change her perineal pad frequently and to wash her hands afterwards. The presence of a wet pad against sutures is an excellent medium for the development of an infection that could potentially spread to the uterus. The

KEY TERMS

Perineum—The area between the rectum and the outlet of the vagina.

Pregnancy-induced hypertension—Vasospasm occurring during pregnancy resulting in such symptoms as hypertension, swelling, and protein in the urine. If not treated, it can sometimes result in a seizure.

Thrombophlebitis—Blood clot formation resulting in inflammation of the lining of a blood vessel.

Umbilicus—Navel; depression in the center of the abdomen where the umbilical cord was attached.

woman is also instructed not to use tampons for six weeks after delivery, since tampon use can cause infection or even toxic shock syndrome.

New mothers may be overwhelmed by the degree of discomfort after giving birth, and may be frustrated by their desire to interact with their new baby while at the same time being limited by pain, discomfort, and exhaustion. The health care team member can help the new mother by providing perineal care for her until she is able to get out of bed, and by administering pain medications as ordered.

Other important things health care providers can do for postpartum women include:

- Evaluate pulse, respiratory rate, and blood pressure every 15 minutes during the first hour postpartum, every 30 minutes for two hours, and then every eight hours. Evaluate the woman's temperature at the end of the first hour postpartum and then every four hours for the first 2–12 hours postpartum.
- Help the woman take a shower as soon as she is allowed to, while monitoring her for lightheadedness.
- Place a warm blanket over the mother after delivery if she experiences shaking and chills.
- Provide emotional support to the mother and family through explanations about childbirth and how it can be a highly emotional and psychologically overwhelming time.
- Promote adequate rest.
- Encourage a generous intake of nutrients and fluids.
- Ask if the woman has had a bowel movement prior to discharge and offer medication to soften stools if desired.

- Monitor the woman's voiding and ensure the woman is not having difficulty. Catheterization is sometimes required.
- Assist with ambulation until the woman is steady on her feet.
- Review laboratory tests for signs of anemia, infection, and electrolyte imbalance.
- Teach the woman muscle-strengthening exercises.
- Prepare the mother and family for discharge through discharge teaching.
- Arrange for a home visit if this is provided for through the facility and/or patient's insurance.

Nadine M. Jacobson

Postpartum depression

Definition

Postpartum depression (PPD) is a major depressive episode that occurs after **childbirth**. There are conflicting data regarding the time of onset. The *Diagnostic and Statistical Manual of Mental Disorders* (1995) supports the theory that PPD occurs within four weeks of childbirth. Other clinical investigations report its occurrence up to 12 weeks post-delivery; yet others state that PPD occurs from 6–12 months after delivery. It is reported that PPD may last longer than one month.

Description

The beginning of PPD tends to be gradual, and may persist for many months. It might develop into a second episode if there is a subsequent **pregnancy**. According to several controlled studies, PPD affects approximately 12–16% of childbearing women. In adolescent mothers,

the figure can be as high as 26%. Women who have a previous history of depression are predisposed to PPD; and up to 30% of women who have had a major depressive episode before they conceived might develop PPD. This rate can rise as high as 50–62% in women who have a history of depression in previous pregnancies or during the postpartum periods.

Mild cases of PPD are sometimes unrecognized by women themselves. Embarrassment about difficulty coping with their new circumstances is sometimes shared by new mothers—so much that they might conceal it. This is a serious problem that disrupts women's lives and can have negative effects on the baby, other children, the new mother's partner, and other significant relationships. Marital problems, inadequate social networks, ambivalence about the pregnancy, and disturbing life events can add to the risk of depression.

The father's risk of becoming depressed increases significantly during the postpartum period as well.

Postpartum depression is often divided into two types: early onset and late onset. An early-onset depression most often presents as “baby blues,” a brief experience during the first days or weeks following birth. During the first week after the birth of their child, up to 80% of mothers may experience the “baby blues.” This period of time is characterized by feelings of oversensitivity, uncontrollable teariness, irritability, **anxiety**, and mood changes. Symptoms tend to peak between three and five days after childbirth, and normally disappear within a few days.

In short, some depression, tiredness, and anxiety often fall within the normal range of reactions after giving birth.

A late-onset PPD appears several weeks after the birth. This may involve a growing feeling of sadness, grief, lack of energy, chronic fatigue, inability to sleep, changes in appetite, significant weight loss or gain, difficulty caring for the baby—and sometimes, thoughts of harming the baby.

Causes and symptoms

As of 2001, experts are not positive about the causes of PPD. It may be caused by factors that vary from person to person. Pregnancy and birth are accompanied by sudden hormonal shifts that can cause a range of emotions. Additionally, the 24-hour responsibilities involved in caring for a newborn present major psychological and lifestyle adjustments for most new mothers. These physical and emotional stresses are usually aggravated by not getting adequate rest until the baby's routine stabilizes.

Experiences of new mothers vary considerably, but may include the following.

Feelings:

- persistent low mood
- inadequacy, failure, hopelessness, helplessness
- exhaustion, emptiness, sadness, teariness
- guilt, shame, worthlessness
- confusion, anxiety, and panic
- fear for the baby and of the baby
- fear of being alone or going out

Behaviors:

- lack of interest or pleasure in usual activities
- insomnia or excessive sleep; nightmares
- changes in appetite
- decreased energy and motivation
- withdrawal from social contact
- poor self-care
- inability to cope with routine tasks

Thoughts:

- inability to think clearly and make decisions
- lack of concentration and poor memory
- inability to deal with stressful situations
- fear of being rejected by partner
- worry about harming herself, her partner, or her baby
- suicidal ideation

Some symptoms may not indicate a severe problem. However, persistent low mood or loss of interest or pleasure in activities, along with four other symptoms occurring at the same time, may signal a problem. If these symptoms persist for a period of at least two weeks, a clinical depression may be occurring, and professional intervention may be required.

There are several important risk factors for PPD, including:

- stress
- loss of pleasure or interest in living
- lack of sleep (sleep deprivation)
- poor nutrition
- lack of support from one's partner, family, or friends
- family history of clinical depression
- complications for mother or baby during labor and delivery
- premature or postmature delivery

- poor newborn health
- separation of mother and baby
- a difficult baby (i.e., problems with temperament, feeding, sleeping, or settling)
- preexisting neurosis or psychosis

Diagnosis

There is no specific diagnostic test for PPD. However, it is important to understand that PPD is a bona fide illness, and that it has specific symptoms, the same as a physical condition. **Blood** tests to measure thyroid hormone levels can rule out postpartum thyroiditis, which can mimic PPD.

It is important to note that a small percentage of women experience postpartum psychosis, a rare disorder. This is the most severe, but least common, postpartum condition. Occurring in only 1–2 births per 1,000, postpartum psychosis appears between 48–72 hours and several weeks after delivery. Symptoms may include elated mood, mood changeability, disorganized behavior, insomnia, religious preoccupation, agitation, suicide attempts or suicidal ideation, bizarre feelings or behavior, and hallucinations. Postpartum psychosis is a serious condition that requires immediate psychiatric intervention and possible hospitalization.

Other psychiatric conditions, such as panic disorder and obsessive-compulsive disorder (OCD), are possible manifestations of PPD.

Complications

If PPD is misdiagnosed or remains untreated, a severely depressed woman may attempt or complete suicide. On a lesser but significant level, untreated PPD can lead to severe depression, anxiety, or postpartum psychosis.

Treatment

Several treatment options exist for mild-to-moderate PPD; these are psychiatric therapies that include interpersonal therapy (IPT) and cognitive-behavior therapy (CBT). Under investigation at the time of this writing in 2001, bright-light therapy may be effective in treating PPD. Clinical studies have reported that pregnant depressed women and postpartum depressed women, respectively, experienced antidepressant effects when bright-light therapy was administered. Another effective treatment combines antidepressant medication with counseling. Antidepressants generally become effective several weeks after a patient has begun taking them.

Medication must be prescribed carefully if the mother is breastfeeding, as it can pass to the baby in the mother's breast milk. This is why the physician must be aware that the baby is being breast-fed. The results of several short-term studies point to relative safety (i.e., lack of toxicity, minimal exposure to the maternal dose, or few adverse effects) in the use of SSRIs (selective serotonin reuptake inhibitors) by nursing mothers.

Postpartum depression also may be treated with "talk" therapy and participation in a support group. The mother needs to feel cared for, and that her feelings are respected. Nursing staff and allied health professionals can positively affect the treatment course by providing the mother with supportive one-on-one therapy, whereby the therapist listens to the woman's specific concerns and fears.

Such alternative treatment measures as **homeopathy** may be helpful, since they are meant to address mental, physical, and spiritual states—all of which are affected by PPD. Acupuncture and Chinese and Western herbs may also help by balancing mood and hormone levels. However, caution is strongly advised when taking herbs; as of 2001, they are unregulated. Toxicity studies have not been conducted to evaluate the safety of these substances. Seeking help from a homeopathic practitioner, however, does provide the new mother with an opportunity to discuss specific nutritional needs or mood problems.

Fortunately, there are useful things that a new mother can do for herself, including:

- Making each day as simple as possible.
- Asking for help from supportive friends and family members whenever possible.
- Avoiding extra pressures or unnecessary tasks.
- Involving her partner more intensively in the care of the baby from the beginning.
- Discussing with her partner how both can share the household chores and responsibilities.
- Scheduling frequent outings, such as walks and short visits with friends.
- Having the baby sleep in a separate room so that she can sleep more restfully.
- Sharing her feelings with her partner or another good listener.
- Talking with other mothers to keep problems in perspective.
- Sleeping or resting when the baby is sleeping.
- Taking care of her health and well-being.
- Not losing her sense of humor or self-esteem.

Prognosis

With appropriate support from friends and family, many mild cases of PPD go away by themselves. If depression becomes severe, a patient should not attempt to care for herself or the baby; in some cases, psychiatric hospitalization may be necessary. However, a three-pronged approach consisting of supervised medication, psychiatric counseling, and support from family, friends, and others, may relieve even severe depression in three to six months.

Health care team roles

Nursing staff and allied health professionals can assist in the diagnosis of postpartum depression by observing the patient for symptoms. Since PPD can present as a mood disorder, anxiety state, or psychotic episode, it is critical that nursing staff and allied health professionals understand the warning signs.

During the treatment phase, nursing staff and allied health professionals can help a new mother by providing her with appropriate **patient education** materials, and referrals for ongoing supportive therapy or group **psychotherapy**, if applicable.

Prevention

Exercise can help enhance a new mother's emotional well-being. New mothers should also cultivate good sleeping habits and rest when physically or emotionally tired. It is important for the health professional to teach the patient how to recognize the signs of fatigue and to make time for herself.

Psychotherapy or the use of antidepressant medication can also help to prevent future episodes of postpartum or ongoing clinical depression.

Postural evaluation

Definition

Posture can be defined as the position of the body in any environment or mode. Some examples of specific postures are sitting, standing, walking, or leaning forward. Posture is based on the position of the spine and all the joints in the musculoskeletal system. Postural evaluation or analysis consists of evaluating a patient’s posture through a series of appropriate tests and measurements. It is part of the branch of **physical therapy** called kinesi-ology, which includes the study of the anatomy and physiology of body movement.

Good or normal posture is defined as an imaginary straight line that connects the earlobe; cervical vertebrae; acromion (bony outgrowth on the shoulder blade); lumbar vertebrae; and a set of points behind the hip and slightly in front of the knee and ankle. In an actual postural evaluation, the patient may be asked to stand by a vertical plumb line so that the examiner can visualize any deviations from normal alignment.

Purpose

Good posture in humans is the end product of a complex combination of mechanical, neurological, and psychological factors, including muscular strength and flexibility, vision, touch, balance, self-esteem, kinesthetic (a sense of the location and movement of muscles and joints) awareness, and a properly functioning vestibular (inner ear) system. Because of the number of body parts and functions involved in good posture, a postural evaluation may serve a variety of purposes:

- As part of the musculoskeletal assessment of a balance evaluation. Postural abnormalities frequently affect an

KEY TERMS

Acromion—A bony prominence on the shoulder blade that articulates with the clavicle, forming the acromioclavicular (AC) joint.

Atrophy—The wasting away of muscle tissue from disuse.

Kinesiology—The branch of physical therapy that deals with the anatomy and physiology of body movement.

Osteoarthritis—A degenerative disorder of the cartilage and bone in the joints.

Osteoporosis—A condition characterized by decrease in bone mass and density, and enlargement of bone spaces.

elderly person’s sense of balance and his or her ability to react quickly to loss of balance.

- As a step in the differential diagnosis of chronic pain syndromes. Chronic neck and back **pain** in particular often result from poor posture, which causes muscles to contract, changes the amount of blood flow to the spine, and leads to deformation of the connective tissues in the spine and neck area.
- As part of a physical examination in sports medicine. Deviations from normal posture increase the risk of certain types of athletic injuries, and may interfere with athletic performance.
- In the evaluation of work-related postural problems and repetitive stress injuries (RSIs). Some physical therapists now visit work places in order to assess the physical demands of certain jobs—especially jobs that require sitting at desks in front of computers for long periods. These assessments are sometimes called ergonomic evaluations, which means that the design of equipment and other physical features of the workplace is coordinated with the physical requirements of the workers.

Precautions

Postural evaluation is noninvasive and should not cause the patient physical discomfort under normal circumstances. Care should be taken, however, to perform the evaluation in an appropriate examination room to protect the patient’s modesty. The room should be kept at a comfortable temperature.

Description

Postural evaluation typically begins with a visual assessment of the patient's posture while he or she is standing by a vertical plumb line. The person's posture is then scored according to check lists for the back view and the side view. Deviations from good posture are rated according to severity, in which a slight deviation is scored as 1 point, a moderate deviation as 2, and a severe deviation as 3 points. The total number of points from both back and side views is then calculated. A score of 12 points or higher is considered poor posture. Some therapists prefer to use posture photographs for a postural evaluation while other practitioners may order x-rays, on the grounds that these imaging modalities yield more accurate results than simple visual examination.

Visual assessment of posture also includes the clinician's careful visual observation of the patient's positioning during walking, sitting, and weight transfers.

Manual muscle testing is an important part of postural analysis. The clinician uses his or her hands to evaluate the various muscles for atrophy (wasting away from disuse), misalignment, overstretching, or constriction and shortening. Manual testing also allows the clinician to determine the extent as well as the presence of muscular imbalance.

Preparation

Accurate evaluation of patients with postural dysfunction requires careful history-taking. This includes family and social history as well as medical history. In most cases changes in posture are due to such anomalies as excessive weight gain, poor postural habits, traumatic injuries, uneven development of the musculature, or congenital defects. A family history may yield information about hereditary disorders that affect posture as well as family members' attitudes toward the patient. In some cases, people develop poor posture in response to physical or emotional abuse.

Results

An accurate postural evaluation provides the physical therapist with necessary information in devising a treatment plan. The goal of rehabilitation is to isolate the cause(s) of postural abnormalities and provide appropriate treatment through postural correction exercises and **patient education**. Other treatments can include such modalities as heat, ice, and massage; flexibility exercises; strengthening programs; and cardiovascular conditioning.

Health care team roles

Postural evaluations may be performed by physical therapists, physicians, nurses, and chiropractors. It is important that physicians—especially pediatricians—nurses, and other allied health professionals routinely evaluate patients' posture in an effort to minimize further complications of various diseases and disorders. Most health care facilities have screening clinics that offer postural assessment free of charge. It is also imperative that individuals with spinal **osteoarthritis**, **osteoporosis**, Marfan's syndrome, and other conditions that affect the spine be properly educated on the importance of good posture. The elderly and others who may have developed balance problems should have their posture evaluated as part of an overall balance evaluation.

Preconception counseling

Definition

Preconception counseling is **patient education** that helps a woman to make lifestyle changes before conception that will assist in promoting a healthy **pregnancy** and a healthy baby.

Purpose

Various health and environmental factors can increase the rate of abnormalities, referred to as birth defects, seen in babies at birth. Examples of these abnormalities are such conditions as cleft palate/lip, congenital **heart** disease, or spina bifida (opening of the spine). Some abnormalities are hereditary.

Pregnancy can worsen some chronic maternal diseases or increase the risk of poor neonatal outcome. In addition, some medications used by the pregnant woman may cause developmental problems in the fetus.

Precautions

Not all women visit a health care provider during the critical early weeks of pregnancy. Thus, as a part of patient education, health care professionals should provide preconception counseling in all encounters with women of childbearing age.

Description

Preconception counseling should address the following areas:

Nutrition

DIET. The importance of a well-balanced, nutritious diet should be emphasized in preconception counseling. A woman who is underweight when she conceives may have a small baby (small babies are more likely to have problems during labor and immediately after delivery). A woman who is overweight is at increased risk of developing elevated **blood pressure** and **gestational diabetes** during pregnancy. Women should be informed that trying to lose weight during pregnancy is not advised, as it could rob a developing baby of essential nutrients.

FOLIC ACID SUPPLEMENTATION. Even though many grains and other products are fortified with **folic acid** (a B vitamin), the level may not be high enough to increase the folic acid intake of most childbearing-age women to the recommended level of 400 micrograms (mcg) per day. Therefore, most women of childbearing age should consume 400 mcg (0.4 milligrams, or mg) of folic acid per day. Women with a previous child with a **neural tube defect** and women on antiseizure medication need extra folic acid. Folic acid is thought to help prevent certain birth abnormalities, including spina bifida, other neural-tube defects, and possibly heart abnormalities. Folic acid may also reduce the likelihood of getting colon **cancer** and coronary heart disease.

MULTIVITAMIN SUPPLEMENTATION. To ensure an adequate daily intake of **vitamins** and **minerals**, women

Obstetric history data

Pregnancies and births (term, preterm, abortions, living)
 Date of each birth (month and year)
 Outcome of each birth:
 Gestational age at birth
 Type of delivery
 Length of labor
 Birth weight
 Gender
 Complications during pregnancy, at delivery, postpartum
 Any depression during the year after birth
 Present health
 Names and location of children
 Feelings about previous pregnancies, birthing experiences, parenting
 Feelings about any perinatal loss or other losses in which children were involved.

SOURCE: Wheeler, L. *Nurse-Midwifery Handbook: A Practical Guide to Prenatal and Postpartum Care*. Philadelphia: Lippincott-Raven Pub., 1997.

of reproductive age should take a multivitamin supplement that contains folic acid. Women planning on a pregnancy should be cautious to avoid an excess intake of **vitamin A**, however. It has been chemically associated with a class of retinoids recognized to cause birth abnormalities. Vitamin A doses larger than 10,000 international units (IU) have been linked to a nearly five-fold increase in the occurrence of congenital heart malformations.

Immunizations

RUBELLA (GERMAN MEASLES). All women of childbearing age should be immunized against rubella. Contracting rubella during pregnancy can result in numerous severe birth abnormalities, including deafness, heart defects, **cataracts**, and mental retardation. Conception is not recommended for at least three months after receiving an immunization for rubella, and the immunization may not be given during pregnancy.

VARICELLA (CHICKEN POX). A woman who has not had varicella should be immunized for it prior to conception. Varicella **infection** can result in serious maternal and fetal complications. For example, 9 percent of women who contract varicella in pregnancy will develop varicella **pneumonia**. The varicella immunization may not be given during pregnancy.

Risk reduction

Women contemplating pregnancy should be counseled concerning the following lifestyle behaviors and their potential implications. A woman may not even be aware that she is pregnant for the first few weeks and may engage in dangerous lifestyle behaviors during a

KEY TERMS

Abruptio placentae—Premature separation of the placenta from the uterine wall. Occurs late in pregnancy and results in bleeding that may or may not establish an obstetrical emergency.

Placenta previa—The placenta usually touches or implants on the posterior aspect of the uterus, away from the cervix. In a placenta previa, the location of implantation of the placenta is low in the uterus and may totally or partially occlude the cervix. A placenta previa may cause complications at delivery, such as excessive bleeding.

Preeclampsia—Also called pregnancy-induced hypertension or toxemia of pregnancy. A condition unique to pregnancy, with symptoms of elevated blood pressure, protein in the urine (proteinuria), and edema. Exists in varying degrees of severity and can result in maternal seizure activity.

critical period of embryonic development. If conception is a possibility, women should try to maintain a healthy lifestyle so that their babies will have the best odds of a good outcome at birth and later on in life.

ALCOHOL. Consumption of alcohol during pregnancy can lead to **fetal alcohol syndrome**, a condition resulting in several physical and behavioral problems in affected children. Even intake of lower levels of alcohol can cause neurological and behavioral problems in children of women who drink during pregnancy. Studies have found that children of women who consumed alcohol during pregnancy had lower birth weights, were shorter, and had smaller head circumferences.

DRUGS. Infants of pregnant drug users are at risk for prematurity, low birth weight, and perinatal death. Women who abuse drugs should be offered support and referred to groups that can help with drug addiction.

TOBACCO. Women who smoke during pregnancy have an increased risk for abruptio placentae, **placenta previa**, and preeclampsia. Their babies may be born prematurely, be smaller, have congenital abnormalities, be at increased risk for sudden infant death syndrome (SIDS), and possibly have developmental delays.

Medical conditions and pregnancy

DIABETES MELLITUS. Women with **diabetes mellitus** should try to attain stability in their **blood** sugar levels prior to conception. Some oral medications for diabetes are contraindicated during pregnancy, so planning is nec-

essary for conception. Complications of diabetes mellitus include large or small babies.

OTHER COMPLICATIONS. Women with medical conditions who are contemplating pregnancy should be counseled as to pregnancy risks for themselves and their babies. For example, a woman who has epilepsy should consult with her physician or nurse practitioner about the toxicity of the current medication she is taking to control seizures; a less toxic medication may be recommended for the period of preconception and pregnancy.

REDUCTION IN EXPOSURE TO TERATOGENS. Exposure to various substances can be teratogenic (capable of causing birth defects). Teratogenic hazards include **anticancer drugs**, and perhaps such occupational substances as organic solvents and anesthetic gases.

Some teratogens can even cause birth defects when the exposure took place prior to conception. The father's exposure to occupational toxins can also cause miscarriages, preterm deliveries, and birth defects.

Genetic counseling

Couples may wish to have **genetic counseling** if there is a family history of a child with a genetic abnormality; because of ethnically associated genetic diseases; or for advanced maternal/paternal age (age 34 or 35 in women, unknown in men).

Other issues

Preconception counseling may include discussions of several other health-related issues:

- contraception
- domestic violence
- exercise
- gynecological screening
- use of prescription and over-the-counter medications
- general health
- safe sex
- sibling concerns

Preparation

Insertion of a form in the patient's chart addressing issues related to preconception counseling can guide the health care provider in performing a thorough assessment and providing appropriate interventions.

Results

Preconception counseling can result in healthier pregnancies, culminating in good birth outcomes.

Health care team roles

The opportunity to provide preconception counseling exists at any time a health care provider is assessing or educating a woman of childbearing age. (Such providers include nurses, nurse-practitioners, obstetricians, perinatologists, dieticians, substance-abuse counselors, social workers, geneticists, radiologists, and radiology technicians.) Health care professionals who are not trained to provide genetic counseling should be prepared to provide support related to **genetic testing**.

Preeclampsia and eclampsia

Definition

Preeclampsia and eclampsia are hypertensive disorders of **pregnancy** that occur in 5%–10% of pregnancies. In developing countries, hypertensive disorders of preg-

nancy are the single most common cause of death in **childbirth**. Preeclampsia is defined by the presence of three elements: **hypertension**, proteinuria (protein in the urine), and **edema** (fluid retention). If seizures develop following the appearance of the first three factors, the condition is called eclampsia.

Description

The cause of preeclampsia is unknown, but is thought to be an immunologic disorder of some kind. Preeclampsia is more likely to develop in primigravidas (women in their first pregnancy); in women who have used barrier methods of **contraception**; in women who have new sexual partners; and in women whose birth parents have similar HLA antigens. Other risk factors include a family history of preeclampsia; age extremes in the mother (younger than 20 years or older than 40); pre-existing kidney disease or vascular disorder; diabetes; **multiple pregnancy**; five or more previous pregnancies; African American descent; and genetic abnormalities in the fetus. Since the 1980s, preeclampsia has been associated with poor **blood** supply to the placenta or placental dysfunction, but the stages in the development of the disorder between damage to the placenta and the appearance of hypertension are not yet fully understood.

Hypertensive disorders of pregnancy affect six major systems or sites in the body: the **central nervous system** (CNS); **kidneys**; **liver**; the blood; the **blood vessels**; and the fetus and placenta. In severe cases, the mother may suffer liver failure, rupture of the liver, or pulmonary edema (fluid in the **lungs**); the fetus may die.

Classification of hypertensive disorders of pregnancy

The most common classification used to define hypertensive disorders of pregnancy is the one recommended by the American College of Obstetricians and Gynecologists (ACOG) and endorsed by the NIH Working Group on High Blood Pressure:

- Chronic hypertension, defined as **blood pressure** greater than or equal to 140 mm Hg systolic or 90 mm Hg diastolic present prior to pregnancy or before the 20th week of pregnancy. During pregnancy the hypertension remains, but proteinuria does not occur. Women who develop hypertension during pregnancy, without proteinuria or seizures, and whose blood pressure remains elevated after pregnancy are also diagnosed with chronic hypertension.
- Gestational hypertension, defined as elevated blood pressure greater than or equal to 140 mm Hg systolic or 90 mm Hg diastolic that arises after midpregnancy with

no proteinuria. Blood pressure returns to normal by 12 weeks postpartum. Final diagnosis of this condition is delayed until the postpartum period. If the patient does not develop preeclampsia, and her blood pressure returns to normal, the final diagnosis is transient hypertension of pregnancy. If her blood pressure remains elevated, a diagnosis of chronic hypertension is given.

- Preeclampsia and eclampsia. Preeclampsia is characterized by blood pressure greater than or equal to 140 mm Hg systolic or 90 mm Hg diastolic occurring after mid-pregnancy (20 weeks gestation), and accompanied by proteinuria. Preeclampsia may be further categorized as mild or severe. A woman is considered to have severe preeclampsia when her blood pressure reading is 160+ mm Hg systolic or 110+ mm Hg diastolic; her proteinuria is equal to or greater than 5 mg of protein in the urine per 24 hours; or other organ systems are involved. She may have headache, visual disturbances, or other CNS symptoms; pulmonary edema, **cyanosis**, or other cardiovascular symptoms; and abdominal pain.
- Preeclampsia superimposed on chronic hypertension. Pregnant women with preexisting chronic hypertension may develop preeclampsia. Superimposed preeclampsia is suspected when proteinuria develops or increases suddenly; when previously controlled hypertension exhibits a sudden increase; or when the patient develops thrombocytopenia or elevated liver enzyme levels. Women with preeclampsia superimposed on chronic hypertension have a poorer prognosis than women with either condition alone.

Measurement of blood pressure

For purposes of accuracy and standardization, health professionals should take blood pressure measurements in pregnant women with the patient seated rather than lying on her side, because substantial differences exist between the blood pressures in the upper and lower arms when the patient is lying on her side. In addition, the National Institutes of Health (NIH) recommends that the diastolic pressure reading should be taken at Korotkoff 5, with the disappearance of sound—not at Korotkoff 4, when sound becomes muffled. To meet strict criteria for hypertension, the patient's readings must be elevated on at least two separate occasions at least six hours apart.

Causes and symptoms

As previously mentioned, the initial cause of preeclampsia/eclampsia is not known but is thought to be immunologic. The relationship among the three factors that define preeclampsia appears to be as follows. First, the normal increase in blood plasma volume and decrease in peripheral vascular resistance that occur dur-

ing an uncomplicated pregnancy are absent. The patient's blood vessels allow fluid to leak from the vessels into the surrounding tissue, which results in edema. The seizures that characterize eclampsia result from edema of the **brain**. The patient's kidneys are under stress because of diminished blood flow through the kidneys and decreased filtration. This process allows protein molecules to spill over into the urine. Damage to the kidneys lowers urine output and increases the levels of sodium in body tissues. Higher concentrations of sodium result in increased fluid retention. Protein lost through the urine also affects the movement of fluid into the tissues, further increasing fluid retention.

The HELLP syndrome

A liver condition related to hypertension in pregnancy is called the HELLP syndrome, which occurs in about 1:150 births. HELLP stands for *hemolysis, elevated liver enzymes, and low platelet count*. Normal liver functioning is altered in the HELLP syndrome as a result of vascular damage related to preeclampsia. Researchers believe that the fetus and mother share a defect in processing fatty acids that leads to destruction of red blood cells, inflammation of the liver, and decreased platelet count. HELLP syndrome is associated with disseminated intravascular coagulation (DIC); **placental abruption** (sudden tearing); acute renal failure; and pulmonary edema. About 30% of pregnancy-related cases of HELLP develop in the postpartum period.

Disseminated intravascular coagulation

Preeclampsia and eclampsia may also be associated with the serious condition known as disseminated intravascular coagulation, or DIC. DIC is a disorder characterized by both bleeding and thrombosis (the formation of intravascular clots). Maternal hemorrhage is a risk in patients with preeclampsia who develop DIC. About 15% of hypertension-related deaths in pregnancy are associated with DIC.

Diagnosis

The diagnosis of preeclampsia is complicated by the fact that the signs of hypertension in pregnancy can be easily confused with the symptoms of chronic hypertension, **gallbladder** and pancreatic diseases, and other disorders. Since prevention of maternal and fetal morbidity and mortality is of the utmost priority, however, the NIH recommends overdiagnosis of preeclampsia rather than underdiagnosis to ensure careful management. Pregnant women should have their weight, blood pressure, and

urine checked at every prenatal visit. Regular prenatal visits are extremely important, as the early symptoms of preeclampsia cause no discomfort. The NIH guidelines suggest that women who develop an increase of 30 mmHg systolic or 15 mmHg diastolic over their prenatal baseline measurements should be closely monitored, especially if their protein or uric acid levels are elevated. Early detection of preeclampsia allows for proper management of the condition.

Treatment

Pre-delivery management

Delivery is the definitive treatment of preeclampsia. Even mild preeclampsia that develops at 36 weeks of gestation or later is managed by delivery. Prior to 36 weeks, severe preeclampsia requires delivery of the fetus. Mild to moderate preeclampsia between 20 and 36 weeks is treated with bed rest. Rest increases central blood flow to the patient's **heart**, kidneys, placenta, and other organs. Bed rest at home is an option for some patients with mild preeclampsia and stable home situations. Patients with severe eclampsia or unstable family situations require hospitalization. Monitoring of fetal heart rate and lung maturity is an important part of the management of preeclampsia.

Medications

Medication for preeclampsia is usually directed toward preventing convulsions rather than controlling blood pressure. Magnesium sulfate is the drug of choice for controlling seizures during pregnancy. Prophylactic magnesium sulfate administration may continue into the postpartum period.

Emergency care

The primary concern in emergency treatment of convulsions is to assure the patient's safety. The patient is placed on her side to allow any secretions in the mouth to drain, thus decreasing the risk of aspiration. In addition, this position improves blood flow to the placenta and fetus. Delivery of the fetus usually follows as soon as possible after the convulsion to minimize the risk of placental abruption.

Vaginal delivery is preferred to caesarean delivery in order to avoid the additional stress of surgery on the patient's organ systems. The NIH recommends a trial of labor induction, regardless of the condition of the patient's cervix. Magnesium sulfate may be given as an anticonvulsant. Antihypertensive medication is restricted

KEY TERMS

Cyanosis—A bluish color to the skin that indicates poor circulation and poor oxygenation of the blood and tissues.

Disseminated intravascular coagulation (DIC)—A disorder of blood coagulation characterized by both bleeding and thrombosis (intravascular clotting).

Edema—Abnormal accumulation of fluid in the tissues, cavities, or joint capsules of the body. It is one of three important indications of preeclampsia.

HELLP—A syndrome related to liver dysfunction that develops in some patients with preeclampsia. The letters stand for Hemolysis, Elevated Liver enzyme levels, and Low Platelet count.

Oliguria—Minimal urine output, usually defined as 500 ml or less over a 24-hour period.

Placental abruption—Sudden rupture or tearing of the placenta. The convulsions that characterize eclampsia increase the risk of placental abruption.

Proteinuria—A significant amount of protein in the urine. It is also sometimes called albuminuria.

Thrombocytopenia—A blood platelet count below 100,000 cells/mm³.

to use for sudden elevations of blood pressure, or if the patient's diastolic pressure reaches 105 to 110 mm Hg.

Prognosis

Risks to the fetus from preeclampsia include intrauterine growth retardation and low birth weight, placental abruption, and stillbirth. The fetus may be delivered prematurely if the condition of the mother deteriorates. Risks to the mother include vascular organ damage; the additional risks of eclampsia include convulsions and accompanying oxygen deprivation, hemorrhage in the brain, temporary blindness, permanent neurological damage, liver or kidney damage, cerebrovascular and cardiovascular complications, and even death. The prognoses for both the fetus and mother are excellent in mild preeclampsia. If blood pressure readings are within normal limits after several weeks postpartum, the mother may still be at increased risk of hypertension later in life, and should have her blood pressure checked yearly.

The long-term prognosis for children born to preeclamptic mothers is not yet known. These individu-

als do, however, appear to be at increased risk of chronic disease in adult life.

Health care team roles

The responsibilities of nursing staff in the management of preeclampsia and eclampsia include **patient education** and monitoring of patient compliance with the physician's instructions as well as assisting with emergency care. Patients resting at home should be visited and assessed periodically by a home health nurse. These functions are essential to good management of high-risk patients. Providing emotional support to patients with complications during pregnancy is also a critical function. If the patient requires hospitalization, a calm and quiet environment can help decrease the risk of seizure.

Prevention

Since the cause of preeclampsia is unclear, prevention focuses on early detection and management to avoid progression. Bed rest improves blood flow to the placenta and to maternal organs. Lying on the side increases sodium excretion and decreases fluid retention through increased diuresis. Magnesium sulfate may be given to lessen the risk of convulsions.

Recent clinical trials appear to indicate that some preventive strategies do not benefit most patients at risk for preeclampsia. These strategies include the prophylactic administration of heparin, **calcium**, or aspirin; and supplemental doses of fatty acids.

Preeclampsia and eclampsia

Pregnancy

Definition

Pregnancy is the condition of having a developing embryo or fetus in the body. The union of an egg (ovum) with sperm is called fertilization, or conception, and it is this union that produces the embryo. Pregnancy includes the period from conception to birth of the fetus, and usually lasts 10 lunar months (40 weeks/280 days), or nine calendar months—as measured from the first day of the last menstrual period (LMP). It is also referred to as a gestation period that consists of three trimesters. The trimesters are not equal, but are defined by different stages of a baby's development. The first trimester includes the first 13 weeks of pregnancy, or the first 12 weeks of life. The second trimester consists of weeks 14–26, and the third trimester is weeks 27–40.

Description

At the time of sexual intercourse, a man ejects millions of sperm into the woman's vagina. The sperm travel in all directions, propelled by their whiplike tails, and many swim through the cervix toward the uterus. A very small number of them may survive as long as 48 hours, but only one has to make it to the fallopian tube to meet the egg that has been released from an ovary. It takes approximately 30 minutes following intercourse for the sperm to meet the egg. One sperm penetrates the egg and its tail is shed, while the remainder of the sperm provides one-half of the genetic material of the future fetus—the other half provided by the egg. The fertilized egg then travels along the fallopian tube, arriving in the uterus four to five days later. Fluid secreted by the tube lining provides it with **nutrition** during its travels. After two to three days in the uterine cavity, the fertilized egg implants into the thick lining of the uterus. Implantation

occurs at about day 22 of a normal menstrual cycle. If the fertilized egg were visible to the naked eye, it would appear to be covered with fine hairs, called villi. These villi become the densest where the **blood** supply is richest, and eventually form the placenta. The mother's blood moves slowly around these villi, permitting them to absorb food and oxygen, and to eliminate waste products. The placenta is completely formed and functioning by 10 weeks after fertilization. Between 12 and 20 weeks' gestation, the placenta weighs more than the fetus, because the fetal organs are not sufficiently developed to deal with the processes needed for nutrition.

First month

At week four of pregnancy, the embryo is about one-eighth of an inch (0.275 cm) long, and weighs about 1/32 of an ounce (3 g). A formed yolk sac is present.

Second month

During the next four weeks, the embryo will grow to be about one inch long (2.5 cm) and weigh about 5/16 of an ounce (8.7 g). The umbilical cord will form, and the pulsation of the **heart** can be noted. The head and tail of the embryo are formed, and sex glands are determined, although the external genitals cannot be visibly identified as male or female. Limbs are well formed, and toes and fingers are present. The development of a skeleton and the formation of bone cells begin. Facial features begin to form, as does the external portion of the ear. The eyelids are fused throughout this period. By this stage, the fetus has a distinctly human appearance and the beginnings of all the main organ systems are established. Since the structures of the **brain**, heart, **liver**, limbs, ears, nose and eyes develop by the end of eight weeks, this is considered the most critical period of development. Any exposure to medications, alcohol, or illicit drugs during this time may cause defects, or anomalies, in the fetus.

Third month

Approximately nine weeks after conception, the baby has developed the features of a human being, and is called a fetus, not an embryo. Limb movements first occur at the end of the embryo stage, although they are not coordinated and cannot be felt. At 12 weeks of pregnancy, the fetus is 1–3 inches (7.5 cm) long from head to heel, and weighs about one ounce (28 g). The formation of red blood cells has already occurred in the liver, but now the spleen takes over making them. Urine formation begins between the ninth and twelfth weeks, and is discharged into the amniotic fluid. The fetus can reabsorb some of this fluid after swallowing it. Waste products are

now transferred to the mother's circulatory system by crossing the placenta.

Fourth month

Growth is very rapid during this period, and limb movements become coordinated, although it is difficult for the mother to feel them. An ultrasound reveals the bones of the fetal skeleton, which are clearly visible. Their development continues as the limbs lengthen. Scalp hair patterning is also determined during this period, and slow eye movements can occur at about 14 weeks. External genitals can be recognized by 14 weeks, and the external ears stand out from the head. The fetus is now about 6 inches (15 cm) long, and weighs about 4 ounces (112 g).

Fifth month

“Quickening” is the mother's feeling the baby move for the first time; it usually occurs during this period. The average time between a mother's first detection of fetal movements and delivery is 147 days, with a deviation between plus or minus 15 days. The baby's skin is now covered with a greasy, cheese-like material called “vernix caseosa,” and it protects the delicate fetal skin from cuts, chapping, and hardening, all of which could occur from exposure to the amniotic fluid. Eyebrows and head hair are also visible at 20 weeks, and the fetus is usually completely covered with fine, downy hair (the lanugo), which helps to hold the vernix on the skin. Brown fat forms during this period to prepare for heat production when the baby is born. By 18 weeks, a female fetus has a formed uterus, and the opening for the vagina has begun. Many egg-forming follicles are also forming in the ovaries. By 20 weeks in a male fetus, the testes have begun to descend, but they are still located inside the abdominal wall. The fetus now weighs about one pound (454 g) and is 10 inches (25 cm) long.

Sixth month

There is a substantial weight gain this month. The skin, usually wrinkled, appears clear, and is pink to red because blood is visible in the capillaries. At 21 weeks, rapid eye movements (REMs) begin, and blink-startle responses are visible on ultrasound following a loud noise. Fingernails are present by 24 weeks, and the cells in the lung have begun to secrete a substance necessary to develop the alveoli of the **lungs**. In most medical practices, a fetus born before 24 weeks is not considered viable or capable of living, but if born at 24 weeks, attempts will be made for survival. The chances of a good outcome are, however, very poor. The fetus now weighs

Chloasma may appear on a woman's face during the last trimester of pregnancy. The brown pigmentation disappears sometime after delivery. (NMSB/Custom Medical Stock Photo. Reproduced by permission.)

about 1.5 pounds (730 g), and is about 13 inches (32 cm) long.

Seventh month

By 26 weeks, the eyes are partially open and eyelashes are present. At 28 weeks, the eyes are wide open and a good head of hair is often present. At this age, a fetus can often survive even if born prematurely, presuming it is given intensive care. The lungs and blood circulation are developed, and can provide a better exchange of oxygen. Also, the **central nervous system** is now more mature, and can manage rhythmic breathing movements as well as assist in controlling body temperature. Toenails are present and more fat is deposited, smoothing the wrinkly skin. At 28 weeks, the bone marrow takes over the red blood cell-making work of the spleen, becoming the major site of this process. At 30 weeks, a light reflex of the eyes can be obtained. The skin is pink and smooth, and the limbs have a chubby appearance. The fetus might weigh as much as 3 lbs (1.3 kg), and is about 14–15 inches (35–37.5 cm) long. The fetus can be observed on ultrasound; it is sucking its thumb and practicing breathing movements. The mother may experience hiccoughs as rhythmic movements when the baby is practicing its breathing.

Eighth month

Fetuses 32 weeks and older usually survive if born prematurely. At 32 weeks, the fingernails reach the fingertips. At 35 weeks, fetuses have a firm grasp and show a spontaneous orientation to light. Growth continues, but slows as the baby begins to take up most of the room in the uterus. Now weighing between 3.5–4.5 lbs (1.7–2.3 kg), and measuring 16–18 inches (40–45 cm) long, the

fetus may prepare for delivery by moving into the head-down position.

Ninth month

At 36 weeks, the body appears plump. The hair covering the body is almost gone. Toenails reach toe tips and the limbs are flexed. A full-term baby is one born anywhere from 37–40 weeks' gestation. A baby born after 41 weeks is considered postdate. Adding 0.5 lb (227 g) a week as the due date approaches, the fetus drops lower into the mother's abdomen and prepares for the onset of labor, which may begin any time between the 37th and 41st week of gestation. The expected date of delivery (EDD) of a fetus is 266 days, or 38 weeks after fertilization (i.e., 280 days or 40 weeks after the LMP). Prolongation of pregnancy occurs in 5–6% of women. If the pregnancy continues past 41–42 weeks, the physician will order fetal monitoring to determine the status of the baby. Since the mortality rate increases significantly after two to three weeks postdate, labor is often induced. Most healthy babies will weigh 6–8 lbs (2.7–3.6 kg) at birth, and will be about 19–21 inches (47–52 cm) long.

Causes and symptoms

The first sign of pregnancy is usually a missed menstrual period. A little bleeding or spotting may occur, due to implantation of the fertilized egg. Some women experience no early symptoms of pregnancy during the first few weeks, while others may experience all of them. A woman's breasts usually seem larger and feel tender as the mammary glands prepare for eventual breastfeeding. Nipples begin to enlarge and the veins over the surface of the breasts become more noticeable. Morning sickness (i.e., nausea and vomiting) is somewhat common, and can happen at any time—day or night. Extreme sensitivity to **smell** may worsen nausea. It is normal to feel bloated and more tired than usual. Frequent urination is common, and the pregnant woman may find herself getting up during the night to urinate. There may be a creamy white discharge from the vagina; that is normal. Food cravings may occur. Most women gain about 2–4 pounds (0.7–1.8 kg) by the end of the first trimester (0–13 weeks), and their clothes begin to feel tight.

In the second trimester (14–26 weeks), morning sickness usually ends and a woman's appetite may increase. There is a weight gain of about 12–15 pounds (5.4–6.75 kg) during this trimester. Most women begin to look pregnant and feel more energetic. Heart rate increases, as does the volume of blood in the body. This increase may cause a woman to feel flushed and warm at times. Some women experience constipation, heartburn and indigestion, backache, sleeplessness, or swollen feet dur-

ing the second trimester. Physical activity, such as swimming and walking, will help constipation as well as drinking plenty of fluids (i.e., at least eight glasses of water a day) and eating high-fiber foods (i.e., fruits, vegetables, and whole grains). For backaches, it is important to maintain good posture, avoid lifting very heavy objects, and wear low-heeled shoes. Eating smaller amounts of food more frequently and avoiding fried or spicy food will help to relieve heartburn or indigestion. When the woman sits down to rest, her feet should be elevated to prevent swelling of the ankles. Pregnant women should not try to stand for long periods of time.

By the third trimester (27–40 weeks), many women begin to experience a range of common symptoms. As the baby grows larger and begins to press against internal organs, a woman may feel somewhat breathless at times. Lying on her left or right side, not on her back, and using pillows to lean on in a semi-propped position can relieve this. Leaking of urine may occur with coughing or sneezing, and frequent urination begins again. As the pelvis widens and the joints become looser, discomfort may be felt in the pelvic joints. Some women feel as if their legs cannot support their weight. This is the body's way of preparing for birth. The joints are loosening so that the baby can fit through the pelvis. Stretch marks may develop on the abdomen, breasts and thighs, and a dark line may appear from the navel to the pubic hair. A thin fluid called "colostrum" may be expressed from the nipples. Hemorrhoids may develop. Gums may become sensitive and bleed more easily, and eyes may dry out, making **contact lenses** uncomfortable to wear. Pica (a craving to eat substances other than food) may occur. **Varicose veins** may be a problem in the second half of pregnancy. This can be alleviated to a certain degree by wearing support hose, not standing for long periods of time, and resting with the feet up. Chloasma (a brown pigment) may appear on the face. This is due to the hormones of pregnancy and will disappear some time after delivery. Weak, irregular, painless tightenings of the uterus become more intense as the body practices for labor. These are called Braxton-Hicks contractions, and feel as if the baby is balling up. In most women, genuine labor consists of regular contractions that increase in intensity. Kicks from an active baby may cause sharp pains, and lower backaches are common. It is important for women in the third trimester to rest often and avoid straining themselves. When resting or sleeping, it may be more comfortable to lie on the left or right side with one leg bent, placing pillows under the **stomach** and between the knees. Weight gain will continue as it did in the second trimester.

In a woman's first pregnancy (later in repeat pregnancies), the baby's head drops down low into the pelvis by the last four weeks. This change may relieve pressure

FDA categories for drugs during pregnancy

Category A	No risk to fetus in first trimester demonstrated in controlled studies, and no evidence of risk in other trimesters.
Category B	No fetal risk shown in animal studies but no controlled studies in pregnant women are available; or animal studies showed an adverse effect not confirmed in controlled studies with pregnant women in the first trimester.
Category C	Adverse effects on fetus found in animal studies but no controlled studies in women; or studies in women and animals are not available. Give drug only if benefit justifies the possible risk to the fetus.
Category D	Positive evidence of fetal risk exists but the benefits may be acceptable despite the risk, as in life-threatening situations or serious disease.
Category X	Fetal abnormalities have been demonstrated or evidence for fetal risk exists, and the risk involved by using the drug outweighs any benefit.

SOURCE: U.S. Food and Drug Administration.

on the upper abdomen and the lungs, allowing a woman to breathe more easily. This new position, however, does place more pressure on the bladder.

Total weight gain recommended in pregnancy is 25–35 pounds (12–16 kg) for women of normal weight for their height. Underweight women should possibly gain up to 40 pounds (18 kg), and overweight women should limit weight gain to 15–25 pounds (7–11 kg). Increased fluid volume makes up 2–3 pounds (0.9–1.4 kg); breast enlargement provides 1–2 pounds (0.45–0.9 kg); 2 pounds (0.9 kg) comes from enlargement of the uterus; and amniotic fluid is about 2 pounds (0.9 kg). At term, an infant weighs about 6–8 pounds (2.7–3.6 kg), and the placenta weighs 1–2 pounds (0.45–0.9 kg). Usually 4–6 pounds (1.8–2.7 kg) are due to maternal stores of fat and protein that are important for breastfeeding.

While many of the symptoms mentioned are considered normal, there are others that may indicate the presence of complications. A pregnant woman experiencing any of the following should contact her doctor or midwife *immediately*:

- abdominal pain
- rupture of the amniotic sac or fluid leaking from the vagina
- bleeding from the vagina
- no fetal movement for 24 hours (after the sixth month)
- continuous headaches
- marked, sudden swelling of eyelids, hands, or face
- dim or blurry vision

KEY TERMS

Alpha-fetoprotein—A substance produced by a fetus' liver that can be found in the amniotic fluid and in the mother's blood. Abnormally high levels of this substance suggests there may be defects in the fetal neural tube, a structure that will include the brain and spinal cord when completely developed. Abnormally low levels suggest the possibility of Down syndrome.

Alveolus/Alveoli—A little hollow space in the thin-walled chambers of the lungs which is surrounded by capillaries for the exchange of carbon dioxide and oxygen.

Amniotic fluid—The fluid or 'bag of waters' that the fetus floats in and maintains a constant body temperature. It is normally clear.

Anomaly—A marked deviation from normal.

Braxton-Hick contractions—Short, fairly painless uterine contractions during pregnancy that may be mistaken for labor pains. They allow the uterus to grow and help circulate blood through the uterine blood vessels.

Cervix—The narrow lower end of the uterus.

Chloasma—A skin discoloration common during pregnancy, also known as the "mask of pregnancy." The blotches may appear on the forehead, cheeks, and nose, and may merge into one dark mask. Chloasma usually fades after pregnancy, but it may become permanent or recur with subsequent pregnancies.

Diffusion—The process of being widely spread.

Embryo—An unborn child during the first nine weeks of development following conception (fertilization with sperm). For the rest of pregnancy, the embryo is known as a fetus.

Fallopian tube—Either of two slender tubes, one on each side of the uterus, where fertilization takes place.

Fetus—An unborn child from the end of the ninth week after fertilization until birth.

Gestation—The period of development of an embryo and fetus or the duration of a pregnancy in a human.

Human chorionic gonadotropin (hCG)—A hormone produced by the placenta during pregnancy.

Osmosis—The diffusion of a substance across a membrane.

Placenta—The organ that develops in the uterus during pregnancy that links the blood supplies of the mother and baby.

Rhythm method—The oldest method of contraception, with a very high failure rate, in which partners periodically refrain from having sex during ovulation. Ovulation is predicted on the basis of a woman's previous menstrual cycle.

Uterus—The hollow muscular organ in females in which the fertilized egg becomes embedded and develops into an embryo and then a fetus.

Villus/Villi—A small protrusion or projection from the surface of a membrane.

- persistent heartburn (unrelieved by **antacids**) or a burning sensation in the chest area
- persistent vomiting

Diagnosis

Many women discover they are pregnant after a positive home **pregnancy test**. Urine tests check for the presence of human chorionic gonadotropin (hCG), which is produced by the placenta. The newest home tests can detect pregnancy six to nine days after a missed menstrual period—sometimes earlier. The manufacturers of these tests claim an accuracy rate of 96–99%; but some factors, such as taking medications, sunlight, heat, and medical conditions can affect the test. A negative result followed by no menstrual period within a week indicates the need

to repeat the pregnancy test. While home tests are very accurate, they are less accurate than a pregnancy test performed in a lab. For this reason, women may want to consider having a second test at their doctor's or midwife's office to verify the accuracy of the result.

Blood tests to determine pregnancy are generally used when a very early diagnosis of pregnancy is needed. This more expensive test, which also looks for hCG, can produce a result within nine to 12 days after conception.

Approximately 3% of live-born infants have a major defect. There are tests that can be performed to determine many of these. As of 2001, there is a prenatal diagnostic screening test for determining the risk of neural tube defects, abdominal wall defects, **Down syndrome**, and trisomy 18. The triple-marker screening test measures

levels of alpha fetoprotein (AFP), human chorionic gonadotropin (hCG), and unconjugated estriol. AFP is a protein produced in the fetal yolk sac during the first trimester and later by the fetal liver. Abnormally high levels of this protein are associated with severe neural tube defects. Human chorionic gonadotropin (hCG) is a hormone produced and secreted by the placenta. During early normal pregnancy, the level of this hormone rises rapidly, then begins to decline between the 10th and 20th week of gestation. High levels of hCG during the second trimester are associated with Down syndrome. Unconjugated estriol is produced by the placenta, the fetal **adrenal glands**, and the liver. It rises as normal pregnancy progresses, and its values are often lower with Down syndrome. A woman must have her blood sample drawn between the 15th and 20th week of gestation in order for this test to be accurate.

Other tests are recommended for women who are at higher risk for having a child with a birth defect. This includes women who have previously given birth to a child with a defect, or who have a family history of birth defects; women who have been exposed to certain drugs or high levels of radiation; and women 35 years of age or older. The presence of any of these risk factors warrants not only **genetic counseling**, but consideration of an ultrasound by a specialist, chorionic villi sampling (CVS), and/or **amniocentesis**.

First prenatal visit

During a woman's first prenatal visit, the following diagnostic tests are usually performed:

- complete blood count (CBC), for anemia
- blood type, Rh, and antibody screen
- syphilis (VDRL)
- rubella titer (German measles)
- hepatitis B virus (HBV)
- urinalysis and culture
- Pap smear
- cervical cultures for gonorrhea and chlamydia
- recommendation of HIV antibody test, with counseling

A screening test for **gestational diabetes** is performed between 24 and 28 weeks' gestation by giving the woman a 50 g glucose drink, then drawing a blood sample one hour later to check the glucose level. A normal value is less than 130-140 mg/dL. A woman with a family history of diabetes, however, should be tested on her first visit to the obstetrician/gynecologist or nurse-midwife.

Treatment

Women with heart disease, diabetes, lupus, and some hereditary conditions should consult a health professional before getting pregnant, as these conditions increase the risk of morbidity and mortality for both the mother and child.

Prenatal care is vitally important for the health of the unborn baby. During the first trimester, the woman should receive 0.4 to 0.8 µg (micrograms) of **folic acid** daily to reduce the chance of neural tube defects. Ideally, this daily dose of folic acid should begin at least one month prior to conception. Generally, requirements for all **vitamins** are increased during pregnancy. Prenatal vitamins prescribed by a physician or midwife usually contain the recommended amount of folic acid, and some contain a stool softener to offset the constipating effects of **iron**. Following delivery, vitamins are also recommended for the breast-feeding woman. Most pregnant women need at least 2,300 calories a day; these should come from good sources of protein, green leafy vegetables, fresh fruit, and breads and cereals. Small meals may be eaten frequently throughout the day.

Since most medications can pass from the mother to the baby, no medication (not even a nonprescription drug) should be taken except under medical supervision. No drug should be considered completely safe (especially during early pregnancy), although many physicians and nurse-midwives approve their patients' use of some drugs, including acetaminophen. Drugs taken during the first three months of a pregnancy may interfere with the normal formation of a baby's organs, leading to birth defects. Drugs taken later on in pregnancy may slow the baby's growth rate, or they may damage specific fetal tissue (such as developing teeth).

To increase the chance of having a healthy baby, a pregnant woman should avoid the following:

- smoking
- alcohol
- street drugs
- large amounts of **caffeine** (more than a cup or two of coffee per day)
- artificial sweeteners (although clinicians debate this)
- more than 5,000 U of vitamin A

Prognosis

Pregnancy is a natural condition and not a disease. If a woman takes good care of herself, plans her pregnancy with medical counseling, maintains optimal health, and obtains good prenatal care, the pregnancy and birth expe-

rience will be joyful events. In choosing a caregiver, the pregnant woman must consider what she wants for herself and her baby. The standard hospital experience, despite the homey decorations and presence of family members, frequently demands that the woman in labor remain in bed attached to a fetal monitor. Bed rest and hydration by IV slow down labor, even when normal. The ability to walk and change position during labor alleviates discomfort felt during contractions.

Many health care facilities are now utilizing nurse-midwives to attend births; their approach permits fewer interventions. Nurse-midwives are nurses who have received additional training in order to care for women having normal pregnancies and birth. If any complications should arise, they are well trained to detect them early, and they will call in the physician with whom they work. The pregnant woman and her partner should make a birth plan for their experience and present it to their caregiver early in the pregnancy to determine if the individual meets their expectations. The American College of Nurse-Midwives, (202) 728-9860, can provide the pregnant woman with a list of midwives in her area.

Childbirth education classes for the woman and her partner are extremely important in helping a couple prepare for labor and delivery. Pregnant women should be made aware of the options for the location and circumstances for birth. Increasing numbers of women are having their babies in their own homes or in birthing centers, as opposed to a traditional hospital setting.

Prevention

There are many methods of **contraception** available to prevent pregnancy. In order of least to most effective, these include:

- spermicide alone
- natural (rhythm) method
- diaphragm or cervical cap
- condom alone
- diaphragm with spermicide
- condom with spermicide
- intrauterine device (IUD)
- contraceptive pill
- sterilization (either man or woman)
- abstinence

Pregnancy massage

Definition

Pregnancy massage is the prenatal use of **massage therapy** to support the physiologic, structural, and emotional well-being of both mother and fetus. Various forms of massage therapy, including Swedish, deep tissue, neuromuscular, movement, and Oriental-based therapies, may be applied throughout pregnancy as well as during labor and the postpartum period.

Origins

Cultural and anthropological studies indicate that massage and movement during the childbearing experience were and continue to be a prominent part of many

cultures' health care. Indian Ayurvedic medical manuals detail therapists' instructions for rubbing specially formulated oils into pregnant patients' stretched abdominal skin. Traditional sculptures depict Eskimo fathers supporting and lovingly stroking their laboring wives' backs. In certain Irish hospitals laboring women are held and touched by a doula (labor assistant) or midwife through most of their notably short, uncomplicated labors. For billions of women, over thousand of years, midwives' highly developed hands-on skills have provided loving support and eased childbearing discomforts. As massage therapy resumes its place within Western health care methods, pregnancy massage is becoming one of its fastest-growing specialized applications.

Benefits

Profound physiologic, functional, emotional, relational, and lifestyle changes occur during gestation and labor, often creating high **stress** levels. Too much stress can negatively affect maternal and infant health, resulting in reduced uterine **blood** supply and higher incidence of **miscarriage**, prematurity, and other complications. Massage therapy can help a woman approach her due date with less **anxiety** as well as less physical discomfort. Even apart from easing specific aches, massage can act as an overall tonic and increase the expectant mother's body awareness.

Massage therapy can address the various physical challenges of pregnancy: **edema**; foot, leg, or hand discomforts; and **pain** in the lower back, pelvis, or hips. Swedish massage may facilitate gestation by supporting cardiac function, placental and mammary development, and increasing cellular respiration. It can also reduce edema and high **blood pressure** as well as contribute to sympathetic nervous system sedation. Deep tissue, trigger point, and both active and passive movements alleviate stress on weight-bearing joints, muscles, and fascial tissues to reduce neck and back pain caused by poor posture and strain on the uterine ligaments. During labor, women whose partners use basic massage strokes on their backs and legs have shorter, less complicated labors. After the baby's birth, massage therapy can gently facilitate the body's return to its pre-pregnancy state, alleviate pain, foster a renewed sense of body and self, and help maintain flexibility despite the physical stresses of infant care. For post-Caesarean mothers, specific therapeutic techniques can also reduce scar tissue formation and facilitate the healing of the incision and related soft tissue areas.

Pregnancy massage increases blood flow, relaxes muscles, reduces water retention, and makes the skin more supple. It is particularly useful in relieving the back pain of late pregnancy. (Photo Researchers, Inc. Reproduced by permission.)

Description

When nestled with pillows or other specialty cushions into a side-lying or semi-reclining position, most women are more comfortable for the 30–60 minutes of a typical massage session. A pregnant woman can expect to enjoy many of the same techniques, draping, and professional demeanor offered all massage therapy clients. The lower back, hips, and neck benefit from sensitively applied deep tissue, neuromuscular, and **movement therapy**. Edema in the legs and arms may be relieved with the gliding and kneading strokes of Swedish or lymphatic drainage massage. Pregnant women should expect a thorough health and prenatal intake interview with their therapists. Cost, procedures, and insurance coverage are similar to those for other massage client populations.

Preparations

In addition to the preparations listed in the massage therapy entry, some expectant women will be asked to secure a release from their maternity health care provider, especially those with complications or high-risk factors.

KEY TERMS

Doula—A woman who assists an expectant mother with physical and emotional support during labor.

Edema—An abnormal accumulation of fluid in specific parts of the body, causing swelling of the area. Many women experience edema of the wrists and ankles during pregnancy.

Precautions

In addition to those listed in the massage therapy entry, the following other precautions are prudent:

- The abdomen should be touched only superficially with a flat, gentle hand.
- Any pressure applied to the inner leg should also be superficial.
- Women who must be on bed rest for any complication are at higher risk of blood clots forming in their legs; therefore, most massage of the legs should be avoided.
- Massage is safest when a woman is either lying on the side or propped semi-sitting at a 45–70-degree angle rather than lying on her back or belly.
- Because there are many other specific body areas and types of techniques that must be avoided or modified according to an individual woman's health condition, advanced specialized training of the therapist and consultation with the expectant mother's physician or midwife are highly recommended. It is better to avoid massage if the woman has vaginal bleeding, abdominal pain, or diarrhea.

Side effects

There are no known side effects to receiving appropriate prenatal massage therapy.

Research and general acceptance

Current research on the benefits of touch is providing a contemporary basis for its reintroduction into maternity care. Scientists have found that rats restricted from cutaneous self-stimulation had poorly developed placentas and 50% less mammary gland development. Their litters were often ill, stillborn, or died shortly after birth due to poor mothering skills. Women who are nauseated and/or vomiting prenatally experienced a decrease in these discomforts when they applied finger pressure to a specific acupuncture point (**acupressure**) on their fore-

arm several times each day. Pregnant women massaged twice weekly for five weeks experienced less anxiety, leg, and back pain. When compared with control groups who practiced **relaxation** exercises only, the women who had had massage reported better sleep and improved moods; and their labors had fewer complications, including fewer premature births. Studies show that when women receive nurturing touch during later pregnancy, they touch their babies more frequently and lovingly. During labor the presence of a doula, a woman providing physical and emotional support, including extensive touching and massage, reduces the length of labor and number of complications, interventions, medications, and cesarean sections.

Training and certification

Some massage therapy schools include comprehensive courses in pregnancy massage therapy. More often, however, therapists receive only introductory guidance in maternity applications during their 500–1000 hours of basic training. They pursue specialization certification in pre- and perinatal massage therapy. Several nationwide programs offer such advanced training in 24–34-hour workshop programs.

Pregnancy test

Definition

Pregnancy is detected by measuring the concentration of human chorionic gonadotropin (hCG) in serum or urine. Human chorionic gonadotropin is a hormone produced by the placenta that supports the corpus luteum after fertilization of the ovum. Production of hCG begins at the time of implantation, and hCG can usually be detected in serum and urine within 10 days after fertilization. The level of hCG in serum and urine is usually above 25 mIU/mL, the cutoff for a positive pregnancy test, before the next expected period. Therefore, pregnancy can be detected reliably within two to three days following the first missed menses using a qualitative hCG test. In addition to diagnosis of pregnancy, the test is used in emergency departments to rule out pregnancy in circumstances in which x ray and other procedures are contraindicated by pregnancy. The test is also used to rule out pregnancy in females with acute abdominal **pain** that suggests the possibility of ectopic pregnancy (i.e., pregnancy outside the uterus).

Quantitative measurements of hCG are used as an aid to the diagnosis of ectopic pregnancy and trophoblastic tumors. Serial measurements may be used to monitor treatment and recurrence of tumors that secrete hCG. Measurement of hCG is also part of the triple marker screening procedure performed on maternal serum between weeks 15 to 20 to assess the fetal risk of **Down syndrome**.

Description

Chorionic gonadotropin is a hormone consisting of two polypeptide chains or subunits designated alpha and beta. The alpha chain is identical to the alpha chain of luteinizing hormone (LH), follicle stimulating hormone (FSH), and thyroid stimulating hormone (TSH). The beta chain is identical to that of LH except for the C-terminal end, which contains an additional 24 amino acids. Antibodies made against the alpha subunit will cross-react with LH, FSH, and TSH, but antibodies can be made to the beta subunit that are hCG-specific. All tests for pregnancy utilize antibodies to both subunits, which makes the pregnancy test highly specific for hCG. Chorionic gonadotropin is produced at an exponential rate through week 12 of gestation, often reaching in excess of 100,000 mIU/mL. In a normal pregnancy, the production of hCG doubles approximately every two days during this period. The level falls off sharply after the first trimester to approximately 20,000 mIU/mL, and is maintained at this level throughout a normal pregnan-

cy. Following a normal delivery, the hCG can be detected in serum and urine for three to four weeks. This period may be longer following an aborted pregnancy, especially if a trophoblastic tumor was present.

All pregnancy tests are double antibody sandwich immunoassays. The most commonly used platform, called immunochromatography, consists of a disposable device containing a membrane on which an antibody to one hCG subunit is immobilized. The membrane also contains an antibody to the other hCG subunit that is mobile. The mobile antibody is conjugated to an enzyme, dyed latex particle, or colloidal gold particle. Sample is added to the device and is drawn by capillary action onto the membrane, where it mixes with the mobile antibody. If hCG molecules are present, they bind to the mobile antibodies, forming antibody-antigen complexes. These migrate along the membrane to the region containing the immobilized antibody. The immobilized antibody binds to the other hCG subunit, forming an antibody-hCG-antibody sandwich that remains fixed to the membrane in the reaction zone region. At this point, the dye or gold particles are focused in the reaction zone and produce color, usually in the form of a plus sign or other visible indicator of a positive test. If an enzyme-conjugated antibody is used, a substrate solution is added, which is hydrolyzed by the enzyme to produce a colored product at the reaction zone.

Precautions

In order to achieve accurate results for home pregnancy tests, the manufacturer's instructions must be followed precisely. A significantly higher error rate has been observed with home pregnancy tests than with laboratory tests for pregnancy, which typically have an error rate below 1%. Diluted urine may cause a false-negative result. False-positive results may be caused by heterophile antibodies, medications containing mouse monoclonal antibodies, autoantibodies, and hyperlipemia. In very early pregnancy, the color reaction may be difficult to interpret. In such cases, the test should be repeated after waiting at least 48 hours. If serum is to be used, standard precautions for the prevention of transmission of bloodborne pathogens should be followed.

Preparation

No preparation is generally required for a pregnancy test. However, if urine is used, the first morning urine is the specimen of choice because the urine will be more concentrated after an overnight fast.

KEY TERMS

Ectopic pregnancy—A pregnancy that develops outside the mother's uterus. Ectopic pregnancies often cause severe pain in the lower abdomen and are potentially life-threatening because of the massive blood loss that may occur as the developing embryo/fetus ruptures and damages the tissues in which it has implanted.

Embryo—In humans, the developing individual from the time of implantation to about the end of the second month after conception. From the third month to the point of delivery, the individual is called a fetus.

Hormone—A chemical produced by a specific organ or tissue of the body that is released into the bloodstream in order to exert an effect in another part of the body.

Human chorionic gonadotropin (hCG)—A hormone produced by the placenta of a developing pregnancy.

Hydatidiform mole—A rare, generally benign grape-like mass that grows in the uterus from the remains of an abnormally developed embryo and surrounding tissue. In extremely rare cases, the mole develops into a choriocarcinoma, a malignant tumor that can invade the wall of the uterus.

Implantation—The attachment of the fertilized egg or embryo to the wall of the uterus.

Menstrual cycle—A hormonally regulated series of monthly events that occur during the reproductive years of the human female to ensure that the proper internal environment exists for fertilization, implantation, and development of a baby. Each month, a mature egg is released from the follicle of an ovary. If an egg is released, fertilized, and implanted, the expanded lining of the uterus is maintained. If fertilization and/or implantation does not occur, the egg and all of the excess uterine lining are shed from the body during menstruation.

Miscarriage—Loss of the embryo or fetus and other products of pregnancy before the middle of the second trimester. Often, early in a pregnancy, if the condition of the baby and/or the mother's uterus are not compatible with sustaining life, the pregnancy stops, and the contents of the uterus are expelled. For this reason, miscarriage is also referred to as spontaneous abortion.

Placenta—The organ that unites the fetus to the mother's uterus. The placenta produces hCG, among other hormones, to help maintain the pregnancy. It transfers nutrients and antibodies to the fetus, and waste products from the fetus. After delivery, the placenta, known at this point as the afterbirth, is expelled.

Aftercare

No special care is required after a urine test for hCG. If **blood** is drawn, discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising; warm packs relieve discomfort. Women who feel faint should be observed until the condition goes away.

Complications

Tests for hCG levels pose no direct risk to a woman's health. The main risk with a home pregnancy test is a false-negative result, which may be lessened by following the manufacturer's instructions carefully and waiting at least several days after the expected menstrual period before performing the test. A false-negative result can cause a delay in seeking **prenatal care**, which can pose a risk to both the woman and her fetus.

Results

HCG levels below 25 mIU/mL will give a negative pregnancy test result for all pregnancy test methods. Home test kits use a cutoff of 50 mIU/mL and will be negative below this level. Following **miscarriage** or abortion, the pregnancy test may remain positive for four weeks or longer. An hCG test performed during this time may be positive in the absence of pregnancy.

The upper limit of normal for a quantitative hCG test is approximately 5 mIU/mL. In rare circumstances, such as pelvic inflammatory disease, the hCG level in non-pregnancy may be greater than 5 mIU/mL. Persons with trophoblastic tumors, molar pregnancies, and choriocarcinoma will have greatly elevated levels of hCG. HCG may be found in persons with testicular **cancer** and other malignancies that secrete hCG or alpha and/or beta subunits. Quantitative hCG measurement is useful in detect-

ing hCG-secreting tumors. Periodic measurements are useful in evaluating treatment and monitoring patients for recurrence. Maternal serum hCG levels are increased by approximately 25% above normal for the gestational age in Down syndrome pregnancies and in some other trisomy syndromes. In ectopic pregnancy, hCG levels are lower than normal, and the hCG doubling time is less than expected. Minimum hCG increases between timed hCG measurements in the first trimester are:

- two measurements one day apart: 29% increase
- two measurements two days apart: 66% increase
- two measurements three days apart: 114% increase
- two measurements four days apart: 175% increase
- two measurements five days apart: 255% increase

Recovery of a lower than expected increase is evidence of ectopic pregnancy. Decreases in hCG are seen in spontaneous abortion.

Health care team roles

If serum is used, a phlebotomist or nurse collects the blood specimen. A laboratory scientist, nurse, physician assistant, or physician can perform the pregnancy test. The result should be reported to the physician who orders the test. Quantitative hCG tests are ordered and interpreted by a physician and performed by a clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or clinical laboratory technician CLT(NCA)/medical laboratory technician MLT(ASCP).

Premature infants

Definition

A premature infant is defined as one born before 37 weeks of gestation (**pregnancy**) without regard to birth weight. The length of a full-term pregnancy ranges from 37 to 42 weeks, measuring from the first day of the last menstrual period. "Preterm" is a word that is sometimes used instead of "premature." Extremely premature infants are defined as those born between 22 and 28 weeks of gestation. As of 2001, babies born at 21 weeks of gestation or less have little chance of survival.

In the United States, about 10% of all infants are born prematurely. African American babies are more likely to be premature (14%) than Caucasian or Hispanic babies (7%). The rates of survival of premature infants, however, have increased dramatically over the last three decades. At one teaching hospital in the Midwest, the survival rate of infants weighing less than 1 lb 12 oz (800 grams) at birth rose from 20% in 1977 to 49% in 1990. In spite of advances in medical technology, these children remain at higher risk of birth defects, weakened immune systems, and a variety of chronic medical and developmental disorders. Many require long-term follow-up care.

Description

Chances for survival

The most important factor affecting survival in extremely premature infants is gestational age at the time of birth, which is defined as the estimated time elapsed since conception. Another term for gestational age is postconceptional age. The likelihood of a preterm infant's survival at specific gestational ages in the United States in the late 1990s is as follows:

- 21 weeks or less: 0% survival rate
- 22 weeks: 0–10% survival rate
- 23 weeks: 10–35% survival rate
- 24 weeks: 40–70% survival rate
- 25 weeks: 50–80% survival rate
- 26 weeks: 80–90% survival rate
- 27 weeks: greater than 90% survival rate

The baby's chances of survival increase 3–4% per day between 23 and 24 weeks of gestation, and 2–3% per day between 24 and 26 weeks.

In addition to gestational age, the baby's weight at birth, the presence of breathing problems, the presence of birth defects, and the presence of severe **infection** are

Premature infants often must stay in an incubator for some time. (NLM. Reproduced by permission.)

important factors influencing survival. Birth weight in premature infants is categorized as follows: birth weight below 5 lb 8 oz (2500 g) is defined as low birth weight (LBW); weight below 3 lb 5 oz (1500 g) is very low birth weight (VLBW); and weight below 2 lb 3 oz (1000 g) is extremely low birth weight (ELBW).

Other factors affecting survival

Other factors that influence the rate of organ development or the fetal oxygen supply also influence a premature infant's chances for survival. These factors include:

- rupture of the amniotic sac with loss of amniotic fluid before 24 weeks of gestation
- male sex (male infants are slower to mature)
- race (African American infants have slightly better chances of survival than Caucasian infants of the same birth weight)
- uncontrolled diabetes in the mother (slows organ development in the fetus)
- severe **hypertension** before the eighth month of pregnancy (slows delivery of nutrients and oxygen to the fetus)

Causes and symptoms

Causes of preterm labor

Labor that begins before the 37th week of pregnancy is called premature or **preterm labor**. It is responsi-

ble for about 85% of illnesses and deaths in newborns in the United States. Premature labor is sometimes induced because of the mother's or the infant's condition. Preeclampsia/eclampsia is the most common reason for inducing labor; other reasons include fetal distress or bleeding. Common causes of spontaneous premature labor include:

- abruptio placentae, or detachment of the placenta from the uterine wall
- premature rupture of the amniotic sac
- incompetent (too easily dilated) cervix
- multiple pregnancy
- abdominal or cervical surgery during the current pregnancy
- placenta previa (the placenta lies between the baby and the birth canal)

Factors that increase the mother's risk of preterm labor include:

- history of preterm delivery
- history of abortions or miscarriages
- heavy smoking (more than 10 cigarettes per day)
- history of drug abuse
- exposure to diethylstilbestrol (DES), a synthetic estrogen given to treat estrogen deficiency conditions
- urinary tract infection
- malnutrition
- height below 5 ft (1.5 m)
- weight below 100 lb (45 kg)
- age below 18

Common medical problems in premature infants

The most common problems in premature infants include **jaundice**, apnea (a pause in breathing lasting longer than 15–20 seconds), and inability to breast-feed or bottle-feed. Apnea in premature infants is accompanied by the baby's turning pale or bluish, and by a slowing-down of its **heart** rate (bradycardia). These problems are particularly likely to affect infants born more than four to six weeks early.

More serious medical problems that are relatively frequent in premature infants are described in the next four subsections.

RESPIRATORY DISTRESS SYNDROME (RDS). **Respiratory distress syndrome** (RDS) is the most common lung disorder in preterm infants. It is caused by a lack of surfactant in the **lungs**. Surfactant is a surface-active substance produced by the body that coats the

lungs and keeps them from collapsing. Babies with RDS typically breathe rapidly, with flaring nostrils and grunting sounds. RDS is usually treated by giving the baby extra oxygen under pressure. Sometimes the baby is also given additional surfactant by intubation.

TRANSIENT TACHYPNEA OF THE NEWBORN (TTNB). Transient tachypnea of the newborn is a disorder lasting for several hours or a few days characterized by rapid, grunting breathing. TTNB is thought to be caused by slow reabsorption of fetal lung fluid. It is also treated with supplemental oxygen.

PATENT DUCTUS ARTERIOSUS (PDA). A patent ductus arteriosus refers to an opening in the **blood** vessel that connects the aorta and the pulmonary artery. In full-term infants, this blood vessel closes in the first few days after birth. In preterm infants, it may remain open, thus allowing too much blood to flow into the baby's lungs. PDAs are treated with indomethacin or ibuprofen to close the blood vessel, or diuretics to decrease the amount of fluid that collects in the baby's lungs. If the medications do not close the ductus, it can be closed surgically.

RETINOPATHY OF PREMATURITY (ROP). Retinopathy of prematurity, or ROP, is the abnormal growth of **blood vessels** in the eyes. ROP is most common in infants who are more than 12 weeks premature. It often resolves on its own, but sometimes requires treatment. Treatment consists of killing the inner lining of the eye at the ends of the abnormal blood vessels to prevent further growth.

Less common but severe medical conditions

The next five subsections briefly describe serious disorders that may affect premature infants.

AIR LEAKS. Air leaks refer to several conditions in preterm infants, all characterized by air leaking from the air sacs in the lungs. The air may be trapped between the chest wall and the lung, trapped in the middle part of the chest, leaked into the abdomen, or leaked into the spaces between the tiny air sacs. Premature infants are vulnerable to air leaks because their lungs are not yet fully developed. In milder cases, the air is gradually reabsorbed by the baby's body. In severe cases, the baby may be treated by placement of a chest tube, or be placed on a ventilator.

NECROTIZING ENTEROCOLITIS (NEC). Necrotizing enterocolitis (NEC) is an inflammatory disorder in which part of the bowel lining or part of the bowel itself is destroyed. It is not always clear why a specific infant may develop NEC. The baby may vomit, have a swollen or abnormally reddish abdomen, or pass blood in the stool. NEC is usually treated with **antibiotics**. If a section of the bowel itself has been destroyed, surgery may be necessary.

BRONCHOPULMONARY DYSPLASIA (BPD). Bronchopulmonary dysplasia, or BPD, is a long-term lung disease that is most likely to develop in infants who were extremely premature, had severe RDS, or developed infections of the lungs. BPD is diagnosed if the baby's chest x-rays remain abnormal and the baby still needs oxygen by the time it is 36 weeks of gestational age (a month before its full-term due date). Babies with BPD are treated with supplemental oxygen, sometimes for as long as a year after they develop BPD. They may also be given steroids or diuretics.

INTRAVENTRICULAR HEMORRHAGE (IVH). Intra-ventricular hemorrhage (IVH) is a **brain** disorder in which blood seeps into the ventricles (a series of connecting cavities) of the brain. IVH develops because the blood vessels in the brain of a premature infant are fragile and break open easily. The preterm babies at highest risk for IVH are those weighing less than 2 lb 4 oz (1000 g). There is no specific treatment for IVH, but the condition can be monitored by ultrasound. In mild cases of IVH, the blood in the ventricles is slowly reabsorbed by the body. Babies with hydrocephalus (abnormal amounts of cerebrospinal fluid collecting in the ventricles of the brain), which is a possible complication of IVH, are at risk for permanent brain injury.

PERIVENTRICULAR LEUKOMALACIA (PVL). Periventricular leukomalacia (PVL) refers to a softening of the white matter of the brain surrounding the ventricles, caused by the death of brain tissue in these areas. The precise causes of PVL are still not fully understood. PVL often develops in babies with IVH. There is no specific treatment for PVL; moreover, infants with this disorder are at very high risk for motor (movement) and developmental disabilities as they mature.

Diagnosis

Many of the problems associated with prematurity depend on the degree of prematurity and the baby's birth weight. The gestational age of the fetus may be calculated from the date of the mother's last menstrual period or by using ultrasound imaging to observe **fetal development**. After the baby is born, such physical assessment scales as the Dubowitz Maturity Scale may be used to estimate gestational age. The Dubowitz scale bases its determination on the infant's physical and neuromuscular maturity.

Once the baby's gestational age and weight are determined, further tests and electronic monitoring may need to be used to diagnose problems or to track the baby's condition. A heart monitor or cardiorespiratory monitor may be attached to the baby's chest, abdomen, arms, or legs with adhesive patches to monitor breathing

KEY TERMS

Apnea—A pause in breathing of more than 15–20 seconds. In premature infants, apnea usually causes a change in the baby's color and a slowing of the heartbeat.

Bronchopulmonary dysplasia (BPD)—A chronic lung disorder that sometimes develops in premature infants who have had severe respiratory distress syndrome or lung infections.

Chronologic or birth age—The infant's age as measured by the time elapsed since birth.

Gestational age—The infant's age as measured by the estimated time since conception; sometimes called postconceptional age.

Hydrocephalus—An abnormal buildup of cerebrospinal fluid in the ventricles of the brain. In premature infants, it is often a complication of IVH.

Intraventricular hemorrhage (IVH)—A condition in which fragile blood vessels within the brain burst and bleed into the hollow chambers (ventricles) of the brain and into the tissue surrounding them.

Kangaroo care—A form of skin-to-skin contact in which either parent of a premature infant holds the baby under the blouse or shirt, against the skin. It is thought to help the infant's development as well as its bonding with the parents.

Necrotizing enterocolitis (NEC)—A condition that sometimes occurs in premature infants in which the lining of the bowel or a section of the bowel itself dies.

Neonatology—The study of the development and

disorders of newborn children. A physician who specializes in this field is called a neonatologist.

Patent ductus arteriosus (PDA)—An opening in the blood vessel that connects the aorta and the pulmonary artery. In full-term infants, this opening closes shortly after birth, but in premature infants, it may remain open and allow blood to collect in the infant's lungs.

Periventricular leukomalacia (PVL)—A brain disorder in which some of the white matter of the brain near the ventricles is softened because of the death of tissue in these areas.

Preeclampsia/eclampsia—Complications of pregnancy related to high blood pressure in a woman whose blood pressure was normal before pregnancy. Preeclampsia and eclampsia are common reasons for inducing premature labor.

Preterm—Another word for premature.

Respiratory distress syndrome (RDS)—A condition in which a premature infant lacks a sufficient amount of surfactant, a protective film that helps air sacs in the lungs to stay open.

Retinopathy of prematurity (ROP)—A condition in which the blood vessels in the retina of the eye display abnormal growth.

Surfactant—A protective film that helps air sacs in the lungs to stay open.

Tachypnea—Rapid breathing. Some premature infants develop rapid breathing for a few hours or days. This condition is known as transient tachypnea of the newborn (TTNB).

and heart rate. A **thermometer** probe may be taped on the skin to monitor body temperature. Blood samples may be taken from a vein or artery. A radiologic technologist may perform x rays or ultrasound imaging to examine the heart, lungs, and other internal organs.

Treatment

Treatment depends on the types of complications that are present. The infant may be placed in a heat-controlled unit (an incubator) to maintain body temperature. Infants that are having trouble breathing on their own may need oxygen either pumped into the incubator, administered through small tubes placed in their nostrils (nasal cannula), or through a respirator or ventilator that

pumps air through an endotracheal tube inserted into the airway. Oxygen may be delivered under pressure by continuous positive airway pressure (CPAP) or positive end expiratory pressure (PEEP).

Medications and surgery

The infant may require fluids and nutrients to be administered through an intravenous line inserted into a vein in the hand, foot, arm, leg, or scalp. If the baby needs medications to treat infections, to close a patent ductus, or to increase urinary output, they may also be administered through the intravenous line. Surgery may be required in the treatment of PDA, NEC, or IVH. If hydrocephalus develops as a complication of IVH, it may

be treated by surgical placement of a shunt, which is a tube connecting one of the ventricles in the brain to a longer tube under the skin that allows the excess cerebrospinal fluid to be absorbed in the abdomen.

Environmental considerations

Premature infants require special attention to their physical and social environment as well as to the symptoms of any disorders they may have. Some modifications are necessary because the nervous systems of preterm infants are not as fully developed as those of full-term infants.

PHYSICAL ENVIRONMENT. Premature infants experience loud noises and bright lights as stressful. In addition, they are more disturbed by frequent handling than full-term infants. Parents and other care givers should be advised to position the infant on its side in a flexed position; because premature infants do not have the muscle strength to move against gravity, they tend to lie with arms and legs in an extended position. Over a period of time, this extended position can delay the baby's motor development.

SOCIAL ENVIRONMENT. Neonatal intensive care units, or NICUs, complicate the premature infant's social environment by exposing him or her to many more clinical staff members than the full-term infant, and at the same time keeping him or her away from the parents more than the full-term infant. For this reason, skin-to-skin contact with parents, sometimes called kangaroo care, and gentle massage are encouraged as promoting infant and parent well-being. Parents should be encouraged to have early contact with the premature baby to facilitate parent-infant bonding.

Prognosis

The prognoses of premature infants vary widely, depending on gestational age, birth weight, the reasons for premature delivery, and the many other factors discussed above.

Health care team roles

Premature infants receive routine care and monitoring in the NICU from nurses. A neonatologist, who is a physician specializing in care of the newborn, may be consulted if a medical intervention seems necessary. A radiologist may be consulted for radiographic or ultrasound studies, and a surgeon may be called in if an operation is required.

Other health professionals involved in the premature infant's care are the respiratory therapist, who monitors

the care of infants requiring supplemental oxygen or **ventilators**; the social worker, who helps families adjust emotionally and provides referrals to hospital and community resources; and the occupational therapist, who evaluates the baby's progress and plans a program of developmental therapy if necessary.

After discharge from the hospital, the infant's growth and development will be monitored by a pediatrician or family physician. This doctor will reinforce the parents' education about caring for their baby, review the hospital records, and give the baby its first immunizations (most can be given at the usual chronological age). Most doctors recommend office visits every one or two weeks until the infant has adapted satisfactorily to the home environment and is gaining an appropriate amount of weight.

Prevention

Some of the risks and complications of premature delivery can be reduced if the mother receives good **pre-natal care**, follows a healthy diet, avoids alcohol consumption, and refrains from cigarette smoking. In some cases of premature labor, the mother may be placed on bed rest or given drugs that can postpone labor for days or weeks, giving the fetus more time to develop before delivery. The physician or nurse-midwife may prescribe a steroid medication to be given to the mother if a premature birth is expected, to assist the baby's lung development.

Prenatal nutrition

Definition

Maternal **nutrition** during **pregnancy** affects both the health of the mother and the growing fetus. Requirements for calories and specific nutrients are increased for the baby's growth and proper development. These needs can be met by increasing healthful food consumption and specific nutrient supplementation.

Purpose

Proper prenatal nutrition helps ensure a healthy start for a new baby and promotes the mother's well-being during and after pregnancy. Nurses and other allied health professionals can play a role in educating pregnant women about sufficient weight gain, the importance of a healthy diet, and the following recommendations for supplementation.

Precautions

Maternal weight gain during pregnancy is an important predictor of a baby's birth weight. The height and weight of the mother before pregnancy should be taken into account when assessing maternal nutrient needs. Both underweight and excessively overweight women need special attention. Underweight women are more likely to give birth to premature or low birth-weight infants, while overweight women have an increased risk of developing pregnancy-related complications. Other high-risk groups for low birth-weight babies include women younger than 15 and those older than 35. Women whose pregnancies are fewer than 12 months apart are also at higher risk.

Description

Maternal weight gain is a measure often used to assess how well a pregnancy is progressing. Normal weight gain is considered to be 25 to 35 pounds, although individual needs should also be taken into account.

Women who are underweight to start with may benefit from gaining more (28-40 pounds), while overweight women may try to gain less (15-25 pounds). Even for overweight women, however, weight gain is important to allow for proper growth of the fetus.

Nutrient needs during pregnancy depend on physical activity and **metabolism** of the mother. For most women, energy needs increase to about 300 extra calories per day during the second and third trimesters. Protein needs increase to allow for new tissue growth and maintenance; deficiency can result in lower a birth weight. An extra 10 to 12 grams of protein per day is recommended during the last half of pregnancy.

Vitamin and mineral requirements are also increased during pregnancy. To meet those needs, most women in the United States are advised to take a multivitamin supplement with **minerals** while they are pregnant. Eating a well-balanced diet with plenty of fruits, vegetables, and whole grains will also help provide the needed **vitamins**. **Iron** and **calcium** are two minerals of special concern. The fetus acquires most of these minerals during the last trimester of the pregnancy. Doctors recommend daily supplementation of 30 mg of iron in the form of ferrous sulfate to avoid **iron deficiency anemia**, which can cause excessive tiredness in the mother. Calcium intake should be 1,200 to 1,500 mg per day, which can be obtained through diet or supplementation. Adequate calcium is important so that the mother does not lose bone mass during pregnancy. There is also some evidence that calcium supplementation reduces the risk of pregnancy-induced **hypertension**, also known as preeclampsia, for women who are at high risk for this condition.

Folate (**folic acid**) is an extremely important vitamin, not only during pregnancy, but before pregnancy as well. Folate is crucial to the development of new cells, and deficiency during pregnancy has been associated with the development of congenital malformations known as neural tube defects (NTDs). The most serious NTDs include spina bifida and anencephaly. Spina bifida is characterized by gaps in the spine, typically resulting in serious lifelong disability. An infant with anencephaly lacks **brain** formation and dies shortly after birth. Because NTDs arise early in pregnancy, before most women know they are pregnant, the U.S. Public Health Service recommends that all women of childbearing age consume 0.4 mg (400 micrograms) of folic acid daily. Adequate amounts of folate can be obtained from the diet, but in practice most women do not consume enough. To help address this problem, in 1996 the U.S. Food and Drug Administration (FDA) approved folate fortification of flour, breads, cereal, and rice.

Complications

Good nutrition is especially important for certain conditions during pregnancy. Diabetes, a disease of poor **blood** sugar regulation, is one common problem requiring special attention to diet. Some women develop it only during pregnancy, when it is termed **gestational diabetes**. It can lead to multiple complications, including abnormally enhanced growth of the fetus, a condition called macrosomia. Such babies need special care at birth until blood sugar levels can be brought under control. Control of gestational diabetes includes careful attention to diet so that maternal blood sugar levels are kept as normal as possible throughout pregnancy. Women should eat frequent small meals; select foods high in fiber and complex **carbohydrates**; and avoid highly refined foods and simple sugars.

Another common problem is nausea and vomiting in early pregnancy. Because hunger seems to exacerbate the problem, suggestions to alleviate nausea include eating small, frequent meals of easily digestible foods, and having dry crackers near the bed to eat immediately upon awakening. Some women have severe enough symptoms that they are in danger of weight loss, **dehydration**, and electrolyte disturbances. This condition, termed hyperemesis gravidarum, may require hospitalization or medications to treat it if simple nutritional measures cannot control it.

Phenylketonuria (PKU) is a more unusual condition, but it is one in which the importance of maternal nutrition is paramount. PKU and the related condition, hyperphenylalanemia (HPA), are genetic disorders involving the impairment of the ability to digest phenylalanine, an essential amino acid found in protein. Before the disease was recognized, people with PKU developed severe mental retardation in childhood. Since routine screening and early dietary treatment has been instituted, people with PKU now can develop normally. However, women with these conditions may be advised not to become pregnant because of the high risk of mental retardation and congenital defects in the developing fetus. Women who desire pregnancy should discuss their plans with health personnel in a clinic that specializes in the treatment of these disorders well before becoming pregnant, so that strict dietary measures can be taken before conception and throughout pregnancy.

An abnormal food behavior that sometimes occurs in pregnant women is pica, which involves the consumption of such nonfood items as cornstarch, dirt, hair, cigarette ashes, or coffee grounds. Pica is sometimes associated with iron deficiency; and some think that the consumption of these substances may relieve the nausea and vomiting associated with pregnancy. Although many of these

KEY TERMS

Congenital malformations—Deformities that occur at birth.

Gestational diabetes—A disorder occurring in pregnancy involving insensitivity to insulin, causing poor blood sugar regulation.

Hyperemesis gravidarum—Excessive vomiting during pregnancy.

Macrosomia—An abnormally large body. Macrosomia of the newborn is a common complication of gestational diabetes.

Phenylketonuria (PKU)—A congenital deficiency of an enzyme that aids in the breakdown of an amino acid, leading to the development of severe mental retardation. PKU can be controlled with a strict diet, which is especially critical during pregnancy of a mother with PKU to avoid physical and mental defects in the fetus.

Pica—A desire that sometimes arises in pregnancy to eat such non-food substances as dirt or clay.

Preeclampsia—A syndrome of high blood pressure that develops during pregnancy. The chief danger of preeclampsia is that it will progress to eclampsia, which is a life-threatening condition characterized by seizures.

substances are not inherently harmful, there is a concern that such habits may displace the intake of nutritious foods during pregnancy.

Alcohol consumption during pregnancy can result in **fetal alcohol syndrome (FAS)**, characterized by varying degrees of numerous physical and mental problems, including mental retardation, facial abnormalities, and **heart** and skeletal defects. Because of the unpredictable effects of even small amounts of alcohol, women are advised to drink no alcohol at any time during pregnancy.

Quitting smoking and avoiding secondhand smoke is especially important during pregnancy. Exposure to tobacco smoke increases the risk of a low birth-weight infant.

The effect of food additives is controversial, but doctors recommend that sugar substitutes, including saccharin and aspartame, be used in moderation if at all. **Caffeine** consumption during pregnancy is another debatable issue, although too much caffeine may have negative effects.

Especially for teenagers and young women, eating disorders may be of concern. Anorexia, bulimia nervosa (characterized by episodes of binge eating and vomiting), use of **laxatives**, or excessive exercising pose a serious risk to the mother and the fetus. Poor weight gain during pregnancy may indicate the presence of a eating disorder.

Results

Good nutrition and adequate weight gain in pregnancy increase the likelihood that the mother will feel her best during pregnancy and that a healthy baby will be born with a normal birth weight. Specific nutrient deficiencies can lead to birth defects, as is well documented for folic acid; or health consequences to the mother (e.g., calcium deficiency's possible role in preeclampsia). In addition, nutritional intervention is the treatment of choice for several conditions, including gestational diabetes, nausea and vomiting in pregnancy, and maternal PKU.

Health care team roles

Dietetic professionals, nurse practitioners, nurse midwives, and physicians play an important role in the **prenatal care** of pregnant women. Dietitians can provide the nutrition counseling and education necessary to ensure the normal growth and development of the fetus. They can warn women about the dangers of improper food intake and the outcome it may have on pregnancy. Physicians are primarily responsible for determining that the fetus is growing properly and for detecting and monitoring medical conditions. In uncomplicated pregnancies, nurse practitioners and nurse midwives may play a more prominent role in prenatal care.

Prenatal care

Definition

Prenatal care is that health care given to a pregnant woman and to the developing fetus until the time of delivery.

Purpose

The purpose of prenatal care is to:

- Establish a baseline for **vital signs** and current health status.
- Identify women at risk for pregnancy-related complications.
- Minimize pregnancy-related complications through prevention techniques, anticipatory action, and intervention as soon as a complication is recognized.
- Offer education to the woman about possible lifestyle and work-related dangers to her and the developing fetus.
- Provide routine evaluation of the growth and development of the fetus.
- Educate the pregnant woman about normal and abnormal conditions in **pregnancy**.
- Teach the woman to recognize the signs of impending labor.
- Assist in connecting the pregnant woman to childbirth- and or parenting-education classes.

Precautions

Practitioners of prenatal care need to be aware of the possibility of domestic abuse, since such violence may begin with a pregnancy. About half of the women who are abused prior to becoming pregnant will continue to be abused during the pregnancy. Questions about abuse should be included at the first prenatal visit, and periodically thereafter if suspicion of it arises.

Description

The prenatal period lasts about 38 weeks from conception to delivery, or 40 weeks from the last menstrual period (LMP). It may also be referred to as the *antenatal* period. While some women come for their first prenatal visit shortly after missing a menstrual period, others may not come for prenatal care until later.

The first prenatal visit is usually the longest, as it includes a complete **health history**, **physical examination** (including pelvic and bimanual exams), and **blood**

and urine testing. A recommended schedule for prenatal visits is:

- Once a month until 28 weeks' gestation.
- Every two weeks from week 28 to week 36.
- Every week from week 36 until delivery.

The pregnancy is confirmed at the first prenatal visit. A urine or blood test may be done as well as a physical examination. A woman may have taken a home **pregnancy test** after a missed period and may already be experiencing some nausea, vomiting, or breast tenderness. Practitioners should assess the woman's feelings about the pregnancy and assist in appropriate referrals if she needs further counseling.

The complete health history should record the following information:

- The first day of the woman's last menstrual period. The LMP date will be used to calculate the estimated date of delivery, referred to as the due date. Calculation of the due date uses a formula called Naegele's rule: subtract three months from the date of the woman's LMP. Then add one week and one year. Most women deliver within two weeks before or after their due date.
- Previous gynecologic and obstetric history. Practitioners should not assume that this is the woman's first pregnancy. A woman may not divulge her complete history if her partner is present and there are aspects of her history that she has not yet shared. This history should include contraceptive choices and prior exposure to sexually transmitted diseases. If she is Rh-negative, did she receive RHOgam with a previous pregnancy, even if it was terminated early?
- Personal medical history. This should include childhood diseases, **allergies**, side effects or allergies to medications, such chronic diseases as high **blood pressure** and diabetes, medications currently being taken, vaccinations, surgeries, and eating disorders. Past conditions may become reactivated during a pregnancy. Women with prior eating disorders may have difficulty gaining weight during a pregnancy. Women should be asked about medication taken before the pregnancy was suspected, as well as any unprotected exposure to x rays. The form of **contraception** at the time of conception needs to be established, and women should be asked if an intrauterine device (IUD) is in place.
- Family medical history, including ethnicity. Women may need screening if there is a family history of sickle-cell anemia, Tay-Sachs, **cystic fibrosis**, or thalassemia. Sometimes there is no family history but testing is still important if suggested by ethnic heritage. Women should be asked if there is a family history of

Prenatal visit schedule recommended by the U.S. Public Health Service

First pregnancy	Second or later pregnancy
First visit: 6–8 weeks	First visit: 6–8 weeks
Second visit: Within 4 wks of first	Second visit: 14–16 weeks
Third visit: 14–16 weeks	Third visit: 24–28 weeks
Fourth visit: 24–28 weeks	Fourth visit: 32 weeks
Fifth visit: 32 weeks	Fifth visit: 35 weeks
Sixth visit: 36 weeks	Sixth visit: 39 weeks
Seventh visit: 38 weeks	Seventh visit: 41 weeks
Eighth visit: 40 weeks	
Ninth visit: 41 weeks

retardation, developmental delay, reproductive loss, or other issues.

- Information about work, lifestyle, and hobbies. This information can be helpful in understanding potential risks for the pregnancy, such as alcohol, tobacco, or drug use, work- and hobby-related risks of chemical exposure or physical hazards, **exercise** patterns, possible exposure to Lyme disease, and nutritional intake. Does the woman's work require heavy lifting or continually standing in one place? Could she be exposed to chemicals that could be teratogenic to the fetus? Exercise during pregnancy helps with **stress** and **anxiety**, and most women can maintain their prepregnancy exercise routines during pregnancy. However, they need to avoid overheating, as this is harmful to the fetus. Overheating includes the use of saunas, hot tubs, and tanning beds. Exercise with potential trauma to the abdomen should be avoided. Exercise may be contraindicated in the case of intrauterine growth retardation, once the membranes have ruptured, vaginal bleeding, or for women at increased risk for **preterm labor**. The extent of the woman's support network should also be assessed. Does she have other children? Is she the primary caregiver for an ailing parent? Does the woman have cats or work in a veterinary office? (Toxoplasmosis is spread through soil, undercooked meat, and cat stool. Pregnant women should avoid contact with used cat litter, sand, or soil.)
- A verbal review of body systems, from head to toe. These questions may prompt a woman to remember or include information that she otherwise may have discounted as unimportant. It also establishes a baseline of her medical condition, especially if she develops symptoms later on in the pregnancy.
- Physical exam. The physical exam on the first visit will include a head-to-toe assessment in order to establish

Important points in prenatal care

	Objective data	Emotional assessment	Laboratory
First visit	Accurate blood pressure (BP) Cervical length and dilation Size/dates Body Mass Index (BMI) Genetic problems	Feelings about this pregnancy/previous birth/losses Stressors Support system Need for referral: counseling, food, shelter, genetics, etc.	Consider: HIV, PPD, sonogram, glucose screen
16 to 19 weeks			Amniocentesis
20 weeks	Fetal heart tones with fetoscope Weight gain	Stressors and body image	
24 to 26 weeks	Cervix check if history of pre-term labor or if first baby	Recurrent or vivid dreams; fears	
28 weeks	Weight gain Review dating	Stressors and body image	Glu screen Rh immune globulin
36 weeks	Presentation	Fears about labor	Consider repeating: Hct., GC and chlamydia, RPR, HIV, HbsAg Schedule version if breech

the presence of any abnormal or unusual findings, along with height, weight, and blood pressure. Women might be encouraged to continue, or begin, monthly breast self-exams for signs of lumps, and to report any physical changes such as thyroid enlargement or the development of varicose veins.

- Pelvic exam. The pelvic exam begins with an assessment of the external genitalia for any signs of redness, **infection**, vaginal discharge, or lesions. It will include a Pap smear for cervical **cancer**, as well as an assessment of the vaginal walls and cervix, checking for any growths, lesions, or signs of infection. The pregnancy will be confirmed by checking for changes in the uterine size. A bimanual exam allows the practitioner to check the uterus as well as the ovaries. A rectal exam checks for any rectal masses. The presence of hemorrhoids will also be noted. Cultures may be taken to check for infection or an undiagnosed sexually transmitted disease (STD), such as gonorrhea or chlamydia. Left untreated, these infections can be harmful to the mother and fetus. During the first visit the practitioner may also evaluate the adequacy of the pelvic size and shape for vaginal delivery.
- Fetal **heart** tones can be heard by 10 to 12 weeks' gestation. The normal fetal heart rate is 120 to 160 beats per minute. The fundal height will be measured at each visit to chart the growth pattern of the uterus.
- Laboratory work may include a **urinalysis**, **complete blood count**, rubella antibody titer, and blood type with **Rh factor**. Testing for hepatitis B is common. Women should be offered the option of HIV screening, as early detection can provide the opportunity of using medication to decrease the risk of transmission to the

fetus. Additional screening may be done for toxoplasmosis, cytomegalovirus, herpes simplex, or group B streptococci.

Normal physical changes to expect during pregnancy should be discussed. The pregnant woman should also be given the emergency number to call when the health facility is closed, along with guidelines about when it is appropriate to call. Teaching about the use of over-the-counter medications should be done, as many people are not aware that nonprescription drugs can be harmful to the developing fetus. Before leaving from the first prenatal visit, the next appointment should be scheduled, to encourage ongoing care.

Subsequent prenatal visits are considerably shorter, unless complications arise. A routine visit includes a urine check for protein, glucose, and possibly ketones; a weight and blood-pressure check; and measurement of fundal height. At each visit the woman should be asked if she is experiencing any of the common discomforts of pregnancy, such as ankle **edema** (swelling), leg cramps, Braxton-Hicks contractions, fatigue, backache, nausea or vomiting, constipation, or shortness of breath. In the first trimester, and again toward the end of pregnancy, the uterus applies pressure on the bladder, possibly resulting in the need for frequent urination. If frequency is accompanied by burning or **pain** with urination, a urinary tract infection should be ruled out.

While nausea and vomiting are common until the fourth or fifth month of pregnancy, excessive vomiting can result in **dehydration** and electrolyte imbalance. Sometimes hospitalization is required. The new mother should also be educated about signs that might indicate a developing problem, such as abdominal pain (perhaps

indicative of an ectopic pregnancy), edema in the face (preeclampsia), headaches, blurred **vision**, vaginal bleeding, continual vomiting, decrease in fetal movement, or presence of vaginal fluid (rupture of the amniotic membranes).

An opportunity should be provided to answer any questions the woman might have. Attendance at **child-birth** and/or parenting classes, and access to classes for older siblings, should be discussed. The pregnant woman should also be assessed for signs of depression. As the pregnancy progresses, lying supine can cause the uterus to compress the vena cava, impeding blood flow to the heart. This may be experienced as an irregular heart rate or a feeling of anxiety. Lying on the left side resolves this problem.

Pregnant women should be encouraged to eat a wide variety of nutritious foods. Women whose prepregnancy weight is within an appropriate range for height should expect to gain about 25 to 35 pounds over the course of the pregnancy. Those who are overweight should gain less, but not try to diet while pregnant. Pica, or the desire to eat nonfood substances, may not cause harm to the fetus if the substances themselves are not harmful and the woman is otherwise eating a balanced diet. Questions to assess for pica should be part of routine visits. A woman's financial situation can affect her ability to purchase nutritious foods. This need should be assessed at the first visit so that an appropriate referral can be made for food stamps or other assistance programs. The use of megavitamins should be evaluated, as high doses of fat-soluble **vitamins** can be harmful. Intake of high doses of **vitamin A** is associated with birth defects.

At 10 to 18 weeks, **genetic counseling** may be provided for women with a family history of congenital, chromosomal, or neural-tube anomalies, or for women above age 35. Chorionic villi sampling (CVS) may be done between 10 and 12 weeks, while **amniocentesis** may be performed between 14 and 18 weeks. Ultrasound may be done between 12 and 24 weeks to confirm dating of the pregnancy or to check fetal anatomy.

A **triple marker screen test** that evaluates maternal serum alpha-fetoprotein, human chorionic gonadotropin (hCG), and unconjugated estriol levels is usually run on a blood sample between 16 and 20 weeks to screen for neural-tube defects. Inadequate intake of **follic acid** is associated with such neural-tube defects as spina bifida. Elevated levels of alpha fetoprotein may indicate a neural-tube defect, but can also be due to a **multiple pregnancy**, inaccurate dates, or fetal death. The test can also indicate if the fetus has Down's syndrome. As with other laboratory tests, false positives can occur.

At 20 to 22 weeks, women should be aware of the danger of premature rupture of the membranes and preterm labor. Fundal height should be at the umbilicus.

Screening for **gestational diabetes** is done around 26 to 28 weeks. The first screening test does not require fasting, and blood is drawn once, an hour after a drink containing 50 gm of glucose is ingested. If the result is abnormal in any way, a three-hour glucose tolerance test (GTT) will be administered. This test is usually done in the morning, after the woman has fasted for eight hours. A sample for the FBS (fasting blood sugar) test is drawn, glucose is given, and blood is then drawn hourly over the next three hours. Babies of mothers with gestational diabetes are at risk of excessive intrauterine growth, and blood sugar abnormalities after birth. While gestational diabetes (GDM) usually resolves when the pregnancy terminates, women with GDM are at increased risk—about 60%—of developing diabetes within the next 16 years.

From 28 weeks to 34 weeks onward, fetal presentation (position) will be checked at each visit.

After 36 weeks the physician may choose to conduct a sterile internal exam to evaluate the condition of the cervix for labor and delivery.

From 40 to 42 weeks fetal well-being and the amount of amniotic fluid may be monitored more closely. Too little or too much may indicate problems. Induction of labor will be considered.

Preparation

In coming to the first prenatal visit, it is helpful for the woman to bring in:

- Medical records from a previous pregnancy not easily accessible by the current practitioner or facility, especially if complications arose.
- Information on family medical history as well as personal medical history.
- Date of last menstrual period.
- Names and dosages of any medications currently being taken (both prescription and over-the-counter products, including any herbal remedies).
- A list of any questions she may have.

At the first visit, a physical exam will be performed. In preparation, the woman will need to undress, put on a gown, and empty her bladder. (The pelvic exam puts pressure on the bladder, creating discomfort if full.) This may be the first pelvic exam for some women; they should be told what to expect before anything is done. Proper draping can help ease discomfort. For the pelvic

KEY TERMS

Braxton-Hicks contractions—Irregular tightening of the uterus that begins in the first trimester of pregnancy. The contractions increase in frequency and strength as the pregnancy progresses and may be confused for labor contractions toward the end of the pregnancy. They are sometimes referred to as “false labor pains.”

Fundal height—Measured by a tape measure from the top of the symphysis pubis, over the arch of the growing uterus, to the top of the fundus.

Gestation—The length of the pregnancy, from fertilization until birth.

Sickle-cell anemia—A form of anemia characterized by crescent-shaped red blood cells containing an abnormal form of hemoglobin. Physical symptoms of crisis include fever, joint pain, and weakness. It is most common in people of African American, Mediterranean, Latin American, and Native American descent.

Tay-Sachs disease—A genetic disorder resulting in the progressive degeneration of the central nervous system. It is found primarily in individuals of Eastern European Ashkenazi Jewish descent.

Thalassemia—A genetic-based anemia in which the red blood cells are easily destroyed and release iron into the blood system, which then deposits it in the skin and internal organs. Thalassemia is most commonly found in individuals of Mediterranean, Middle Eastern, and Asian descent.

exam the woman will need to lie on her back with her feet in stirrups. Warming the speculum prevents the woman from tensing as the speculum is inserted.

If an ultrasound is to be done, the woman will need to drink about a quart of water one to two hours prior to the test, without voiding, in order to better visualize the fetal structures. Later in the pregnancy, when there is more amniotic fluid, this will not be necessary. While the ultrasound is painless, having a full bladder can become quite uncomfortable. The nurse or radiology technician should ensure that the test can begin on time whenever possible.

If a woman is considering an amniocentesis or chorionic villi sampling, she should understand the risks accompanying these procedures (which include a slightly increased chance of **miscarriage**), the information that

can be expected, and the options available if abnormal results are found.

Aftercare

After a woman has an internal exam, she should be given a tissue to remove lubricant used for the exam. A sanitary pad may be offered if spotting occurred. If abnormal results have been reported, the woman or her partner may need additional time to ask questions, receive appropriate referral information, or be consoled.

Complications

At each visit, weight, blood pressure, and urine are checked. A rapid weight gain, increased blood pressure, and proteinuria signal the development of preeclampsia. Vaginal bleeding at any time during pregnancy needs evaluation. Third-trimester bleeding may indicate **placenta previa** or **placental abruption**, two conditions that put the fetus at risk. Sharp abdominal pain may indicate an ectopic pregnancy; the woman needs to be evaluated right away should such pain occur. An ectopic pregnancy can result in rupture of the fallopian tube and internal bleeding. A gush of fluid from the vagina can signal the rupture of the amniotic membranes. If this sign occurs at the end of pregnancy, it may indicate that labor is about to begin. However, once the membranes have ruptured, the uterus is more easily exposed to infection. Without adequate amniotic fluid, the umbilical cord can prolapse, reducing the oxygen flow to the fetus. Loss of fluid needs to be evaluated to determine if it was due to ruptured membranes or stress incontinence.

Results

The goal of prenatal care is the delivery of a healthy baby at term, from a healthy mother prepared to handle the challenges of parenthood.

Health care team roles

Nurses, dieticians, social workers, childbirth educators, midwives, nurse practitioners, obstetricians, and perinatologists play important roles in prenatal care, through careful listening both to what is said and what may be omitted, thorough assessment and documentation, and education and referral. Radiology technicians will see the woman during ultrasound, amniocentesis, and chorionic villi sampling, at a time when she may be anxious about the test being performed. Laboratory technicians may see the woman at the end of a difficult visit, perhaps after she has received bad news or is anxious about an upcoming test. If the pregnant woman is dehy-

drated, venous access is more challenging to obtain. Providing an understanding, reassuring, and calm environment, and utilizing one's experience to perform the task at hand with the greatest of skill, can minimize any further sense of trauma.

Preoperative care

Definition

Preoperative care is the preparation and management of a patient prior to surgery. This care includes physical and psychological preparation.

Purpose

Patients who are physically and psychologically prepared for surgery tend to have better outcomes after surgery. Preoperative teaching meets the patient's need for information regarding the surgical experience, which in turn may alleviate most fears the patient has. Knowing what to expect after the surgery, and enlisting the patient's input about goals and expectations, often helps the patient cope better with postoperative **pain** and decreased mobility. Preoperative care is extremely important prior to any invasive procedure, regardless of whether the procedure is minimally invasive or major surgery.

Precautions

There are no contraindications to preoperative care. Even in an emergent situation, the patient must be physically prepared and should be prepared psychologically to the degree possible, as indicated by the patient's physical status. If the patient is unresponsive, emotional and psychological preparation should be focused on the family.

Preoperative teaching must be individualized for each patient, since some people want as much information as possible while others want only the minimum. For some patients, receiving too much information increases their **anxiety**. Patients have different capabilities in understanding medical procedures; if printed materials are used for teaching, the nurse must ascertain the patient's literacy level in order to provide appropriate material. The health care professional must maintain a balance between relaying essential information and meeting the patient's information needs.

Description

Preoperative care involves many components and may be done the day before surgery, in the hospital, or during the weeks before surgery on an outpatient basis. Many surgical procedures are now performed in a day-surgery setting and the patient is never admitted to the hospital.

Physical preparation

Physical preparation should include obtaining a complete history and physical, including the patient's surgical and anesthesia history. It should be determined if the patient has ever had an adverse reaction to anesthesia (such as anaphylactic **shock**), or if there is a family history of malignant hyperthermia. Such laboratory tests as CBC, electrolytes, prothrombin time, activated partial thromboplastin time, or **urinalysis** may be done. An EKG should be done if the patient has a history of cardiac disease or is over 50 years of age. A chest X-ray should be taken if the patient has a history of respiratory disease. The patient should be assessed for risk factors that might impair healing, such as nutritional deficits, steroid use, radiation or **chemotherapy**, drug or alcohol abuse, or such metabolic diseases as diabetes. The patient should also provide a list of all medications, **vitamins**, and herbal or food supplements that they use. Supplements are often overlooked, but some can cause adverse effects when used with general anesthetics (e.g. St John's wort, valerian root) and others can prolong bleeding time (e.g. garlic, ginkgo biloba).

Latex allergy merits mention because it is becoming a **public health** concern. Latex is found in most sterile

KEY TERMS

Activated partial thromboplastin time (APTT)—A lab test that detects coagulation defects in the intrinsic clotting cascade. Used to regulate heparin dosing.

Complete blood count (CBC)—A lab test that determines the number of red and white blood cells per cubic millimeter of blood.

Electrocardiogram (EKG)—A graphic record showing the electrical activity of the heart.

Incentive spirometer—Device that is used postoperatively to prevent lung collapse and promote maximum inspiration. The patient inhales until a preset volume is reached, then sustains the volume by holding the breath for three to five seconds.

Prothrombin time (PT)—A lab test that detects coagulation defects in the extrinsic clotting cascade. Used to regulate coumadin dosing.

surgical gloves and is a common component in other medical supplies, including **general anesthesia** masks, tubing, and multi-dose medication vials. It is estimated that one percent to six percent of the general population and eight to seventeen percent of healthcare workers have this allergy. At least 50% of children with spina bifida are latex-sensitive as a result of early frequent surgical exposure. There is currently no cure available for latex allergy, and research has found that up to 19% of all anaphylactic reactions during surgery may be a result of latex allergy. The best treatment is prevention, but immediate symptomatic treatment is required if the allergic response occurs. Every patient should be assessed for a potential latex reaction. Patients with latex sensitivity should have their chart flagged with a caution label. Latex-free gloves and supplies must be used for anyone with a documented latex allergy.

Bowel clearance may be ordered if the patient is having surgery of the lower gastrointestinal (GI) tract. The patient should start the bowel preparation early in the evening to prevent interrupted sleep during the night. Some patients may benefit from a sleeping pill the night before surgery.

Often skin preparation is ordered for the night before surgery. Skin preparation can take the form of scrubbing with a special soap (i.e., Hibiclens), or hair removal from the surgical area. However, as of this printing (in 2001), shaving hair is no longer recommended because studies

show that shaving the area may increase the chance of **infection**. Instead, adhesive barrier drapes can contain hair growth on the skin around the incision.

Psychological preparation

Patients are often fearful or anxious about having surgery. Health care workers can help decrease anxiety by listening to the patient's concerns, validating their legitimacy, and answering the patient's questions honestly. This responsiveness can be especially beneficial for patients who are critically ill or who are having a high-risk procedure. The family needs to be included in psychological preoperative care as much as the patient. In the hospital, pastoral care can be offered. If the patient expresses a fear of dying during surgery, this concern should not be discounted. The surgeon should be notified. In some cases, the procedure may be postponed until the patient feels more secure.

Children may be especially fearful. They should be allowed to have a parent with them as much as possible, as long as the parent is not demonstrably fearful and contributing to the child's apprehension. Children should also be encouraged to bring a favorite toy or blanket with them on the day of surgery.

Preparing the patient and family psychologically helps them to cope better with the patient's postoperative course. Preparation leads to superior outcomes, since the goals of recovery are known ahead of time and the patient is able to manage postoperative pain more effectively.

Informed consent

Obtaining the patient's or guardian's written consent for the surgery is a vital portion of preoperative care. By law, the physician who will perform the procedure must explain the risks and benefits of the surgery, along with other treatment options. However, the nurse is often the person who actually witnesses the patient's signature on the consent form. The nurse should verify that the patient understands everything the physician told them by asking the patient to explain what they have been told.

Patients who are mentally impaired, heavily sedated, or critically ill are not considered legally able to give consent. In this situation, the next of kin (spouse, adult child, adult sibling, or person with medical power of attorney) may act as a surrogate and sign the consent form. Children under age 18 must have a parent or guardian sign.

Preoperative teaching

Preoperative teaching includes teaching about the preoperative period, the surgery itself, and the postoperative period.

Instruction about the preoperative period deals primarily with where the patient should go on the day of surgery, the time they should arrive, and how they should prepare for surgery. For example, they should be told how long they should be NPO (nothing by mouth); which medications to take prior to surgery; and the medications that should be brought with them (such as inhalers for patients with **asthma**).

Instruction about the surgery itself includes informing the patient about what will be done during the surgery and how long it is expected to take. The patient should be told where the incision would be. Children having surgery should be allowed to “practice” on a doll or stuffed animal. It may be helpful to demonstrate procedures on the doll prior to doing them on the child. It is also important to tell the family (or other concerned parties) where they can wait during the surgery; when they can expect progress information (and from whom); and how long it will be before they can see the patient.

Informing the patient about what to expect during the postoperative period is one of the best ways to improve the patient’s outcome. Instruction about expected activities can also increase compliance and help prevent complications. This includes the opportunity for the patient to practice coughing and deep breathing exercises, use an incentive spirometer, and practice splinting the incision. Additionally, the patient should be informed about early ambulation. The patient should also be taught that the respiratory interventions decrease the occurrence of **pneumonia** and that early leg exercises and ambulation decrease the risk of **blood** clots.

Patients hospitalized postoperatively should be informed about the tubes and equipment that they will have. These may include multiple IV lines, drainage tubes, dressings, and monitoring devices. In addition, they may have sequential compression stockings on their legs to prevent blood clots until they start ambulating.

Pain management is the primary concern for many patients having surgery. Preoperative instruction should include information about the pain management method that they will utilize postoperatively. Patients should be encouraged to ask for or take pain medication before the pain becomes unbearable, and should be taught how to rate their pain on a pain scale. This instruction allows the patients, and others who may be assessing them, to evaluate the pain consistently. If they will be using a patient-controlled analgesia (PCA) pump, they should be taught

how to use it during the preoperative period. Use of alternative methods of pain control (distraction, imagery, positioning, mindfulness meditation, music therapy) may also be presented.

Finally, long-term goals should be discussed, such as when the patient will be able to eat solid food, when they will be discharged if they are hospitalized, and when they will be able to drive a car or return to work.

Preparation

Preparation for preoperative care involves ensuring that all supplies for physical preparation are accessible. To prepare for teaching, any applicable patient handouts or videos should be gathered and offered to the patient. The consent form should be ready for the patient to sign, with the name of the physician and the procedure filled in. A sufficient amount of time should be scheduled so that the patient does not feel rushed, and the patient should understand that they have the right to add or strike out items on the generic consent form that they do not wish to agree to. For example, a patient who is about to undergo a tonsillectomy might choose to strike out (and initial) an item that indicates sterility might be a complication of the operation.

Aftercare

The only aftercare required is to ensure that the patient understands the surgery and that all of their questions are answered.

Complications

Complications can result from improper preoperative care. For example, surgery may be done on the wrong side of the body if the incorrect body part is marked during physical preparation. Hospitalized patients may be given the wrong preoperative medications; or sedatives may be inadvertently given before **informed consent** is obtained.

Results

The anticipated outcome of preoperative care is a patient who is informed about their surgical course and able to cope with it successfully. The goal is to decrease complications and promote recovery.

Health care team roles

As mentioned above, the physician is legally responsible for discussing the risks and benefits of the procedure and for obtaining the patient’s informed consent.

However, the nurse is often the one who witnesses the patient's signature. If the nurses were not present for the physicians' discussions with the patients, the nurses must ensure that the patients understand the risks and benefits of the surgery by having the patients relate what they were told by their physician. The nurse is usually responsible for preoperative instruction, although a respiratory therapist often teaches about the postoperative respiratory exercises, especially in a hospital setting. Laboratory personnel may draw blood samples and perform laboratory tests. Radiology personnel perform the chest x-ray if one is ordered.

Presbyopia

Definition

The term presbyopia means "older eye," and is a **vision** condition involving the loss of the eye's ability to focus on close objects.

Description

Presbyopia is a condition that occurs as a part of normal aging. The condition develops gradually over a number of years. Symptoms are usually noticeable by age 40 to 45, and continue to develop until the process stabilizes some 10 or 20 years later. Presbyopia occurs without regard to other eye conditions.

Causes and symptoms

In the eye, the crystalline lens is located just behind the iris and the pupil. Tiny ciliary muscles pull and push the lens, adjusting its curvature, and thereby adjusting the eye's power to bring objects into focus. As individuals age, the lens becomes less flexible and elastic, and the muscles become less powerful. Because these changes result in inadequate adjustment of the lens of the eye for various distances, objects that are close will appear blurry. The major cause of presbyopia is loss of elasticity of the lens of the eye. Loss of ciliary muscle power and loss of elasticity of the zonules that connect the ciliary muscle to the lens, however, are also believed to contribute to the problem.

Symptoms of presbyopia result in the inability to focus on objects close at hand. As the lens hardens, it is unable to focus the rays of light that come from near objects. Individuals typically have difficulty reading small print, such as that in telephone directories and newspaper advertisements, and may need to hold reading materials at arm's length. Symptoms include headache and eyestrain when doing close work; blurry vision; and eye fatigue. Symptoms may be worse early in the morning or when individuals are fatigued. Dim lighting may also aggravate the problem.

Diagnosis

Presbyopia is officially diagnosed during an **eye examination** conducted by optometrists (O.D.s) or ophthalmologists (M.D.s).

O.D.s or M.D.s, with the help of ophthalmic assistants, should perform a comprehensive eye exam to diagnose the condition. The assistant should take a detailed patient history prior to the exam. This is especially important when diagnosing premature presbyopia.

The optometrist or ophthalmologist, or in some cases a highly trained assistant, will begin the ocular examination by testing visual acuity and refraction. During the exam the clinician will also determine ocular motility and alignment, nearpoint of convergence, near fusional vergence amplitudes, relative accommodation measurements, accommodative amplitude and facility of accommodation.

To further determine presbyopia, the clinician should perform near retinoscopy and intermediate distance testing, which can be performed with a phoropter or trial lens.

There are five different types of presbyopia:

- Incipient presbyopia is the earliest stage in which symptoms are documented. Usually the patient has trouble

reading small print, but may perform well on testing and may actually reject a near vision prescription.

- Functional presbyopia is the point at which patients usually notice the difficulties with near vision. The age when this occurs varies and depends on environment, task requirements, **nutrition**, or general health.
- Absolute presbyopia is the result of continuous gradual decline in accommodation, and is the next phase after functional presbyopia. At this stage, little accommodative ability remains.
- Premature presbyopia is the appearance of the disease at an earlier age than expected because of nutritional, environmental, or disease-related causes. Pharmaceuticals may also be a cause of premature presbyopia.
- Nocturnal presbyopia occurs when accommodation decreases in low-light conditions.

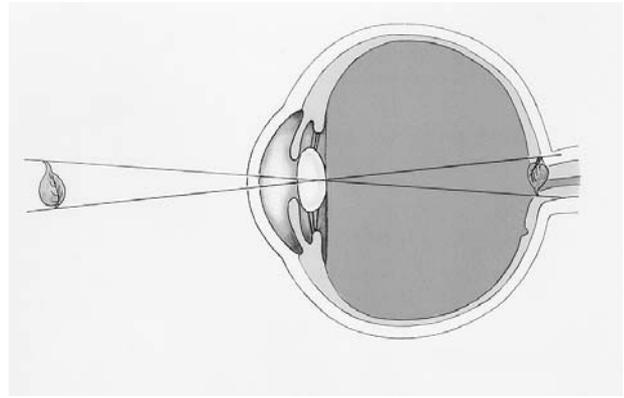

Treatment

Presbyopia cannot be cured, but physicians can help patients compensate for it by prescribing reading, bifocal, or trifocal eyeglasses. A convex lens is used to make up for the lost automatic focusing power of the eye. Half-glasses can be worn, which leave the top open and uncorrected for distance vision. Bifocals achieve the same goal by allowing correction of other refractive errors (improper focusing of images on the retina of the eye).

In addition to glasses, **contact lenses** can be useful in the treatment of presbyopia. Contact lens technicians need to take the patient's medical history to ensure the patient is a good candidate for contact lenses. Some lenses require a greater care commitment, so each patient's expectations need to be discussed before any lens is prescribed.

The two common types of contact lenses prescribed for presbyopia are bifocal and monovision contact lenses.

Bifocal lenses come in two designs, simultaneous vision and alternating vision. Soft and rigid lenses are available in the simultaneous vision design, but only RGP lenses are available in the alternating vision design. Alternating vision lenses behave more like bifocal eyeglasses than the simultaneous design. This alternating lens allows patients to look through two distinct visual zones and adjust their gaze for distance vision or for reading. To prevent rotation while in the eye, bifocal contact lenses use a specially manufactured type of lens. Good candidates for bifocal lenses are those patients who have a good tear film (moist eyes); good binocular vision (ability to focus both eyes together) and visual acuity in each eye; and no disease or abnormalities of the eyelids.

Changes in the elasticity of the lens cause people with presbyopia to lose the ability to focus on close objects.
(June Hill Pedigo/Custom Medical Stock Photo. Reproduced by permission.)

The bifocal contact lens wearer must be motivated to invest the time it requires to maintain contact lenses, and be involved in occupations that do not impose high visual demands. Further, bifocal contact lenses may limit binocular vision. Bifocal contact lenses are relatively expensive, in part due to the time it takes the patient to be accurately fitted.

An alternative to wearing eyeglasses or bifocal contact lenses is monovision contact lenses. Monovision fitting provides one contact lens that corrects for near vision and a second contact lens for the alternate eye that corrects for distance vision. If distance vision is normal, the individual wears only a single contact lens for near vision. Monovision works by having one eye focus for distant objects while the other eye becomes the reading eye. The **brain** learns to adapt to this and will automatically use the correct eye depending on the location of material in view. Advantages of monovision lenses are patient acceptability, convenience, and lower cost.

Several problems exist with the use of contact lenses in the treatment of presbyopia. Physicians need to ask patients to report any headache and fatigue or decrease in visual acuity during the adjustment period. Monovision contact lenses usually result in a small reduction in high-contrast visual acuity and reduced depth perception as compared with bifocal contact lenses. In addition, since monovision corrects one eye for distance and one for eye for near vision, objects at intermediate distances are often out of focus, especially in absolute presbyopia.

Some ophthalmologists are performing laser thermal keratoplasty (LTK) on presbyopic patients. The LTK procedure was approved to treat **hyperopia** in mid-2000, but some surgeons are treating presbyopia as an “off-label” procedure. The LTK procedure takes three seconds per eye and involves no cutting or removal of corneal eye tis-

KEY TERMS

Accommodation—The ability of the eye to change its focus from near to distant objects.

Binocular vision—Using both eyes at the same time to see an image.

Ciliary muscles—The small muscles that permit the lens to change its shape in order to focus on near or distant objects.

Lens (or crystalline lens)—The eye structure behind the iris and pupil that helps focus light on the retina.

Visual acuity—Sharpness or clearness of vision.

sue. Instead, the surgeon uses a holmium:YAG laser to direct eight simultaneous spots of laser energy to the periphery of the cornea to shrink the corneal collagen. The laser heats the corneal collagen and steepens its shape, improving its refractive (focusing) power. Presbyopes receiving this treatment should be advised of regression after possibly just a few years.

Laser-assisted in-situ keratomileusis (LASIK) is another option for presbyopes. Surgeons correct one of the patient's eyes to achieve a monovision effect. This technique allows for good intermediate vision that facilitates reading menus or putting on makeup, but it can cause reduction in binocular distance vision and depth perception.

In preparatory interviews with patients, physicians and ophthalmic assistants should stress that with whatever surgical treatment the patient chooses, there will be regression. The aging process continues and therefore advancing presbyopia is unavoidable.

Prognosis

The changes in vision due to aging usually start in a person's early 40s and continue for several decades. At some point, there is no further development of presbyopia, as the ability to accommodate is virtually gone.

Health care team roles

Nurses, ophthalmic assistants, and well-trained technicians can perform a number of tasks previously required of an ophthalmologist or optometrist. Technicians can assist in diagnosing presbyopia by per-

forming the first-level testing of refraction, as well as taking medical and lifestyle history, retinal photography, automated refractometry, automated keratometry and corneal topography.

Allied health professionals also play an important role in performing the contact lens examination. Before prescribing contact lenses, technicians take a written and oral interview of the patient to determine if the patient is a suitable contact lens candidate. The technician must assess the technical aspects of the patient's ocular status. Next, the technician must discuss the patient's needs and expectations and evaluate all the information to make the correct lens choice. This is especially important for presbyopic patients choosing monovision, as this modality requires a larger commitment from patients.

The physician, or sometimes a contact lens technician, selects the lens material and design, then determines which trial lens is needed. A technician determines the lens parameters by using the results from the trial lens insertion. The patient's palpebral aperture and visual iris diameter are measured to determine the appropriate diameter for the contact lens. The technician will review the findings and make the recommendation to the prescribing physician for the proper contact lenses.

Before the patient is sent home with the lenses, the technician will give a detailed demonstration of inserting, removing, and cleaning the lenses.

Nurses and assistants also prepare patients for surgery by taking history, **blood pressure** and inserting eye-drops. They also may be involved in preparing the surgical areas, especially if surgery is performed in an ambulatory surgery center. Ophthalmic nurses are specially trained to assist in ocular surgeries.

Patient education

Doctors should emphasize with patients the challenges of choosing monovision and bifocal contact lenses to treat presbyopia. Doctors also should stress that surgical procedures are not permanent, and that patients may have to be retreated if regression occurs.

Prevention

There is no known way to prevent presbyopia.

Pressure ulcer

Definition

Pressure ulcers, also commonly known as bedsores, decubitus ulcers, and pressure sores, are among the most serious skin injuries. These tender or inflamed patches

develop when skin covering a weight-bearing part of the body is squeezed between bone and another body part or some other hard object. The ulceration results from the loss of **blood** flow and oxygen (ischemic hypoxia) to the tissues owing to prolonged pressure on a body part.

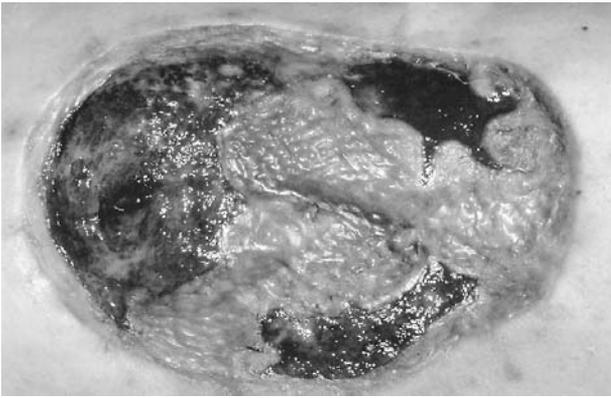

Description

Pressure ulcers are most likely to occur in people who have decreased mobility, including the frail, elderly, or seriously ill. People who have atherosclerosis (artery disease), diabetes, **heart** disease, incontinence, malnutrition, **obesity**, **paralysis**, and **spinal cord** injuries are all at high risk for developing pressure ulcers. This often-painful condition usually begins with shiny red skin that quickly blisters and deteriorates into open sores that can harbor life-threatening infections. These ulcerations are most likely to develop on the:

- ankles
- back of the head
- heels
- hips
- knees
- spine
- shoulder blades

Pressure ulcers usually develop over bony prominences and are graded, or staged, to classify the amount of tissue damage that is observed. These stages are:

- Stage I. The skin is reddened, and the damage may be superficial. The first sign of skin ulceration occurs when pressure squeezes the tiny **blood vessels** that supply the skin with nutrients and oxygen. The area does not return to its normal appearance after the source of pressure is removed.
- Stage II. There is partial-thickness skin loss involving the epidermis (outer layer), the dermis (inner layer), or both. The skin is blistered, peeling, or has a shallow crater, though the damage is still minor.
- Stage III. There is full-thickness skin loss involving damage to, or necrosis (death) of, the subcutaneous (under the skin) tissue. It may extend down to, but not through, the underlying fascia (connective tissue). This type of ulcer usually appears as a deeper crater. Drainage may be seen.
- Stage IV. Full-thickness skin loss is present, with extensive tissue destruction and damage to muscle, bone, or the supporting structures such as tendons. This stage of ulceration is associated with high morbidity.

Bed sore. (Photograph by Michael English, M.D., Custom Medical Stock Photo. Reproduced by permission.)

Causes and symptoms

The primary risk factors leading to the formation of a pressure ulcer include all of the following:

- **Pressure.** Very intense pressure, even if it occurs for a short time, may cause a pressure ulcer. Less intense pressure that lasts over a long period of time may also cause ulceration.
- **Friction.** This phenomenon occurs when two forces move against each other. When a patient's skin is dragged or pulled over bed sheets, friction occurs, with possible tissue injury resulting. This friction injury often happens when a patient is pulled, instead of lifted, up in bed.
- **Shear.** Deeper than a friction injury, shear happens when the skin located over a bony prominence slides over a hard surface. The skin and surrounding structures remain in one position because pressure keeps the skin stuck to a surface such as bed sheets. The shearing literally tears at the skin, the subcutaneous layer, and the muscle as well. Deep tissue injury and vascular damage may occur.
- **Tissue maceration.** Prolonged moisture on the skin can decrease the skin's resiliency and alter its pH (the measure of acidity and alkalinity).

Pressure ulcers usually develop in six stages:

- erythema
- erythema, swelling of tissue, and possible peeling of the outer layer of skin
- dead skin, draining wound, and an exposed layer of subcutaneous tissue
- tissue necrosis through the skin and subcutaneous layers, into the muscle
- inner fat and muscle necrosis

- destruction of bone, local infections, and potential for sepsis

Diagnosis

Physical examination, medical and nursing history, and patient and caregiver observation are the basis of diagnosis. Special attention must be paid to any physical or mental impairment such as incontinence or confusion that could complicate a patient's recovery. Staging is done based on the wound's characteristics and depth of soft tissue damage. Correct staging can only be done after all necrotic (dead) tissue has been removed, allowing for complete inspection of the wound bed (area). According to the National Pressure Ulcer Advisory Panel, once a particular stage (I, II, III, or IV) has been assigned to a pressure ulcer, it will always remain at that stage. Although pressure ulcers will heal to progressively more shallow depths, they do not replace the lost muscle, fat, or dermis. Instead, the ulcer is filled in with scar tissue. Therefore, when a Stage IV ulcer has healed, it should be classified as a healed Stage IV ulcer, not a Stage 0 ulcer.

Treatment

The desired outcomes of pressure ulcer treatment are to protect the remaining healthy cells, heal the ulcer completely, and prevent the formation of other pressure ulcers. If addressed promptly, surface pressure ulcers can be prevented from developing into more serious **wounds.**

Pressure ulcer management contains four basic components:

- **Debridement.** This is a procedure that involves the removal of dead tissue or other debris from the wound. Debridement can be done by a sharp method, where the tissue is actually cut out with a scalpel or other sharp instrument; and is usually performed by a physician, physician's assistant, or an advanced practice nurse. Another method is mechanical debridement, which utilizes wet-to-dry dressings, wound irrigation, and dextranomers (beads placed into the wound bed to absorb drainage). Enzymatic debridement utilizes certain topical debriding agents to help remove the dead tissue. Autolytic debridement uses synthetic dressings that help the involved tissue self-digest from enzymes that are contained in wound fluids. This last-mentioned method should not be used for infected pressure ulcers.
- **Cleansing.** Normal saline is the recommended solution for cleansing wounds because it does not harm the wound bed, and it adequately cleanses the majority of wounds. Such solutions as hydrogen peroxide, povi-

done iodine, iodophor, and acetic acid are cytotoxic (toxic to cells), and should not be used. There are several commercially prepared wound cleansers containing surfactants (surface-active substances) and other ingredients, but these may also have some toxic effects on the cells. In order to minimize wound damage during cleansing, appropriate irrigation methods should be used. Too little pressure, such as that produced with a bulb syringe, yields poor results; while too much pressure will cause damage to healthy tissue. Irrigating the ulcer using a 35-ml syringe with a 19-gauge angiocatheter will usually provide enough pressure to get rid of eschar (scabs), **bacteria**, and other debris. In addition, the use of daily whirlpool treatments may help facilitate the removal of necrotic tissue.

- **Infection** management. Because of the various factors that may affect a patient's resistance to infection, the patient should be closely monitored for any signs of infection in the wound so that **antibiotics** can be initiated promptly. These signs include a sudden deterioration of the ulcer; changes in the color or texture of the granulation (new capillaries formed on the surface of a wound in healing) tissue; or alterations in the amount or appearance of the wound drainage. In addition, any increase in redness, **edema**, or tenderness of the ulcerated area should be reported to the physician.
- **Dressings**. When selecting a dressing for a pressure ulcer, the most important factor is the ability of the dressing to keep the wound bed moist and the surrounding healthy, intact skin dry. There are numerous types of dressings available; and selecting one should be a determination based on the preference of the physician and nurse, the time available to perform **wound care**, and the specific conditions of each wound.

Other adjunctive treatments that promote healing include electrical stimulation, ultrasound, hyperbaric (high pressure) oxygen, and laser irradiation. If there is extensive tissue necrosis, or if there are signs of infection, the physician may order topical and/or systemic antibiotic treatment. Very deep ulcers that do not respond to treatment may require skin grafts or plastic surgery.

Many patients are interested in complementary or alternative treatments, and several have been suggested in the treatment of pressure ulcers. **Zinc** and **vitamins A, C, E, and B** complex help skin repair injuries and stay healthy, but large doses of vitamins or **minerals** should not be used without consulting a physician. Various herbal remedies, including a tea tree oil rinse and an herbal tea made from the calendula plant, may act as anti-septic agents. Again, the physician or health care profes-

KEY TERMS

Cytotoxic—The characteristic of being destructive to cells.

Ischemia—The temporary deficiency of blood flow to a tissue or organ.

Necrotic—Relating to the death of a portion of tissue.

sional should be consulted when considering any of these treatments.

Prognosis

With prompt, appropriate treatment, pressure ulcers should begin to heal in two to four weeks. If the ulcer exhibits no signs of progress in three weeks, the treatment plan should be reevaluated. The National Pressure Ulcer Advisory Panel recommends that if a non-healing wound is clean, then the ulcer should be treated with topical antibiotics. If the bedsore still does not respond within two weeks, then other factors need to be explored.

Health care team roles

Several members of the health care team are important when treating the patient with a pressure ulcer. The physician orders treatment and performs any necessary surgical interventions. The nurse plays a primary role in assessing the wound and administering treatment; consulting with the physician on wound care decisions; and providing **patient education**. Physical therapists may also participate in pressure ulcer care by providing whirlpool treatments.

Prevention

It is usually possible to prevent pressure ulcers from forming and/or worsening. A variety of measures can be taken to accomplish this goal. At-risk individuals should be identified. These individuals include those with a history of previous pressure ulcers, since healed full-thickness pressure ulcers have only 80% of the strength of non-injured skin. A systematic skin assessment should be performed daily on all patients at risk for ulcer formation. Because a health care professional may not be available to assess homebound patients, the family or other caregivers should be educated on the symptoms of early skin breakdown and on when to notify their health care professional.

Other methods of pressure ulcer prevention are:

- Always cleanse the skin of incontinent patients at the time of soiling.
- Moisturize dry skin to keep it well hydrated.
- Turn and reposition the patient at least every two hours. Keep a turning schedule posted at the bedside.
- Utilize proper patient positioning, lifting, and transferring methods to avoid friction and shear. Use a lift sheet when moving the patient.
- Use pillows or cushions to pad bony prominences and support limbs.
- Consider using an alternating pressure mattress or other support surface designed to reduce pressure on the skin.
- Do not massage bony prominences, as this practice could cause deep tissue damage.
- Encourage adequate consumption of protein, calories and fluids.
- Maintain or improve the patient's activity level. Perform range of motion exercises, if possible.
- Instruct the patient, family, and any other caregivers regarding appropriate preventative care.

Preterm labor

Definition

Preterm labor is characterized by contractions or irritability of the uterus between weeks 20-36 of gestation that cause effacement and/or dilatation of the cervix.

Description

The usual length of a human **pregnancy** is from 37 to 42 weeks after the first day of the last menstrual period. The baby is more likely to survive and be healthy if it remains in the uterus for the full term of the pregnancy. Between eight to ten percent of births in the United States are preterm births. Preterm labor is the greatest cause of newborn illness and death in the United States.

Causes and symptoms

The causes of preterm labor are often not identifiable. Women with a previous history of preterm labor have the highest risk of developing it again, between 17 and 37%. Other risk factors are: low socioeconomic status, minority race, maternal age less than 18 or greater than 40, premature rupture of membranes (bag of waters), multiple gestation (twins, triplets, etc.), harmful maternal behaviors (smoking, drug use, alcohol use, no **prenatal care**), uterine abnormalities (fibroid tumor, abnormally shaped uterus, incompetent cervix, exposure to diethylstilbestrol—their mothers took DES when they carried them), infectious causes (**infection** of the uterus, kidney infection), fetal causes (intrauterine fetal death, intrauterine growth retardation, birth defects), and abnormal implantation of the placenta.

The symptoms of preterm labor can include contractions of the uterus or tightening of the abdomen occurring every 10 minutes or more often. The uterine contractions of preterm labor, sometimes painful, will usually increase in frequency, duration, and intensity. Other symptoms associated with preterm labor can include menstrual-like cramps; abdominal cramping with or without **diarrhea**; pressure or **pain** in the pelvic region; low backache; or a change in the color or amount of vaginal discharge. As labor progresses the cervix, the opening of the uterus, will open (dilate) and the tissue around it will become thinner (efface). Premature rupture of membranes (when the water breaks) may also occur.

An occasional contraction can occur anytime during pregnancy and does not necessarily indicate that labor is starting. Premature contractions are sometimes confused with Braxton-Hicks contractions, which can occur throughout the pregnancy. Braxton-Hicks contractions do not cause the cervix to open or efface and are considered "false labor."

Diagnosis

The health care provider will conduct a pelvic examination and ask about the timing and intensity of the contractions. A physician or nurse will conduct a vaginal examination and determine if the cervix has started to

dilate or efface. An ultrasound technician may proceed with a transvaginal ultrasound (ultrasound of the vagina by use of a probe that is inserted into the vagina), to measure cervical length. A cervical length of < 0.98-1.18 in (2.5-3.0 cm) is associated with preterm labor.

Urine may be collected to screen for infection. A cervical culture or a wet smear may also be done to look for infection. Presence of fetal fibronectin in vaginal and cervical secretions, between 24 and 24 weeks gestation, may indicate impending preterm labor. Fibronectin is a substance that functions as an adhesive between the fetal membranes and the underlying decidua.

A fetal **heart** monitor is placed on the mother's abdomen to record the heartbeat of the fetus and to time the contractions. Occasionally the woman will have home monitoring of contractions and fetal activity.

A fetal ultrasound may be performed to determine the age and weight of the fetus, the condition of the placenta, and to see if there is more than one fetus present. Another test, **amniocentesis**, may be done to determine if the baby's **lungs** are mature. During an amniocentesis, a needle-like tube is inserted through the mother's abdomen into the uterus to draw out some of the fluid surrounding the fetus (amniotic fluid). Analysis of the amniotic fluid can determine if the baby's lungs are mature. A baby with mature lungs is much more likely to survive outside the uterus.

Treatment

The goal of treatment is to stop preterm labor and to prevent the fetus from being delivered prior to term. A first recommendation may be for the woman with premature contractions to lie down and to drink water or other fluids. If contractions continue or increase, medical attention should be sought. In addition to bed rest, medical care may include intravenous fluids. Sometimes, this extra fluid is enough to stop contractions.

In some cases, oral or injectable drugs, like terbutaline sulfate (Bricanyl), ritodrine (Yutopar), magnesium sulfate, nifedipine (Procardia), or indomethacin (Indocin) are administered to delay delivery. When used to treat preterm labor, these medications are called tocolytic agents. Unfortunately, no study has conclusively demonstrated that the use of tocolytic drugs has significantly improved neonatal outcome. Medications used to treat preterm labor can have maternal and fetal side effects. Magnesium sulfate can lead to pulmonary **edema**, profound muscular **paralysis**, and respiratory depression. Terbutaline and Ritodrine can cause arrhythmias and hypoglycemia as well as pulmonary edema. Pregnant

women who are treated with these medications need to be monitored closely in a hospital environment.

An advantage of tocolysis is in delaying delivery so that drugs that will enhance fetal lung maturity can be administered. A delay in delivery also allows for transfer to a tertiary facility that is equipped to care for premature babies. The preferred drugs to stimulate lung maturity are dexamethasone and betamethasone, **corticosteroids** that promote the fetal production of surfactant after 24 hours of administration. The benefit of these corticosteroids will last up to seven days, at which time the medications can be readministered.

If a vaginal or urinary tract infection is detected, antibiotic therapy is usually indicated. **Antibiotics** may briefly prolong the pregnancies of women who have ruptured their membranes.

Prognosis

Once symptoms of preterm labor occur during the pregnancy, the mother and fetus need to be monitored regularly. If the preterm labor cannot be stopped or controlled, the infant will be delivered prematurely. These infants that are born prematurely have an increased risk of health problems, including birth defects, lung problems, mental retardation, blindness, deafness, and developmental disabilities. If the infant is born too early, its body systems may not be mature enough for it to survive. Evaluating the infant's lung maturity is one of the keys to determining its chances of survival.

Health care team roles

Prior to initiating tocolytic medications, it is important to obtain such baseline laboratory test results as **hematocrit**, serum glucose, potassium, sodium chloride, and carbon dioxide levels. An electrocardiogram is frequently ordered because tocolytic drugs can cause an increased heart rate (tachycardia) and sometimes arrhythmias. An external uterine and fetal monitor should be put in place, and often monitors of maternal **vital signs** are also applied. Accurate fluid intake and output measurements are important in detecting the development of pulmonary edema (fluid in the lungs).

Other potentially serious complications of tocolytic therapy include: low **blood pressure** (hypotension), cardiac arrest, respiratory depression, low potassium, high **blood** sugar, maternal death, kidney failure, hepatitis, and gastrointestinal bleeding.

Ritodrine is a drug that is sometimes used in the management of preterm labor. To administer the medication accurately, it should be delivered as a piggyback to a main intravenous solution that goes through an infusion

KEY TERMS

Braxton-Hicks contractions—Tightening of the uterus or abdomen that can occur throughout pregnancy. These contractions do not cause changes to the cervix and are sometimes called false labor or practice contractions.

Cervix—The opening at the bottom of the uterus, which dilates or opens in order for the fetus to pass into the vagina or birth canal during the delivery process.

Contraction—A tightening of the uterus during pregnancy. Contractions may or may not be painful and may or may not indicate labor.

Decidua—The part of the lining of the uterus that sloughs off during menstruation.

pump and a microdrip tubing set. To avoid hyperglycemia, a potential side effect, the woman should receive few IV solutions containing dextrose. The ritodrine drip is increased gradually, usually every 10 minutes until uterine contractions cease, the maximum dose is reached, and/or side effects become too intense. The nurse should assess the patient's vital signs every 15 minutes during titration, and then every 30 minutes until uterine contractions stop. Ask the patient to inform the health care provider if she starts to experience any chest pain or shortness of breath. The health care provider should listen to the lungs for any abnormal breath sounds that could indicate the development of pulmonary edema. A heart rate greater than 120 beats per minute (bpm), a blood pressure lower than 90/60, and any cardiac arrhythmias should be reported immediately. Continue to monitor laboratory values every four hours. The fetal response to contractions and medication administration should be monitored continuously. Closely monitor daily weights to assess for possible pulmonary edema resulting from fluid retention. If therapy with ritodrine is successful in halting uterine contractions, then oral administration of ritodrine or terbutaline will often be ordered. Other tocolytic medications that are delivered in a similar manner are magnesium sulfate, subcutaneous terbutaline, nifedipine, and indomethacin.

Patient education

Health care professionals should educate all pregnant women about the signs and symptoms of preterm labor, ensuring an understanding of even the more subtle symptoms. Pregnant women should be alert for symptoms that

could be indicative of preterm labor, such as constant, dull, low back pain; vaginal spotting; pelvic pressure and/or tightening of the abdomen; increased vaginal discharge; and intestinal-like cramping.

Pregnant women who are at home on bed rest should be given the following instructions:

- Stay on bed rest except to get up to use the bathroom.
- Drink eight to ten glasses of liquids a day.
- Do not engage in such activities as nipple stimulation that could trigger contractions.
- Do not engage in sexual activities, including masturbation.
- Promptly inform the health care provider if the membranes rupture (sudden gush of vaginal fluid) or if there is any vaginal bleeding.
- Communicate to the health care provider any symptoms of a urinary tract infection (burning on urination and frequent urination) or of a vaginal infection (vaginal burning, itching or discomfort).

Prevention

Smoking, poor **nutrition**, and drug or alcohol abuse can increase the risk of premature labor and early delivery. Smoking, drug and alcohol use should be stopped. A healthy diet and prenatal vitamin supplements (prescribed by the health care provider) are important for the growth of the fetus and the health of the mother. Pregnant women are advised to see a health care provider early in the pregnancy and to receive regular prenatal examinations throughout the pregnancy. The health care provider should be informed of any medications that the mother is receiving and any maternal health conditions.

Preventive dentistry

Definition

Preventive dentistry is the area of dentistry that focuses on those procedures and life practices that help people to prevent the beginning or progression of oral disease. It includes at-home dental care performed by patients, as well as dental care and education by professional dental staff in the office or clinic.

Purpose

Preventive dentistry includes two aspects of dental care, both performed to help patients avoid dental disease or to catch it in its early, more treatable stages. In part, it is the **oral hygiene** care performed by the patient at home. Preventive dentistry also encompasses what is done by the dental staff in their offices to help patients maintain healthy teeth and gums. In either case, the objective is to stop the development of oral disease or to find it at an early stage. Dental health professionals most often look for early signs of periodontal disease, dental decay, and other changes in the soft tissue of the mouth that could lead to **oral cancer**.

Precautions

Preventive dentistry should always be prescribed and not harm patients when done correctly. At times, dentists do need to take precautions when someone has a medical condition that would be affected by some of the procedures. Dentists need to be aware of certain medical conditions, such as mitral valve prolapse, which need to be treated with prophylactic **antibiotics**. **Allergies** to any of the medications or materials used in preventive dentistry are rare.

Description

Preventive care in a dental office includes prophylaxis, or the cleaning of the teeth, which removes accumulations of calculus. It includes examination of the teeth and soft tissue, using visual and tactile exams, radiographic examination, such as x rays, and oral **cancer** screening. Newer techniques to diagnose periodontal, or gum disease, include computerized measurement devices that measure the bacterial content in the mouth. Sometimes, dentists prescribe medications to help prevent dental disease. These include anti-inflammatory mouthwashes to prevent periodontal problems.

Preventive procedures often performed by dentists for children include the use of fluoride supplements and applications. Dentists apply dental sealants to children's

teeth, forming a barrier between tooth crevasses and **bacteria** to help ward off dental decay. Dental health professionals also look for malocclusions, and might refer patients to a dental specialist, such as an orthodontist, to correct a patient's bad bite. Experts state that children should be evaluated by an orthodontist by age seven.

An important part of preventive dentistry performed by dental professionals is educating patients about at-home care, **nutrition**, and smoking cessation. At-home procedures performed by patients that help ward off dental disease include regular and proper brushing, flossing and sometimes use of mouth rinses and at-home fluoride applications. Dentists and their staff explain proper brushing and flossing techniques. Proper brushing includes use of a soft nylon toothbrush with round-ended bristles. Patients should place the bristles along the gum line at a 45-degree angle to cover the tooth surface and gum line. The brushing technique should be gentle and in a rolling back-and-forth motion, with two to three teeth being brushed at a time. Patients should brush the inner surfaces of their teeth and tilt the brush vertically to brush the front teeth. Ideally, patients should use a back-and-forth motion to brush the biting surface of the teeth and the tongue. Flossing removes plaque from between teeth and at the gum line. It should be done with an 18-inch strip of floss wrapped around the middle fingers of each hand. The remaining one to two inches of floss that is inserted between the teeth should be directed by the thumbs. By keeping the floss taut, patients can use their index fingers to guide the floss between the lower teeth with a gentle zig-zag motion, while contouring the floss around the sides of the teeth. They should floss each tooth with a clean section of the floss and ensure that the floss goes under the gum line.

Preventive dental care should begin in infancy, within the first year of life before teeth first appear, and continue throughout life. Even before teeth erupt, parents can clean infants' gums after feeding. Preventive care in adolescence includes brushing and flossing, as well as wearing custom-made mouth guards to protect the teeth during contact sports. Considering that 75% of Americans have some form of dental disease, regular dental visits are particularly important for adults. Seniors often benefit from training in proper techniques of **denture care** and cleaning, which include brushing the replacement teeth. Those who have problems moving their hands because of arthritis, for example, also benefit from tips for adapting toothbrushes for easier handling.

KEY TERMS

Calculus—A hard deposit formed when teeth are not brushed properly.

Dental decay—The destruction of the tooth enamel.

Fluoride—A naturally occurring mineral in all water sources, which effectively prevents and reverses the early signs of tooth decay.

Malocclusion—Bad bite.

Periodontal disease—Gum disease, which is an infection of the soft tissues supporting the teeth.

Plaque—The thin, sticky film of bacteria that grows on teeth.

Prophylaxis—Dental cleaning.

Results

The results of good preventive dental care are healthy teeth and gums throughout one's life and the early detection of oral disease. Preventive procedures, such as fluoride applications and sealants, can prevent tooth decay. Regular dental checkups and oral cancer screenings can catch oral cancer at its most treatable stages. Dental checkups and consistent at-home preventive dental care can stave off caries (tooth decay) and periodontal disease, which can lead to tooth loss. An estimated 75% of adults have periodontal disease. Regular dental checkups can reduce the risk of permanent tooth and gum damage, and expensive treatment in the future. As a result of preventive dental care, people tend to keep their original teeth throughout life and don't need as much restorative dental work. Preventive dental examinations also ensure that a dentist will notice any oral signs of systemic disease. A dental checkup might reveal a lesion in the mouth that could lead to a referral to a physician for further investigation.

Treatments resulting from preventive dental procedures are designed to stop the process of the disease. Restorative dentistry, including the placement of fillings, crowns, and dental work, addresses tooth decay and tooth loss that can result from periodontal disease. Periodontal treatments help restore healthy gums and can prevent tooth loss.

Health care team roles

The dentist oversees the process of examination, diagnosis, treatment planning, and education. The allied

dental personnel include the dental hygienist and dental assistant. Dental hygienists sometimes perform preventive techniques, including cleaning, fluoride and sealant application, and **patient education**. The dental assistant in some states, depending on state licensing, can perform many of the same procedures as the hygienist, assist the dentist during checkups, and provide patient guidance and education.

Private insurance plans

Definition

Private insurance plans include all forms of health insurance that are not funded by the government. These plans are intended to protect their beneficiaries from the high costs that may be incurred for health care. Most private insurance plans in the United States are employment-based; of the 194 million Americans who were covered by private health insurance in 1999, 172 million, or 89%, were enrolled in employment-based plans.

Description

Private health insurance plans may be purchased on an individual or a group basis. Most group plans are offered by large employers, although some are offered by voluntary associations. Individual policies are usually more expensive than group policies; they may also have additional coverage restrictions.

There are several major categories of private health insurance in the United States.

Indemnity plans

Indemnity plans are private insurance plans that allow beneficiaries to choose any physician or hospital when they need medical care. Most indemnity plans have a deductible, or amount that the policyholder must pay before the plan will pay any benefits. After the deductible, indemnity plans pay a co-insurance percentage, most often 70%–90% of the charges. The beneficiary pays the remainder of the bill.

Preferred Provider Organization (PPO) plans

PPO plans are like indemnity plans in that they usually have both a deductible and a co-insurance percentage. Unlike indemnity plans, however, PPOs offer beneficiaries a list of physicians and hospitals from which they must select in order to receive the plan's maximum benefit. PPOs tend to be less expensive than indemnity plans because health care providers are often willing to reduce their fees in order to participate in these plans. Many large companies have moved their insured employees into PPOs because of their cost effectiveness.

A person enrolled in a PPO can choose to go “out of network” and continue under the care of their present physician. They may also propose their physician for membership in the PPO so that continuity of service can be provided.

Health Maintenance Organization (HMO) plans

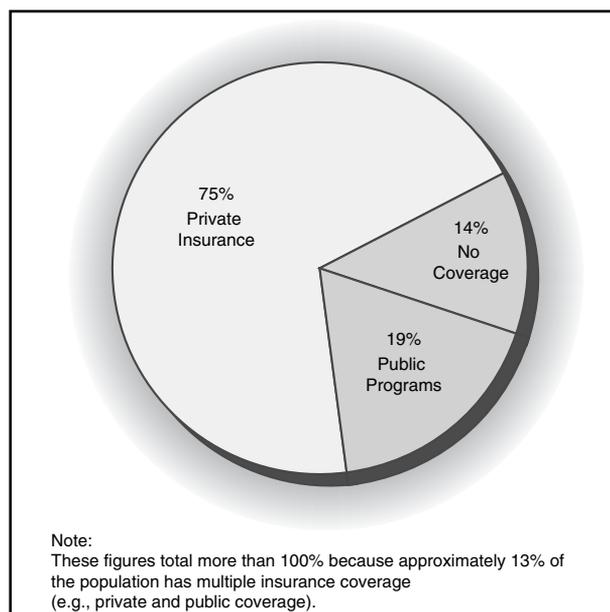

HMOs usually have no deductibles; the beneficiary is charged a small co-payment, typically \$5 or \$10, per visit, and the plan covers all other charges. Beneficiaries are, however, usually offered a much smaller list of health care providers from which to choose. In most HMOs, each beneficiary selects a primary care doctor who is responsible for all health care needs. Referrals to specialists must be made through the primary care doctor. Like PPOs, HMOs are usually able to charge lower premiums because their health care providers agree to substantially reduced fees.

Long-term care (LTC) insurance

Long-term care insurance, or LTC, is a type of private health insurance intended to cover the cost of custodial or nursing **home care**. It can be very expensive, and persons considering this form of insurance should not purchase it if the premiums would cause financial hardship in the present.

Medigap insurance plans

Medigap insurance plans are private plans intended to supplement **Medicare** coverage, because Medicare

Insurance coverage in the United States. (Delmar Publishers, Inc. Reproduced by permission.)

does not offer complete health insurance protection. There are ten standard Medigap benefit “packages,” identified by the letters A through J, that are available in most states, United States territories, and the District of Columbia. Medigap policies pay most or all of the co-insurance amounts charged by Medicare, and some Medigap policies cover Medicare deductibles.

Medical savings accounts

Medical savings accounts (MSAs) are not health insurance plans in the strict sense, but offer a partial alternative to expensive individual private insurance plans. MSAs are similar to Individual Retirement Accounts (IRAs) and have been considered a significant tax break for self-employed individuals. They were created as a four-year pilot project by the Health Insurance Portability and Accountability Act (HIPAA) of 1996. The federal government issued an extension on these accounts for two years, effective December 31, 2000. The government will not revoke these accounts once they have been opened.

An MSA must be combined with a qualified high-deductible private health plan. Without an MSA, a self-employed individual can deduct qualified medical expenses only under the itemized deductions of a 1040 tax form; and the expenses must exceed 7.5% of the adjusted gross income.

KEY TERMS

Co-insurance—The percentage of health care charges that an insurance company pays after the beneficiary pays the deductible. Most co-insurance percentages are between 70% and 90%.

Deductible—An amount of money that an insured person is required to pay on each claim made on an insurance policy.

Indemnity plans—Private health insurance plans that allow the policyholder to choose any physician or hospital when health care is needed.

Long-term care (LTC) insurance—A type of private health insurance intended to cover the cost of long-term nursing home care or home health care.

Medigap—A group of ten standardized private health insurance policies intended to cover the coinsurance and deductible costs that Medicare does not cover.

Portability—A feature that allows employees to transfer health insurance coverage or other benefits from one employer to another when they change jobs.

Preferred provider organizations (PPOs)—Private health insurance plans that require beneficiaries to select their health care providers from a list approved by the insurance company.

Premium—The amount paid by an insurance policyholder for insurance coverage. Most health insurance policy premiums are payable on a monthly basis.

Viewpoints

The high cost of health insurance

The cost of private health insurance has risen steadily over the past two decades, largely because of the rising cost of health care in the United States. Between 1980 and 1995, the total amount spent on health care in the United States rose from \$247.2 billion to \$1.04 trillion, more than a 400% increase. The reasons for the escalating costs include the following:

- Increased longevity. The life expectancy of most Americans is around 75 years. When older people join an insured group, the whole group's health care risks and costs rise.
- Advances in medical technology. New technology is often expensive.

- Increased use of health care. Between 1991 and 1996, the average number of visits to doctors' offices rose from 2.7 per person to 3.4.

The rising costs of health insurance over the past thirty years have caused many employers to curtail or drop health insurance as an employee benefit. The cost of health insurance premiums increased from \$16.8 billion in 1970 to \$310 billion in 1995. Some employers have increased the amount of money that employees are expected to contribute toward their health care. Others, particularly smaller businesses, do not offer insurance at all. A 1997 study found that only 34% of workers in smaller businesses were covered through their employers, whereas 82% of employees in the largest companies were covered. Workers in large-employer health insurance plans are also more likely to have policies that cover more health services, policies with lower deductibles, and more opportunities to enroll in HMOs.

The uninsured

The U. S. Census Bureau reported in 1997 that 43.4 million people in the United States, or 16.1% of the population, had no health insurance coverage. Between 1998 and 1999, both the number and the proportion of uninsured Americans declined slightly, to 42.6 million and 15.5% respectively.

Some workers do not have health insurance because they cannot afford it. In the 1950s, employer-based health insurance served most American families reasonably well because many workers were employed by large firms and remained with them for life. Over the past two decades, however, more and more people are employed by small firms that do not offer health insurance as a benefit, and more workers move from company to company every few years. Most uninsured workers are either self-employed, work only part-time, or work in low-wage jobs that do not give them access to lower-cost employer-sponsored group plans. At the same time, workers in these three categories do not qualify for coverage by government programs for low-income people.

The other major category of uninsured people includes those who cannot purchase private insurance at affordable rates because they are likely to need expensive medical services. Those who have a high risk of developing **cancer** or are HIV-positive may not be able to obtain coverage from any insurance company. Some insurance companies began introducing so-called "preexisting condition" clauses in their policies as early as the 1980s that denied private insurance to anyone already diagnosed with a serious medical condition. The Health Insurance Portability and Accountability Act of 1996 was intended to help workers who could not change their jobs

because they had family members with serious health problems. They would be denied health insurance by the preexisting condition clauses in the plan offered by their new employer. HIPAA requires employer-sponsored insurance plans to accept transfers from other plans without imposing preexisting condition clauses.

An individual private health insurance plan can be expensive and restrictive. It may, however, be the only choice for a consumer who is not employed; is self-employed; or is a new hire at a company and must wait for several months or more before the company's coverage takes effect.

Tax credit proposals

One approach to the rising costs of private health insurance that is gaining bipartisan political support is to offer tax credits that would allow more Americans to purchase health insurance. The present federal tax code favors workers who already have employer-sponsored health insurance. Supporters of the tax credit approach maintain that it would give workers a wider choice of health plans; create greater portability of health insurance; and encourage groups other than employment-based populations (e.g., church groups, unions, fraternal organizations, etc.) to sponsor insurance plans for their members.

Professional-patient relationship

Definition

The professional-patient relationship is a bond of trust between the patient and the medical professional who is performing treatment.

Description

The relationship established between patients and health care providers is fiduciary in nature, which means that it is based on trust. In this respect it is similar to the relationships between lawyers and clients or between clergy and their congregations. The professional trusts the patient or client to disclose all the information that may be relevant to his or her condition or illness, and to be truthful while disclosing it. In return, the patient or client trusts the health care professional to maintain high standards of competence; to protect the confidentiality of private information; and to carry out his or her work in the best interests of the patient rather than taking advantage of the patient's vulnerability.

Ethical principles

Health care professionals are obligated to act according to ethical and legal standards. Ethical guidelines refer to the moral standards that are considered to govern health care. The fundamental ethical principles underlying Western medical practice have not changed since they were first enunciated by Hippocrates (460-377 BC). These principles include:

- **Honesty:** The professional does not withhold necessary information from the patient or lie to the patient about the nature or seriousness of his or her condition.
- **Beneficence (doing good):** The professional uses his or her knowledge and skills to balance good results and potential harms, and act in the patient's best interests.

- Justice. The professional does not refuse treatment on the basis of a patient's race, religion, nationality, income, or other personal characteristic.
- Avoiding conflicts of interest. This principle means that the professional must not benefit personally from his or her professional actions or influence. For example, a physician should prescribe a particular medication because it is the best choice for the patient, not because the professional owns stock in the company that manufactures the drug.
- Pledging to do no harm. This principle means that the professional must avoid actions detrimental to the patient.

All major organizations of health care providers, including the American Hospital Association, the American Medical Association, the American Dental Association, and the American Nurses Association have formal ethical guidelines for professional-patient relationships. These ethical policy statements are based on the ancient Hippocratic oath.

Legal obligations

In the United States and Canada, the legal obligations of health care providers are based on and presuppose the traditional ethical standards of good medical practice. These legal obligations include accepting federal and state examination and licensure standards; government regulation of **medical records**; court orders regarding reporting or disclosure of a patient's medical records; and a number of other obligations.

The legal obligations and liabilities of health care professionals have become increasingly complex over the last 30 years. This development is partly the result of technological advances that pose new questions to the legal system. For example, the safe operation of **medical lasers** depends on proper engineering and maintenance procedures as well as on the surgeon's skill and training in using the laser. A patient injured by a malfunctioning laser might decide to sue the manufacturer and the **hospital administration** as well as the surgeon. In addition, however, the growing complexity of health care legislation is part of a larger trend toward resolving social issues through litigation rather than through public debate or other means.

Viewpoints

Historical background

Prior to the second half of the twentieth century, the patient-physician relationship was strictly hierarchical. The physician was assumed to know what was best for the patient, and the patient was expected to follow "doc-

tor's orders." After World War II, however, patients in the developed countries began to take a more active role in their health care. This change was related to the larger proportion of high-school students going on to college, and to the rapid spread of medical information via television and health care books written for the general public. Patients who were employed in other fields requiring specialized training, or who read widely, were less impressed by the physician's educational credentials and more likely to question his or her advice.

The social context of contemporary health care

In addition to the rise in education level among the general population in Europe and North America, several other factors have helped to reshape patient-professional relationships. The most important factors are the following:

- The loss of a social consensus regarding moral issues. At one time, health care professionals could be fairly sure that they and their patients agreed on the major moral issues that were likely to arise in health care situations. Today, however, there is widespread disagreement within the professions as well as in the general population about such questions as abortion, **euthanasia**, organ donation, limitations on medical research, and others. A patient who disagrees with his or her health care provider on the moral implications of a procedure is now generally allowed to refuse the procedure.
- The high-pressure education of health care professionals. Over the past thirty years, the training of physicians, nurses, dentists, pharmacists, and other health care professionals has become much more demanding. One factor is the sheer accumulation of scientific knowledge; today's medical, dental, or nursing student must master a much larger body of information than students of previous generations. Another factor is the increased tendency toward professional specialization, which makes it more difficult for health care providers to see patients as whole human beings.
- Managed care. Managed care has changed physician-patient relationships by requiring patients to choose their doctor from a list of providers approved by the managed care organization. In many instances patients have left physicians who were trusted and who had cared for them for years. In other instances managed care organizations have terminated physicians on short notice, thus disrupting continuity of patient care. Some observers have remarked that patients' attitudes toward physicians have become increasingly adversarial because they think doctors are more concerned with

pleasing insurance companies than to provide good care.

- Changes in communications technology. The widespread use of computers in managed care and health insurance organizations to store databases of patient information has raised questions about preserving confidentiality. In addition, the increasing popularity of e-mail for communication between patients and professionals opens up concerns about the security and privacy of electronic files.
- Multicultural issues. Hospitals and medical or dental offices have been increasingly confronted with the complications that can arise in cross-cultural professional-patient relationships. Different ethnic and racial groups in the United States have widely varying customs and attitudes toward such matters as expressing physical **pain** or grief; undressing in front of a professional of the opposite sex; asking questions about their diagnosis and treatment; and other issues that arise in medical settings.

Professional implications

Now, at the beginning of the twenty-first century, the major emphasis of the professional-patient relationship is on the medical professional and the patient as partners making a joint decision about the patient's treatment. Patients have requested and been given more rights concerning their medical treatment. Medical professionals should encourage patients to learn about their medical problems, weigh the benefits of different treatments, and make choices based on their own beliefs and values.

Some specific issues

Recent changes in professional-patient relationships have tended to cluster around several specific issues.

INVOLVEMENT OF FAMILY MEMBERS IN PROFESSIONAL/PATIENT RELATIONSHIPS. Although discussions of professional-patient relationships often proceed as if the relationship concerns only two people, the care provider and the patient, in many cases family members are also involved. In the cases of children and elderly patients, family members may be needed to describe the patient's symptoms or provide care at home. With regard to the elderly, different family members may have sharp disagreements about the level of health care that is necessary, which can complicate the professional's work.

CONFIDENTIALITY. The computerization of patient information, combined with the increasing involvement of federal and state governments in health care, has led some observers to ask whether present security measures

KEY TERMS

Boundaries—The limits that define a human being's personal space. Boundaries may be physical, psychological, emotional, or spiritual.

Confidentiality—The protection and maintenance of strict privacy and secrecy in relationships between professionals and their patients or clients.

Ethics—The rules of conduct recognized as governing a particular group, as medical professionals.

Hippocratic Oath—The ethical pledge attributed to Hippocrates that is used as a standard for care by physicians worldwide.

Rapport—The relation between professional and patient, particularly one that is harmonious and empathic.

are adequate. Both trends—the use of computers and the expansion of government regulation—increase the number of people who have access to patient records and private information.

In the United States and Canada, the courts generally recognize two limitations on the professional's obligation to preserve confidentiality. The first is a court order that requires the physician to deliver confidential information about a patient. The second limitation concerns situations in which a patient is endangering his or her own life or the lives of others.

SEXUAL MISCONDUCT. The most explosive issue in recent years has been the rise in the number of reported incidents of sexual harassment or abuse of patients on the part of health professionals. The two specialties that have studied the issue most carefully are psychiatry and obstetrics-gynecology. Most such incidents (about 85%) involve male professionals and female patients; another 12% involve male professionals and male patients. The remaining 3% involve female professionals.

Studies of sexual misconduct on the part of professionals have reported the following findings:

- The greater degree of patient participation in medical decision-making does not do away with a basic inequality in professional-patient relationships. The patient is dependent on the professional's knowledge and authority, and the professional is obligated not to exploit that advantage.

- People who are seriously ill are emotionally vulnerable. They are less able to protect themselves against violation of their physical or psychological boundaries. Thus they cannot be regarded as “consenting” to a sexual relationship with a health care provider.
- Many adult patients were abused as children and find it difficult to protect themselves in adult life even apart from health crises. In particular, many women have been trained in childhood to be passive and compliant in the face of aggressive or exploitative behavior from men. These patients should not be accused of inviting or “asking for” sexual abuse.
- Some medical procedures appear to be fertile ground for poor communication or misunderstanding between the professional and patient.

Most medical, dental, and nursing schools in the United States and Canada now include courses in professional ethics, communication skills, and understanding of the social context of professional-patient relationships. Students are taught that mutual respect and clear communication between professionals and patients are the most effective safeguards against abuse.

Prophylactic antibiotic premedication

Definition

Prophylactic antibiotic premedication is the practice of prescribing limited antibiotic therapy to dental patients who are at risk of contracting microbial disease as a result of invasive dental procedures.

Purpose

Oral **bacteria** can enter the bloodstream during dental procedures and are normally destroyed by the body’s **immune system**. In certain cases, however, bacteria may settle on abnormal **heart** valves or tissue that has been weakened by surgery or an existing heart problem. Infective **endocarditis**, an **infection** of the endocardium or heart valves, can be the result. Prophylactic premedication with approved **antibiotics** manages and reduces the risk of infection.

A study published in November 2000 has called into question whether antibiotic prophylaxis is necessary for dental treatment. Such treatment, the study concluded, does not seem to be a risk factor for infective endocarditis. The American Dental Association (ADA) and American Heart Association have stated that their current recommendations are valid, although further research is warranted. The ADA’s Council on Scientific Affairs continues to monitor, analyze, and assess research in prophylactic premedication with antibiotics.

The use of prophylactic premedication in oral health care has undergone many changes since its inception. Dosages have been decreased, and the conditions requiring premedication have changed. Premedication for

patients who are recipients of large joint prostheses is no longer universally recommended. Some associations of orthopedists, for instance, state that routine antibiotic coverage is not necessary for patients who have joint prostheses and are undergoing dental procedures. It is recognized, however, that decisions regarding premedication should be made on an individual basis.

Precautions

According to the American Heart Association, endocarditis rarely occurs in people with normal hearts. Certain preexisting heart conditions are susceptible to bacteremia, however. These include:

- an artificial (prosthetic) heart valve
- a history of previous endocarditis
- heart valves damaged (scarred) by such conditions as rheumatic fever
- congenital heart or heart valve defects
- mitral valve prolapse with a murmur
- hypertrophic cardiomyopathy

Description

Procedures affected

Dental procedures for which antibiotic premedication is indicated include those in which bleeding is likely. They include:

- dental extractions
- periodontal procedures, including surgery, scaling and root planing, probing, and periodontal maintenance
- dental implant placement and reimplantation of avulsed (torn out) teeth
- endodontic (root canal) instrumentation or surgery—only beyond the apex
- subgingival placement of antibiotic strips
- initial placement of orthodontic fibers
- intraligamentary local anesthetic injections
- prophylactic cleaning of teeth or implants where bleeding is anticipated
- restorative dentistry with or without retraction cord
- local anesthetic injections
- intracanal endodontic treatment, post-placement and buildup
- placement of rubber dams
- postoperative suture removal

KEY TERMS

Bacteremia—Presence of bacteria in the blood.

Cardiomyopathy—Chronic disorder of the heart muscle that may involve hypertrophy and obstructive damage to the heart.

Endocardium—Membrane lining the chambers of the heart and covering the cusps of the various valves.

Infective endocarditis—A systemic disease characterized by focal bacterial infection of the heart valves, with formation of bacteria-laden vegetation.

Mitral valve prolapse—Downward displacement of the valve between the left atrium and ventricle of the heart.

- placement of removable prosthodontic/orthodontic appliances
- taking of oral impressions, fluoride treatments
- taking of oral radiographs, orthodontic appliance adjustment
- shedding of primary teeth

Dosages recommended

The American Heart Association recommends the following standard regimens for dental treatment in patients at risk of bacterial endocarditis.

- General adult patients: 2 grams amoxicillin (children, 50 mg/kg) given orally one hour before procedure.
- Adult patients unable to take oral medications: 2 grams ampicillin (children, 50 mg/kg) given intramuscularly or intravenously within 30 minutes before procedure.
- Adult patients allergic to amoxicillin, ampicillin, or penicillin: 600 mg clindamycin (children, 20 mg/kg) given orally one hour before procedure. Alternatively, use 2 grams cephalexin or cefadroxil (children, 50 mg/kg) given orally one hour before procedure. Cephalosporins should not be used in patients with immediate-type hypersensitivity reaction to penicillins. Another alternative is 500 mg azithromycin or clarithromycin (children, 14 mg/kg) given orally one hour before procedure.
- Adult patients allergic to amoxicillin, ampicillin, or penicillin who are unable to take oral medications: 600 mg clindamycin (children, 20 mg/kg) intravenously within 30 minutes before procedure. Alternatively, use

1 gram cefazolin (children, 25 mg/kg) intramuscularly or intravenously within 30 minutes before procedure.

Preparation

Antibiotic premedication is given to the patient either one hour (oral) or 30 minutes (intramuscular and intravenous) prior to the procedure.

Complications

When prophylactic premedication is prescribed for dental treatment, prior use of antibiotics should be considered. Resistant organisms may develop, especially if the proposed dental treatment closely follows prior antibiotic exposure. In that case, it is recommended that dentists consult with the patient's physician on the drug chosen and its dosage.

Possible allergic reactions to antibiotics must also be considered. Careful attention to the patient's **health history** is indicated to determine any prior allergy.

Patients who have difficulty swallowing may be given antibiotics intravenously or intramuscularly.

Results

Prophylactic antibiotic premedication manages and reduces the risk of infective endocarditis as a result of dental treatment.

Health care team roles

Dentists prescribing prophylactic antibiotic premedication should consult with the patient's physicians, both general and specialty. When treating a patient with heart problems, for instance, the dentist would contact the patient's cardiologist. In determining whether a patient with a large joint prosthesis should be premedicated, the dentist should confer with the patient's orthopedic specialist.

Every member of the dental team must be aware of the risks of infective endocarditis to their patients. Health questionnaires should be scrutinized at the initial visit to identify patients at risk. On follow-up visits, health histories should be updated.

Proprioceptive neuromuscular facilitation

Definition

Proprioceptive neuromuscular facilitation (PNF) is a rehabilitation technique that was initiated over 50 years ago. It is used to stimulate the neuromuscular system in an effort to excite proprioceptors (sensory organs in muscles, tendons, bones and joints) in order to produce a desired movement.

Purpose

An individual with a neuromuscular disorder may have dyscoordinated movement; that is, movement that is jerky or unsteady. PNF is a specific treatment approach that attempts to make movement more efficient and to improve function during activities of daily living.

Precautions

When using PNF, care must be taken during the movements. Injuries to tendons, muscles, or ligaments can occur if movement is not indicated or is too aggressive.

Description

PNF involves many combinations of motions. The goal is to incorporate postural and righting **reflexes**, which are important for maintaining balance. Usually during PNF motions or patterns, resistance is given, first during the stronger part of the range and followed by the weakest part of the range. Other techniques in PNF have the patient isometrically contract the involved muscle or muscle group (agonist), followed by immediately contracting the muscle or muscle group opposite the involved group (antagonist). This technique is called rhythmic stabilization. Another technique incorporates rhythmic stabilization alternately. Contraction of agonist and antagonist in an alternating fashion is called slow reversal.

PNF is based on flexion and extension, but is performed in diagonal patterns. This practice maximizes neuromuscular facilitation by lengthening the muscle or muscle group as much as possible, thus incorporating the stretch reflex.

There are various types of movement patterns in PNF, including unilateral and bilateral patterns. Unilateral patterns are usually based on one limb, either upper or lower, and can incorporate head and trunk movement. Bilateral patterns are done on either both upper or lower limbs at the same time. There are other techniques within the scope of PNF that are used to facilitate. Facilitatory techniques used to stimulate the neuromuscular system include stretch, traction, approximation, and maximal resistance. Other techniques that require significant participation by the patient are rhythmic stabilization, contract-relax, hold-relax, slow reversal, and repeated contractions.

Complications

Which PNF technique is used in therapy depends on a patient's needs. For example, it would not be advisable to apply a stretch technique to an area of known muscle tearing or around a fracture area. Overstretching a limb with known hypertonicity may cause significant muscle or tendon damage. Care must be taken to minimize stresses placed on muscle, tendon, or joints when known pathology is present.

KEY TERMS

Agonist—The muscle that contracts to create movement or tension. For example, the quadriceps muscles are the agonists in knee extension.

Antagonist—The muscle that opposes the movement being completed. The hamstrings are antagonists to the quadriceps during knee extension.

Dyscoordinated—Movement that is asynchronous, jerky, and unsteady.

Extension—The act of straightening a joint to bring the bones more in line, e.g., straightening the knee or elbow.

Flexion—Bending of a joint, such as bending or flexing the knee.

Postural—Pertaining to the position of the head, neck, trunk and lower limbs in relation to the ground and the vertical.

Proprioceptors—Sensory organs in muscle, tendon, bone, and joint that provide information to the brain about the surrounding environment, such as position.

Righting—The ability to maintain one's head and center of gravity within one's base of support. For example, while standing on a moving bus, an individual adjusts to maintain an upright posture as the bus comes to a stop.

Results

The goal of PNF is to restore neuromuscular function to an individual who presents with impairment to the neuromuscular system. By restoring neuromuscular function, the individual can improve gait, mobility, and self-care. Thus, the goal of PNF is to restore movement, control posture and body awareness, improve coordination, and improve muscle function.

Health care team roles

PNF techniques are typically used by physical and occupational therapists. Nurses and other allied health care professionals must realize that PNF alone does not restore neuromuscular function. Activities of daily living (ADL) must be integrated within the total construct of rehabilitation; that is, during self-care, recreation, and socialization. Nurses and other allied health care professionals must provide an environment that facilitates this integration of rehabilitation with other activities.

Prostate biopsy

Definition

Prostate biopsy is a surgical procedure to remove small samples of prostate tissue for microscopic examination. The prostate gland lies just below the urinary bladder and surrounds the urethra. The gland produces enzyme-rich secretions that contribute to the seminal fluid via ducts that enter the urethra.

Purpose

A prostate biopsy is usually performed to determine whether the patient has **prostate cancer**. Occasionally, it may also be used to diagnose a condition called benign prostatic hypertrophy (BPH), a progressive enlargement of the prostate that may cause obstruction of urine flow in older males.

A prostate biopsy is ordered when other tests have indicated a need to visualize samples of prostate tissue for abnormalities. These tests are the digital rectal examination (DRE) and the prostate-specific antigen (PSA) **blood** test. The DRE is a routine screening test performed by the physician to feel for any enlargement or nodular growth of the patient's prostate. Higher than normal levels of the protein marker PSA can be an indicator of prostate **cancer**. If either the DRE or PSA results are abnormal, the physician may order additional tests, including a prostate biopsy. Computed tomography scans, **magnetic resonance imaging**, and ultrasonograms provide detailed pictures of the prostate and can

also be used to determine the extent and spread of prostate disease. However, a prostate biopsy (examination of the cells of the gland under a **microscope**) remains the most definitive test for diagnosing and staging prostate cancer.

Precautions

A prostate biopsy is ordered only when the physician has used prior diagnostic tools that indicate an abnormal prostate. Prostate biopsies are usually performed by a urogenital system specialist (urologist). Special precautions will be required before the biopsy if the patient has a history of abnormal bleeding or is currently taking a blood-thinning medication.

Description

According to the American Cancer Society, next to skin cancer, prostate cancer continues to be the most commonly diagnosed cancer in American men. Prostate biopsies are usually performed in one of two ways. They can be performed by inserting a needle through the wall of the rectum or by inserting a needle through the perineum (the area between the base of the penis and the rectum). The patient may be given a sedative to help him relax. In preparation for the biopsy the patient will have an enema, and will begin antibiotic therapy to prevent an **infection**.

Needle biopsy via the rectum

This procedure, called a transrectal ultrasound-guided biopsy, is the most commonly performed type of prostate biopsy, and can usually be performed in the physician's office without **general anesthesia**. The patient is asked to lie on his side or on his back with his legs in stirrups. Local anesthetic is administered, and the urologist uses a thin needle attached to a spring-loaded gun directed by ultrasound to collect samples from the prostate. The gun is able to insert and remove the needle into the prostate tissue rapidly, creating less discomfort and trauma for the patient. The procedure can often be completed within 30 minutes. Usually the tissue samples are obtained by fine-needle aspiration, as opposed to larger core tissue samples that create more discomfort for the patient.

Needle biopsy via the perineum

If the chances of a complication for the patient are too great for the transrectal ultrasound-guided biopsy, the urologist may choose another route through the perineum for access to the prostate. The skin of the perineum is thoroughly cleansed and a local anesthetic is injected at

the site where the biopsy is to be performed. Once the area is numb, the physician makes a small (1 in/2.5 cm) incision in the perineum. The physician places one finger in the rectum to guide the placement of the biopsy needle, and the needle is then inserted into the prostate. A small amount of tissue is collected and the needle is withdrawn. The needle is then reinserted into another part of the prostate and another sample of tissue is collected. In this manner, samples are collected from several areas. After the procedure, pressure is applied at the biopsy site to stop bleeding. The patient usually experiences only slight discomfort and the procedure can often be completed within 30 minutes.

Preparation

Before scheduling the biopsy, the physician, nurse, or physician assistant completes a thorough medical history of the patient to include all medications that the patient is taking; a list of any medications to which the patient is allergic; and a history of any bleeding problems. The patient may be given an antibiotic shortly before the test to reduce the risk of infection. Usually an enema is required prior to the biopsy procedure, and the patient will be given instructions on administering the enema.

Aftercare

The physician, nurse, or physician assistant should monitor the patient for any complications, excessive bleeding, or **pain** from the procedure. After the procedure, the patient commonly experiences minor rectal bleeding, blood in urine or feces, and sometimes blood in the semen. These side effects usually last for only a few days. Often, the physician will prescribe **antibiotics** to guard against potential infection. The patient should drink fluids to help reduce any burning sensation and the chances of a urinary tract infection.

Complications

Prostate biopsy performed with a bioptic gun is a low-risk procedure. The possible complications include abnormal bleeding, urinary tract infection, or an inability to urinate. These complications are treatable, and the patient should notify the physician promptly if symptoms occur. If the patient develops a high **fever**, chills, or unusual pain or bleeding after the procedure, he should notify the physician immediately.

Results

The prostate tissue is fixed, stained, and prepared on glass slides for microscopic analysis by a pathologist

KEY TERMS

Benign prostatic hypertrophy (BPH)—A non-cancerous condition of the prostate that causes growth of the prostate tissue, thus enlarging the prostate and obstructing urination.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Computed tomography (CT) scan—A medical procedure in which a series of x rays is taken at different angles and reconstructed by a computer in order to form detailed pictures of areas inside the body.

Digital rectal examination—A routine screening test that is used by physicians to detect any enlargement in the prostate gland or any hardening or other abnormality of the prostate tissue. The doctor inserts a gloved and lubricated finger (digit) into the patient's rectum, which lies just behind the prostate. Typically, since a majority of tumors develop in the posterior region of the prostate, they can be detected through the rectum.

Magnetic resonance imaging (MRI)—An imaging procedure that creates a detailed computer-constructed image of the target tissue based upon its deflection of a magnetic field produced by a powerful magnet. The magnetic field deflection is measured using radio waves (not x rays).

Pathologist—A doctor who specializes in the diagnosis of diseases by studying cells and tissues removed by biopsy.

Ultrasonogram—An image produced by high-frequency sound waves that cannot be heard by human ears. The sound waves are deflected by internal organs and tissues. These sound waves produce a pattern of echoes that are then used by the computer to create pictures of areas inside the body.

who will examine the samples for the presence of cancerous cells. If the prostate tissue samples show no sign of inflammation, and if no cancerous cells are detected, the results are normal. If malignant cells are present, the pathologist grades them, in order to estimate the aggressiveness of the tumor. The most commonly used grading system is called the Gleason system; the higher the Gleason score, the more likely it is that the cancer is fast-growing and may have already spread to other areas (metastasized).

Health care team roles

Training

The urologist and several non-physician health care providers are involved in the biopsy process. The urologist has received specialized training in ultrasound-guided biopsy procedures. The additional health care team members have obtained specialized training to assist the urologist by preparing the patient for the procedure and monitoring the patient during the procedure. They also ensure that the urologist has all of the instruments and equipment required before, during, and after the procedure. A health care provider properly packages and labels the specimens for transport to the pathology laboratory.

Patient education

The health care provider can be an important resource for patients who require a prostate biopsy. Health care professionals should make men aware of certain risk factors that can increase their chances of developing prostate cancer. Three important risk factors are age greater than 50; family history of prostate cancer; and African American descent. A health care provider should explain in detail the procedure to be performed and the possible complications associated with the biopsy.

The health care provider will instruct the patient in self-administering an enema. Following a needle biopsy, the health care providers should tell the patient that he may experience some minor discomfort, and that he should avoid strenuous activities for the remainder of the day. The health care provider should also inform that patient that he may notice a small amount of blood in his urine or minor bleeding from his rectum for two or three days after the test. The provider should emphasize to the patient that he should call the physician immediately if he experiences unusual bleeding, pain, fever, or an inability to urinate for 24 hours. The health care provider should provide the patient with the results of the test as soon as they are available.

Prostate cancer

Definition

Prostate **cancer** is a disease in which the cells of the prostate (a gland found in the **male reproductive system**) become abnormal and start to grow uncontrollably, forming tumors. Tumors that can spread to other parts of the body are called malignant tumors or cancers. Tumors that are not capable of spreading in this way are said to be benign.

Description

The prostate is a gland that produces the fluid (semen), which contains sperm. The prostate is about the size of a walnut and lies just beneath the urinary bladder. Usually prostate cancer is slow-growing, but it can grow faster in some instances. As a prostate cancer grows, some of the cells may break off and spread to other parts of the body through the lymphatic or the **blood** systems. This process is known as metastasis. The most common sites of spreading are the lymph nodes and various bones in the spine and the pelvic region.

The **lymphatic system** is composed of ducts that transport extracellular fluid from distant areas of the body to the **heart**. Fluid enters lymph ducts and travels toward the heart. Any fluid collected is mixed with the blood. Any excess fluid is eliminated from the blood by the **kidneys**. Along the lymph system are clusters of specialized tissue called lymph nodes. These nodes act as strainers and retain cellular debris to prevent it from entering the blood stream. Lymph nodes also retain cancer cells that escape from tumors. For this reason, surgeons often remove some lymph nodes for analysis to determine the extent that a cancer may have spread beyond its original (primary) site.

The cause of prostate cancer is not clear; however, several risk factors are known. The average age at diag-

nosis of prostate cancer is approximately 72 years. In fact, 80% of prostate cancer cases occur in men over the age of 65. As men grow older, the likelihood of developing prostate cancer increases. Hence, age appears to be a risk factor for prostate cancer. Race may be another contributing factor. African Americans have the highest rate of prostate cancer in the world while the rate in Asians is one of the lowest. However, although the rate of prostate cancer in native Japanese men is low, the rate in Japanese Americans is closer to that of white American men. This finding suggests that environmental factors also play a role in prostate cancer.

There is some evidence to suggest that a diet high in fat increases the risk of prostate cancer. Studies also suggest that such nutrients as soy isoflavones, **vitamin E**, selenium, **vitamin D** and carotenoids (including lycopene, the red color agent in tomatoes and beets) may decrease prostate cancer risk. These substances contain particularly high levels of molecules called antioxidants, which seem to oppose the formation of cancer cells. Vasectomy may be linked to increased prostate cancer rates as well. Workers in such industries as welding, with exposure to the metal cadmium, appear to have a higher than average risk of prostate cancer. Male sex hormone levels also may be linked to the rate of prostate cancer. In addition, some studies have linked increased prostate cancer risk to smoking.

Genetic profile

An estimated 5-10% of prostate cancer is due to hereditary causes. Among men with early prostate cancer, a hereditary cause is likely in up to a third of cases before age 60 and in almost half of men diagnosed with prostate cancer at age 55 or less. Studies have found around a two- to three-fold increased rate of prostate cancer in close relatives of men with the disease. Hereditary prostate cancer is likely in a family if there are three cases of prostate cancer in close relatives; or three affected generations (on either mother's or father's side); or two relatives with prostate cancer before age 55.

Studies suggest that hereditary prostate cancer is likely to be caused by several different genes instead of a single gene. At least four other genes have been reported, including one thought to increase the risk of both prostate and **brain** tumors. Other genes known to increase the risk of other cancers, such as **breast cancer**, also may be linked to increased prostate cancer risk. Common variations in certain genes also may increase susceptibility to prostate cancer, including one gene linked to male sex hormones. Since no clear cause has been identified for the majority of hereditary prostate cancer, **genetic testing**, as of 2001, is typically done through research studies.

Demographics

Prostate cancer is the most common cancer among men in the United States, and is the second leading cause of cancer deaths. The American Cancer Society estimates that in 2001, 198,100 new cases of prostate cancer will be diagnosed, and it will cause 31,500 deaths. One in six men in the United States will be diagnosed with prostate cancer. Prostate cancer affects black men about twice as often as it does white men, and the mortality rate among African Americans is also higher. African Americans have the highest rate of prostate cancer in the world. The prostate cancer rate varies considerably around the world. The highest rates are in North America and Western Europe, whereas the rates are moderate in Africa and lowest in Asia. It is unclear what roles genetics, diet, economics, and health care access play in these rates.

Causes and symptoms

Frequently, prostate cancer has no symptoms, and the disease is diagnosed when a man goes for a routine screening examination. However, when the tumor is larger or the cancer has spread to nearby tissues, the following symptoms may be seen:

- weak or interrupted flow of urine
- frequent urination (especially at night)
- difficulty starting urination
- inability to urinate
- **pain** or burning sensation when urinating
- blood in the urine (hematuria)
- persistent pain in the lower back, hips, or thighs (bone pain)
- difficulty having or keeping an erection (impotence)

Diagnosis

Although prostate cancer may be very slow-growing, it can be quite aggressive, especially in younger men. When the disease is slow-growing, it may often go undetected. Because it may take many years for the cancer to develop, many men with the disease are likely to die of other causes rather than from the cancer.

Prostate cancer is frequently curable when detected early. However, because the early stages of prostate cancer may not have any symptoms, it often goes undetected until a man goes for a routine **physical examination**. Diagnosis of the disease is made using some or all of the following tests.

This patient's prostate cancer has metastasized, swelling the lymph nodes in the left groin. (Photograph by Dr. P. Marazzi. Photo Researchers, Inc. Reproduced by permission.)

Digital rectal examination (DRE)

In order to perform this test, a physician puts a lubricated, gloved finger (digit) into the rectum to feel for any lumps in the prostate. The rectum lies just behind the prostate gland, and a majority of prostate tumors begin in the posterior region of the prostate. The posterior portion of the prostate is most accessible to a physician's examining finger. If the physician does detect an abnormality, additional tests may be ordered to confirm these findings.

Blood tests

Blood tests are used to measure the amounts of certain protein markers, such as prostate-specific antigen (PSA), found circulating in the blood. The cells lining the prostate generally make this protein and a small amount can normally be detected in the bloodstream. However, prostate cancers typically produce large amounts of this protein, and it can be easily detected in the blood. Hence, when PSA is found in the blood in higher than normal amounts (for a man's age group), cancer may be present. Occasionally, other blood tests also are used to help with the diagnosis.

Transrectal ultrasound

A small sound-producing device (transducer) is placed in the rectum and sound waves are released from it. These sound waves bounce off the prostate tissue and an image is created by a computer using the reflected sound waves. Since normal prostate tissue and prostate tumors reflect the sound waves differently, the test can be used to detect tumors. Though the insertion of the transducer into the rectum may be slightly uncomfortable, the procedure is generally painless and takes only about 20 minutes.

PROSTATE BIOPSY. If cancer is suspected from the results of any of the above tests, a physician will remove

a small piece of prostate tissue with a hollow needle. This sample is then analyzed under a **microscope** for the presence of cancerous cells. **Prostate biopsy** is the most definitive diagnostic tool for prostate cancer.

If cancer is detected during the microscopic examination of the prostate tissue, a pathologist will grade the tumor. This means that the tumor will be scored on a scale of two to 10 to indicate how aggressive it is. Tumors with a lower score are less likely to grow and spread than are tumors with higher scores. This method of grading tumors is called the Gleason system. This is different from staging of the cancer. When a physician stages a cancer, a number is assigned. The number indicates whether it has spread and the extent of spread of the disease. In Stage I, the cancer is localized in the prostate in a single area; while in the last stage, Stage IV, the cancer cells have spread to other parts of the body.

X rays and imaging techniques

X-ray studies may be ordered to determine whether the cancer has spread to other areas. Imaging techniques (such as computed tomography [CT] scans and **magnetic resonance imaging** [MRI]), in which a computer is used to generate a detailed picture of the prostate and adjacent areas, may be undertaken to get a clearer view of the internal organs. A bone scan may be used to check whether the cancer has spread to bones.

The American Cancer Society and other organizations recommend that PSA blood testing and digital rectal examinations be offered to men with at least a 10-year life expectancy beginning at age 50. Men at higher risk for prostate cancer, such as those with a family history of the disease or African American men, may wish to consider screening at an earlier age, such as 45. A low-fat diet may slow the progression of prostate cancer. Hence, the American Cancer Society recommends a diet rich in fruits, vegetables and dietary fiber; and low in red meat and saturated **fats**, in order to reduce the risk of prostate cancer.

Treatment

A physician and an affected man will decide on a treatment after considering many factors. For example, the man's age, the stage of the tumor, his general health, and the presence of any coexisting illnesses have to be considered. In addition, a man's personal preferences and the risks and benefits of each treatment method are also taken into account before any decision is made.

Surgery

For early-stage prostate cancer, surgery is frequently considered. Radical prostatectomy involves complete

removal of the prostate. During the surgery, some of the lymph nodes near the prostate are removed to determine whether the cancer has spread beyond the prostate gland. Because the seminal vesicles (the glands where seminal fluid is made) are removed along with the prostate, **infertility** is often a side effect of this type of surgery. In order to minimize the risk of impotence (inability to have an erection) and incontinence (inability to control urine flow), a procedure known as a nerve-sparing prostatectomy is used.

In a different surgical method, known as the transurethral resection procedure or TURP, only the cancerous portion of the prostate is removed, by using a small wire loop that is introduced into the prostate through the urethra. This technique is most often used in men who cannot have a radical prostatectomy due to age or other illness, and it is infrequently recommended.

Radiation therapy

Radiation therapy involves the use of high-energy x-rays to kill cancer cells or to shrink tumors. It can be used instead of surgery for early-stage cancer. The radiation can be administered either from a machine outside the body (external beam radiation), or from small radioactive pellets implanted in the prostate gland in the area surrounding a tumor.

Hormone therapy

Hormone therapy is commonly used when the cancer is in an advanced stage and has spread to other parts of the body. Prostate cells need the male hormone testosterone to grow. Decreasing the levels of this hormone or inhibiting its activity may cause the cancer to shrink or stop growing. Hormone levels can be decreased in several ways. Orchiectomy is a surgical procedure that involves complete removal of the testicles, leading to a decrease in the levels of testosterone. Alternatively, drugs (such as LHRH agonists or anti-androgens) that bind to the male hormone testosterone and block its activity can be given. Luteinizing hormone releasing hormone (LHRH) agonists stimulate the **pituitary gland** in the brain to release luteinizing hormone. This release results in a decreased level of testosterone. Another approach involves administering the female hormone estrogen. When estrogen is given, the body senses the presence of a sex hormone and stops making the male hormone testosterone. However, there are some side effects to hormone therapy. Men may have “hot flashes,” enlargement and tenderness of the breasts, or impotence and loss of sexual desire—as well as blood clots, heart attacks, and strokes, depending on the dose of estrogen.

Chemotherapy

Chemotherapy is the use of drugs to kill cancer cells. The drugs can either be taken in pill form or injected into the body through a needle that is inserted into a blood vein. This type of treatment is called systemic treatment because the drug enters the blood stream, travels through the whole body, and kills cancer cells that are outside the prostate. Chemotherapy is sometimes used to treat prostate cancer that has recurred after other treatment. Research is ongoing to find more drugs that are effective for the treatment of prostate cancer.

Watchful waiting

Watchful waiting means that no immediate treatment is recommended, but physicians keep the man suspected of having prostate cancer under careful observation. This option is generally used among older men when the tumor is not very aggressive and they have other, more life-threatening illnesses. Prostate cancer in older men tends to be slow-growing. Therefore, the risk of a man dying from prostate cancer, rather than from other causes, is relatively small.

Prognosis

According to the American Cancer Society, the survival rate for all stages of prostate cancer combined has increased from 50% to 87% over the last 30 years. Due to early detection and better screening methods, nearly 60% of the tumors are diagnosed while they are still confined to the prostate gland. The five-year survival rate for early-stage cancers is almost 99%. Sixty-three percent of the men survive after 10 years, and 51% survive 15 years after initial diagnosis. Studies on the prognosis of hereditary prostate cancer are ongoing.

Health care team roles

A family physician or internist often makes an initial diagnosis of prostate cancer. A urologist often confirms the diagnosis and supervises treatment. A cancer oncologist may administer radiation or chemotherapy treatments. A surgeon may excise a tumor of the prostate. Nurses provide care throughout hospitalization. Nurses also provide education to the patient and family according to the physician’s orders, as well as **home care**.

Prevention

There is no known way to prevent prostate cancer. Some experts feel that dietary modifications may delay the onset of prostate cancer. This view is not universally shared.

KEY TERMS

Anti-androgen drugs—Drugs that block the activity of male hormones.

Benign—A term for a tumor that does not metastasize and is not life-threatening.

Benign prostatic hyperplasia (BPH)—A non-cancerous condition of the prostate that causes growth of prostatic tissue, thus enlarging the prostate and blocking urination.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Chemotherapy—Treatment of the cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Estrogen—A female sex hormone.

Hematuria—Blood in the urine.

Hormone therapy—A treatment for prostate cancer that involves reducing the levels of the male hormone testosterone so that the growth of the prostate cancer cells is inhibited.

Lymph nodes—Small, bean-shaped structures that are scattered along the lymphatic vessels. These nodes serve as filters and retain any bacteria or cancer cells that are traveling through the system.

Malignant—A tumor that is capable of spreading to

other organs and poses a serious threat to a person's life.

Metastasis—The spreading of cancer from the original site to other locations in the body.

Prostatectomy—The surgical removal of the prostate gland.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Rectum—The last 5-6 inches of the large intestine that leads to the anus.

Semen—A whitish, opaque fluid released at ejaculation.

Seminal vesicles—Tubes above the prostate that make seminal fluid.

Testicles—Two egg-shaped glands that produce male sperm and sex hormones.

Testosterone—A male sex hormone produced mainly by the testicles.

Transrectal ultrasound—A procedure in which a probe is placed in the rectum. High-frequency sound waves that cannot be heard by humans are sent out from the probe and reflected by the prostate. These sound waves produce a pattern of echoes that are then used by the computer to create sonograms or pictures of areas inside the body.

Prostate ultrasound

Definition

A prostate ultrasound is a diagnostic test used to detect potential problems with a man's prostate. An ultrasound test involves very high-frequency sound waves that pass through the body. The pattern of reflected sound waves, or

“echoes,” shows the outline of the prostate. This test can show whether the prostate is enlarged, and whether an abnormal growth that might be **cancer** is present.

Purpose

The prostate is a chestnut-shaped organ surrounding the beginning of the urethra in men. It produces a milky fluid that is part of the seminal fluid discharged during ejaculation. Prostate disorders are common in men over 50. In cases of **prostate cancer**, ultrasound is often crucial, since early detection, when the lesion is localized and curable, can lead to effective therapy.

A doctor may decide to do a prostate ultrasound following a digital rectal examination (DRE) that reveals any prostate abnormalities such as lumps or an enlarged prostate; or following a **blood** test that reveals abnormal levels of a substance called prostate-specific antigen (PSA), a normal protease produced by the prostate epithelium. Currently, testing for PSA is the best available tumor marker. Abnormal levels of PSA may indicate the presence of cancer. However, the PSA test is non-specific, and PSA can be elevated without the presence of prostate cancer.

The ultrasound procedure involves a special probe inserted into the rectum that sends sound waves to the prostate gland. The waves bounce off the prostate surface and are translated by computer as an image on a screen.

If cancer is suspected, the doctor will want to take a tissue sample (**prostate biopsy**) to test it to see if it is cancerous. An ultrasound can show the location on the prostate from which the sample should be taken. It can also reveal if the cancer has begun to spread to other locations.

Ultrasound is also used in treatment of prostate cancer. If a doctor decides to treat the cancer with a surgical freezing procedure, ultrasound is used as an aid in the procedure. Doctors are also experimenting with a procedure that uses heat to kill cancerous prostate tissue. During this procedure, called high-intensity focused ultrasound (HIFUS), an ultrasound probe first creates an image of the prostate; then high-energy ultrasound beams target specific areas, generating heat that destroys cancerous tissue.

Ultrasound also can reveal such other types of prostate disease as prostatitis.

Precautions

A prostate ultrasound study is generally not performed on men who have recently had surgery on their lower bowel. This is because the test requires placing an ultrasound probe about the size of a finger into the rectum.

KEY TERMS

Benign prostatic hypertrophy (BPH)—An enlargement of the prostate that is not cancerous. However, BPH may cause problems with urinating or other symptoms.

Doppler—In ultrasound, a technique used to detect and evaluate moving structures that is usually applied to the evaluation of blood flowing in vessels.

Prostate-specific antigen (PSA) test—A blood test to detect PSA, a substance that is often produced by cancers of the prostate.

Urethra—The tube through which urine passes from the bladder and is excreted outside the body.

Description

The prostate ultrasound technique performed is called transrectal ultrasonography. This technique not only allows for visualization of the prostate; it is used to position the needle if a biopsy is performed. During the procedure, the cylinder-shaped ultrasound probe, or transducer, is gently placed in the rectum as the patient lies on his left side with the knees bent. This position allows for more comfort and easier insertion. The probe is rocked back and forth to obtain images of the entire prostate. Pictures of the prostate are produced and measurements are taken. The procedure takes about 15-25 minutes to perform. After the test, the patient's doctor can be notified right away, and usually he or she will have a written report within 36 hours.

During a biopsy, a small needle is inserted very rapidly into the prostate gland. Sample tissue is taken and sent to a pathology lab for preparation. Transrectal ultrasound-guided core biopsy of the prostate is regarded as the most effective determinant of the grade, volume, and localization of a tumor and of its distribution within the prostate. Usually, six to eight biopsies are taken.

Recently, in an effort to improve prostate cancer diagnosis, physicians have performed experiments with ultrasound contrast-agent enhanced color Doppler imaging. By revealing increased vascularity associated with prostate cancer, the procedure can allow for more targeted biopsies, thus reducing the number of biopsies needed.

Preparation

Patients are instructed to have an enema two to four hours before an exam. Feces or gas could impede the

progress of the rectal probe. Patients also are instructed not to urinate for one hour before the test. If biopsies may be done, the doctor will prescribe an antibiotic that usually is taken in four doses, starting the night before the biopsy; the morning of the test; the evening after the test; and the following morning.

Aftercare

For the most part, transrectal ultrasound is a painless procedure. The patient may be warned that there could be some discomfort as the probe is inserted. Generally, the patient is allowed to leave after a radiologist or urologist has reviewed the results. There may be some mucus or a small amount of bleeding from the rectum after the ultrasound. Some patients notice a small amount of blood in the urine for up to two days after the test. Blood may also be present in the semen. As long as the amount of blood is small and resolves after one to two days, there is no cause for concern.

Complications

There are no serious risks from a prostate ultrasound study. **Infection** is rare and is probably a result of biopsy rather than the sonogram itself. If the ultrasound probe is moved too vigorously, some bleeding may continue for a few days.

Results

Modern ultrasound techniques can display both the smooth-surfaced outer shell of the prostate and the core tissues surrounding the urethra. The entire volume of the prostate should be less than 20 milliliters, and its outline should appear as a smooth echo-reflecting (echogenic) rim. Some irregularities within the substance of the gland and **calcium** deposits are normal findings.

An enlarged prostate with dimmed echoes may indicate either prostatitis or benign enlargement of the gland, called benign prostatic hypertrophy (BPH). A distinct focal lump of tissue more likely means cancer. Cancer also often appears as an irregular area within the gland that distorts the normal pattern of echoes. In either case, a biopsy should clarify the diagnosis.

Health care team roles

The procedure is performed by a specially trained diagnostic medical sonographer. The sonographer assists the physician and radiologist in gathering sonographic data necessary to diagnose prostate cancer. Sonographers can have extensive, direct patient contact that may include performing some invasive procedures. The sono-

grapher obtains and records patient history; performs diagnostic procedures and obtains diagnostic images; analyzes technical information; and provides an oral and written summary of technical findings to the physician for medical diagnosis. A urologist or radiologist performs the biopsy.

Training

Medical sonography programs vary in length from one to four years depending on the program design and degree or certificate awarded. Program entry requirements vary as well, and range from a high-school diploma to specific qualifications in a clinically related health profession. Graduation from an accredited program is followed by a qualifying exam administered by the American Registry of Diagnostic Medical Sonographers (ARDMS). Continuing education is required.

Prosthetics

Definition

Prosthetics is the branch of surgery concerned with the replacement of missing body parts with artificial substitutes.

Artificial knee joint attached to human bones. (Photograph by Mike Devlin. National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)

Description

While prosthetics is defined as a branch of surgery, those involved in this profession include the surgeon, nurse, prosthetist, and physical therapist. Others involved in treatment can include a prosthetics technician, prosthetics assistant, rehabilitation counselor, and social worker.

The goal of prosthetics is to replace all or part of a missing limb so that a patient can function. This replacement can involve fitting a man with an artificial leg so that he can walk, or equipping a woman with an artificial hand so that she can hold objects. An artificial appliance is often called a "prosthetic" or a "prosthesis." Prosthesis can also refer to the replacement of a missing part with a prosthetic.

Historical perspective

The practice of prosthesis dates back to ancient times. During the sixteenth century, a German knight was

Guide for preprosthetic evaluation

Item to be evaluated	Observe for:
Activities of daily living	Transfers; ambulatory status; home (including hazards and barriers); self-care
Medical status	Cause of amputation; associated diseases/symptoms; medications
Neurologic	Sensation; neuroma; phantom pain; mental status
Psychological	Emotional status; family and work situations; prosthetic goals
Range of motion	Hips; knee; ankle
Residuum length	Bone length; soft-tissue, redundant-tissue length
Residuum shape	Cylindrical, conical, hourglass, "dog-ears," bulbous, above-knee adductor roll
Skin	Scar; open lesions; sensation; grafts
Vascularity (both limbs if vascular disease is cause of amputation)	Pulses; color; temperature; edema; pain; trophic changes

SOURCE: Sanders, G.T. *Lower Limb Amputation: A Guide to Rehabilitation*. Philadelphia: F.A. Davis Co., 1986.

known as Gutz of the Iron Hand because of his prosthetic. The appliance's movable fingers enabled the knight to hold a sword.

Wood, however, served as the primary material for prosthetics until the twentieth century. In the aftermath of two world wars, research led to the development of prosthetics made of aluminum alloys, metals, and fiber material.

Throughout the centuries, prosthetics were made with mechanical devices and rubber band-type material to allow their wearers to grip objects and move more easily. Movement devices in prosthetics now include hydraulic knees and computer-programmable hands that sense muscle movement.

Legs, arms, feet, and hands are the most commonly known artificial appliances. Other prosthetics include artificial eyes, hip joints, breasts, and **heart** valves. Prosthodontics is the branch of dentistry concerned with the replacement of teeth.

Contemporary prosthetic care

Patients requiring prosthetic care range from children born with missing limbs to elderly adults requiring hip joint replacement surgery. Such trauma as an automobile accident may cause the loss of a limb, and such conditions as diabetes may lead to the amputation of a limb.

Health care roles

Patients are seen by a prosthetics health care team, which can include a surgeon, nurse, prosthetist, pro-

sthetics technician, prosthetics assistant, and physical therapist.

Prosthetics is sometimes also grouped with orthotics in allied professions. Orthotics is concerned with producing and fitting braces (orthoses) for patients' limbs and spines.

Work settings

Members of the prosthetics health care team work in hospitals, rehabilitation facilities, medical centers, medical schools, colleges, and universities. Prosthetics technicians may work in those settings or in labs and facilities that manufacture prostheses.

The prosthetist designs and fits prostheses. When surgery is planned, the prosthetist consults with the surgeon about where a limb is to be amputated. The prosthetist's input includes recommendations about fitting the prosthesis after surgery.

Pre-operative preparation

For some members of the health care team, patient contact begins before surgery. The doctor examines the patient to determine if more treatment is needed. If amputation is required, those who counsel the patient may include the doctor, nurse, and social worker. They will try to help the patient prepare emotionally and physically for surgery and rehabilitation.

The prosthetics health care team

Prosthetists may supervise several staff members. In some workplaces, the prosthetics assistant assists the prosthetist and may fabricate, repair, and maintain artificial appliances. However, prosthetics may be made by the prosthetics technician, an allied health worker who takes direction from the prosthetist and the prosthetics assistant. The technician also repairs and maintains prostheses. In some settings, the technician may have no contact with patients.

After surgery, the patient may be seen by the surgeon or primary care doctor. During the rehabilitation phase, the prosthetist and therapist will help the patient adjust to the prosthetic. The nurse and social worker may provide **patient education** and support. If needed, the patient may be referred to a rehabilitation counselor or a vocational counselor.

In addition, the patient will see the prosthetist, prosthetics assistant, or prosthetics technician if the prosthetic needs adjusting.

The early stages of all prosthetic treatment usually involves the prosthetist working with the physical thera-

pist. The therapist can evaluate such factors as the patient's strength and ability to wear a prosthetic.

Education and training

Members of the health care team, such as surgeons, nurses, physical therapists, and social workers, may receive training in the use of prosthetics while studying for their respective professions. Prosthetists earn a four-year bachelor of science degree that includes specialized prosthetic training. They also serve a clinical residency. Programs for prosthetics assistants and technicians range from six months to two years. In addition, people working in these allied health professions can receive certification through the American Academy of Orthotics and Prosthetics. Board certification is based on education, employment, completion of certification of program modules (continuing education courses), and membership in the academy.

Advanced education and training

The name of the American Academy of Orthotics and Prosthetics reflects the relationship between the fields of orthotics and prosthetics. While orthotics usually focuses on temporary treatment with a brace, prosthetics involves permanent replacement of a body part with an artificial appliance. However, some patients require both prosthetics and orthotics, so schools offer degrees and certificates in both disciplines. Allied health professionals with education and experience in both disciplines will be twice as employable as those with degrees or certificates in only one of the professions.

Education is the key to career advancement for an allied health employee with only one specialty. A prosthetics technician can advance to assistant and then prosthetist by completing more classes.

The American Academy of Orthotics and Prosthetics offers continuing education courses and forums so that allied health workers remain knowledgeable about new developments in their professions.

Future outlook

The need for prosthetists, prosthetics assistants, and prosthetics technicians is expected to increase with the aging of the baby boomer generation. The existence of a rapidly growing senior population is a global trend, and prosthetics care should be in increasing demand worldwide. Among the needs for older populations are hip replacement and replacement of limbs amputated because of diabetes and other conditions.

Protein electrophoresis test

Definition

Electrophoresis is a technique used to separate the different components (fractions) of a mixture, such as **proteins** in a biological sample. Separation is based on differences in the charge (and sometimes size) of the molecules, which determines their rate of movement in an electric field. Serum protein electrophoresis is a screening test that measures the major **blood** proteins. Protein electrophoresis testing can also be performed on urine and cerebrospinal fluid (CSF) samples.

Purpose

Protein electrophoresis testing is used to evaluate, diagnose, and monitor a variety of diseases and conditions through examination of the amounts and types of protein in a blood, urine, or CSF specimen.

Precautions

Certain other diagnostic tests or prescription medications can affect the results of protein electrophoresis

Protein electrophoresis	
Electrophoresis results	Disease
Total protein: 6.4–8.3 g/dl (64.0–83.0 g/L)	Normal results
Albumin: 3.5–5.0 g/dl (35–50 g/L)	
Alpha ₁ globulin: 0.1–0.3 g/dl (1–3 g/L)	
Alpha ₂ globulin: 0.6–1.0 g/dl (6–10 g/L)	
Beta globulin: 0.7–1.1 g/dl (7–11 g/L)	
Decreased albumin	Acute infections, tissue necrosis, burns, surgery, stress, myocardial infarction
Increased alpha ₂ globulin	
Slightly decreased albumin	Chronic infection, granulomatous diseases, cirrhosis, rheumatoid-collagen diseases
Slightly increased gamma globulin	
Normal alpha ₂ globulin	
Greatly decreased albumin	Nephrotic syndrome
Greatly increased alpha ₂ globulin	
Normal increase in beta globulin	
Decreased albumin	Far-advanced cirrhosis
Increased gamma globulin	
Incorporation of beta and gamma peaks	
Greatly increased gamma globulin	Cirrhosis, chronic infection, globulin with a broad peaksarcoidosis, tuberculosis, endocarditis, rheumatoid-collagen disease
Decreased gamma globulin with normal other globulin levels	Light-chain multiple myeloma
Thin spikes in gamma globulin	Myeloma, macroglobulinemia, gammopathies

SOURCE: Pagana, K.D., and T.J. Pagana. *Mosby's Diagnostic and Laboratory Test Reference*, 3rd ed. St. Louis: Mosby, 1997.

tests. The administration of a contrast dye used in some other tests may falsely elevate apparent protein levels. Drugs that can alter results include aspirin, bicarbonates, chlorpromazine (Thorazine), **corticosteroids**, isoniazid (INH), and neomycin (Mycifradin). The total serum protein concentration may also be affected by changes in the patient's posture or by the use of a tourniquet during venipuncture.

Protein is less concentrated in urine and CSF than in blood. Urinary and CSF proteins must be concentrated before analysis, and the added sample handling can lead to contamination and erroneous results. In the collection of a CSF specimen, it is important that the sample not be contaminated with blood proteins that would invalidate the CSF protein measurements.

Description

Proteins are biologically important organic molecules—polymers of amino acids—that contain the ele-

ments carbon, hydrogen, nitrogen, and oxygen. Certain proteins may also contain sulfur, **phosphorus**, **iron**, iodine, selenium, or other trace elements. There are twenty-two amino acids commonly found in all proteins. The human body is capable of producing fourteen of these amino acids; the remaining eight so-called essential amino acids must be obtained from food. Proteins are found in muscles, blood, skin, hair, nails, and the internal organs and tissues. Enzymes, hemoglobin, and antibodies are proteins, as are many hormones.

Protein mixtures can be fractionated into individual component proteins by a variety of techniques, including precipitation, chromatography, ultracentrifugation, or electrophoresis.

A serum protein electrophoresis test is used to determine the percentage of each protein in the blood by separating them into five distinct classes: albumin, alpha₁-globulin, alpha₂-globulin, beta-globulin, and gamma-globulins (immunoglobulins). High-resolution protein electrophoresis uses a higher current to separate the major proteins comprising the alpha₁-globulin, alpha₂-globulin, and beta-globulin fractions. This procedure produces nine or more bands, including alpha₁ anti-trypsin, alpha₂ macroglobulin, haptoglobulin, transferrin, and complement proteins.

In addition to standard protein electrophoresis, the immunofixation electrophoresis test (IFE) may be used to assess the blood levels of specific immunoglobulins. An IFE test is usually ordered if a serum protein electrophoresis test shows an unusually high amount of protein in the gamma-globulin fraction. The IFE tests determine whether the increase in the gamma-globulin fraction is caused by excess immunoglobulins (antibodies), and whether it is polyclonal or monoclonal in nature. Polyclonal increases are caused by infections, **allergies**, and inflammatory diseases, while monoclonal increases are caused by malignant or benign proliferations of the antibody-producing cells (plasma cells).

Serum proteins

The total serum protein concentration may be used to assess a patient's hydration state: **dehydration** leads to high total serum protein concentration. Further, the levels of different blood proteins rise or fall in response to such disorders as **cancer**, intestinal or kidney protein-wasting syndromes, disorders of the **immune system**, **liver** dysfunction, impaired **nutrition**, and chronic fluid-retaining conditions.

ALBUMIN. Albumin, which is produced in the liver, is the most abundant blood protein. It makes a major contribution to the osmotic pressure that regulates the movement of water between the tissues and the bloodstream.

Albumin binds **calcium**, thyroid hormones, fatty acids, and many drugs, maintaining them in the circulation and preventing filtration in the **kidneys**. Low serum albumin levels can be indicative of pathology, and can increase free therapeutic drug levels and decrease total calcium levels. Albumin levels can play a role in the efficacy and toxicity of therapeutic drugs, and in **drug interactions**.

GLOBULINS. Serum globulins are present in protein electropherograms as four main fractions: alpha₁-, alpha₂-, beta-, and gamma-globulins.

- The major alpha₁-globulin is the “acute-phase” protein alpha₁-antitrypsin, a protease inhibitor produced by the **lungs** and liver. Alpha₁-antitrypsin deficiency is a marker of an inherited disorder characterized by an increased risk of **emphysema**.
- Alpha₂-globulins include serum haptoglobin, alpha₂-macroglobulin, and ceruloplasmin. Haptoglobin is an acute-phase protein that binds free hemoglobin released from red blood cells during hemolysis. Haptoglobin binding prevents excretion of free hemoglobin by the kidneys. In addition to hemolysis, low haptoglobin levels can indicate chronic liver disease, tumor metastasis, or severe sepsis. Alpha₂-macroglobulin, a broad-spectrum protease inhibitor, accounts for about one-third of the alpha₂-globulin fraction: its concentration is increased during nephrosis. Ceruloplasmin is an acute-phase protein involved in the storage and transport of **copper** and iron: its concentration is increased during **pregnancy** and decreased in Wilson’s disease.
- Beta-globulins include transferrin, low-density lipoproteins (LDL), and complement components. Transferrin transports dietary iron to the liver, spleen, and bone marrow. LDL (also referred to as beta lipoprotein) is the major carrier of cholesterol in the blood: high levels are associated with atherosclerosis. Complement is a system of blood proteins required for antibody-mediated cell lysis and involved in the inflammatory response.
- The gamma-globulin fraction contains the immunoglobulins, a family of proteins that function as antibodies. Antibodies, produced in response to **infection**, allergic reactions, and organ transplants, recognize and bind antigens to facilitate destruction by the immune system. The **immune response** is regulated by a large number of antigen-specific gamma-globulins that fall into five main classes called IgG, IgA, IgM, IgO, and IgE. Immunoglobulin deficiency due to inherited disorders can range from partial or complete loss of a single immunoglobulin class to complete absence of all immunoglobulins. An abnormally high level of immunoglobulins is generally found in acute and chronic infections, and is an indicator of autoimmune disease.

When the serum protein electrophoresis test demonstrates a significant deviation from the normal gamma-globulin levels, an IFE test should be ordered to determine the polyclonal or monoclonal nature of the specific globulin(s) involved.

Quantification of each immunoglobulin class and each of the proteins mentioned above may be performed by a procedure called immunonephelometry. This technique uses an antibody specific for the protein to be measured. When the antibody binds to the protein, an immune complex is formed that increases the amount of light scattered by the sample.

Deviations in serum proteins levels from reference levels are considered in conjunction with symptoms and results from other diagnostic procedures.

Urinary proteins

Protein electrophoresis is performed on urine samples to classify disorders that cause protein loss via the kidneys. Hemoglobin and myoglobin are found in the urine of trauma and burn victims, and in patients with infection or hemolysis. Protein electrophoresis of urine is most often performed in order to detect the presence of light chain fragments of immunoglobulins. These protein fragments are sufficiently small to filter through the kidneys and are excreted in the urine. They are called Bence-Jones proteins, and are found in patients who have multiple myeloma, a malignant proliferation of antibody-producing cells. Bence-Jones proteins may also be found in other variants of multiple myeloma, such as light chain disease, and in patients with systemic autoimmune diseases that result from degradation of immune complexes.

Cerebrospinal fluid (CSF) proteins

An increase in total protein concentration in the CSF is often found in bacterial and fungal **meningitis** and with **central nervous system** (CNS) tumors. The main use of CSF protein electrophoresis testing is in the diagnosis of **multiple sclerosis**.

The protein electrophoresis test method

In a clinical protein electrophoresis test, proteins are separated on the basis of how fast they move on a medium in an electrical field. In a standard electrophoresis test, a small amount of sample is applied to a cellulose acetate strip or gel made of agarose or polyacrylamide. The strip or gel is positioned between the apparatus electrodes, and a voltage is applied across it. Under the conditions of the test, the proteins in the sample are negatively charged and migrate toward the positive electrode at different rates. The migration rate is mainly dependent

KEY TERMS

Acute-phase proteins—Proteins produced during the acute-phase response, a set of physiological changes that occur in response to trauma conditions.

Albumin—A blood protein produced in the liver that helps to regulate water distribution in the body.

Antibodies—Immunoglobulin protein molecules produced by B cells and plasma cells during the immune response. Each antibody-binding site can bind part of an antigen to trigger immune defenses.

Antigen—Foreign body that triggers immune response.

Bence-Jones protein—The Ig light chain, part of an immunoglobulin, that is detected by urine protein electrophoresis in the case of multiple myeloma.

Complement—A group of complex proteins of the beta-globulin type in the blood that bind to antibodies during anaphylaxis. In the complement cascade, each complement component interacts with another in a cascade that causes cell membrane damage, leading to lysis.

Electropherogram—The pattern of stained proteins on an electrophoresis gel, or a graph showing peaks of proteins separated by electrophoresis.

Electrophoresis—A technique used to separate the proteins in a biological sample on the basis of charge and size as they migrate under the influence of an applied electric field.

Globulins—Plasma or serum proteins other than albumin, so named because of their globular shape. Four globulin fractions can be measured by electrophoresis in order to diagnose or monitor a variety of serious illnesses.

Paraprotein—An immunoglobulin produced by a clone of identical B-cells. Also called monoclonal protein.

Protein—Proteins, such as enzymes and antibodies, are biologically important polymers of amino acids that contain the elements carbon, hydrogen, nitrogen, and oxygen. Certain proteins may also contain sulfur, phosphorus, iron, iodine, selenium, or other trace elements.

on the charge of the protein molecules; however, on polyacrylamide gel it is also dependent on size. When electrophoresis is complete, the gel is treated with a dye to stain the proteins, and the intensity of stain in the bands is measured and recorded by a densitometer. In a capillary electrophoresis test, samples are automatically transferred from the collection tubes to the head of a fluid-filled glass capillary tube: the electrophoretic separation occurs during the transport of the proteins through the capillary, and the individual proteins are detected and quantified on-line by absorption of ultraviolet light. Both gel and capillary electrophoresis procedures produce a recording of each protein fraction as a peak. The area under the peak is used to calculate the percentage of the fraction. This is multiplied by the total protein concentration (determined by chemical analysis) to give the concentration of each fraction. The levels of proteins thus determined are compared with reference levels to ascertain whether a disease state is present.

Standard electrophoresis systems

High-throughput and semi-automated protein electrophoresis testing is available in most laboratories through the use of integrated systems of gels, reagent kits, and densitometers.

Capillary electrophoresis systems

In 1998, the introduction of fully automated clinical capillary electrophoresis instruments was introduced. The advantages of the capillary electrophoresis methodology include direct sampling of a minimal volume from the primary collection tube; automated detection of proteins without staining; rapid sample throughput; and improved accuracy and reproducibility. Agarose and capillary systems are also used to separate DNA, an increasingly important technology.

Preparation

The sample for the serum protein electrophoresis test is obtained by venipuncture. No anticoagulant should be used. It is usually not necessary for the patient to restrict food or fluids before the test; a 12-hour fast is requested before drawing blood for lipoprotein testing. The urine protein electrophoresis test requires either an early morning urine sample or a 24-hour urine sample according to the physician's request. CSF is collected by lumbar puncture performed in a hospital setting; because of risks associated with the procedure, the patient must sign a consent form. Any factors that might affect test results,

such as whether the patient is taking any medications, should be noted.

Complications

Risks posed by the venous puncture are minimal but may include slight bleeding from the puncture site; fainting or lightheadedness after the sample is drawn; or the development of a small bruise at the puncture site.

Lumbar puncture can lead to leakage of cerebrospinal fluid from the puncture site, headache, infection, symptoms of meningitis, nausea, vomiting, or difficulty urinating. Rarely, pre-existing intracranial pressure can lead to **brain** herniation resulting in brain damage and/or death. The patient must be kept lying flat in the hospital under observation for at least 6 to 8 hours after the procedure.

Results

The following serum protein electrophoresis reference values are representative; some variation among laboratories and specific methods is to be expected. The values were obtained by standard electrophoresis on agarose gels.

- total protein: 6.4 to 8.3 g/dL (about 0.5 g/dL lower in nonambulatory patients)
- albumin: 3.5 to 5.0 g/dL
- alpha₁-globulin: 0.1 to 0.3 g/dL
- alpha₂-globulin: 0.6 to 1.0 g/dL
- beta-globulin: 0.7 to 1.2 g/dL
- gamma-globulin: 0.7 to 1.6 g/dL

Albumin levels are increased in dehydration and decreased in malnutrition, pregnancy, liver disease, inflammatory diseases, and such protein-losing states as **malabsorption syndrome** and certain kidney disorders.

Alpha₁-globulins are increased in inflammatory diseases and decreased or absent in juvenile pulmonary emphysema, a hereditary disease.

Alpha₂-globulins are increased in acute and chronic inflammation and nephrotic syndrome; decreased values may indicate hemolysis.

Beta-globulin levels are increased in conditions of high cholesterol (hypercholesterolemia), in multiple myeloma, and in **iron deficiency anemia**; and decreased in disorders associated with complement depletion.

Gamma-globulin levels are increased in chronic inflammatory disease and such autoimmune conditions as rheumatoid arthritis and systemic lupus erythemato-

sus; cirrhosis; in acute and chronic infection; and in multiple myeloma. The gamma-globulins are decreased in a variety of genetic immune disorders; in secondary immune deficiency related to steroid use; leukemia; or severe infection.

Detection of a discrete (monoclonal) band in the gamma region of the electropherogram indicates the presence of a paraprotein. Type IgG or IgA paraproteins associated with multiple myeloma may be found by serum protein electrophoresis testing; however, the tumor may produce only Ig light chains that are removed from the blood by the kidneys. The Ig light chain (Bence-Jones protein) can be detected by urine protein electrophoresis.

In CSF, the total protein concentration is normally 0.015 to 0.045 g/dL, with gamma-globulin accounting for 3–12%. Increased gamma-globulin indicates multiple sclerosis, bacterial or fungal meningitis, neurosyphilis, or Guillain-Barré syndrome. Detection of monoclonal bands in CSF plays an important role in the diagnosis of multiple sclerosis.

In urine, normally no globulins and less than 0.050 g/dL albumin are present. Abnormal results indicate disruption of kidney function or acute inflammation. The presence of the Bence-Jones protein indicates multiple myeloma.

Health care team roles

Nurses are involved in the collection of blood samples by venipuncture, in patient support during and after lumbar puncture, and in instructing patients in the procedure for midstream collection of urine samples. A lumbar puncture is generally performed by a physician. Medical laboratory workers are responsible for preparation of samples for electrophoresis testing.

Training

The preparation of urine and CSF samples for electrophoresis testing often involves concentration and, in the case of urine samples and some CSF samples, centrifugation. Electrophoresis is classified as a high-complexity test and is performed by laboratory personnel with special training, most often by a clinical laboratory scientist (CLS) or medical technologist (MT).

Proteins

Definition

Proteins are linear chains of amino acids connected by chemical bonds between the carboxyl group of each amino acid and the amine group of the one following. These bonds are called peptide bonds, and chains of only a few amino acids are referred to as polypeptides rather than proteins.

Description

Proteins are all around us. Much of the body's dry weight is protein; even bones are about one-quarter protein. The animals we eat and the microbes that attack us are likewise largely protein. The leather, wool, and silk clothing that we wear are nearly pure protein. The insulin that keeps diabetics alive and the "clot-busting" enzymes that may save **heart** attack patients are also proteins. Proteins can even be found working at industrial sites—protein enzymes produce not only the high-fructose corn syrup that sweetens most soft drinks, but also fuel-grade ethanol (alcohol) and other gasoline additives.

Within our bodies and those of other living things, proteins serve many functions. They digest foods and turn them into energy; they move our bodies and move molecules about within our cells; they let some substances pass through **cell membranes** while keeping others out; they turn light into chemical energy, making both **vision** and photosynthesis possible; they allow cells

to detect and react to hormones and toxins in their surroundings; and, as antibodies, they protect our bodies against foreign invaders. There are simply too many proteins—possibly more than 100,000—to even consider mentioning them all.

Proteins are made up of separate compounds called amino acids. It is these amino acids that our bodies actually need, not the entire protein molecule. Some amino acids are essential—they must be obtained from diet because they cannot be synthesized by humans in adequate amounts. There are nine essential amino acids. Others are nonessential, because they can be made in the body from precursors (components) of other amino acids. There are eleven nonessential amino acids.

Protein structure

Many proteins have components other than amino acids. For example, some may have sugar molecules chemically attached. Exactly which types of sugars are involved and where on the protein chain attachment occurs will vary with the specific protein. In a few cases, it may also vary among different people. The A, B, and O **blood** types, for example, differ in precisely which types of sugar are or are not added to a specific protein on the surface of red blood cells.

Other proteins may have fat-like (lipid) molecules chemically bonded to them. These sugar and lipid molecules are always added after synthesis of the protein's amino acid chain is complete. Such molecules can significantly affect the protein's properties.

Many other types of molecules may also be associated with proteins. Some proteins, for example, have specific metal ions associated with them. Others carry small molecules that are essential to their activity. Still others associate with nucleic acids in chromosomal or ribosomal structures.

Scientists have traditionally addressed protein structure at four levels: primary, secondary, tertiary, and quaternary. Primary structure is simply the linear sequence of amino acids in the peptide chain. It determines the protein's shape. Secondary and tertiary structure both refer to the three-dimensional shape into which a protein chain folds. The distinction is partly historical: secondary structure refers to certain highly regular arrangements of amino acids that scientists could detect as long ago as the 1950s, while tertiary structure refers to the complete three-dimensional shape. Tertiary structure determines the function of the protein. Determining a protein's tertiary structure can be difficult even today, although researchers have made major strides within the past decades.

The tertiary structure of many proteins shows a “string of beads” organization. The protein includes several compact regions known as domains, separated by short stretches in which the protein chain assumes an extended, essentially random configuration. Some scientists believe that domains were originally separate proteins that, over the course of evolution, have come together to perform their functions more efficiently.

Quaternary structure refers to the way in which protein chains—either identical or different—associate with each other. For example, a complete molecule of the oxygen-carrying protein hemoglobin includes four protein chains of two slightly different types. Simple laboratory tests usually allow scientists to determine how many chains make up a complete protein molecule.

PRIMARY PROTEIN STRUCTURE: PEPTIDE-CHAIN SYNTHESIS. Proteins are made (synthesized) in living things according to “directions” given by DNA and carried out by RNA and proteins. The synthesized protein’s linear sequence of amino acids is ultimately determined by the linear sequence of DNA bases—or of base triplets known as codons—in the gene that codes for it. Each cell possesses elaborate machinery for producing proteins from these blueprints.

The first step is copying the DNA blueprint, essentially fixed within the cell nucleus, into a more mobile form. This form is messenger ribonucleic acid (mRNA), a single-stranded nucleic acid carrying essentially the same sequence of bases as the DNA gene. The mRNA is free to move into the main part of the cell, the cytoplasm, where protein synthesis takes place.

Besides mRNA, protein synthesis requires ribosomes and transfer ribonucleic acid (tRNA). Ribosomes are the actual “factories” where synthesis takes place, while tRNA molecules are the “trucks” that bring amino acids to the ribosome and ensure that they are incorporated at the right spot in the growing chain.

Ribosomes are extremely complex assemblages. They comprise almost 70 different proteins and at least three different types of RNA, all organized into two different-sized subunits. As protein synthesis begins, the previously separate subunits come together at the beginning of the mRNA chain; all three components are essential for the synthetic process.

Transfer RNA molecules are rather small, only about 80 nucleotides long. (Nucleotides are the fundamental building blocks of nucleic acids, as amino acids are of proteins.) Each type of amino acid has at least one corresponding type of tRNA (sometimes more). This correspondence is enforced by the enzymes that attach amino acids to tRNA molecules, which “recognize” both the

amino acid and the tRNA type and do not act unless both are correct.

Transfer RNA molecules are not only trucks but translators. As the synthetic process adds one amino acid after another, they “read” the mRNA to determine which amino acid belongs next. They then bring the proper amino acid to the spot where synthesis is taking place, and the ribosome couples it to the growing chain. The tRNA is then released and the ribosome then moves along the mRNA to the next codon; that is, the next base triplet specifying an amino acid. The process repeats until the “stop” signal on the mRNA is reached, upon which the ribosome releases both the mRNA and the completed protein chain and its subunits separate to seek out other mRNAs.

SECONDARY STRUCTURE. The two major types of secondary structure are the alpha helix and the beta sheet, both discovered by Linus Pauling and R. B. Corey in 1951.

In an alpha helix, the backbone atoms of the peptide chain—the carboxyl carbon atom, the α -carbon atom (to which the side chain is attached), and the amino nitrogen atom—take the form of a three-dimensional spiral. The helix is held together by hydrogen bonds between each nitrogen atom and the oxygen atom of the carboxyl group belonging to the fourth amino acid up the chain.

Beta sheets feature several peptide chains lying next to each other in the same plane. The stabilizing hydrogen bonds are between nitrogen atoms on one chain and carboxyl-group oxygen atoms on the adjacent chain. Since each amino acid has its amino group hydrogen-bonded to the chain on one side and its carboxyl group to the chain on the other side, sheets can grow indefinitely.

TERTIARY STRUCTURE. Within seconds to minutes of their synthesis on ribosomes, proteins fold up into an essentially compact three-dimensional shape—their tertiary structure. Ordinary chemical forces fully determine both the steps in the folding pathway and the stability of the final shape. Some of these forces are hydrogen bonds between side chains of specific amino acids. Others involve electrical attraction between positively and negatively charged side chains. Perhaps most important, however, are what are called hydrophobic interactions—a scientific restatement of the observation that oil and water do not mix.

Some amino acid side chains are essentially oil-like (hydrophobic—literally, “water-fearing”). They accordingly stabilize tertiary structures that place them in the interior, largely surrounded by other oil-like side chains. Conversely, some side chains are charged or can form hydrogen bonds. These are hydrophilic, or “water-loving,” side chains. Unless they form hydrogen or electro-

static bonds with other specific side chains, they will stabilize structures in which they are on the exterior, interacting with water.

The forces that govern a protein's tertiary structure are simple. With thousands or even tens of thousands of atoms involved, however, the interactions can be extremely complex. Today's scientists are only beginning to discover ways to predict the shape a protein will assume and the folding process it will go through to reach that shape.

Digestion, metabolism, and elimination

Food in the human diet consists of proteins, **carbohydrates**, **fats**, **vitamins**, and **minerals**. The majority of minerals and vitamins pass through to the bloodstream without the need for further digestive changes, but other nutrient molecules must be broken down to simpler substances before they can be absorbed and used. Foods in the **stomach** are broken down by the action of the gastric juice containing hydrochloric acid and a protein-digesting enzyme called pepsin. Gastric juice is needed mainly for the digestion of protein by pepsin. If a hamburger and bun reach the stomach, there is no need for extra gastric juice for the bun (carbohydrate), but the hamburger (protein) will require a much greater supply of gastric juice. The gastric juice already present will begin the breakdown of the large protein molecules of the hamburger into smaller molecules: polypeptides and peptides.

From the time a protein-containing food is eaten, to its breakdown and subsequent use or excretion, many complicated processes and steps take place in the body. These processes are part of **metabolism**, in which a series of metabolic pathways are involved in the breakdown of the foods. Proteins are initially degraded into constituent amino acids, which may be converted to compounds called pyruvic acid or acetyl-CoA before being passed into the metabolic pathway known as the Krebs cycle; or they may enter the Krebs cycle directly after being converted into one of the metabolites of this metabolic pathway.

Proteins contain substantial amounts of nitrogen. When dietary protein is broken down into amino acids, nitrogen is produced and is eliminated in the urine in the form of urea, and in smaller amounts as uric acid, ammonia, and creatinine. Unabsorbed protein is excreted in the feces, but only about 10 grams per day because protein is used very efficiently in the body. Amino acids may be recycled many times for different functions. There are minute losses of protein as skin, or in menstrual blood, semen, and hair.

Function

After water, protein makes up the greatest percentage of human body weight. This key nutrient provides the building blocks children and adults need for growing, maintaining, and repairing worn-out cells. Without protein, human bodies could not regulate fluids and immune systems would shut down. In fact, if not for protein there would be no hormones or enzymes—the protein compounds that take part in every single physical function. The role of protein in the diet is mainly as a source of amino acids, some of which are essential because they cannot be produced in the body. Others are referred to as nonessential because they can be made in the body from simple precursors. Amino acids are central to every human bodily function with every chemical reaction that occurs. Some of the uses of amino acids are:

- Synthesis of substances called purines and pyrimidines, important for deoxyribonucleic acid (DNA).
- Producing creatine in skeletal muscle; creatine is needed for subsequent production of creatinine.
- Building and maintaining muscle and tissues.
- Maintaining proper cellular function.
- Controlling chemical reactions through enzymes.

There are also circulating proteins in the plasma of the blood that vary depending on the levels in the diet. Some examples of plasma proteins with important functions in the body are: serum albumin, retinal binding protein, fibrinogen, etc. If the protein intake is low, these proteins will be reduced in the blood and therefore their functions in the body may be affected.

Approximately 300 grams of protein is produced per day in the body with a dietary intake of about 100 grams. Some of the protein needed is acquired from endogenous sources (in the body from protein breakdown) and is released into the intestinal lumen; it is estimated at about 70 grams per day.

Role in human health

The human body, minus water, is mostly composed of amino acids. Almost all of the hormones are amino acids. Regulation of protein metabolism is necessary to maintain proper bodily function; therefore, it is important to eat protein-rich foods. Protein is also important for building body tissue and synthesizing enzymes. Twenty amino acids are used for protein synthesis. Animals and plants are quick and available sources of what are termed “essential” amino acids; they are called essential because the body cannot internally build them. Normal growth and health are dependent upon these essential amino acids. These essential amino acids are histidine, trypto-

phan, lysine, methionine, phenylalanine, threonine, valine, leucine, isoleucine and possibly arginine. Tyrosine and cysteine are produced in the body from phenylalanine and methionine respectively. The “nonessential” amino acids include alanine, glycine, serine, glutamic acid, aspartic acid, asparagine, glutamine, proline. They are considered nonessential because the body can produce them with simple precursors.

Protein requirements

On a per kilogram basis, protein requirements in humans are highest in infancy and gradually decline throughout one’s life, except in such circumstances as **pregnancy**, **lactation**, and illness. The Recommended Daily Allowance (RDA) suggests protein requirements based on age incrementally. The amount of protein needed also depends on body weight, but it is not a linear relationship. A person who weighs 400 lbs (181.43 kg) does not need four times as much protein as a person weighing 100 lbs (45.35 kg). From birth to three months, protein needs are at their highest (2.2 grams per kilogram of body weight). The requirement for adult males and females is 0.8 g/kg. This amount is equal to about 63 grams of dietary protein for a male aged 25-50 years who weighs 174 lbs. (79 kg), and 50 grams for a female aged 25-50 years who weighs 139 lbs. (63 kg). The average Western diet contains ample amounts of protein. In fact, most people in industrialized countries eat more protein than they need. In the United States, true protein deficiency is rare except when excess protein is lost and protein requirements are increased, as in cases of:

- **burns**
- **fever**
- fractures
- surgery
- wasting and/or cachexia associated with **cancer** (Approximately half of all cancer patients experience cachexia, a wasting syndrome that induces metabolic changes leading to a loss of muscle and fat.)
- chronic renal failure, when the patient is undergoing hemodialysis or peritoneal dialysis

Protein requirements may also be increased in training athletes because of greater muscle mass during training season.

In general, consequences of inadequate protein intake may include a faster loss of muscle mass from the body; higher risks of **infection**; and reduced protein reserves for use during periods of trauma or infection. In

addition, protein breakdown is rapid when a person is fasting or bedridden.

Dietary sources of protein

Meat, milk, eggs, poultry, and seafood are considered high-quality, “complete” proteins because they have all the essential amino acids (protein’s building blocks) in just the right proportion. Those sources are considered more complete than vegetable protein, such as beans, peas, and grains, also considered a good—even if not complete—source of amino acids. Except for soy, plant sources—nuts, beans, seeds, and grains—are deficient in one or more of the essential amino acids. But plant foods contain other vital nutrients (such as phytochemicals and fiber) not found in animal foods. Dietitians recommend that a healthy diet should consist of foods from a variety of sources and should include 10–20% of daily calories from protein (poultry, fish, dairy, soy protein, nuts, legumes, eggs, peanut butter, and vegetable sources).

Dietary guidelines

The food pyramid, developed by nutritionists, provides a visual guide to healthy eating. At its base are those foods that should be eaten numerous times each day, while at its apex are those foods that should be used sparingly. The pyramid suggests a range of servings in each group so that the number of servings can be adjusted to suit each individual’s caloric requirements. The daily recommendations (from bottom to top) of the food pyramid include:

- Bread, cereal, rice, and pasta: 6–11 servings.
- Vegetables: 3–5 servings.
- Fruits: 2–4 servings.
- Milk, yogurt, and cheese: 2–3 servings.
- Meat, poultry, fish, dried beans, eggs, and nuts: 2–3 servings.
- Fats, oils, and sweets: use sparingly.

Protein-modified diets

High-protein diets are designed to provide about 1.5 g of protein for each kilogram of a person’s body weight. Complex proteins, such as milk and meats, should make up one-half to two-thirds of the daily protein requirement. High-protein diets are recommended for people who:

- Have an increased need for protein due to protein-calorie malnutrition; severe **stress**; or such conditions as **AIDS**, cancer, or burns with high metabolic rates that lead to the loss of large amounts of protein.

KEY TERMS

Alpha helix—A type of secondary structure in which a single peptide chain arranges itself in a three-dimensional spiral.

Beta sheet—A type of secondary structure in which several peptide chains arrange themselves alongside each other.

Cachexia—A condition in which the body weight “wastes” away, characterized by a constant loss of weight, muscle, and fat.

Creatine—A substance found in skeletal muscles; it is produced by other amino acids.

Domain—A relatively compact region of a protein, separated from other domains by short stretches in which the protein chain is more or less extended; different domains often carry out distinct parts of the protein’s overall function.

Enzymes—Enzymes are protein catalysts that increase the speed of chemical reactions in the cell without themselves being changed.

Hormones—Hormones are messengers that travel to tissues or organs, where they may stimulate or inhibit specific metabolic pathways.

Messenger ribonucleic acid (mRNA)—A molecule of RNA that carries the genetic information for producing one or more proteins; mRNA is produced by copying one strand of DNA, but is able to move from the nucleus to the cytoplasm (where protein synthesis takes place).

Peptide bond—A chemical bond between the carboxyl group of one amino acid and the amino nitrogen atom of another.

Phenylketonuria (PKU)—A rare hereditary condition in which phenylalanine (an amino acid) is not

properly metabolized. PKU may cause severe mental retardation.

Polypeptide—A group of amino acids joined by peptide bonds; proteins are large polypeptides, but no agreement exists regarding how large they must be to justify the name.

Primary structure—The linear sequence of amino acids making up a protein.

Quaternary structure—The number and type of protein chains normally associated with each other in the body.

Protein-calorie malnutrition—A lack of protein and calories are consumed to sustain the body composition, resulting in weight loss and muscle wasting.

Ribosome—A very large assemblage of RNA and protein that, using instructions from mRNA, synthesizes new protein molecules.

Secondary structure—Certain highly regular three-dimensional arrangements of amino acids within a protein.

Tertiary structure—A protein molecule’s overall three-dimensional shape.

Transfer ribonucleic acid (tRNA)—A small RNA molecule, specific for a single amino acid, that transports that amino acid to the proper spot on the ribosome for assembly into the growing protein chain.

Wasting—When inadequate calories are consumed, it can lead to “wasting” or depletion of body mass. Wasting results in weight loss in such tissues as skeletal muscle and adipose tissue (fat).

- Have malabsorption syndromes, celiac disease, or other disorders characterized by poor food absorption.

A low-protein diet excludes dairy products and meats, and requires that about three-fourths of the daily allowance of protein come from high-value protein sources. Supplements may be prescribed to prevent amino-acid deficiencies. Low-protein diets are used in treatment of conditions such as **liver** cirrhosis and kidney disease (excluding chronic renal failure patients who have increased protein needs because of losses that occur during dialysis).

Common diseases and disorders

The metabolic pathways in the body for protein metabolism and energy metabolism are interrelated. Certain metabolic conditions distort this relationship, namely diabetes, kidney failure, fever, cancer, and liver cirrhosis.

Inborn errors of metabolism (also called human hereditary biochemical disorders) have genetic origins; these errors interfere with the synthesis of proteins, carbohydrates, fats, enzymes, and many other substances in

the body. Abnormalities in the breakdown, storage, or production of proteins, fats and carbohydrates, or in the energy cycles of cells are typically the manifestation of this disorder. Disease and death may result from the absence or excess of normal or abnormal metabolites. For example, phenylketonuria (PKU) is a hereditary condition in which phenylalanine (an amino acid) is not properly metabolized. PKU may cause severe mental retardation. Some inborn errors of metabolism require dietary and/or nutrient modification depending on the specific metabolic error. A low-phenylalanine diet is normal treatment for PKU.

Celiac disease, also known as nontropical sprue, gluten enteropathy, or celiac sprue, is an inherited disorder resulting in malabsorption because of an allergic reaction after consumption of a protein called gluten. This intolerance causes patients with celiac disease to suffer weight loss, **diarrhea**, malnutrition, and bloating. By eliminating foods containing gluten from the diet, further damage to the intestines can be prevented, symptoms are relieved, and malabsorption of nutrients is corrected. Gluten is found in wheat, rye, barley, and oats. Registered dietitians and physicians can assist the patient with the diet modifications needed for each disease.

Other conditions that may occur due to protein metabolism or absorption abnormalities include:

- muscle wasting and atrophy, which may occur when there is decreased protein absorption and metabolism due to causes such as malabsorption syndrome
- edema (fluid retention in the body's tissues) due to decreased protein absorption
- malnutrition and weight loss due to decreased fat, carbohydrate, and protein absorption

Protein-calorie malnutrition (or protein-energy malnutrition) is a condition associated most closely with weight loss, starvation, or illness and is common in cancer patients. It occurs when a lack of protein and calories are consumed to sustain body composition. When inadequate calories are consumed, the body's functionality declines, which may lead to illness and perhaps death. Exhaustion, weakness, decreased resistance to infection, and a progressive wasting of body muscle and fat stores occur.

Certain conditions may require protein restrictions; for example, acute liver or kidney failure, and uremia (increased urea in the blood).

Powder and tablet forms of amino acids have become popular as health supplements. But their prolonged excessive use can upset the natural amino acid balance and lead to kidney, liver, and nervous system

damage. Do not take these supplements without first consulting a registered dietitian or physician.

Psychiatric assisting

Definition

A psychiatric assistant, also known as a psychiatric technician or mental health technician, works in a variety

KEY TERMS

Interdisciplinary team—A team of professionals from many different disciplines, such as nurses, psychotherapists, social workers, psychologists, occupational therapists, and physicians.

Paraprofessional—A paraprofessional assists professional-level personnel such as nurses, physicians, and therapists in hospitals, medical facilities, and mental health facilities.

of inpatient psychiatric settings with mentally ill adults and children or those with behavioral disorders.

Description

Psychiatric assistants or technicians work with emotionally disturbed or mentally impaired individuals, usually in psychiatric hospitals or mental health clinics. They work as members of interdisciplinary teams of mental health professionals, such as psychiatrists, psychologists, registered nurses, clinical social workers, and others. In general, psychiatric aides help patients with personal grooming and participation in educational, recreational, and therapeutic activities. They may interact and spend more time with patients than any other treatment team members. Psychiatric assistants usually have some type of formal training or education in the behavioral sciences. These paraprofessionals participate in both the planning and implementing of individual patient treatment plans. They may be given responsibility for interviewing patients, record keeping, assisting in administration of medications, and coordinating therapy and group therapy sessions. Psychiatric assistants must have good observation skills, as their job entails recognizing and reporting changes in the behavior of patients to other team members.

Work settings

Psychiatric assistants or technicians work in a wide variety of settings, including psychiatric hospitals, community general hospitals, community mental health centers, psychiatric clinics, schools for the mentally retarded, social service agencies, geriatric **nursing homes**, child or adolescent centers, and halfway houses. They generally work a 35- to 40-hour week. Because patients need care 24 hours a day, scheduled work hours may include nights, weekends, and holidays. Most of the psychiatric assistants' work time is spent on their feet.

Psychiatric assistants are often confronted with violent patients who must be restrained, which is an emotionally draining and sometimes dangerous task. However, many psychiatric assistants glean satisfaction from assisting those in need of support and encouragement. Individuals in this field should be healthy, tactful, patient, understanding, assertive, emotionally stable, dependable, and have a strong desire to help people. They should also be able to work as part of a team, have good communication skills, and be willing to perform repetitive routine tasks. Opportunities for advancement within these occupations are limited. To enter other health occupations, psychiatric assistants often need additional formal training. Some employers and unions provide opportunities by simplifying the educational paths to advancement. Working as a psychiatric assistant can also help individuals decide whether to pursue a career in the health care field.

Education and training

Most psychiatric technicians are required to have at least a bachelor's degree and several hours of clinical training on the psychiatric unit. Individual requirements vary from state to state, but many states require specific college coursework credits in nursing science, mental disorders, developmental disabilities, and **pharmacology**. To help keep psychiatric assistants current with recent advances in their field, some states require employees to complete several hours of continuing education courses every two years in order to maintain their position or certification. Some facilities provide classroom instruction for newly hired assistants, and others rely exclusively on informal on-the-job instruction from a licensed nurse or an experienced team member. Such training may last several days to a few months. From time to time, psychiatric assistants may also attend lectures, workshops, and in-service training.

Advanced education and training

Advanced training and education is not always required of psychiatric assistants. However, some psychiatric assistants choose to pursue a master's degree in clinical social work or psychology to further their career and gain useful clinical expertise. Advanced or "senior" psychiatric assistants may be required to hold a postgraduate degree in some states. The American Association of Psychiatric Technicians offers a voluntary certification exam for psychiatric assistants to test their knowledge of basic psychiatric technology. This certification is a benefit to mental health assistants, psychiatric aides and related employees in the 46 states that do not have licensed psychiatric technicians, and also to those in

the armed forces. The examination is a 201-question, open-book written test that individuals can take at home. Although it tests for basic knowledge about nursing, mental illness and developmental disabilities, it is not nearly as comprehensive as the licensing exams that some states require. National certification allows individuals to put the initials NCPT after their names, which stands for Nationally Certified Psychiatric Technician. In some cases, those who are certified receive better pay and promotional opportunities. In some instances, such as for mental health workers employed by the Navy, certification is required.

Future outlook

Nationally, employment of psychiatric assistants is predicted to grow more slowly than average through 2008. On the one hand, some growth will result from the increasing population of elderly people. Elderly adults may have such mental health problems as **Alzheimer's disease** that require care. In addition, outpatient mental health centers will need more aides, because people are often more accepting of treatment for drug abuse and **alcoholism**. Thus, more people will go to these centers, and there will be a greater need for psychiatric assistants. On the other hand, employment in hospitals is predicted to decline. Because hospitals employ about half of all psychiatric assistants, this decline will have a significant effect on the occupation. The main reason for this decline is that hospitals are admitting fewer psychiatric patients because of poor reimbursement rates from insurance companies and government agencies. The turnover rate in this field is high because of low wages and lack of advancement opportunities. Therefore, many jobs are expected to open as workers leave this occupation.

According to the American Association of Psychiatric Technicians, a major area of expansion for psychiatric assistants is the compelling need to provide treatment to thousands of state prison inmates with serious mental illness and developmental disabilities. The Department of Corrections estimates that one out of every 12 inmates suffers from serious mental illness. Because the prison population is expected to grow to more than 240,000 inmates by the turn of the century, a tremendous opportunity exists for psychiatric assistants and technicians. Psychiatric assistants function in various aspects of this challenging new program, including crisis intervention, mental health screening, patient assessment, implementation of treatment programs, supervising suicide risks, administering medications, maintaining **medical records**, and quality assurance. Another function involves parole programs that prepare inmates for productive lives after release.

Psychiatric rehabilitation

Definition

Psychiatric rehabilitation involves helping people with mental illness gain or improve skills while obtaining the necessary resources and support to reach their goals.

Purpose

The purposes of psychiatric rehabilitation include helping individuals cope more effectively with the symptoms of their disorders; preventing or delaying the reemergence of symptoms; assisting the individual in managing or reducing secondary symptoms not relieved by medication, e.g., social withdrawal or apathy; teaching or restoring social and living skills that may never have been learned or that have atrophied during periods of illness or hospitalization; and enhancing support while lessening **stress** in the individual's environment.

Therefore, the goals of rehabilitation professionals are to sustain symptomatic relief, establish or reestablish interpersonal and independent living skills, and help individuals reach a satisfactory quality of life.

Description

The concepts of mental health and mental illness are culturally determined. In the United States mental illness is generally viewed as a maladaptive response to stress, evidenced by thoughts, feelings, and behaviors that interfere with social, occupational, or physical functioning.

Of the estimated 40 million people in the United States who have psychiatric disabilities, approximately five million are considered seriously mentally ill. People with psychiatric disabilities often have limited daily functioning that includes difficulties in relating, problems coping with stress, difficulty concentrating, and a lack of energy or initiative.

Psychiatric rehabilitation takes place in a variety of settings, including mental health centers, hospitals, shel-

tered workshops, halfway houses, correctional facilities, places of employment, and the individual's home. It most often involves assessment, training, and modification of personal and community environments. Because rehabilitation focuses on adjustment to everyday life, it is important for the individual to participate as much as possible in choosing the objectives.

Complications

Medications prescribed for severe mental illnesses, called neuroleptic drugs, have a number of side effects. Standard drugs prescribed for **schizophrenia**, one of the most debilitating mental illnesses, include Haldol, Thorazine, Trilafon, Mellaril, Serentil, Stelazine, and Prolixin. Side effects include agitation, sleepiness and lethargy, dry mouth, eye problems, allergic reactions, weight gain, menstrual irregularities, and **sexual dysfunction**. Malignant neuroleptic syndrome, a less common but more serious side effect, causes very high body temperatures that can be fatal in some cases if not treated promptly. Hyperprolactinemia or high levels of the female hormone prolactin are common among those taking neuroleptics. This side effect causes menstrual abnormalities while increasing the risk for **osteoporosis** and **breast cancer**.

The most disturbing and common of the side effects are known as extrapyramidal symptoms, which cause movement and coordination difficulties. Women are at higher risk for these symptoms, and the risk increases with the length of time the drug is taken and age. Nearly every neuroleptic drug can cause extrapyramidal side effects, which occur in up to 70% of patients taking these medications. A condition known as acute dystonia can develop shortly after taking **antipsychotic drugs**, resulting in abnormal muscle spasms, particularly of the neck, jaw, trunk, and eye muscles. The most serious effect of antipsychotic therapy is tardive dyskinesia, which causes repetitive and involuntary movements or tics—most often of the mouth, lips, legs, arms, or trunk.

Results

The effectiveness of medication is determined by the degree to which it helps the individual manage the symptoms of their illness. Effectiveness of treatments that help develop an individual's coping skills are assessed on the basis of how well the individual is able to develop these skills.

Health care team roles

Professionals involved in psychiatric rehabilitation vary according to setting and may include nurses, psychiatric social workers, rehabilitation counselors, clinical psychologists, psychiatrists, recreation therapists, and paraprofessionals.

A psychiatric nurse's responsibilities may include case management, client advocacy, managing medications, facilitating therapy (individual, family, or group), clinical supervision, serving as a liaison, and consulting.

Psychiatric social workers are skilled in assessing family, social, and environmental factors that contribute to dysfunctional behavior in the individual or the family. They are also primary contributors to the planning and implementation of follow-up care.

Rehabilitation counselors most often are involved in case management and in assisting individuals with employment, housing, coping skills, and academic preparation.

Psychologists most directly involved in the diagnosis and treatment of mental illness are called clinical psychologists. Clinical psychologists are concerned with the diagnosis of mental illness and have expertise in diagnosing and assessing treatment effects by using personal inventories and tests, including intelligence tests.

The role of the psychiatrist involves making medical diagnoses, prescribing medications, and administering such additional treatments as electroconvulsive therapy (ECT), commonly known as shock treatment.

Recreation or activity therapists provide structured activities designed to help individuals deal with their problems. They assist in diagnostic and personality evaluation through observing clients during activities. Activity therapists often prescribe activities that enable individuals to express emotions and develop skills in relating with others.

Psychological tests

Definition

Psychological tests are written, visual, or verbal evaluations administered to assess the cognitive and emotional functioning of children and adults.

Purpose

Psychological tests are used to assess a variety of mental abilities and attributes, including cognitive skills, motivation, personality traits, and neurological functioning.

Achievement and ability tests

For children, academic achievement, ability, and intelligence tests may be used as tools in school placement; in determining the presence of a learning disability or a developmental delay; in identifying giftedness; or in tracking intellectual development. Intelligence testing may be used with adults to determine vocational ability (e.g., in career counseling) or to assess adult intellectual ability in the classroom.

Personality tests

Personality tests are administered for a wide variety of reasons, from diagnosing psychopathology (e.g., personality disorder, depressive disorder) to screening job candidates. They may be used in an educational or vocational setting to determine personality strengths and weaknesses, or in the legal system to evaluate parolees.

Neuropsychological tests

Patients who have experienced a traumatic **brain** injury, brain damage, or organic neurological problems (for example, **dementia**) are administered neuropsychological tests. Neuropsychological testing evaluates cognitive function, including general intelligence, attention, **memory** span, and judgment; and motor, sensory and

speech ability. Tests can also be used to assess emotional stability, quality of language production, distractibility and other qualities. These tests can document impairments that can be used to diagnose specific neurological illness or damage. In addition, certain neuropsychological measures may be used to screen children for developmental delays and/or learning disabilities.

Precautions

Psychological testing requires a clinically trained examiner to administer the tests. All psychological tests should be administered, scored, and interpreted by a trained and experienced professional—preferably a psychologist or psychiatrist with expertise in the appropriate area.

Psychological tests are only one element of a psychological assessment. They should never be used alone as the sole basis for a diagnosis. A detailed history of the test subject and a review of psychological, medical, educational, or other relevant records are required to lay the groundwork for interpreting the results of any psychological measurement.

Cultural and language differences in the test subject may affect test performance and may result in inaccurate test results. The test administrator should be informed before psychological testing begins if the test taker is not fluent in English and/or belongs to a minority culture. In addition, the subject's motivation and motives may also affect test results.

Description

Psychological tests are formalized measures of mental functioning. Most are objective and quantifiable; however, certain projective tests may involve some level of subjective interpretation. Also known as inventories, measurements, questionnaires, and scales, psychological tests are administered in a variety of settings, including preschools, primary and secondary schools, colleges and universities, hospitals, outpatient healthcare settings, social agencies, prisons, and employment or human resource offices. They come in a variety of formats, including written, verbal, and computer-administered.

Achievement and ability tests

Achievement and ability tests are designed to measure the level of an individual's intellectual functioning and cognitive ability. Most achievement and ability tests are standardized, meaning that norms were established during the design phase of the test by administering the test to a large representative sample of the test population. Achievement and ability tests follow a uniform test-

KEY TERMS

Norms—A fixed or ideal standard; normative or mean score for a particular age group.

Psychopathology—A mental disorder or illness, such as schizophrenia, personality disorder, or major depressive disorder.

Quantifiable—Can be expressed as a number. The results of quantifiable psychological tests can be translated into numerical values, or scores.

Reliability—Capable of producing trustworthy results. Projective tests, such as the Rorschach and Thematic Apperception (TAT) tests, often produce unreliable results because they are easily influenced by the examiner's own assumptions.

Representative sample—A random sample of people that adequately represent the test-taking population in age, gender, race, and socioeconomic standing.

Standardization—The process of determining established norms and procedures for a test to act as a standard reference point for future test results.

Validity—Producing creditable results because of precision of method or adherence to an established norm. Projective tests, such as the Rorschach and Thematic Apperception (TAT) tests, often have questionable validity because they are easily influenced by the examiner's own assumptions.

ing protocol, or procedure (i.e., test instructions, test conditions, and scoring procedures), and their scores can be interpreted in relation to established norms. Common achievement and ability tests include the Wechsler intelligence test (WISC-III and WAIS) and the Stanford-Binet intelligence scales.

Personality tests

Personality tests and inventories evaluate the thoughts, emotions, attitudes, and behavioral traits that comprise personality. The results of these tests determine an individual's personality strengths and weaknesses, and may identify certain disturbances in personality, or psychopathology. Such tests as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) and the Millon Clinical Multiaxial Inventory III (MCMI-III), are used to screen individuals for specific psychopathologies or emotional problems.

Another type of personality test is the projective personality assessment. A projective test asks a subject to interpret some ambiguous stimuli, such as a series of inkblots. The subject's responses provide insight into his or her thought processes and personality traits. The best known projective psychological test is the Rorschach, or inkblot test. The patient is asked to look at each blot and to say what it looks like or what it could be. Because the stimulus is ambiguous, the patient must impose his or her own interpretation. In doing so, thoughts, feelings, and themes, some of which are unconscious, are projected into the material. Projective tests have lower validity and reliability than objective tests. However, the information they provide tends to be richer and more varied. Another projective assessment, the Thematic Apperception Test (TAT), asks the subject to tell a story about a series of pictures. The TAT is often used in a test battery in conjunction with the Rorschach. The TAT purports to provide information about important themes in a person's life or the content of their thinking, whereas the Rorschach provides information about the process and form of a person's thoughts. Although these tests are widely used, research has demonstrated that the examiners' subjective interpretations often affect the outcomes of these tests.

Neuropsychological tests

Many insurance plans cover all or a portion of diagnostic neuropsychological or psychological testing. As of 1997, **Medicare** reimbursed for psychological and neuropsychological testing. Billing time typically includes test administration, scoring and interpretation, and reporting.

Preparation

Prior to the administration of any psychological test, the administrator should provide the test subject with information on the nature of the test and its intended use; complete standardized instructions for taking the test (including any time limits and penalties for incorrect responses); and information on the confidentiality of the results. After these disclosures are made, **informed consent** should be obtained from the test subject before testing begins (except in cases of legally mandated testing, in which consent is not required of the subject).

Results

All psychological and neuropsychological assessments should be administered, scored, and interpreted by a trained professional. When interpreting test results for test subjects, the test administrator will review with sub-

jects: what the test evaluates, its precision in evaluation, any margins of error involved in scoring, and what the individual scores mean in the context of overall test norms and the background of the test subject.

Health care team roles

Nursing staff and allied health professionals can assist in the administration of psychological tests by being familiar with each test and the reason it is being administered. Prior to the administration of psychological tests, nursing staff can provide appropriate **patient education** materials as necessary.

Psychotherapy

Definition

Psychotherapy can be defined as a means of treating such psychological or emotional problems as neurosis or personality disorder through verbal and nonverbal communication. It is the treatment of psychological distress through talking with a specially trained therapist, and learning new ways to cope rather than merely using medication to alleviate the distress. It is done with the immediate goal of aiding the person in increasing self-knowledge and awareness of relationships with others. Psychotherapy is carried out to assist people in becoming

more conscious of their unconscious thoughts, feelings, and motives.

Psychotherapy's longer-term goal is making it possible for people to exchange destructive patterns of behavior for healthier, more successful ones.

Different approaches to psychotherapy

The psychodynamic approach was derived from principles and methods of psychoanalysis, and it encompasses psychoanalysis, Jungian analysis, Gestalt therapy, client-centered therapy, and somatic or body therapies, among other forms of psychotherapy. Psychoanalysis is therapy based upon the work of Austrian physician Sigmund Freud (1856–1939), and those who followed—Carl Jung, Alfred Adler, Erich Fromm, Karen Horney, and Erik Erikson. The basis of psychoanalytic therapy is the belief that behavior and personality develop in relation to unconscious wishes and conflicts from childhood. Gestalt therapy, developed by Frederick (Fritz) Perls, emphasizes the principles of self-centered awareness and accepting responsibility for one's own behavior. Client-centered therapy was formulated by Carl Rogers; it introduced the idea that individuals have the resources within themselves for self-understanding and for change. Part of this concept is that the therapist exposes his or her own true feelings and does not adopt a professional posture, keeping personal feelings unclear. Somatic or body therapies include: **dance therapy**, holotropic breathwork, and Reichian therapy.

The behavioral approach to psychotherapy encompasses various behavior modification techniques and theories, including assertiveness training/social skills training, operant conditioning, hypnosis/hypnotherapy, sex therapy, systematic desensitization, and others. Systematic desensitization was pioneered by Joseph Wolpe after he became frustrated with psychoanalysis. This therapy is a combination of deep muscular **relaxation** and emotive imagery exercises, in which the client relaxes and the therapist verbally sets scenes for the client to imagine. These scenes include elements of the client's fears, building from the smallest fear toward the largest fear. The therapist monitors the client and introduces the scenes, working to maintain the client's relaxed state.

The cognitive approach stresses the role that thoughts play in influencing behavior. Rational-emotive therapy and reality therapy are both examples of the cognitive approach. Rational-emotive therapy was pioneered by Albert Ellis in the mid-1950s. This therapy is based on the belief that events in and of themselves don't upset people, but people get upset about events because of their attitudes toward the events. Ellis's therapy set out to

change people's attitudes about events through objective, firm direction from the therapist and talk therapy. Reality therapy, developed by William Glasser, is based upon the idea that humans seek to satisfy their complex needs, and the behaviors they adopt are intended to accomplish that satisfaction. In Glasser's theory, some people usually fulfill themselves and are generally happy, while others are unable to fulfill themselves and get angry or depressed.

The family systems approach includes family therapy in several forms and attempts to modify relationships within the family. Family therapy views behaviors and problems as the result of family interactions, rather than as belonging to a specific family member. One theory, developed by Murray Bowen, has become its own integrated system with eight basic concepts, including differentiation of self and sibling position. This system attempts to help an individual become differentiated from the family, while remaining in touch with the family system.

In the practical application of these approaches, psychotherapy can take many forms. Some of the most commonly practiced forms include:

- Counseling, the provision of both advice and psychological support, is the most elemental form of psychotherapy. Counseling can be short-term therapy done to assist a person in dealing with an immediate problem such as marital problems or family planning, substance abuse, bereavement, or terminal illness. Or it can be longer-term, more extensive treatment that addresses feelings and attitudes that impair success.
- Group psychotherapy requires less therapist time, and is thus less expensive. In fact, the interactions that occur between members of the group are expected to provide the change and healing each member receives. The therapist functions as a facilitator, or one who encourages and directs the group interchanges. Group therapy provides each member with the additional benefit of sharing and feedback from others experiencing similar emotional problems. This sharing and feedback has been found to be therapeutic; and the group can actually function as a trial social setting, allowing people to try out newly-learned behaviors.
- Family therapy began in the 1930s, when Freudian analyst Alfred Adler used it in working with his patients' entire families. Since the 1950s, it has been a widely used and highly respected modality of therapy based upon the belief that the relationships and interactions within a family have a profound impact upon the patient's mental difficulties. Family therapy generally does not deal with internal conflicts, but rather encourages positive interactions between the various family members.

All forms of psychotherapy require an atmosphere of absolute mutual trust and confidentiality. Without this total safety, no form of therapy will be successful.

Origins

Psychotherapy had its beginnings in the ministrations of some of the earliest psychologists, priests, magicians, and shamans of the ancient world. They attempted to determine the causes of a person's emotional distress by talking, counseling, and educating, and interpreting both behavior and dreams. Many of these practices became suspect as the work of charlatans, and fell into disrepute over the centuries. There was little change or progress in the treatment of mental illness over the centuries that followed.

Austrian physician Franz Anton Mesmer (1734–1815) began using what he termed *magnetism* and both the power of suggestion and hypnosis in 1772. Mesmer's treatments, too, fell into disrepute after his theories were rejected by a medical board of inquiry in 1784. Then, nearly a century later, Mesmer's ideas were rediscovered by French neurologist Jean-Martin Charcot (1825–1893). Dr. Charcot used suggestion and hypnosis for treating psychological difficulties at the Salpêtrière Hospital in Paris in the late nineteenth century. Mesmer is now known as the Father of Hypnosis.

In the late nineteenth and early twentieth century, Austrian physician Sigmund Freud studied Charcot's work, and came to believe that hypnosis was less a treatment for mental illness than a means of determining its underlying cause. Freud used hypnosis as one means of uncovering the often traumatic, not consciously recalled memories of his neurotic patients, just as he used their dreams to evaluate their mental conflicts. He later abandoned hypnosis because he did not induce successful trances in his neurology patients. His *The Interpretation of Dreams*, published in 1899, made the point that a person's dreams were actually a window into the inner, unknown mind—the royal road to the unconscious. He used the information he obtained not only to help his patients, but also to collect data that eventually helped verify some of his psychodynamic assumptions.

Sigmund Freud theorized that the human personality is composed of three basic parts, the id, the ego, and the superego. The id is defined as the most elemental part, the one that unconsciously motivates people toward fulfilling instinctive urges. The ego is more related to intellect and judgment. It arbitrates between the internal, usually unrecognized desires all human beings have and the reality of the external world. The superego, unconscious controls dictated by moral or social standards outside of

ourselves, is probably most easily described as another name for the conscience.

Freud believed that mental illness was the result of people's being unable to resolve conflict, or inadequate settlement of disharmony among the ego, superego, and id. To deal with these internal psychic conflicts, people develop defense mechanisms, which is normally a healthy response. The defense mechanisms become harmful to mental health when overused, or used inappropriately. Freud further postulated that childhood psychic development is primarily based upon sexuality; he divided the first eighteen months of life into three sex-based phases, oral, anal, and genital.

Freud's earliest students, including Carl Jung and Alfred Adler, came to believe that Freud had overestimated the influence sexuality has on psychic development, and found other influences that help to shape human personality. In the late 1800s and into the twentieth century, 1904 Nobel Prize winner Ivan Petrovich Pavlov pioneered the research that would later result in behavioral therapies, such as the work of American behaviorist Burrhus Frederic Skinner. And in the 1930s, American psychologist Carl Ransom Rogers began his school of psychology that emphasized the importance of the relationship between the patient (or client, according to Rogers) and the therapist in bringing about positive psychic change.

Primal therapy, developed by Arthur Janov in the 1960s, is based upon the assumption that people must relive early life experiences with all the acuity of feeling that was somehow suppressed at the time in order to free themselves of compulsive or neurotic behavior. Primal therapy was a cathartic approach that many therapists now believe can impede progress because a person can become addicted to the release (even "high") associated with the catharsis and seek to keep repeating it for the momentary satisfaction. Transactional analysis, based on Eric Berne's work, came into favor in the 1970s, and supposes that all people function as either a parent or child at various times. It teaches the person to identify which role he or she is filling at any given time and to evaluate whether this role is appropriate.

Benefits

The generally accepted aims of psychotherapy are:

- Increased insight into or improved understanding of one's own mental state. This can range from simply knowing one's strengths and weaknesses, to understanding that symptoms are signs of a mental illness, to deep awareness and acceptance of inner feelings.

- The resolution of disabling conflicts, or working to create a peaceful and positive settlement of emotional struggles that stop a person from living a reasonably happy and productive life.
- Increasing acceptance of self by developing a more realistic and positive appraisal of the person's strengths and abilities.
- Development of improved and more efficient and successful means of dealing with problems so that the patient can find solutions or means of coping with them.
- An overall strengthening of ego structure, or sense of self, so that normal, healthy means of coping with life situations can be called upon and used as needed.

Though there are no definitive studies proving that all five of these goals are consistently realized, psychotherapy in one form or other is a component of nearly all in patient and community-based psychiatric treatment programs.

Description

Classic Freudian psychotherapy is usually carried out in 50-minute sessions three to five times per week. The patient lies on a couch while he or she talks with the therapist. Freudian therapy characteristically requires ongoing treatment for several years, though in Freud's era it did not. Most other forms of individual psychotherapy, including Jungian, counseling, humanistic, Gestalt, or behavioral therapies, are carried out on a weekly basis (or more frequently, if necessary), in which the person meets with his or her therapist in the therapist's office, and may or may not continue for longer than a year.

Group therapy is held in a variety of settings. A trained group therapist chooses the people that presumably would benefit and learn from interactions with one another. The size of a group is usually five to 10 people, plus a specially trained therapist who guides the group discussion and provides examination of issues and concerns raised.

Child psychotherapy is done for the same reasons as adult psychotherapy—to treat emotional problems through communication. The obvious difference is that child psychotherapy must acknowledge the child's stage of development. This recognition means that the therapist may use different techniques, including play, rather than only talking to the patient.

A newer direction in the treatment of mental disorders is the use of brief psychotherapy sessions, often combined with medication, to treat neurotic conditions. Another short-term psychotherapy modality is often

KEY TERMS

Behavioral therapy—A collection of techniques for treating mental disorders based upon changing abnormal behavior rather than attempting to analyze its fundamental basis. It is particularly used in phobic or obsessional disorders, and seeks to eliminate symptoms rather than uncovering the underlying psychological cause.

Magnetism—(Animal magnetism) A discredited theory put forth by Viennese physician Franz Anton Mesmer, stating that all persons possess magnetic forces that can be used to influence magnetic fluid in other people and therefore effect healing. Mesmer opened a clinic in Paris in 1778, and appeared to cure people apparently suffering from hysterical conditions, such as emotionally caused paralysis.

Neurosis—A term commonly used to describe a range of relatively mild psychiatric disorders in which the sufferer remains in touch with reality. Neurotic disorders include mild depression; anxiety disorders (including phobias and obsessive compulsive disorders); somatization disorders; dissociative disorders; and psychosexual disorders.

Personality disorder—A group of conditions characterized by a general failure to learn from experience or adapt appropriately to changes, resulting in personal distress and impairment of social functioning.

termed crisis intervention, and is used to aid people in dealing with specific crises in their lives, such as the death of a loved one.

Research and general acceptance

Psychotherapy in its many forms has been accepted and used throughout the world for over one hundred years. It is normally covered as a valid treatment of mental disorder by both public and private health insurers. Because the various types of psychotherapy have different aims, and mental illnesses usually do not have absolute measurable signs of recovery, evaluating psychotherapy's effectiveness is difficult. As a general rule, the majority of people who undergo treatment with psychotherapy can expect to make appreciable gains. Studies have revealed, however, that not everyone who goes into therapy will be helped, or helped as much as others, and some will even be harmed.

Training and certification

Though the actual clinical practice of psychotherapy is very much the same among disciplines, therapists come from a variety of different fields, including medicine, psychology, social work, and nursing.

Psychiatrists are required to complete four years of medical school and one year of internship, followed by a three-year residency in psychiatry. In order to be a psychoanalyst, a minimum of three years, further training at a psychoanalytic institute is necessary, along with personal ongoing analysis.

Psychologists earn a Ph.D. in clinical psychology followed by a year of supervised practice, and additionally may take specialized training at a specific psychotherapeutic school, including therapy for themselves.

Social workers who specialize in mental health must earn a master's degree or doctorate before being allowed to practice.

Psychiatric nurses generally earn a master's degree and practice in hospitals or community mental health centers.

Most states in the United States require a license to practice as a psychotherapist, and by law in the majority of the states, they are accountable only to the other members of their profession.

Puberty

Definition

Puberty is the period of human development during which physical growth and sexual maturation occur.

Description

Beginning as early as age eight in girls—and two years later on average in boys—the hypothalamus (part of the **brain**) signals hormonal changes that stimulate the pituitary. In turn, the pituitary releases its own hormones called gonadotrophins that stimulate the gonads and **adrenal glands**. From these glands comes a flood of sex hormones—androgens and testosterone in the male, estrogens and progestins in the female—that regulate the growth and function of the sex organs. The gonadotrophins are the same for males and females, but the sex hormones they induce are different.

In the United States, the first sign of puberty occurs on average at age 11 in girls, with menstruation and fertility following about two years later. Boys lag behind by about two years. Puberty may not begin until age 16 in boys and may continue in a desultory fashion beyond age 20. In contrast to puberty, which triggers physiological changes, adolescence is more of a social/cultural term referring to the interval between childhood and adulthood.

Diagnosis

Puberty has been divided into five Sexual Maturity Rating (SMR) stages by two doctors, W. Marshall and J. M. Tanner. These ratings are often referred to as Tanner Stages 1-5. Staging is based on pubic hair growth, male genital development, and female breast development. Staging helps determine whether development is normal for a given age. Both genders also grow axillary (armpit) hair and develop pimples. Males develop muscle mass, a deeper voice, and facial hair. Females redistribute body fat. Along with the maturing of the sex organs, there is a pronounced growth spurt averaging 3-4 inches (7.5-9 cm) and culminating in full adult stature. Puberty can be precocious (early) or delayed. It all depends upon the sex hormones.

Puberty falling outside the age limits considered normal for any given population should prompt a search for the cause. As health and **nutrition** have improved over the past few generations, there has been a gradual lowering of the average age for the normal onset of puberty.

- Excess hormone stimulation is the cause of precocious puberty. It can come from the brain in the form of gonadotrophins or from the gonads and adrenals.

Overproduction may be caused by functioning tumors or simple glandular overactivity. Brain overproduction can also be the result of brain infections or injury.

- Likewise, delayed puberty is due to insufficient hormone. If the pituitary output is inadequate, so will be the output from the gonads and adrenals. On the other hand, a normal pituitary will overproduce if it senses there are not enough hormones in circulation.
- There are several congenital disorders (polyglandular deficiency syndromes) that include failure of hormone output. These children do not experience normal puberty, but it may be induced by giving them the proper hormones at the proper time.
- Finally, there are abnormalities in hormone production in females that produce male characteristics—so called virilizing syndromes. Should one of these appear during adolescence, it will disturb the normal progress of puberty. The reader should note that virilizing requires abnormal hormones in a female, while feminizing results from the lack of hormones in a male. Each embryo starts out life as a female. Male hormones transform it into a male if they are present.

Delayed or precocious puberty requires measurement of the several hormones involved to determine which are lacking or which are in excess. There are **blood** tests for each one. If a tumor is suspected, imaging of the suspect organ needs to be done with x rays, computed tomography scans (**CT scans**), or magnetic resonance imaging (MRI).

Treatment

Puberty can be a period of great **stress**, both physically and emotionally. The psychological changes and challenges of puberty are compounded if its timing is off.

If puberty is early, the offending gland or tumor may require surgical attention, although there are several drugs now that counteract hormone effects. If it is delayed, puberty can be stimulated with the correct hormones. Treatment should not be delayed, because necessary bone growth is also affected.

Prognosis

For individuals facing delayed or accelerated puberty, properly administered hormones can restore the normal growth pattern.

Health care team roles

Pediatricians or family physicians usually diagnose abnormalities of puberty. Endocrinologists may assist

KEY TERMS

Adrenals—Glands on top of the kidneys that produce four different types of hormones.

Computed tomography scan (CT)—A method of creating images of internal organs using x rays.

Embryo—The life in the womb during the first two months.

Hormone—A chemical produced in one place that has an effect somewhere else in the body.

Hypothalamus—Part of the brain located deep in the center of the skull and just above the pituitary.

Gonads—Glands that make sex hormones and reproductive cells—testes in the male, ovaries in the female.

Magnetic resonance imaging (MRI)—A method of creating images of internal organs. Magnetic resonance imaging (MRI) uses magnetic fields and radio-frequency signals.

Pituitary—The “master gland” of the body, controlling many of the others by releasing stimulating hormones.

Syndrome—A collection of abnormalities that occur often enough to suggest they have a common cause.

with assessment and treatment. Therapists and counselors may provide emotional support as needed.

Prevention

As puberty is an entirely normal process, there is neither a way nor a need to prevent it.

Public health

Definition

Public health is the science and clinical practice of population and community-based efforts to prevent disease and disability, and promote physical and mental

health. It considers the health of groups, communities, or populations as opposed to the health of individuals. Public health addresses a variety of medical and social issues including:

- environmental health
- nutrition and food safety
- immunization and infectious diseases
- injury and violence prevention
- maternal, infant, and child health
- substance abuse
- chronic disease prevention and treatment
- access, availability, and affordability of health care
- education, screening, and outreach services

Description

The science of public health is called epidemiology. It is the study of the occurrence of disease in such naturally existing populations as nations, cities, or communities. The term “epidemiology” comes from the Greek word epidemic, which means “upon the people.” The earliest epidemiologists (public health scientists) worked to prevent the spread of epidemics.

Today, epidemiologists gather and analyze information about populations to manage and prevent disease. Epidemiologists are trained in highly specialized research methods: surveillance, investigation, analysis, and evaluation. Surveillance refers to systematic data collection and analysis; it enables the epidemiologists to detect changes that may require investigation. Epidemiological investigation involves observation, detailed descriptions of the problem, documentation of data, and analysis. Evaluation is the process that helps to answer such a question as “How often should men between the ages of 40 and 60 be screened for **hypertension** (high **blood** pressure)?”

By analyzing population data, epidemiologists also are able to describe diseases and determine the factors that cause them. Epidemiology is a quantitative science; it measures rates and proportions. Two commonly used rates are prevalence and incidence rates. Prevalence describes the characteristics of a given population at a specific moment in time; it is like a snapshot.

Incidence describes the rate of development of a disease in a given population over a specified time interval. Incidence offers a longer view of population dynamics, like a video, as opposed to the snapshot offered by the prevalence rate. Epidemiologists also analyze such other rates as morbidity (disease-related illness) and mortality (death).

Public health practitioners rely on the findings of epidemiologists to develop health services, allocate resources, and determine standards of care. The results of epidemiological studies also influence health policy. For example, epidemiological research helps to determine how many health care professionals are needed based on population; the effectiveness of various treatments; and schedules for immunization or screening.

Viewpoints

Historically, public health disease prevention activities focused primarily on sanitation (also referred to as environmental health) and hygiene. Public health measures aimed to ensure the safety of food and water supplies, and to prevent transmission of communicable (capable of being transmitted) diseases. In some developing countries, these same basic public health problems, such as adequate food supplies and potable (fit to drink) water, continue to threaten health and longevity.

During and after World War II, such advances in medicine as the development of **antibiotics**, cardiac surgery, and physical rehabilitation changed the emphasis of public health in the United States. Federal, state, and local governments enacted legislation to protect public health. Federal laws aimed at safeguarding public health. Major regulations passed during the twentieth century include:

- the 1938 Food, Drug and Cosmetic Act, which bans distribution of unsafe products and prohibits false advertising
- the 1972 Clean Water Act, which forbids release of pollutants into rivers, streams, and waterways
- the 1974 Safe Drinking Water Acts, which established standards for safe drinking water
- the 1976 Resource Conservation and Recovery Act, which stipulates the safe storage, transport, treatment and disposal of hazardous waste materials
- the 1990 Clean Air Act, which reduced industrial discharge or emission of pollutants into the air and set standards for vehicular emissions

Today, public health practitioners continue to work to prevent disease. However, their efforts are often directed to addressing such social issues as access to health care, and promoting such lifestyle changes as smoking cessation, responsible sexual behavior, and violence prevention.

Frequently, public health professionals must work cooperatively with persons in other disciplines to achieve health promotion objectives. For example, public health practitioners may work with educators and schools to

KEY TERMS

Communicable—Capable of being transmitted.

Epidemiology—The study of disease occurrence in human populations.

Incidence—The rate of development of a disease in a given population over time.

Potable—Safe to drink.

Prevalence—The rate describing the characteristics of a given population at a specific moment in time.

help combat illiteracy, since persons unable to read may be less able to obtain needed health care services. Similarly, they may work with urban planners and housing specialists to identify such health hazards as lead-based paints or asbestos.

The Healthy People 2010 initiative is a national plan to assist states, communities and professional associations to develop programs to improve health. Coordinated by the Office of Disease Prevention and Health Promotion (ODPHP) of the Department of Health and Human Services, the program's goals are to: increase quality and years of healthy life; and eliminate health disparities. Healthy People 2010 targets ten areas for improving health standards in the United States. They are:

- physical activity
- overweight and obesity
- tobacco use
- substance abuse
- responsible sexual behavior
- mental health
- injury and violence
- environmental quality
- immunization
- access to health care

Professional implications

Medical, nursing and allied health professionals and practitioners work in the field of public health. Public health professionals are employed by hospitals, health plans, managed care organizations, clinics, medical relief organizations (e.g., American Red Cross, American Heart Association, American Cancer Society) and

schools as well as federal, state, and local government health departments. Careers in public health include:

- public health nursing
- environmental health technologists and specialists
- restaurant and food safety inspectors
- community health educators
- epidemiologists, biostatisticians, and researchers
- administrators
- patient and consumer health advocates

Public health nursing began in the United States during the late 1800s. Public health nurses helped to prevent and manage outbreaks of smallpox, cholera, typhoid, **tuberculosis**, and other communicable diseases. The profession continues to attract nurses interested in community health education and preventive services. Public health nurses (also called community health nurses) work in clinics, schools, voluntary agencies, and provide skilled nursing assessments, visiting nurse services, and **home care**.

Federal government agencies that belong to the U.S. Department of Health and Human Services provide many vital public health services. The agencies devoted to health care include the Health Care Financing Administration (HCFA), Office of Development Services, Food and Drug Administration (FDA), National Institutes of Health (NIH) and the Centers for Disease Control and Prevention (CDC).

HCFA administers **Medicare** and **Medicaid**, programs that finance health care services for older adults, persons with disabilities and those unable to afford medical care. The FDA is the agency responsible for ensuring food, drug, and cosmetic safety. It also enforces labeling practices, so that consumers receive accurate, truthful information about the content, benefits, and risks of products).

Each of the 13 institutes of the NIH is involved in organ or disease-specific research activities. The seven centers of the CDC research and track infectious and other diseases in order to identify sources of disease and prevent their spread.

Public health administration

Definition

Public health administration is the component of the field of public health that concentrates on management of people and programs. On a day-to-day basis, administration is needed to ensure that organizations operate efficiently and with success. Programs must be guided. The field of administration is concerned with theory and techniques derived from a variety of fields, mainly management.

Description

The work of a public health administrator is at the same time similar to and different from that of persons engaged in administration in other fields. The administrative elements are similar. These include supervising employees, coordinating programs, preparing budgets, monitoring programs, and evaluating results and outcomes. Other aspects that are germane to the field of public health are different from other fields. Public health administrators are concerned with health and disease prevention programs. They administer educational campaigns and try to keep the people they serve healthy. Other health professionals have similar aims of maintaining health but often are restorative or curative rather than preventive.

There are 10 core public health functions with which an administrator must be familiar. There is a specialized body of public health law. Data are constantly being generated. They must be sorted, classified, stored, and interpreted. There are systems to keep track of diseases, vital

events, waste materials, insects and a host of other aspects of public health. Data that are developed must be organized and presented to such various constituencies as members of the public, governmental agencies and professionals. The overall health of the public being served must be periodically assessed. Intervention programs must be created, implemented and evaluated. Other forms of research are conducted.

The day-to-day activities of a public health administrator include human resources management; finance; performance measurement and improvement; communications and marketing; and maintaining relations with members of the media and local government. A public health administrator must build relationships with such various constituencies as consumer groups, health providers and legislators. Leadership is an important aspect of public health administration.

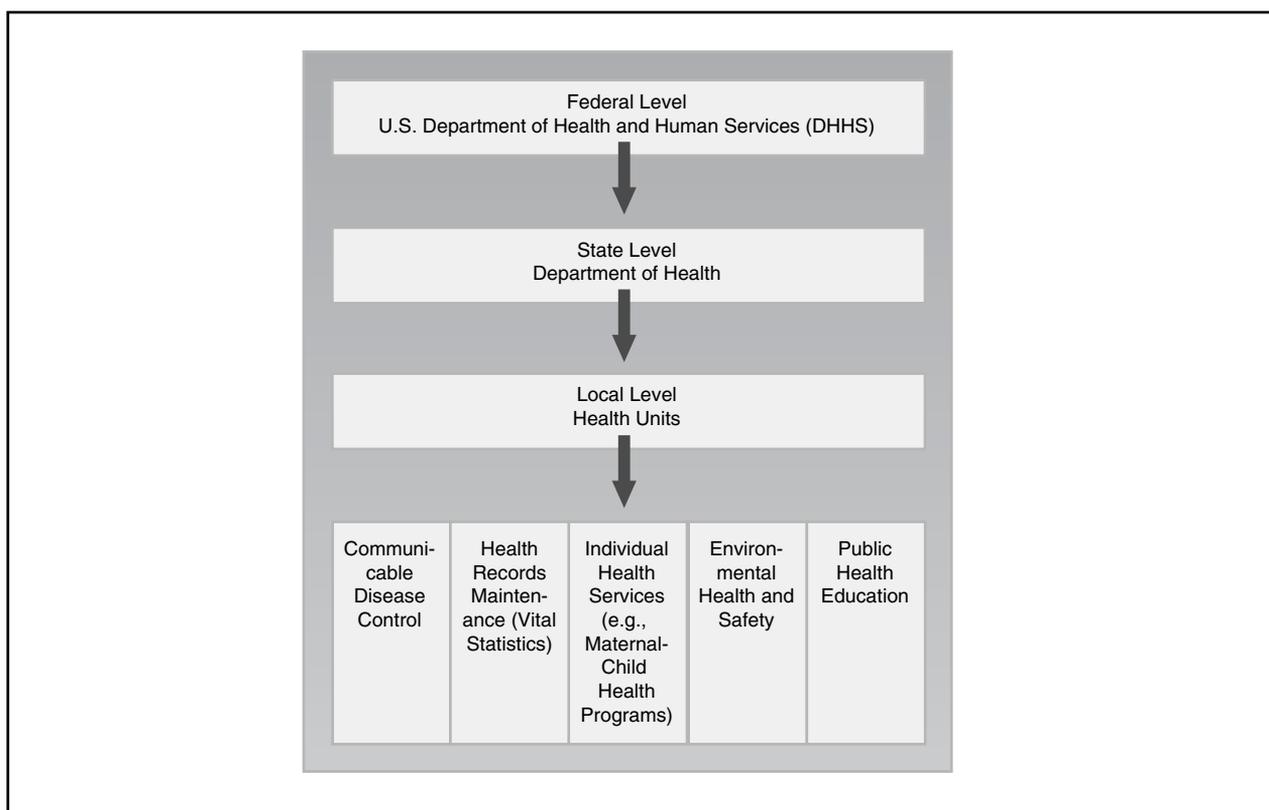

Work settings

The most common work setting for a public health administrator is an office within a local health department or public health agency. There are approximately 3,300 local boards of health in the United States. Their size varies from a single municipality to an entire state. Many consist of one or more counties. Each employs a staff of professionals who provide specialized services. Each provider has a supervisor; larger organizations have more than one layer of supervision. In addition, there are public and private organizations that provide public health services. Governments also employ public health administrators. The number of persons who provide some administrative services within the realm of public health is thus extensive. A conservative estimate for the United States would exceed 20,000 persons.

The majority of public health administrators work in offices. However, this is not universally the case. Using data from a study conducted by the National Association of Local Boards of Health, as of 1997 approximately 70% of all health boards had access to computers, but only 18% had access to the Internet. Among public health employees, as of 2001 about 5% lacked access to computers. This number is declining with passing time. Most administrators have and regularly use electronic tools. Many administrators who work in the field routinely use laptop communication devices.

Education and training

Basic preparation for a career in public health administration usually begins with a college degree. There are persons currently in the work force with less formal education. These people have been typically been

Levels of public health administration. (Delmar Publishers, Inc. Reproduced by permission.)

working in the public health system for many years, having started at a time when formal training in public health or administration was uncommon and largely unavailable. However, their numbers are decreasing. As these people retire, their replacements are entering with more formal training and credentials.

It is possible to learn administration from experience on the job but the time required is increasing each year. As of 2001, a college degree is the functional minimum level of education for admission into the field of public health administration. The actual field of study can vary but an undergraduate degree in management, public health, nursing, community health, applied health, allied health or a related discipline is useful. An optimal undergraduate curriculum should include course work in the following subject areas: management, accounting, finance, economics, biology, environmental health or science, marketing, business, health law, and budgeting. These courses will most likely be supplemented by advanced formal education and practical on-the-job training.

Initial training begins with job orientation. This is relatively similar for most entry-level positions in the

field. During orientation, the structure and reporting relationships of an organization are described. Basic laws and other legal requirements are outlined. Job duties of a particular position are explained. Organizational regulations and requirements are reviewed.

Ongoing training occurs at two levels. The first is specific to a particular working agency or environment. It consists of office and organizational updates, program changes, and information pertaining to other local issues. The second is specific to the field of public health. These updates typically occur at professional conferences and through articles in the secondary literature of public health. They consist of changes in programs that have been proposed or imposed by federal or other funding agencies. They also include new findings related to theories or practice that have been developed by researchers. Changes in reporting procedures are in this category.

Advanced education and training

Advanced training in public health administration can be obtained from a formal graduate degree program

or through continuing education offerings. The most commonly earned graduate credential is a Master of Public Health (MPH) degree. This degree provides a broad-based curriculum for anyone in the field of public health and is appropriate for persons just entering the field as well as those with experience. Other master-level preparations are also useful. These include Master of Business Administration (MBA), Master of Health Services Administration (MHSA), Master of Public Administration (MPA), Master of Hospital Administration (MHA) and Master of Management (MM) degrees. The core requirements of the different degree programs are similar and typically include course work in statistics, economics, management, finance, marketing, issues, law and human resource administration. Elective courses help to tailor a graduate curriculum to the specific needs of each individual student.

There are some differences among the degree courses described. These are typically related to the focus afforded by the training. For example, an MPH degree is specifically concentrated on public health. An MBA provides more general training. While both are useful, the MPH is focused on health. In an analogous manner, MHSA course work focuses on issues related to managing health service providers and organizations. MPA focuses on administration in a public or not for profit environment. The MHA is geared for hospital administrators while the MM is very general. An MPH degree curriculum includes courses in epidemiology and environmental health. The others typically substitute additional courses in economics, accounting, or labor relations.

Some workers in public health administration require continuing education units to maintain a license or certification. Examples of such workers include nurses, social workers, health officers, sanitarians, and physicians. The rules for many of these professionals are not set by federal or national agencies but rather may be specific to the state that has issued the credential. Professionals earning continuing education credits may include courses and seminars that cover aspects of public health administration. In this way, they acquire new and updated knowledge.

Public health administration as a profession does not require practitioners to be certified as of 2001. There is a movement to require certification for public health administrators. If this trend becomes law, more individuals will be seeking advanced education credits in the future. A likely degree option is the MPH.

Future outlook

The future outlook for persons seeking employment in public health administration is quite favorable. With the advent of managed care, prevention and public health have assumed new emphasis in the mainstream practice of medicine. Demand for persons with training in public health administration is likely to increase. In addition, as of 2001, performance standards are being instituted within the field of public health. This trend will increase the demand for people with advanced and specific training in public health administration. With increased requirements for training and preparation, salaries for public health administrators are also likely to rise. As the baby boomer generation ages and retires, the number of agencies and organizations providing services is expected to increase. These demands, too, are likely to drive up salaries for public health administrators.

All persons seeking to enter the field of public health administration will require professional training and preparation. This requirement will translate into opportunities for teachers of this subject. As of 2001, there are not enough people with appropriate professional experience and training to meet the demand for teachers in schools and programs of public health. With demand for trained persons increasing, the demand for teachers is likely to increase over the demand in the recent past.

Puerperal infection

Definition

Puerperal **infection** is a bacterial infection that occurs following **childbirth**. The diagnostic criteria require that the childbearing woman have a temperature elevated over 100.4°F (38°C) on any two of the first 10 post-partum days after day one, or over 101.5°F (38.6°C) during the first 24 hours.

Description

The incidence of puerperal infection is 1%-8% of the post-partum female population in the United States. The incidence is 5 to 10 times higher when a woman delivers by cesarean section. As most births in the United States occur in hospitals, the majority of puerperal infections are considered nosocomial, or hospital-acquired. With **antibiotics** readily available in industrialized countries, death related to puerperal infection is very rare, at 0.3 in 100,000. In developing nations, the death rate due to puerperal infection is estimated to be 100 times higher. Puerperal infection may occur in the genital tract, breast, urinary tract, **lungs**, **blood** vessel, or wound.

Causes and symptoms

The usual cause of puerperal infection is a bacterial infection in the genital tract, primarily the uterus. This infection, called endometritis, is associated with prolonged rupture of membranes; difficult vaginal birth which involved the use of forceps or vacuum extractor; multiple vaginal examinations; low socioeconomic status; and the primary predisposing factor of cesarean section delivery, with an incidence of postoperative infection reported at 29%-85%.

Symptoms of endometritis include elevated temperature, low abdominal **pain** or tenderness, vaginal discharge, or a heavy, malodorous lochia usually in the first two to seven days post-partum. Endometritis is usually polymicrobial; that is, more than one bacterial species is found upon culture. The mixed species tend to multiply their negative effects. Other symptoms in puerperal infection are dependent on the infected site. **Mastitis** or breast infection can be caused by bacterial contamination from the breastfeeding infant’s mouth. Symptoms include elevated temperature, localized inflammation, breast tenderness, general malaise, and muscle aching. Symptoms of a urinary tract infection include elevated temperature, frequent voiding, urgency to void, and pain upon voiding. Back pain, as well as nausea and vomiting, are common with pyelonephritis. Lung infection, or

pneumonia, may be seen especially in the patient who has received **general anesthesia**. Symptoms include decreased or abnormal breath sounds, cough, and chest wall discomfort. An infection in a blood vessel, phlebitis, may be caused by the introduction of **bacteria** by a contaminated intravenous needle or at the site of a blood clot, thrombophlebitis. Wound sites in the post-partum woman may include the episiotomy or cesarean section incision. These sites, if infected, would have inflammation, swelling, and drainage, and the patient would have an elevated temperature. It is interesting to note that while vaginal secretions contain up to 10 billion organisms per gram of fluid, only 1% of post-partum women develop infection in perineal tears or episiotomies.

Diagnosis

Diagnosis of puerperal infection is made on the basis of the presenting symptoms, which must be thoroughly investigated. In addition, diagnostic testing may include a **complete blood count**, chest x-ray, **urinalysis**, or **wound culture**. High vaginal or endocervical cultures are not helpful in identifying a uterine pathogen, and transabdominal uterine aspiration is not recommended, as it may only serve to spread the infection. Blood cultures may be done, but they are positive only 8% of the time. Radiologic testing is helpful if symptoms are resistant to initial treatment or if pneumonia is suspected. Ultrasound or a computed tomography scan (CT scan) may identify a potential abdominal **abscess** or blood clot. **Magnetic resonance imaging** (MRI) may also be used if symptoms of a blood clot are present.

Treatment

Antibiotic therapy is the mainstay of treatment in puerperal infection. Hospitalization may or may not be necessary. Clindamycin and gentamicin may be used as initial therapy, as they are broad-spectrum antibiotics; that is, covering more than one organism. Ampicillin may be added if symptoms persist. If an abscess has been diagnosed, surgical drainage may be required. In the presence of thrombophlebitis, heparin therapy will be needed to provide anticoagulation.

Prognosis

With access to appropriate antibiotics, the prognosis of rapid recovery from puerperal infection is excellent.

Health care team roles

Physicians and nurses are involved in the prevention, diagnosis, and treatment of puerperal infection.

KEY TERMS

Endometritis—Inflammation of the mucous membrane lining the inner surface of the uterus.

Lochia—Discharge from the uterus of blood, mucus, and tissue during the puerperal period.

Mastitis—Inflammation of the breast.

Nosocomial—Pertaining to a hospital or infirmary.

Post-partum—After childbirth.

Puerperal—Period immediately following childbirth.

Good **prenatal care** is essential for avoiding the risk of infection after childbirth. Post-partum nurses assess patients for signs and symptoms of infection and educate patients about these signs and symptoms prior to discharge. Home health nurses making follow-up visits assess patients for signs and symptoms of infection. Emergency physicians are seeing an increasing number of post-partum patients presenting with a **fever** or evidence of infection due to earlier discharge from the hospital after childbirth.

Prevention

Identification of such risk factors as premature rupture of membranes or the use of prophylactic antibiotics at the time of an emergent cesarean section will lower the incidence of puerperal infection. The fundamental practice of strict **aseptic technique** is the first line of prevention.

Pulmonary artery catheterization see **Swan-Ganz catheterization**

Pulmonary function test

Definition

Pulmonary function tests are a group of procedures that measure the function of the **lungs**, revealing problems in the way a patient breathes. These tests can determine the cause of shortness of breath and may help confirm the diagnosis of such lung diseases as **asthma**, chronic bronchitis, or **emphysema**. The tests may also be performed before any major lung surgery to make sure the person will not be at risk of complications because of reduced lung capacity.

Purpose

Pulmonary function tests can help diagnose a range of respiratory diseases that might not otherwise be obvious to the clinician or the patient. These tests are important, since many kinds of lung problems can be successfully treated if detected early.

The tests are also used to measure how a lung disease is progressing, and how serious the lung disease has become. Pulmonary function tests can also be used to assess a patient's response to different treatments.

If a patient shows signs of decreased lung function relative to the normal values for a person of his or her race, sex, age, height, and weight, that person may suffer from a pulmonary disease. There are two types of causes of abnormal pulmonary function, obstructive lung diseases and restrictive lung diseases.

Obstructive lung diseases are characterized by a decreased ability to get air out of the lungs. A patient with an obstructive lung disease generally does not experience difficulty getting air into his or her lungs. Obstructive lung diseases are most easily remembered with the acronym CABBE: **cystic fibrosis**, asthma, bronchiectasis, chronic bronchitis, and emphysema.

Restrictive lung diseases are characterized by a decreased capacity to draw air into the lungs. A patient with a restrictive lung disease generally does not experience difficulty getting air out of his or her lungs. The cause of restrictive lung diseases may be either directly related to a dysfunction of the lungs (intrapulmonary) or not related to a dysfunction of the lungs (extrapulmonary). Intrapulmonary restrictive lung diseases include **pneumonia**, pulmonary fibrosis, and pulmonary **edema**. Extrapulmonary causes of restrictive lung diseases include rib **fractures**, head trauma, and neuromuscular disorders.

Precautions

Before any pulmonary function test is performed by a patient, the clinician ordering the test should be aware of any conditions that the patient may have that may affect the reliability of the test results. Also, because pulmonary function testing requires deep breathing, the test itself may aggravate these same conditions.

Conditions in a patient that contraindicate pulmonary function testing include: the coughing-up of **blood** from the respiratory tract (hemoptysis); a collapsed or partially collapsed lung (pneumothorax); an unstable **heart** condition, recent heart attack, or blood clot near the lungs; an abnormal localized bulging of a blood vessel (aneurysm) in the chest, abdomen, or head; recent surgery of the chest or abdomen; recent eye surgery; and current nausea or vomiting. If a patient suffers from one or more of these conditions, pulmonary function tests should be postponed until these conditions are resolved.

The patient should not wear clothing that constricts the chest area. Patients should not have eaten a heavy meal three hours or less before the test. Smokers should provide their smoking history and the time of their last cigarette. In order for pulmonary function tests to yield accurate results, the patient must be able to respond to direction; so the tests may not be useful in very young children, uncooperative patients, and physically incapacitated individuals.

Description

One of the most common of the pulmonary function tests is spirometry. This test, which can be given in a hospital or doctor's office, measures how much and how fast the air is moving in and out of the lungs. This test is covered in greater detail in the separate **spirometry tests** entry.

A peak flow meter can determine how much a patient's airways have narrowed. A test of **blood gases** is a measurement of the concentration of oxygen and car-

bon dioxide in the blood, which shows how efficient the **gas exchange** is in the lungs.

Another lung function test reveals the efficiency of the lungs in absorbing gas from the blood. This efficiency is measured by testing the volume of carbon monoxide a person breathes out after a known volume of the gas has been inhaled.

Preparation

The healthcare provider conducting a pulmonary function test should explain the test and any and all potential side effects to the patient prior to the test being performed. The health care provider should then demonstrate the proper breathing technique for the patient, and the patient should then practice this technique until he or she is able to accurately duplicate the proper technique on two consecutive trials. The health care provider should also indicate that while most side effects of pulmonary function tests are extremely rare, the patient should stop the test if he or she becomes extremely uncomfortable or feels intense **pain** in the head, eye, chest, or abdomen while performing the test.

Prior to the test, the age, race, and sex of the patient should be recorded, along with a height measurement in stocking feet and a weight measurement. This information will allow each individual's results to be compared to normal values for people in the same demographic category.

Aftercare

There is usually no patient care required after the administration of a pulmonary function test. If a patient feels lightheaded or dizzy, he or she should lie down until the symptoms subside. In rare cases, oxygen may have to be administered to prevent pneumothorax or to restore normal breathing patterns.

Complications

In general, pulmonary function tests are safe procedures that simply require deep breathing. In very rare instances complications can occur. These include pneumothorax; increased fluid pressure between the bones of the **skull** and the **brain** (increased intracranial pressure); loss of consciousness, dizziness, and/or lightheadedness; chest pain; uncontrollable coughing; and contraction of an **infection** from the test equipment.

Results

Normal results

Normal test results are based on a person's age, height, weight, race, and gender. Normal results are

A cystic fibrosis patient receives treatment. (Custom Medical Stock Photo. Reproduced by permission.)

expressed as a percentage of the predicted lung capacity for a person of the same age, height, weight, race, and sex. Any measurement within 20% of the predicted value is considered a normal result.

Abnormal results

Abnormal results mean that the person's lung capacity is less than 80% of the predicted value. Such findings usually mean that there is some degree of chest or lung disease.

Health care team roles

Pulmonary function tests are generally ordered by a primary care doctor (M.D. or D.O.) or advanced practice nurse; and performed either by a physician, nurse, or respiratory technician under the direction of a doctor specifically trained in pulmonary function testing. When the results of pulmonary function testing are inaccurate, the most frequent reason is inadequate **patient education**

KEY TERMS

Asthma—A disease that causes recurrent and generally unpredictable narrowing of the larger airways of the lungs (bronchi), which makes breathing difficult. Asthma may be caused by infection, allergies, smoking, exercise, or stress.

Bronchitis—Inflammation of one or more of the airways (bronchi) that lead from the windpipe (trachea) into the lungs. Bronchitis is usually caused by an infection.

Emphysema—A disease in which the small air sacs in the lungs become damaged, causing shortness of breath. In severe cases it can lead to respiratory or heart failure.

Obstructive lung disease—Any disease that lessens a patient's ability to get air out of his or her lungs. Generally, people with obstructive lung disease do not have difficulty getting air into their lungs.

Pneumothorax—A collapsed or partially collapsed lung.

Restrictive lung disease—Any disease that lessens a patient's ability to get air into his or her lungs. Generally, people with restrictive lung disease do not have difficulty getting air out of their lungs.

and/or technician training. It is recommended that personnel conducting pulmonary function testing have one of the following credentials: certified **respiratory therapy** technician (CRTT); registered respiratory therapist (RRT); certified pulmonary function technologist (CPFT); or registered pulmonary function technologist (RPFT). A doctor specializing in diseases of the lungs (pulmonologist) may be consulted to examine abnormal pulmonary function test results.

Pulmonary rehabilitation

Definition

Pulmonary rehabilitation is a multidisciplinary, individually designed intervention program, including **exercise** and education, that helps patients with chronic lung disorders manage the physiological and psychosocial symptoms of their condition and improve their level of daily functioning and well-being.

Purpose

The purpose of a pulmonary rehabilitation program is to help patients with chronic obstructive pulmonary disease (COPD) or other chronic lung conditions manage their condition. Exercise and education are provided to help increase the patient's level of fitness and independent functioning; reduce dyspnea and psychological symptoms (**anxiety**, depression, social isolation); slow down or prevent the progression of disease; and improve quality and possibly length of life.

Pulmonary rehabilitation has not been found to improve pulmonary function, and that is not its goal. Other measures of physiologic improvement such as improved muscle function, cardiac function, and aerobic function have been found, and the main purpose of **cardiac rehabilitation** is to "reverse the deconditioning and psychosocial accompaniments of pulmonary disability." Pulmonary rehabilitation is also increasingly recognized as valuable in preparation for lung transplantation and lung volume-reduction surgery, which require patients to have good physical conditioning.

Precautions

Patients should be examined by a physician before beginning rehabilitation. Certain coexisting medical conditions, especially those that preclude or limit exercise, may contraindicate pulmonary rehabilitation, or require

Essentials of pulmonary therapy

Treatment components	Purpose	How to perform	When to use
Breathing exercises	Assists in removing secretions; relaxation; and used to increase thoracic cage mobility and tidal volume	Patient is taught to produce a full inspiration followed by a controlled expiration; use hand placement for sensory feedback	When patients are breathing spontaneously
Coughing	Removal of secretions from the larger airways	Steps: (1) Inspiratory gasp; (2) Closing of the glottis; (3) Contraction of expiratory muscles; (4) Opening of the glottis	When patients are breathing spontaneously
Percussion	Used with postural drainage for mobilization of secretions	Rhythmic clapping of cupped hands over bare skin or thin material covering area of lung involvement; performed during inspiration and expiration	When coughing or suctioning, breathing exercises, and patient mobilization are not adequate to clear retained secretions
Postural drainage	Mobilize retained secretions through assistance of gravity	Patient positioned so that involved segmental bronchus is uppermost	Same as above
Vibration	Used with postural drainage for mobilization of secretions	Intermittent chest wall compression over area of lung involvement; performed during expiration only	Same as above

modification and special precautions. Since treatment is individualized, any special needs will be addressed in the exercise prescription and program design. Some particular conditions that may contraindicate participation in pulmonary rehabilitation include acute respiratory **infection**, ischemic cardiac disease, congestive **heart failure**, serious **liver** dysfunction, disabling stroke, severe psychiatric or cognitive disorders, acute cor pulmonale, severe pulmonary **hypertension**, and metastatic **cancer**.

Description

Pulmonary rehabilitation is a multidisciplinary, comprehensive program of education, exercise, and behavior modification, individually designed for patients with such lung diseases as COPD. COPD includes such conditions as chronic bronchitis and **emphysema**, which can be progressive and life-threatening. Other chronic lung conditions that may be suitable for pulmonary rehabilitation include **cystic fibrosis**, **asthma**, bronchiectasis, and environmental lung disease, as well as such neuromuscular disorders as **Parkinson's disease** and **multiple sclerosis**.

The rehabilitation program is designed to help patients learn more about their condition and how to manage its symptoms, as well as to take active steps, such as smoking cessation, oxygen use, and exercise, in order to improve their level of physical functioning; stop the progression of the disease as much as possible; and learn how to better live with the condition. Improved physical functioning, reduction in physical and psychological symptoms, and ability to perform activities of daily living (ADLs) more easily and independently, can contribute to improved quality of life.

A typical program, which is individually designed but involves group participation, may last up to three hours per session, a few days each week. Programs generally last a few weeks to a few months, and prepare the patient to continue exercise, symptom management, and other skills learned in the program on their own. An in-home follow-up program may also be included. Patients may participate in rehabilitation as inpatients or outpatients, and will also be encouraged to exercise on their own at home if it is safe for them to do so without monitoring. Some insurance companies cover all or part of the rehabilitation program.

The two main components of the daily program are exercise and education. Exercise is important for maintaining or improving muscle strength, endurance and overall fitness, which may have declined due to inactivity and symptoms of the disease. Decreased physical activity and associated decline in fitness play a large part in causing the physical limitations associated with COPD. A regular exercise program can improve overall fitness and energy, and make performance of ADLs easier.

The exercise program is individually prescribed to meet the physical needs of each patient, and includes a warm-up and cool-down period, and aerobic activity. The warm-up and cool-down periods may include stretching and light strength or resistance training. Exercises involving upper and lower extremities are important for overall fitness and for improvement in function during specific activities. For example, lower body exercise helps with ambulation, stair climbing, and general fitness; and conditioning of the arms facilitates improved functioning in many tasks that require arm and upper body use, such as grooming, cooking, and household

KEY TERMS

ADL—Activity of daily living.

COPD—Chronic obstructive pulmonary disease. Included are such conditions as chronic bronchitis and emphysema.

Dyspnea—Difficulty breathing or shortness of breath

Spirometer—A device used to measure lung performance.

tasks. Some of the muscle groups used in arm and upper torso positioning serve respiratory functions, and thus upper extremity conditioning can also have a beneficial effect on ventilation.

The aerobic exercise component comprises such activities as walking or using a stationary bicycle, treadmill, or other equipment. Exercise is monitored by physical therapists, respiratory nurses, or other qualified health care providers. **Blood pressure, heart rate, oxygen saturation, and dyspnea levels** are evaluated to determine the appropriate exercise prescription, and may be monitored during exercise sessions. Ventilatory training may also be included in the exercise program for certain patients. This therapy involves controlled breathing exercises; such **chest physical therapy** techniques as postural drainage, chest percussion, directed cough, and vibration; and training of the inspiratory muscles.

The educational component of the rehabilitation program consists of classes, reading materials, and counseling or training sessions that cover various specific subjects, procedures, and issues of importance to patients with chronic pulmonary disease. Education is provided by a variety of professionals, including respiratory nurses, respiratory therapists, occupational therapists, physical therapists, social workers, and dietitians. A psychologist or other mental health professional may provide counseling to address depression, anxiety, social isolation, or other psychosocial symptoms related to COPD.

Some of the educational subjects covered include anatomy and physiology related to pulmonary function and disease; exercise theory; **nutrition**; techniques for using oxygen and inhalers; and ways to conserve energy. Education related to good nutrition and weight management can be helpful, because patients may be undernourished and have muscle wasting of the respiratory muscles, which can make breathing more difficult. If anemia is present, it can decrease oxygen-carrying capacity. Electrolyte imbalances affect cardiopulmonary perform-

ance, so these and other deficiencies should be treated in order to improve functioning. If patients are overweight, the extra weight increases oxygen and energy demands and may increase fatigue. Patients who have not yet stopped smoking should be strongly encouraged to do so.

Preparation

Examination and referral by a physician are generally required before a patient begins pulmonary rehabilitation. A medical history should be provided to the rehabilitation team. Some tests that may be administered prior to the patient's entry into a rehabilitation program include pulmonary function tests (PFTs), chest x-rays, arterial **blood gas (ABG)** analysis, pulse oximetry, and sputum examination. PFTs are performed with a spirometer to measure lung performance and determine the presence and extent of lung disease. A chest x-ray can detect emphysema and other lung disease, including **lung cancer**, for which there is increased risk among smokers with COPD. Pulse oximetry measures oxygen in the blood and helps determine when supplemental oxygen is required. Exercise tests may be used to determine the length and intensity of the exercise prescription.

Aftercare

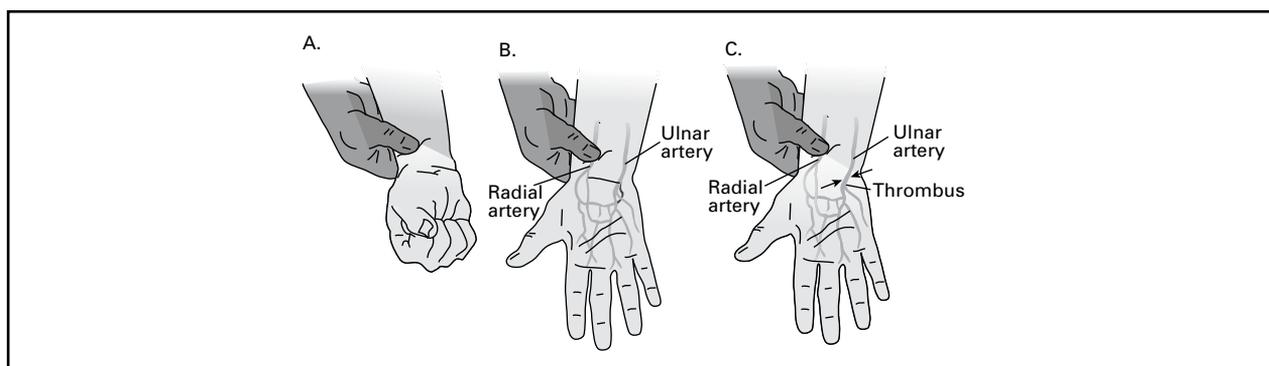

Patients may be able to participate in various follow-up or maintenance programs or support groups, as well as check-ins with their physician, in order to maintain benefits and continue monitoring their condition.

Complications

Risk of such complications as muscle injury or cardiac reactions is always present with exercise, but will be minimized by careful exercise prescription and monitoring. Disease-related complications that should be watched for include **fever**, unusual or extreme shortness of breath, irregular pulse, unanticipated weight changes, gastric complaints, or any other change that is unusual for the patient.

Results

The primary goals of cardiac rehabilitation are to reduce symptoms and respiratory impairment, and to improve the patient's quality of life and possibly prolong their life. Some of the specific changes that affect overall improvement in health, functioning and quality of life include: improvement in pulmonary function, reduction of the work involved in breathing, increased efficiency of energy use, improved exercise performance, increased function in activities of daily living, alleviation of dysp-

Thumb placement for pulse assessment. (Delmar Publishers, Inc. Reproduced by permission.)

nea, nutritional correction, and improved emotional state. Other possible results are a decrease in frequency and duration of hospital stays and decrease in use of other health care resources.

Health care team roles

The various educational and therapeutic components of a comprehensive pulmonary rehabilitation program are best addressed by a variety of health care professionals. The team may include respiratory nurses; respiratory, physical and occupational therapists; psychologists or other mental health professionals; exercise specialists; and dietitians, as well as a program director. The physical therapist may be involved in exercise prescription and monitoring; providing education in areas related to anatomy, physiology, exercise, and **physical therapy**; and providing such other therapeutic treatments as chest physical therapy.

Pulse assessment

Definition

Pulse assessment is the detection of a patient's pulse.

Purpose

Pulse assessment is performed to establish a baseline on a patient's admission (from which to compare any significant changes), and to detect any abnormalities from the healthy state.

Precautions

As there may be no prior knowledge of the patient's previous pulse recordings for comparison, it is important for the nurse or other health professional to know the range of normal values that apply to patients of different ages. Any known medical and surgical history or abnormal readings of any of the **vital signs**, as well as details

A doctor checks a patient's pulse at the bilateral radial artery. (Photograph by Dagmar Ehling. Science Source/Photo Researchers. Reproduced by permission.)

of any current medication the patient is taking, should be obtained. Exertion, such as climbing stairs, may affect the results. Therefore the patient should have rested prior to having their pulse taken, and refrained from consuming tobacco, caffeinated drinks, and alcohol 30 minutes prior to the procedure. Of course, these precautions cannot be taken in an emergency situation.

Description

The pulse is checked as one indicator of abnormalities of the **heart** by observing the rate, rhythm, and the strength and tension of the beat against the arterial wall. The pulse may be recorded hourly to every four hours, or p.r.n. (when required), based on the patient's condition. For example, the pulse may be recorded postoperatively every 15 minutes in the recovery room.

Preparation

The equipment required for pulse assessment is a watch with a sweep second hand or a digital readout. The pulse may be read where a surface artery runs over a bone, e.g. the radial artery (in the forearm), carotid artery

(in the neck), temporal artery (at the temple), popliteal artery (at the back of the knee), or dorsalis pedal artery (at the instep). The radial artery in the wrist is the option used most often. The physician may choose such sites as the carotid artery pulse if atrial or ventricular problems are suspected.

To take the radial pulse, the patient should be sitting or lying comfortably, so that the readings are taken in similar positions each time and that there is little excitement to affect the results. The patient's forearm should not be raised to a level higher than the heart, as this position will change the reading. The nurse should place the index, middle, and ring fingers over the radial artery, which is located above the wrist on the anterior surface of the thumb side of the wrist. Apply gentle pressure to avoid obstructing the patient's **blood** flow. The rate, rhythm, strength and tension of the pulse should be noted. Using a watch, the pulsations that are felt where the artery rests against the bone are counted for half a minute, and the result doubled to give the beats per minute. However, any irregularities noted within the 30-second count means that the pulse should be recorded for one full minute to avoid any discrepancies.

Aftercare

The nurse should make the patient comfortable and reassure him or her that recording the pulse is part of normal health checks and that it is necessary to ensure the patient's health is being correctly monitored. Any abnormalities in the pulse must be reported in the nurse's notes and relayed to the attending physician.

Results

The average heart rate for older children and adults can range from 50 to 90 beats per minute (bpm). This is an average; rates vary between males and females, with age, and with the patient's health and level of fitness. It is not abnormal for athletes to display a low pulse rate.

The pulse is an indicator of the health of the heart and the arterial circulation. Such factors as **anxiety**, medication, or pulmonary disease may also cause the heart rate to be faster or slower.

A low-volume, or weak, pulse may be caused by a number of factors, including **myocardial infarction**, **shock**, intracranial pressure, or the use of vasoconstrictor drugs.

Pulse pressure may become raised due to arteriosclerosis, as the heart has to pump harder to promote the flow of blood around the body. This high-pressure pulse is called a bounding pulse, and may also be caused by such conditions as **fever**, **pregnancy**, or thyrotoxicosis. It may also be an indicator that pulmonary disease is present.

Other conditions that can be detected in part by pulse assessment include tachycardia (a heartbeat that is too fast) and bradycardia (a heartbeat that is too slow). The nurse would also be able to detect missed heart beats and pulsus alternans (alternating strong and weak beats).

The pulse is recorded and compared with normal ranges for the patient's age, gender, and medical condition, and a decision is made regarding the interpretation of the results as to whether any further action should be taken.

Health care team roles

Patients may ask questions about specific concerns they have regarding pulse recordings or a particular disease. Nurses should have a thorough knowledge of what pulse irregularities indicate to enable them to answer the patient's questions, or provide counseling on the prevention of illness and injuries, or direct the person to their doctor. Further tests may be performed to evaluate the heart and diagnose abnormalities.

KEY TERMS

Amplitude—The fullness of the pulse.

Arteriosclerosis—Hardening and thickening of the walls of the arteries, causing loss of elasticity. It may also include calcium deposits in the arteries.

Bradycardia—A slow heartbeat or pulse below 60 bpm in an adult.

p.r.n.—*pro re nata*, when required.

Pulsus alternans—Alternating weak and strong beats of the pulse.

Tachycardia—A rapid heartbeat or pulse above 100 bpm in an adult.

Thyrotoxicosis—Hyperthyroidism.

Pulse oximeter

Definition

The pulse oximeter is a photoelectric instrument for measuring oxygen saturation of the **blood**.

A pulse oximeter uses infrared light and a photo sensor to detect the amount of oxygen in a patient's blood.

(Illustration by Argosy. Courtesy of Gale Group.)

Purpose

A pulse oximeter measures the amount of oxygen present in the blood by registering pulsations within an arteriolar bed. It is a noninvasive method widely used in the hospital, including for newborns, patients with pulmonary disorders, and patients undergoing pulmonary and cardiac procedures. Oxygen levels can be estimated during **exercise**, surgery or medical procedures, or while the patient is asleep.

Description

Oximeters are used in such hospital settings as intensive care units, pulmonary units, and in health care centers. Portable hand-held devices are available, and are used for spot-checking patients and for in-home use with a doctor's supervision.

The oximeter consists of a light-emitting diode (LED); a photodetector probe containing a permanent or disposable sensor; alarms for pulse rate and oxygen levels; a display screen; and cables. The device works by emitting beams of red and infrared light that are passed through a pulsating arteriolar bed. Sensors detect the amount of light absorbed by oxyhemoglobin and deoxyhemoglobin in the red blood cells. The ratio of red to infrared light measured by the photodetector indicates the amount of oxygen present in the blood. The sensor is attached to the body over the arteriolar area in the ear, the finger tip, the big toe, or across the bridge of the nose. Clip sensors can be used on fingers and the earlobe.

Operation

Several steps can be taken to enhance accurate readings. If possible, the patient should be instructed not to

KEY TERMS

Arteriolar bed—An area in which arterioles cluster between arteries and capillaries.

Arterioles—The smallest branches of arteries.

Capillaries—Tiny blood vessels with a diameter of a red blood cell through which a single layer of cells flows.

Deoxyhemoglobin—Hemoglobin with oxygen removed.

Oxyhemoglobin—Hemoglobin combined with oxygen.

smoke 24 hours prior to pulse oximetry. Fingernail polish should be removed if the oximeter will be attached to the finger. For patients with poor circulation, hands should be slowly warmed with warm towels before attaching the oximeter. Abnormally high or low temperatures, as well as reduced hemoglobin, can influence the amount of oxygen adhering to the hemoglobin within the red blood cells, altering the reading.

Care should be taken with attaching the sensors and selecting the site for optimum reading levels. The sensor should be wrapped securely around the finger to prevent outside light from interfering with the reading and rendering it invalid. An appropriate site is chosen to monitor the oxygen levels by ensuring that there is strong arterial pulsation, and that the capillary bed fills promptly if squeezed.

The device must not be used near flammable anesthetics.

Maintenance

Older devices may be affected by motion. They should be checked regularly to insure proper function.

Health care team roles

Nurses and allied health professionals attach the pulse oximeter and explain to the patient that it is used for monitoring purposes. Staff monitor the site where the sensor has been applied every four hours for clip sensors and every six hours for wrapped sensors. Any loss of pulsation, swelling, or change in color requires a change of site.

Training

Staff should be familiar with the device and the department's protocol to ensure standardization in operating the equipment.

Q

Qigong

Definition

Qigong (pronounced “chee-gung,” also spelled *chi kung*) is translated from the Chinese to mean “energy cultivation” or “working with the life energy.” Qigong is an ancient Chinese system of postures, exercises, breathing techniques, and meditations. Its techniques are designed to improve and enhance the body’s *qi*. According to traditional Chinese philosophy, *qi* is the fundamental life energy responsible for health and vitality.

Origins

Qigong originated before recorded history. Scholars estimate qigong to be as old as 5000–7000 years. Tracing the exact historical development of qigong is difficult, because it was passed down in secrecy among monks and teachers for many generations. Qigong survived through many years before paper was invented, and it also survived the Cultural Revolutions in China of the 1960s and 1970s, which banned many traditional practices.

Qigong has influenced and been influenced by many of the major strands of Chinese philosophy. The Taoist philosophy states that the universe operates within laws of balance and harmony, and that people must live within the rhythms of nature—ideas that pervade qigong. When Buddhism was brought from India to China around the seventh century A. D., **yoga** techniques and concepts of mental and spiritual awareness were introduced to qigong masters. The Confucian school was concerned with how people should live their daily lives, a concern of qigong as well. The martial arts were highly influenced by qigong; and many of them, such as **t’ai chi** and kung fu, developed directly from it. Traditional Chinese medicine also shares many of the central concepts of qigong, such as the patterns of energy flow in the body. Acupuncture and **acupressure** use the same points on the body that qigong seeks to stimulate. In China,

qigong masters have been renowned physicians and healers. Qigong is often prescribed by Chinese physicians as part of the treatment.

Due to the political isolation of China, many Chinese concepts have been shrouded from the Western world. Acupuncture was only “discovered” by American doctors in the 1970s, although it had been in use for thousands of years. With an increased exchange of information, more Americans have gained access to the once-secret teachings of qigong. In 1988, the First World Conference for Academic Exchange of Medical Qigong was held in Beijing, China, where many studies were presented to attendees from around the world. In 1990, Berkeley, California hosted the First International Congress of Qigong. In the past decade, more Americans have begun to discover the beneficial effects of qigong, which motivate an estimated sixty million Chinese to practice it every day.

Benefits

Qigong may be used as a daily routine to increase overall health and well-being, as well as for disease prevention and longevity. It can be used to increase energy and reduce **stress**. In China, qigong is used in conjunction with other medical therapies for many chronic conditions, including **asthma**, **allergies**, **AIDS**, **cancer**, headaches, **hypertension**, depression, mental illness, strokes, **heart** disease, and **obesity**.

Description

Basic concepts

In Chinese thought, *qi*, or *chi*, is the fundamental life energy of the universe. It is invisible but present in the air, water, food and sunlight. In the body, *qi* is the unseen vital force that sustains life. We are all born with inherited amounts of *qi*, and we also get acquired *qi* from the food we eat and the air we breathe. In qigong, the breath is believed to account for the largest quantity of acquired

qi, because the body uses air more than any other substance. The balance of our physical, mental, and emotional levels also affect qi levels in the body.

Qi travels through the body along channels called meridians. There are twelve main meridians, corresponding to the twelve principal organs as defined by the traditional Chinese system: the lung, large intestines, **stomach**, spleen, heart, **small intestine**, urinary bladder, kidney, **liver**, **gallbladder**, pericardium, and the “triple warmer,” which represents the entire torso region. Each organ has qi associated with it, and each organ interacts with particular emotions on the mental level. Qigong techniques are designed to improve the balance and flow of energy throughout the meridians, and to increase the overall quantity and volume of qi. In qigong philosophy, mind and body are not separated as they often are in Western medicine. In qigong, the mind is present in all parts of the body, and the mind can be used to move qi throughout the body.

Yin and yang are also important concepts in qigong. The universe and the body can be described by these two separate but complementary principles, which are always interacting, opposing, and influencing each other. One goal of qigong is to balance yin and yang within the body. Strong movements or techniques are balanced by soft ones, leftward movements by rightward, internal techniques by external ones, and so on.

Practicing qigong

There are thousands of qigong exercises. The specific ones used may vary depending on the teacher, school, and objective of the practitioner. Qigong is used for physical fitness, as a martial art, and most frequently for health and healing. Internal qigong is performed by those wishing to increase their own energy and health. Some qigong masters are renowned for being able to perform external qigong, by which the energy from one person is passed on to another for healing. This transfer may sound suspect to Western logic, but in the world of qigong there are some amazing accounts of healing and extraordinary capabilities demonstrated by qigong masters. Qigong masters generally have deep knowledge of the concepts of Chinese medicine and healing. In China, there are hospitals that use medical qigong to heal patients, along with herbs, acupuncture, and other techniques. In these hospitals, qigong healers use external qigong and also design specific internal qigong exercises for patients' problems.

There are basic components of internal qigong sessions. All sessions require warm-up and concluding exercises. Qigong consists of postures, movements, breathing techniques, and mental exercises. Postures may involve standing, sitting, or lying down. Movements include

stretches, slow motions, quick thrusts, jumping, and bending. Postures and movements are designed to strengthen, stretch, and tone the body to improve the flow of energy. One sequence of postures and movements is known as the “Eight Figures for Every Day.” This sequence is designed to quickly and effectively work the entire body, and is commonly performed daily by millions in China.

Breathing techniques include deep abdominal breathing, chest breathing, relaxed breathing, and holding breaths. One breathing technique is called the “Six Healing Sounds.” This technique uses particular breathing sounds for each of six major organs. These sounds are believed to stimulate and heal the organs.

Meditations and mind exercises are used to enhance the mind and move qi throughout the body. These exercises are often visualizations that focus on different body parts, words, ideas, objects, or energy flowing along the meridians. One mental **exercise** is called the “Inner Smile,” during which the practitioner visualizes joyful, healing energy being sent sequentially to each organ in the body. Another mental exercise is called the “Microscopic Orbit Meditation,” in which the practitioner intently meditates on increasing and connecting the flow of qi throughout major channels.

Discipline is an important dimension of qigong. Exercises are meant to be performed every morning and evening. Sessions can take from 15 minutes to hours. Beginners are recommended to practice between 15–30 minutes twice a day. Beginners may take classes once or twice per week, with practice outside of class. Classes generally cost between \$10–\$20 per session.

Preparations

Qigong should be practiced in a clean, pleasant environment, preferably outdoors in fresh air. Loose and comfortable clothing is recommended. Jewelry should be removed. Practitioners can prepare for success at qigong by practicing at regular hours each day to promote discipline. Qigong teachers also recommend that students prepare by adopting lifestyles that promote balance, moderation, proper rest, and healthy diets, all of which are facets of qigong practice.

Precautions

Beginners should learn from an experienced teacher, as performing qigong exercises in the wrong manner may cause harm. Practitioners should not perform qigong on either full or completely empty stomachs. Qigong should not be performed during extreme weather, which may have negative effects on the body's energy systems.

Menstruating and pregnant women should perform only certain exercises.

Side effects

Side effects may occur during or after qigong exercises for beginners, or for those performing exercises incorrectly. Side effects may include dizziness, dry mouth, fatigue, headaches, insomnia, rapid heartbeat, shortness of breath, heaviness or numbness in areas of the body, emotional instability, **anxiety**, or decreased concentration. Side effects generally clear up with rest and instruction from a knowledgeable teacher.

Research and general acceptance

Western medicine generally does not endorse any of the traditional Chinese healing systems that utilize the concept of energy flow in the body, largely because this energy has yet to be isolated and measured scientifically. New research is being conducted using sophisticated equipment that may verify the existence of energy channels as defined by the Chinese system. Despite the lack of scientific validation, the results of energy techniques including qigong and acupuncture have gained widespread interest and respect. Furthermore, qigong masters have demonstrated to Western observers astounding control over many physical functions, and some have even shown the ability to increase electrical voltage measured on their skin's surface. Most of the research and documentation of qigong's effectiveness for medical conditions has been conducted in China, and is slowly becoming more available to English readers. Papers from the World Conferences for Academic Exchange of Medical Qigong are available in English, and address many medical studies and uses of qigong.

Training and certification

In China, qigong has been subject to much government regulation, from banning to increased requirements for teachers. In the United States at this time, qigong has not been regulated. Different schools may provide teacher training, but there are no generally accepted training standards. Qigong teachings may vary depending on the founder of the school, who is often an

Radial keratotomy

Definition

Radial keratotomy (RK) is eye surgery performed to correct **myopia** by changing the cornea's shape.

Purpose

RK was introduced in North America in 1978. RK is one of several surgical techniques for reducing or eliminating the need for corrective lenses. It is most successful in patients with low to moderate nearsightedness—people whose eyes require up to -5.00 diopters of correction.

Precautions

RK cannot help patients whose nearsightedness is caused by keratoconus, a condition in which the cornea is cone-shaped. The procedure usually is not performed on patients under 18 because their **vision** is unstable. Women who are pregnant, have just given birth, or are breast-feeding should not have RK because hormones may cause temporary corneal changes. **Glaucoma** patients or patients with any disease that interferes with healing should not have RK.

Radial keratotomy weakens the cornea, making it vulnerable to injuries long after surgery. A **head injury** after RK can cause the cornea to tear and can lead to blindness. Sports enthusiasts should be warned of this danger.

RK's success cannot be guaranteed. An ophthalmologist estimates the probability of the surgery's success in correcting vision. In some cases, patients with myopia that has caused their near vision to be clear prior to surgery may need corrective lenses for near vision following surgery. Some patients still require lenses for distance vision. RK does not eliminate **presbyopia** and the eventual need for reading glasses.

Description

With clear vision, light passes through the cornea and the lens of the eye and focuses on the retina. In a myopic patient, the eyeball is usually too long, so that light focuses in front of the retina. RK reduces myopia by flattening the cornea. This flattening reduces the cornea's focusing power, allowing the light to focus further back onto the retina, forming a clearer image.

For RK, a surgeon uses a small diamond-blade knife to make four to eight radial incisions approaching the edge of the cornea. These slits are made in a pattern that resembles the spokes of a wheel. As the cornea heals, its center flattens.

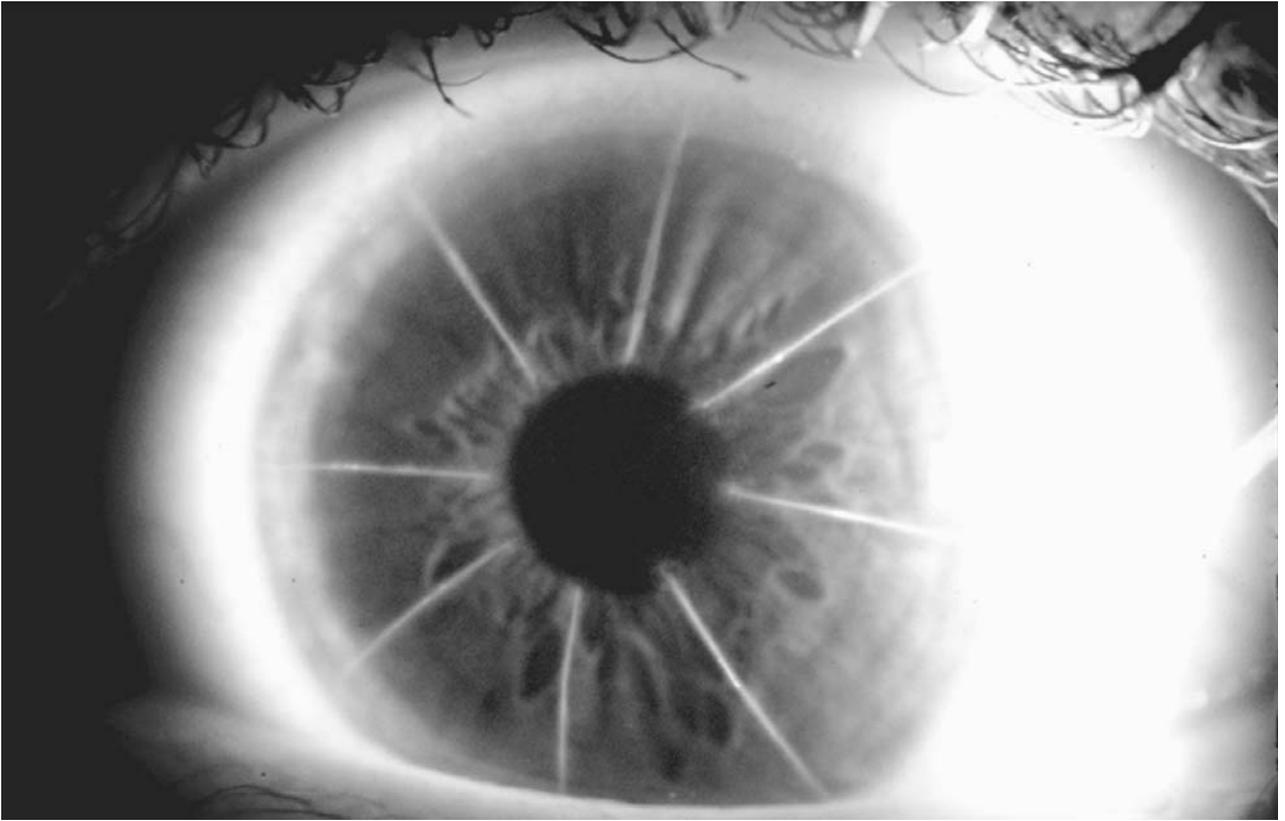

Before surgery the patient is given a sedative. A local anesthetic—usually eye drops—is used to numb the eye. The patient remains conscious during the procedure. The surgeon utilizes a surgical **microscope** to magnify the cornea while making the slits. The treatment usually lasts 30 minutes.

Most ophthalmologists perform RK on one eye at a time. Surgeons once thought they could use the results of the first eye to predict how the well the procedure would work on the second eye. However, a study in the *American Journal of Ophthalmology* in 1997 found that this was not the case. The authors cautioned that there might be other reasons not to operate on both eyes at once, such as increased risk of **infection**.

RK's costs depends on the surgeon, but usually range from \$1,000 to \$1,500 per eye. It is usually not covered by insurance.

Preparation

RK patients should be carefully screened by an ophthalmic assistant or physician before surgery is approved to avoid possible complications. This screening should include a comprehensive eye exam, either by the ophthalmologist, or a co-managing optometrist at least a few days before surgery. At this time, the physician or ophthalmic

Radial keratotomy scars on the cornea of an eye. (Photograph by Bob Masini, Phototake NYC. Reproduced by permission.)

assistant should chart any dry eye or any corneal disease that may hinder surgery. They also should perform corneal topography, which creates a map of the patient's eye.

Assistants must advise patients to discontinue wearing contact lenses weeks prior to the visual exams to make sure vision is stable; and they must also advise the doctor of contact lens wear.

Before surgery, ophthalmic staff administer eye drops and a sedative to the patient. The physician tests the patient's vision, and the patient rests while waiting for the sedative to take effect. Immediately before the surgery, ophthalmic staff administer local anesthetic eye drops.

Before beginning the procedure, the surgeon measures the cornea's thickness to decide how deep the slits should be, and marks an area in the center of the cornea called the optical zone. This is the part of the cornea in the area over the pupil that the patient sees through. No cuts are made in this region.

Aftercare

After surgery, some patients feel **pain** and are given eye drops and medications to relieve discomfort. For sev-

eral days the eye may feel scratchy and look red. This is normal. The eye also may water, burn, and be sensitive to light.

Patients should be advised to use eye drops for several weeks to protect against infection. Patients also should be told to protect the head and eyes.

The cornea heals slowly, and full recovery can take months. This is one reason RK has fallen out of favor with surgeons and patients. Laser-refractive surgeries, such as laser-assisted in situ keratomileusis (LASIK), have better results with faster recovery. Such procedures as LASIK and corneal rings have rendered RK virtually obsolete.

While the cornea is healing, patients may experience better eyesight in the morning than in the evening (or vice versa); pain; glare; starburst or halo effects; or a hyperopic shift. As the cornea flattens, vision may become more hyperopic. For this reason, the surgeon may initially undercorrect the patient. This gradual shift may occur over several years. This procedure leaves permanent scars on the cornea.

If RK does not completely correct nearsightedness, corrective lenses may be needed. Presbyopic patients will still require reading glasses.

Patients return to the surgeon for a follow-up exam one day post-operatively. After that, patients may be referred to the co-managing optometrist for the subsequent three or four visits. Patients should be advised to report any pain or nausea immediately to the attending physician.

Complications

Complications from RK include:

- cataract
- infection
- lasting pain
- tears along an incision, especially after being hit in the head or eye
- vision loss
- hyperopic shift

Complications are reduced when an ophthalmologist experienced with RK performs the surgery. Younger patients also tend to heal faster.

Results

The desired result of radial keratotomy is myopia reduction. A study reported by the National Eye Institute in 1994 tracked the success of 374 patients who had RK 10 years earlier. The study found that:

- 85% had at least 20/40 vision
- 70% did not need corrective lenses for distance vision
- 53% had 20/20 vision without glasses
- 30% still needed glasses or **contact lenses** to see clearly
- 1-3% had worse vision than before they had RK
- 40% had a hyperopic shift

Health care team roles

Allied health professionals help prepare patients for refractive surgery. Advanced and intermediate level ophthalmic technicians perform refractions and help determine the patient's eligibility for surgery. These professionals also may perform corneal topography.

Specially trained ophthalmic nurses assist during surgery. They prepare the operating room and equipment, and administer eye drops. Advanced ophthalmic technologists, who are trained for such additional duties as taking ophthalmic photographs and using ultrasound, may administer eye medications, perform tests, maintain surgical equipment and assist in refractive surgery.

KEY TERMS

Cornea—The transparent part of the eye that covers the iris and the pupil.

Diopter (D)—Unit describing the amount of focusing power of a lens.

Iris—The colored part of the eye.

Laser-assisted in situ keratomileusis (LASIK)—A type of refractive eye surgery using a laser and microkeratome to change the shape of the cornea.

Local anesthetic—Used to numb an area in which surgery or another procedure is to be done, without causing the patient to lose consciousness.

Myopia—Nearsightedness. People with myopia cannot see distant objects clearly.

Ophthalmologist—A physician who specializes in treating eyes.

Photorefractive keratectomy (PRK)—A type of refractive eye surgery using a laser to change the shape of the cornea.

Pupil—The part of the eye that looks like a black circle in the center of the iris. It is actually an opening through which light passes.

Retina—A membrane lining the back of the eye onto which light is focused to form images.

Training

The American Society of Cataract and Refractive Surgery keeps physicians informed of the latest advances in surgery. Optometrists are advised to observe surgeries and attend seminars to learn more about follow-up treatments.

Ophthalmic assistants who want to assist in these surgeries can receive additional training from certified education programs.

Radiation injuries

Definition

Radiation injury, also known as radiation sickness, results from exposure to excessive radiation. The seriousness of the condition depends on the type of radiation, amount of radiation, length of exposure time, and the part of the body affected. Radiation can be defined as the process of emitting energy in the form of particles or waves. Radiation is emitted by atoms in the process of changing, whether the atomic action is a naturally occurring or humanly directed process.

Description

Found throughout the universe, radiation comes in many forms. The better known forms of radiation include light, television and radio waves, microwaves, and radar, which generally do not cause injury. There are a number of potentially damaging forms of radiation including, for example, x rays, gamma rays, the energy emitted by such radioactive substances as uranium, and the radiation generated during nuclear reactions. Perhaps the most infamous events associated with widespread radiation injury and sickness occurred during the atomic bombing of

Hiroshima and Nagasaki, Japan, which helped bring about the end of World War II; and the more recent nuclear meltdown at Chernobyl in 1986.

Radiation exposure can occur as a single large exposure, referred to as acute; or as a series of small exposures over time, referred to as chronic. Radiation sickness is generally associated with acute exposure. Chronic exposure is usually associated with such delayed medical problems as **cancer** and premature aging.

Radiation can cause damage by separating molecules into electrically charged particles, a process known as ionization. Some forms of ionizing radiation include cosmic rays, gamma rays, and x rays. Ionizing radiation damages deoxyribonucleic acid (DNA), which causes genetic mutation.

Several units of measure are used to quantify radiation energy. The roentgen, named after Wilhelm Conrad Roentgen, who discovered x rays in 1895, measures ionizing energy in air. A rad (short for radiation) indicates the transferred absorbed dose. The rem (taken from "Roentgen equivalent man") measures tissue response.

A roentgen generates approximately one rad of effect, producing approximately one rem of response. The gray and the sievert are international units equivalent to 100 rads and rems, respectively. A curie, named after the French physicists (Pierre and Marie Curie) who first began working with radiation, is a measure of radioactivity given off by a radioactive element. The average annual human exposure to natural background radiation is roughly 3 milliSieverts (mSv).

Radiation is pervasive. For example, the sun generates cosmic rays, and there are traces of radioactive elements in the air (radon), as well as in the Earth (uranium and radium, among others). Any amount of ionizing radiation will produce some damage.

Although the earth's atmosphere protects us from most of the sun's radiation, living at 5,000 ft (1,700 m) altitude in, for example, Denver, Colorado, doubles the exposure to radiation; and a flight in a commercial airliner increases it 150-fold.

Ionizing radiation is used for medical diagnosis and treatment, most commonly in the form of x rays and **CT scans**. Nuclear medicine employs radioactive isotopes to diagnose and treat medical conditions. Radioactive elements localize to specific tissues, giving off tiny amounts of radiation. Detecting that radiation provides anatomical and functional information. Radioactive chemicals are also used in the treatment of certain conditions, most common of which is the overactive thyroid. Because the thyroid is the only gland that utilizes iodine, all iodine in the body is concentrated there. A radioactive isotope of

iodine (I-131) will gradually destroy overactive thyroid tissue.

Before the potential dangers posed by excessive radiation exposure were known, those who first began working with x rays frequently died from its long-term effects, most commonly leukemia. Doses now used for medical examinations are ordinarily too small to be of concern. Methods of magnification, lead shielding, and a greater awareness of the risks have nearly eliminated the danger from diagnostic radiation. However, no level of exposure is completely safe.

It is believed that radiation is responsible for less than 1% of all human disease and for approximately 3% of all cancers. This figure does not include **lung cancer** from environmental radon, which is difficult to determine because such effects are confounded by tobacco's similar effects. Because cancers are usually faster-growing than their host tissues, they can be selectively killed by carefully measured radiation. This is most true of the lymphomas. Other cancers are less radiosensitive. Whenever radiation is used to treat cancer, care must be taken to measure the dose and aim it accurately. Even so, many cancers differ so little from the surrounding tissue that undesirable damage is unavoidable.

Newer techniques of directing radiation now provide greater safety. The gamma knife is a new surgical tool that focuses radiation with a high degree of accuracy in three dimensions, sparing surrounding tissue from radiation injury.

Causes and symptoms

Radiation damage depends upon the amount of radiation, the time over which it is absorbed, and the susceptibility of the tissue. The fastest-growing tissues are the most vulnerable, because radiation as much as triples its effects during the growth phase. Bone marrow cells that produce **blood** are the fastest-growing cells. Fetuses are also extremely vulnerable. Germinal cells in the testes and ovaries may be rendered useless by very small doses of radiation. More resistant cells include those of the skin. **Brain** cells are most resistant because they grow the slowest.

The most common symptoms of radiation sickness include:

- nausea and vomiting
- **diarrhea**
- skin **burns** (redness, blistering)
- weakness, fatigue, exhaustion, fainting
- dehydration

This person's nose is inflamed and scaly due to radiation exposure. (Custom Medical Stock Photo. Reproduced by permission.)

- inflammation of areas (redness, tenderness, swelling, bleeding)
- hair loss
- ulceration of the oral mucosa
- ulceration of the esophagus and gastrointestinal system
- vomiting blood
- bloody stool
- bleeding from the nose, mouth, gums, and rectum
- bruising
- sloughing of skin
- open sores on the skin

Exposure over time causes accumulating damage, which if not sufficient to kill cells, distorts their growth and causes scarring and cancers. In addition to leukemia, cancers of the thyroid, brain, bone, breast, skin, **stomach**, and lung are more likely to occur.

Mortality and morbidity risk are dictated by the total dose absorbed.

- Massive doses incinerate tissue immediately.
- A sudden whole-body dose over 50 Sv produces such profound neurological, **heart**, and circulatory damage that patients die within two days.
- Doses in the 10–20 Sv range strip intestinal lining and lead to death within three months from vomiting, diarrhea, starvation, and **infection**.
- Victims receiving 6–10 Sv all at once usually experience bone marrow failure and death within two months, due to loss of **blood coagulation** factors and the protection against infection provided by white blood cells.
- Those exposed to 2–6 Sv may survive if they are treated with blood transfusions and antibiotics.

KEY TERMS

DNA—Deoxyribonucleic acid.

Gonad—Testes (males); ovaries (women).

Isotope—An unstable form of an element that emits radiation.

- One or 2 Sv produces a brief, non-lethal sickness with vomiting, loss of appetite, and generalized discomfort.

Treatment

It is important to ascertain the dose received as early as possible, so that attention can be directed to those victims in the 2–10 Sv range who might survive with treatment. Blood transfusions, protection from infection, and possibly the use of blood formation stimulants save many victims in this category.

Radiation exposure usually damages the skin and requires careful **wound care**, dead tissue removal, and possible skin grafting. **Infection control** is imperative.

Alternative treatment

Studies strongly suggest that diets rich in free radical scavengers, also known as antioxidants, are recommended. The more commonly recommended antioxidants include beta-carotene, **vitamins E and C**, and the trace mineral selenium. Beta-carotene is present in yellow and orange fruits and vegetables. **Vitamin C** can be found in citrus fruits. Traditional Chinese medicine (TCM) and acupuncture, botanical medicine, and **homeopathy** all have contributions to make to recovery from radiation injuries.

Prognosis

Prognosis depends on the amount of exposure to radiation and the corresponding level of injury. High doses of radiation can be fatal, and minimal exposure can have virtually no effect. Some exposures may affect victims later in life, in the form of slow-growing cancers or reproductive difficulties.

Health care team roles

Physicians diagnose and treat radiation injuries. Nurses administer appropriate medications and otherwise supervise patient care. X ray technologists can help prevent radiation exposure to themselves and to their patients by making sure equipment is proper working

order and that appropriate preventative measures, such as the use of shields and radiation badges, are taken.

Radiologic technology

Definition

Radiologic technology is a general term applied to the allied health profession that encompasses the use of ionizing radiation (x-ray), sound or radio waves, radioactive substances to produce an image, and magnetic imaging. These resultant images are used by the radiologist to help in making a diagnosis.

Description

Radiologic technology is a broad-based category that includes general x-ray, ultrasound, **mammography**, nuclear medicine, computerized axial tomography (CAT scan), radiation therapy, and **magnetic resonance imaging (MRI)**. General x-ray technology is a primary link between the physician and the diagnosis. X rays are often required so that the physician can diagnose and treat the patient based on the patients' complaints or conditions.

The x-ray image is created by the controlled and careful use of radiation through the body part being examined. The image is captured on a film, which is placed under the patient. The x-ray beam passes through the body part being examined, and creates a latent image on the film. The latent image is processed, and then is evaluated by the radiologist, with the written and/or verbal report given to the referring physician. Some examples of subspecialties of medical radiography are contrast studies, pediatrics, trauma, surgery, and special procedures (e.g., **angiography** or other interventional procedures).

Mammography is another name for breast imaging and evaluation of breast disease. Mammographers are radiographers who are proficient in screening and diagnostic imaging, as well as such interventional procedures as needle localizations (pre-biopsy), core biopsies, and breast ultrasound.

Ultrasonography is the imaging of anatomy using high-frequency sound waves. The sonographer obtains diagnostic images or patterns that the physician evaluates in the diagnosis of disease. A scan is created by using gel and a transducer, or probe, moving it over the surface of the relevant anatomy. The transducer bounces sound into and back from the anatomic area, and an image is then created on the monitor attached to the machine. This specialty has several distinct areas: **abdominal ultrasound**, adult and pediatric **echocardiography**, obstetrical-gynecological ultrasound, and vascular ultrasound.

Nuclear medicine is very different from medical radiography, because in radiography the x-ray beam from the machine is the source of radiation. It is instantaneous, and is controlled by the technical factors selected by the radiographer. In nuclear medicine, the patient becomes the source of radiation, and the radiation itself is constantly emitted. The patient orally ingests or is intravenously injected with a radioactive substance, or radioisotope. The images are 'collected' via the nuclear medicine camera sorting radioactive signals from the patient. The radioactivity levels are different for the body part or organs being imaged. The nuclear medicine technologist has protocols that are followed for selecting the type of radioisotope to inject, based on the exams ordered.

Computerized axial tomography, or CAT scans, are studies that image the body using multiple projections of the x-ray beam to create sectional images of an organ or anatomic region. These axial sections are selected and manipulated by the technologist, using computer programs that direct the protocols for these exams.

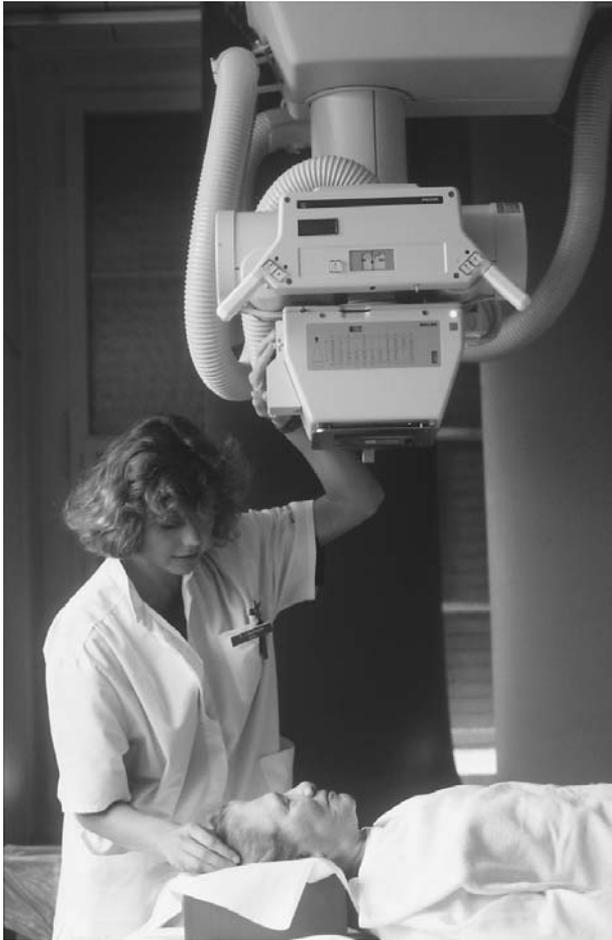

The radiation therapy technologist applies therapeutic radiation doses in strictly controlled circumstances to cure

A patient is prepared for a magnetic resonance imaging (MRI) brain scan. (Photograph by Simon Fraser. Science Source/Photo Researchers. Reproduced by permission.)

or arrest disease. In daily or weekly contact with the **cancer** patient, and working directly with the physician, the technologist assists in the calculation of radiation dosage, and operates a variety of sophisticated radiation treatment equipment and instruments, including computers.

MRI (magnetic resonance imaging) uses radio waves and a strong magnetic field rather than ionizing radiation to provide three-dimensional images of the organs or body structures being examined. The technique has proven critical in diagnosing a variety of conditions throughout the body, including cancer, cardiovascular disease, stroke, and bone and joint disorders. MRI requires specialized equipment and expertise; and allows evaluation of some body structures that may not be as visible with more conventional imaging methods. MRI is highly accurate in showing soft tissue structures near and around bones, the **cardiovascular system**, as well as major organs. Additionally, because it is a non-ionizing

A radiologic technologist positions a patient for an x ray.
(Science Source/Photo Researchers. Reproduced by permission.)

modality, it is gaining increasing popularity in imaging the reproductive system.

Work settings

The majority of radiology technologists work in a hospital setting. Others are employed in government, health industries, **public health**, mental health, education, private offices and clinics. Those professionals with advanced degrees might also pursue careers in the areas of management, quality control, equipment maintenance, or application specialties.

Education and training

The radiologic technologist must first complete a two-year accredited radiology technology program. This consists of both classroom and clinical training. Typically, student radiographers will demonstrate their ongoing training in the classroom, and will rotate through

each segment of the radiology department. The students will work with the registered technologist, and must show clinical competency prior to working independently. The students will pass clinical tests in order to progress through the training process. Upon completion of the program, the students will be required to take the national registry exam given by the American Registry of Radiologic Technology (ARRT). This is a national registry for technologists who pass and maintain the standards set forth by this organization.

Advanced education and training

For those radiographers that choose to specialize in the previously mentioned areas, further study is mandated. In some cases, both clinical and didactic requirements exist. Some disciplines will require approximately one year beyond the requisite radiography coursework, such as sonography, CAT scan, MRI, and mammography. For a nuclear medicine technologist, it is the standard to obtain a four-year university degree. In each case, the technologist needs recorded hours of clinical experience in the core discipline. The registered technologist (RT) must also document 24 hours of continuing education credits every two years in order to maintain certification and compliance with the ARRT as well as with state and federal agencies that regulate certain areas such as mammography.

Future outlook

Employment opportunities for radiologic technologists continue to expand. These professionals are expected to be increasingly in demand due to technological expansions, and the increased need for faster, more detailed diagnoses. As technology refines, so must the varying disciplines of radiologic technology. With the introduction of digital imaging, and better quality equipment and contrast media, changes continue at breakneck speed. In addition, access to higher technology has become more widespread as these newer modalities become the gold standard in some cases. Although this is positive for the profession, there continues to be a shortage of primary x-ray technologists, as those new graduates pursue specialties and bigger salaries. This specialization, while important, has caused serious hardship in many radiology departments, working with staffing shortages and creating tech fatigue, while the demand remains high. This is a challenge that is being addressed industry-wide.

KEY TERMS

Contrast—A substance used by injection or ingestion to demonstrate certain organs or anatomy.

Latent image—The x-ray image created on film, prior to development.

Processing—Film development.

Radioactive—Giving off radiation.

Radioisotope—A chemical element used in injections for nuclear medicine that can be detected in the body by the emission of radiation.

Radiologist—The physician who interprets the films and makes a diagnosis.

Radiotherapy

Definition

Radiotherapy is the use of high-energy penetrating radiation (x rays, gamma rays, proton rays, and neutron rays) to kill **cancer** cells.

Purpose

The primary purpose of radiotherapy is to eliminate or shrink localized cancers. It is also sometimes used to treat metastases— often **brain** metastases—in cases in which surgical treatment would be riskier. The aim of radiotherapy is to kill as many cancer cells as possible, while doing as little damage as possible to healthy tissue. In some cases, the purpose is to kill all cancer cells and effect a cure. In other cases, when cures are not possible, the purpose is to alleviate the patient's **pain** by reducing the size of the tumors that cause pain.

For some kinds of cancers (for example, Hodgkin's disease, non-Hodgkin's lymphoma, **prostate cancer**, and laryngeal cancer), radiotherapy alone is often the preferred treatment. Radiation is, however, also used in conjunction with surgery, **chemotherapy**, or both; and survival rates for combination therapy in these cases are often greater than survival rates for any single treatment modality used alone. Radiotherapy is especially useful when surgical procedures cannot remove an entire tumor without damaging the function of surrounding organs. In these cases, surgeons remove as much tumor mass as possible, and the remainder is treated with radiation (irradiated).

Precautions

Radiotherapy has serious side effects; therefore, anyone considering it should be sure that it is the best possible treatment option for their cancer. Cancer treatment research moves so rapidly that some doctors may not be aware of the latest advances in treatments outside their own specialties that might be safer and better. Accordingly, patients who have had radiotherapy recommended to them should consider getting a second opinion.

Description

Radiotherapy is also known as radiation therapy, radiation treatment, x-ray therapy, cobalt therapy, and electron beam or "gamma knife" therapy. Recent advances in medical technology have made it even more useful for patients and have reduced some of its unpleasant side effects. Radioactive implants allow delivery of radiation to localized areas, with less injury to surrounding tissues than radiation from an external source that must pass through those tissues. Proton radiation also causes less injury to surrounding tissues than traditional photon radiation, because proton rays can be tightly focused. Current research with radioimmunotherapy and neutron capture therapy may provide ways to direct radiation exclusively to cancer cells—and in the case of radioimmunotherapy, to cancer cells that have metastasized (spread to other sites throughout the body).

Patient undergoing radiation therapy on a linear accelerator to treat Hodgkin's disease. The illuminated discs over the patient's chest indicate the areas that are to receive radiation. The pattern is defined by an arrangement of lead blocks suspended below the head of the accelerator, which shields the lungs from excess irradiation. *Martin Dohm, Photo (Photograph by Researchers, Inc. Reproduced by permission.)*

How radiotherapy works

High-energy radiation kills cells by damaging their DNA and thus blocking their ability to divide and proliferate. Other cytotoxic mechanisms include the production of poisonous OH⁻ free radicals in the cellular cytoplasm.

Radiation kills normal cells about as well as cancer cells; but cells that are undergoing rapid growth and division (such as cancer cells, skin cells, **blood** cells, **immune system** cells, and **digestive system** cells) are the most susceptible to radiation. Fortunately, most normal cells are better able to repair radiation damage than are cancer cells. Accordingly, radiation treatments are parceled into component treatments that are spaced over a given time interval (usually about seven weeks). The spacing of radiation treatments allows cells to repair themselves during the time between treatments. Since the repair rate of normal cells is greater than the repair rate of cancerous cells, a smaller fraction of the radiation-damaged cancerous cells will have been replaced by the time of the next treatment. This procedure is called fractionation because the total radiation dose is divided into fractions. Fractionation allows cancer cells to be killed more effectively with less ultimate damage to the surrounding normal cells. Ideally all the cancer cells will be gone after the last treatment session.

Types of radiation used to treat cancer

PHOTON RADIATION. Early radiotherapy made use of x rays and gamma rays. X rays and gamma rays are essentially high-energy, ionizing electromagnetic rays composed of massless particles of energy called photons.

The distinction between the two is that gamma rays originate from the decay of radioactive substances (like radium and cobalt-60), while x rays are generated by devices that excite electrons (such as cathode ray tubes and linear accelerators). These ionizing rays are part of the electromagnetic spectrum, which also includes ultraviolet, visible, and infrared light; radio waves; and microwaves. Ionizing rays act on cells by disrupting the electrons of atoms within the molecules inside cells. These atomic changes disrupt molecules and hence disrupt cell functions, most importantly their ability to divide and make new cells.

PARTICLE RADIATION. Particle radiation is expected to become an increasingly important part of radiotherapy. Proton therapy has been available since the early 1990s on a limited scale. Proton rays consist of protons, which have mass and charge, in contrast to photons, which have neither mass nor charge. Like x rays and gamma rays, proton rays disrupt atomic electrons in target cells. The advantage of proton rays is that they can be directed to conform to the shape of the tumor more precisely than x rays and gamma rays. Consequently, proton rays cause less injury to surrounding tissue and fewer side effects. They allow physicians to deliver higher radiation doses to tumors without increasing damage to the surrounding tissue. Proton therapy is therefore more effective and requires fewer treatment sessions than conventional x-ray therapy.

Neutron therapy is a second type of particle radiation. Neutron rays are very high-energy rays composed of neutrons, which are particles with mass but no charge. Unlike x rays, gamma rays, and proton rays, they disrupt atomic nuclei rather than electrons; thus the likelihood of cells repairing this kind of intensive damage is very small. Neutron therapy can also effectively treat larger tumors than conventional radiotherapy. The central parts of large tumors lack sufficient oxygen to be susceptible to damage from conventional radiation, which depends on oxygen. Neutron radiation, however, can do its damage in the absence of oxygen, so it can kill cells in the centers of large tumors. Neutron therapy has been shown to be especially effective for the treatment of inoperable salivary gland tumors, bone cancers, and some advanced cancers of the **pancreas**, bladder, lung, prostate, and uterus.

Another promising type of neutron therapy, neutron capture therapy, is still in the experimental stage. It has, however, the advantage of being able to deliver high doses of radiation to a very limited area. Neutron capture therapy begins with a medication that binds to tumor cells but not to other cells. The medication is chemically combined with boron and given to the patient. The tumor is then irradiated with neutrons. When the neutrons inter-

act with the boron atoms, the boron nuclei split, creating tiny nuclear fission events just big enough to kill one cell. If the drug doesn't bind to neighboring noncancerous cells, then only cancer cells will be damaged, and the damage to these cells should be irreversible.

Phototherapy is the newest approach to radiotherapy. In phototherapy, a porphyrin derivative is used to attach to and illuminate the tumor. The tumor can then be targeted for selective uptake of radiation.

Modes of delivery

EXTERNAL BEAM THERAPY. Traditionally, radiotherapy has been delivered from a beam of radiation originating outside the body. This modality is called "external beam therapy." The external beam passes through the body before and after it irradiates the tumor; thus it can injure tissue in its path.

BRACHYTHERAPY. In brachytherapy, the radiation remains inside the body. Brachytherapy uses such gamma ray-generating radioactive isotopes as cesium-137 or iodine-125. The isotope is placed in small tubes and implanted close to or inside the tumor. The patient stays in the hospital for a few days; after that time, the radioactive isotope has either decayed to a low level, or the implant is removed. This form of therapy is especially useful in treating tumors for which surgery or external beam therapy radiation would cause critical damage to tissues surrounding the tumor. Brachytherapy has been effective against prostate cancer and cervical cancer.

RADIOIMMUNOTHERAPY. Until the mid-1990s, the only way to treat cancer that has spread (metastasized) to multiple locations throughout the body has been with traditional chemotherapy, which uses drugs that kill cells that divide and reproduce quickly (proliferate) in a non-specific way. Recently, cancer vaccines have been used successfully to extinguish metastatic melanoma. Vaccine treatment is a form of immunotherapy; it specifically kills melanoma cells and not other cells, even though they may also be proliferating.

Radioimmunotherapy is another form of immunotherapy that is still experimental. Researchers expect that radioimmunotherapy will be able to kill metastatic cancer cells almost anywhere in the body. Antibodies are immune system molecules that specifically recognize and bind to only one molecular structure, and they can be designed to bind specifically to a certain type of cancer cell. To carry out radioimmunotherapy, antibodies with the ability to bind specifically to a patient's cancer cells will be attached to an isotope that emits gamma rays when it is injected into the patient's bloodstream. These special antibody molecules will travel around the body until they encounter a cancer cell, and

then they will bind to it. Then the gamma rays will kill the cancer cell. It will be difficult, however, for researchers to calculate the correct dose of antibody and isotope that will kill an unknown number of cancer cells and at the same time use isotope levels that won't destroy the antibody molecules before they encounter cancer cells.

Preparation

Before radiotherapy, the size and location of the patient's tumor, as well as the nature of the surrounding tissue in the path of the radiation beam, must be determined as accurately as possible so that the radiation treatment will be maximally effective. **Magnetic resonance imaging (MRI)** and computed tomography (CT) are used to provide detailed images of the tumor. The correct radiation dose, the number of sessions (fractions), the interval between sessions, and whether to give each fraction from the same direction or from different directions to lower the total dose imparted to a given surrounding area, are calculated on the basis of the tumor type, its size, and the sensitivity of the nearby tissues.

Shields are sometimes constructed for the patient to protect certain areas of the body. The patient's skin may be marked with ink or tattoos to help achieve correct positioning for each treatment, or molds may be built to hold tissues in exactly the right place each time.

Three-dimensional conformal external beam therapy

For some types of tumors, including prostate cancer, a beam-shaping technique known as three-dimensional conformal therapy is used to deliver higher doses of radiation to the tumor site while sparing surrounding tissue to a greater extent than is possible with the nonconformal approach. Three-dimensional conformal therapy requires **CT scans** that allow the radiologist and physicist to accurately plan field shapes and prepare shields appropriately shaped for the treatment plan.

Intensity-modulated radiotherapy (IMRT)

As with three-dimensional conformal therapy, intensity-modulated radiotherapy requires a CT scan prior to dose planning. The information from the CT scan is used to plan the delivery of the radiation. The key difference between three-dimensional conformal therapy and IMRT is that IMRT produces a plan that can be transferred to a floppy or optical disk. The diskette is then used to control a dynamic beam-shaping device called a collimator that is attached to the linear accelerator. The collimator has multiple small fingers about three millimeters wide that

KEY TERMS

Antibody—A protein molecule made by the immune system cells in response to a foreign substance; it recognizes and binds specifically to that substance.

Atom—The smallest part of an element having the chemical properties of the element.

Cancer vaccine—A drug given to induce a patient's immune system to attack his or her cancer.

Fractionation—In radiotherapy, a procedure in which a radiation treatment regimen is divided into many (usually 10–25) treatment sessions over a time span of several weeks.

Gamma rays—Short-wavelength, high-energy electromagnetic radiation emitted by radioactive substances.

Hodgkin's disease—Cancer of the lymphatic system, characterized by lymph node enlargement and the presence of large polyploid cells called Reed-Sternberg cells.

Immunotherapy—A treatment modality that utilizes cells or molecules of the immune system.

Ionizing radiation—High-energy radiation that has enough energy to move atomic electrons out of their orbits and thereby ionize the surrounding medium.

Isotope—One of two or more atom types of the same element that have the same number of protons in their nuclei but different numbers of neutrons.

Melanoma—One of the three most common types of skin cancer; melanoma is the most dangerous type because it frequently metastasizes.

Metastasis (plural, metastases)—A secondary tumor resulting from the spread of cancerous cells from the primary tumor to other parts of the body.

Neutron—A subatomic particle with a charge of zero and a mass slightly greater than that of a proton.

Proton—A subatomic particle with a charge of +1 and a mass about 1836 times that of an electron.

X rays—Short-wavelength, high-energy electromagnetic radiation produced by atom bombardment.

move in and out of the radiation field during treatment. The information on the floppy or optical disk controls the movement of the beam-shaping fingers. The beam rotates around the patient in some treatment regimens. The ability of IMRT to precisely shape the beam in very small increments even while it's moving allows the therapist to deliver even higher doses to the tumor and spare even more of the healthy surrounding tissues than three-dimensional conformal therapy does. For some tumors, like prostate cancer, even greater precision can be attained by using a special ultrasound machine. Prior to each treatment, the ultrasound machine is used to pinpoint the location of the prostate gland relative to the radiation source. The information from the ultrasound scan allows the therapist to position the patient with a degree of precision measured in millimeters before the therapy begins.

Aftercare

Follow-up is important for patients who have received radiotherapy. They should go to their radiation oncologist at least once within the first several weeks after their final treatment to see if their treatment was successful. They should also see an oncologist every six to twelve months for the rest of their lives so they can be checked to see if the tumor has reappeared or spread.

Treatment of symptoms following radiotherapy depends on which part of the body is being treated and the type of radiation. Nevertheless, many patients experience skin burn, hair loss, fatigue, nausea, and vomiting regardless of the treatment area.

Affected skin should be kept clean and can be treated like a sunburn, with skin lotion or **vitamin A** and **D** ointment. Patients should avoid perfume or scented skin products, and protect affected areas from the sun.

Nausea and vomiting are expected when the dose is high, or if the abdomen or another part of the digestive tract is irradiated. Sometimes nausea and vomiting occur after radiation to other regions, but in these cases the symptoms usually disappear within a few hours after treatment. Nausea and vomiting can be treated with **antacids** or with such antiemetics as Compazine, Tigan, or Zofran.

Fatigue frequently sets in after the second week of therapy and may continue until about two weeks after the therapy is finished. Patients may want to limit their activities, cut back their work hours, or take time off from work. They also may need to take naps and get extra sleep at night.

Patients who receive external beam therapy do not become radioactive and should be assured that they do

not pose a danger to others. Some patients who receive brachytherapy, however, do go home with low levels of radioactivity inside their bodies. These patients should be given instructions about any dangers they might pose to children and people of childbearing age, and how long these dangers will last.

Emotional support is an important part of the care for patients undergoing any treatment for cancer. Radiotherapy can cause significant changes in a patient's appearance—particularly hair loss—and many patients fear that their spouses or partners will no longer find them attractive. There are many support groups available for radiotherapy patients and their families, as well as resources to help them cope with the external side effects of radiation treatment.

Complications

Radiotherapy can be highly toxic to patients because it kills normal cells as well as cancerous ones. There are risks of anemia, nausea, vomiting, **diarrhea**, hair loss, skin burn, sterility, and death. The benefits of radiation therapy, however, almost always exceed the risks involved.

Results

The probable outcome of radiation treatment is highly variable depending on the disease. For some diseases like Hodgkin's disease, about 75% of the patients are cured. Moreover, up to 86% of prostate cancer victims treated with both external and internal radiation are symptom-free five years after radiotherapy. On the other hand, radiation therapy is less successful in treating **lung cancer**; only about 9% of lung cancer patients are cured.

Rapid streptococcus antigen tests

Definition

A rapid streptococcus antigen test is used to quickly diagnose **strep throat**, a contagious **infection** of the pharynx caused by a Group A streptococcus (*Streptococcus pyogenes*), commonly referred to as GAS.

Purpose

Rapid streptococcus antigen tests are used to identify a strep throat. While a **throat culture** remains the gold standard for diagnosis of group A streptococcus infection, this procedure takes 24-48 hours for results. A rapid strep test takes only five minutes to perform. Since streptococci are sensitive to penicillin and related drugs, antibiotic therapy can be initiated immediately when the test is positive. A positive test result eliminates the need for bacterial throat culture.

Precautions

An untreated strep throat can increase the patient's risk of developing scarlet or rheumatic **fever**, which is associated with **meningitis**; and diseases affecting the **heart**, skin, **kidneys**, and joints. False-negative results occur with this test with a frequency ranging from 4-39%. Therefore, negative test results should be confirmed by throat culture.

Description

Approximately 10-19% of all sore throats are caused by group A beta-hemolytic streptococci. The majority of strep throat infections occur in children between the ages of five and fifteen, although adults with weakened immune systems are also at risk. The highest incidence of strep throat occurs during the winter and early spring months. Rapid streptococcal tests utilize antibodies to detect streptococcal antigens. There are four different direct streptococcal antigen detection platforms available in a wide number of different commercial products. These are latex agglutination; optical immunoassay; double antibody sandwich immunoassay; and immunochromatographic detection. The majority of rapid assays used today are based on double antibody sandwich and/or immunochromatography because these techniques do not require mixing, multiple reagent addition, or washing. An example of a combined double antibody sandwich immunochromatography method is described below.

The first step of a rapid strep test is the extraction of specific Group A streptococcal carbohydrate antigen from the swab. The swab is placed in a test tube to which the extracting reagents have been added. The swab is rotated vigorously in the solution while pressing the tip against the sides of the test tube. After all fluid is pressed from the swab, it is discarded and the extract is applied to a nitrocellulose membrane containing both immobilized antibodies and nonimmobilized antibodies to different regions of the Group A strep antigen. The nonimmobilized antibodies are conjugated to dyed colloidal gold particles. If Group A streptococcal carbohydrate antigen is present in the extract, the conjugated antibodies bind to it, forming antigen-antibody complexes. These migrate along the membrane until they reach the reaction zone containing immobilized antibodies to the same Group A strep antigen. These antibodies capture the antigen-antibody complexes, forming a colored band or line (usually pink or blue) in the reaction zone area.

Specificity of these tests is approximately 97-98%. Few causes of false positives have been reported. False positives are possible when the patient's throat contains a

heavy growth of *Staphylococcus aureus*. False-negative test results are commonly reported and often occur when insufficient antigen is obtained from the swab extraction procedure.

Preparation

All rapid group A strep tests require a sample from the infected patient's throat. The sample is obtained by depressing the tongue and swabbing the back of the throat and tonsils, while avoiding the tongue, saliva and lips. The swab should come in contact with all the inflamed areas, vesicles and pustular tonsils. Swabs made of rayon or Dacron should be used. Swabs containing cotton, **calcium** alginate, or wooden shafts, or that have been placed in transport medium containing charcoal are not recommended.

Aftercare

There are no aftercare concerns with this test.

Complications

There are no complications associated with this test.

Results

Normal results are negative. However, these assays tend to have low sensitivity, and thus it is recommended that all negative tests be followed by culture of a different throat swab on a blood agar plate for the isolation of beta-hemolytic streptococci. A positive result indicates an infection with group A streptococcus, and does not require culture follow-up.

Health care team roles

These tests are usually performed in a doctor's office by a nurse.

Recreation therapy

Definition

Recreation therapy, or therapeutic recreation, strives to improve the functioning and independence of individuals who are ill or disabled. Recreation therapists provide services in clinical facilities and in the community.

Description

Incorporating a variety of interventions to treat individuals with physical, cognitive, and emotional conditions, recreation therapists educate their patients to make them better-informed participants in their own health care. As a result, patients are taught to use activity to cope with the stresses of illness and disability. Therapeutic recreation activities may include, for example, wheelchair sports, **exercise** programs, and social activities—which preserve physical, cognitive, social and emotional health, thereby reducing the need for medical services.

A recreation therapist's responsibilities vary according to the setting and the patients served. Most recreation therapists are involved in the assessment of physical, mental, emotional, and social functioning towards determining the patient's needs, interests, and abilities based on information from standardized evaluations, observations, **medical records**, medical staff, family, and the patients themselves. The role of the recreation therapist is to then develop and implement therapeutic interventions consistent with the individual's needs and interests. For example, patients who place themselves in isolation may be encouraged to play games with others; a person with **paralysis** may be instructed in adaptation and compensatory strategies to throw a ball or swing a racket. Patients may be instructed in **relaxation** techniques to reduce **stress** and tension, correct stretching and limbering exercises, proper body mechanics for participation in recreation activities, pacing and other energy conservation techniques, and individual as well as team activities.

Work settings

Recreation therapists employed in hospitals are typically members of an interdisciplinary treatment team

that develops patient treatment plans. Recreation therapists are often responsible for one or more group activities each day. Such activities might include, for example, stress management groups, community outings, family activities, exercise, and leisure education groups. Depending on the needs of the individuals, recreation therapists are responsible for the provision of programs that may include adapted aquatics, wheelchair basketball, social recreation for adults with mental retardation, downhill skiing for individuals with physical disabilities, summer camps, or adapted golf lessons. In addition, the patient may be met by the recreation therapist to conduct an assessment, or for developing a discharge plan. Responsibilities also include documenting the individual's progress in charts and communicating with other professionals, as well as with the patient's family members. Recreation therapists employed in an institution are usually expected to plan evening and weekend activities, special events, and holiday activities. Patients are often encouraged to participate in the creation and organization of these activities. The recreation therapist is also responsible for adapting activities as needed, and for providing adaptive equipment to enable the participation of individuals with disabilities or limitations. These services are designed to help meet the goals identified in the individual's treatment plan.

A variety of agencies and organizations employ recreation therapists. They may hold positions in acute-care hospitals, rehabilitation centers, **nursing homes**, psychiatric hospitals, community recreation centers, pediatric hospitals, group homes, senior centers, community mental health centers, public and private schools, correctional facilities, and private practice. Individuals of all ages and walks of life benefit from the services provided by recreation therapists.

The services of community-based recreation therapists are also used in park and recreation departments, special education programs for school districts, or programs for older adults and people with disabilities. In these programs, clients are helped to develop leisure activities. The role of the recreation therapist is to provide them with opportunities for exercise, mental stimulation, creativity, and fun.

In schools, recreation therapists assume an important role in helping counselors, parents, and special education teachers address the special needs of students. Recreation therapists are especially important in helping to ease the transition phase into adult life for children with disabilities. The recreation therapist may work with the client, the client's family, and other professionals to design and implement treatment and education plans.

Many recreation therapists fulfill the role of advocate on behalf of the individual with a disability. This may include addressing such issues as limited transportation resources, inaccessible facilities, and legislation that affects people with disabilities. Participation on advisory committees is a frequent activity of the recreation therapist, whose job also includes consultations with outside agencies to ensure that resources and services are provided for people with disabilities.

Education and training

Most employers require a minimum of a bachelor's degree in therapeutic recreation or in recreation with an option or emphasis in therapeutic recreation. In addition, an associate degree in recreation therapy; training in art, drama, or music therapy; or qualifying work experience may be sufficient for employment in nursing homes.

A bachelor's degree in therapeutic recreation is awarded upon successful completion of required course work and a supervised internship. During an internship, students are placed in an agency for a minimum of one semester so that what they have learned in the classroom can be put into practice.

In recent years, professional credentialing has become more important for employment. National certification is available through the National Council for Therapeutic Recreation Certification (NCTRC), an independent credentialing body. The National Council for Therapeutic Recreation Certification awards the title of Certified Therapeutic Recreation Specialist (CTRS) based upon prescribed education and experience requirements and successful performance on a 200-item national examination. Some states have additional requirements for licensure, registration or certification as well. Credentialing helps ensure that the minimum requirements needed to safely provide therapeutic recreation services have been met.

Future outlook

Employment opportunities for recreation therapists are expected to grow. The projected demand is due to the increase in the need for long-term care, and physical and **psychiatric rehabilitation**.

In 1996, there were approximately 38,000 employed recreation therapists. Hospitals have 42% in their employ; nursing homes had 38% employed. Residential facilities, community mental health centers, **adult day care** programs, correctional facilities, community programs for people with disabilities, and substance abuse

centers had these therapists working for them. One out of every four recreation therapists were self-employed; this vocational path generally involves contracting with long-term care facilities or community agencies to develop and oversee programs.

Rectal cancer see **Colorectal cancer**

Rectal medication administration

Definition

Rectal medicines are medications prepared specifically for insertion into the rectum. They are compounded in many forms. Liquid rectal medicine solutions are given by enema. Creams, lotions and ointments are applied externally or inserted internally using an applicator. Suppositories are prepared by mixing medicine with a wax-like substance to form a semi-solid, bullet-shaped form that will melt after insertion into the rectum.

Purpose

Rectal medications are administered for a localized effect on the rectum or for a systemic effect when a patient is vomiting, unable to swallow, or unconscious. Rectal medicine is most commonly used as a localized treatment for constipation or as a topical treatment for rectal inflammation or **infection**. Rectal suppositories may be used for the treatment of **fever**, nausea, and **pain**; they may also be prescribed to induce sedation or bronchodilation, or to reduce the nausea and vomiting that can accompany **chemotherapy**. Medicated **enemas** may be used to cleanse the bowel, to combat **bacteria**, or to kill parasites.

Precautions

Rectal medications must be used with caution in the cardiac patient who has arrhythmias or has recently had a **myocardial infarction** (i.e., **heart attack**). Insertion of a rectal medicine can cause vagus nerve stimulation and may trigger an arrhythmia—such as bradycardia. Rectal medicines should not be given to the patient with undiagnosed abdominal pain because peristalsis of the bowel can cause an inflamed appendix to rupture. Rectal medicines should be used cautiously in patients who have undergone recent surgery on the rectum, bowel, or prostate gland. If the patient has rectal bleeding or a prolapse of rectal tissue from the rectal opening, the medicine should be withheld and the physician consulted before administration. Rectal medicines should not be taken orally, and only medications labeled as rectal preparations should be placed in the rectum.

Description

Administration of rectal medication should be done after the patient is positioned correctly. Lifting the upper buttocks will enable visualization of his or her rectal opening. External lotions, ointments or creams can be applied directly, using a gloved finger or a 4x4 gauze pad. Prior to administering internal rectal medicine, the tip of the suppository, enema catheter, or applicator should be lubricated with a water-soluble lubricant. To insert a rectal suppository, the lubricated, tapered end of the suppository should be placed at the rectal opening and gently pushed into the rectum. The suppository should be pushed continually toward the umbilicus until the full length of the nurse's gloved index finger has been inserted into the rectal opening (i.e., about 3 inches, or 7.5 cm, for an adult patient). When inserting suppositories into children, the suppository should be pushed about 1 inch (2.5 cm) beyond the rectal opening, or up to the first knuckle of the nurses's index finger. When inserting suppositories into infants, the little finger should be inserted one-half inch (1.25 cm) beyond the rectal opening. The buttocks should be released and the finger removed.

Administration of internal rectal medicated cream or ointment requires placement of the applicator's lubricated tip at the rectal opening, gently pushing the applicator into the rectal opening about 3 inches (7.5 cm) for an adult (or as indicated on the applicator's directions). The correct dosage of medicine should then be squeezed into the rectum. After withdrawal of the applicator tip, the buttocks should be released.

To administer rectal medicine using an enema solution, the lubricated tip of the enema catheter must also be

placed at the rectal opening. The tip of the catheter should then be gently advanced into the rectum, about 3 inches (7.5 cm) for an adult (or as indicated on the enema tubing). After the patient is alerted, the enema tubing should be opened, allowing the enema solution to flow into the rectum. A prepared enema should also be administered in this manner. When all of the solution has been administered, the enema catheter should be removed. Then, the buttocks should be released.

Preparation

Before administering rectal medicine, the door to the room should be closed to assure patient privacy. The patient should be encouraged to empty his or her bladder and bowels before the procedure. After removing lower garments and underwear, the patient should be positioned in bed on his or her left side, with the top knee bent and pulled slightly upward. A waterproof pad should be placed under the patient's hips to protect the bedding, and a sheet should be draped over the patient to cover all of his or her body except the buttocks.

After placing a bedpan within quick access, the nurse should explain the procedure to the patient. This explanation should include the importance of breathing slowly through the mouth to enhance relaxation of the rectal sphincter and to avoid oppositional pressure. The patient should be made aware that there may be an urge to push the medicine out, but that he or she should try to hold it for at least 10–15 minutes after instillation (30 minutes for suppositories), as most rectal medications need time to be absorbed. It is advisable for the professional to check the medication label each time the medicine is given, to avoid medication errors. It must be the right medicine and the right dose (strength), the right time, the right patient, and the right method. The expiration date on the label should be inspected. If the medicine is outdated, it should not be used.

The nurse should wash his or her hands and put on gloves. The foil wrap should be removed from the rectal preparation or suppository. To prepare internal rectal creams, lotions or ointments, the applicator should be examined so that the nurse can estimate the proper amount to instill after insertion. In preparation for rectal enema instillations, the directions on the package of pre-mixed disposable enemas should be read. Most pre-mixed disposable enemas come with the tip already lubricated. The cap from the tip should be removed, and air should be expelled from the apparatus before use. If liquid medicine solutions are given using a standard enema bag and tubing, the procedure for enema instillation should be followed.

KEY TERMS

Arrhythmia—An irregularity of the heartbeat.

Bradycardia—An abnormal slowing of the heart rate to fewer than 60 beats per minute.

Myocardial infarction—A cardiac condition caused by decreased blood flow and oxygen to the heart muscle; may cause tissue death and heart damage. Commonly known as a heart attack.

Peristalsis—The wave-like muscular contractions of the intestinal walls that move food and refuse through the gastrointestinal system.

Prostate gland—A gland found in males, located below the bladder and around the urethra, that secretes the fluid for semen and controls the release of urine from the bladder.

Rectum—The last portion of the large intestine located just above the anal canal, where stool collects prior to evacuation from the body.

Vagus nerve—One of the paired cranial nerves that supplies motor and sensory enervation to the abdominal and thoracic organs.

Aftercare

After administering rectal medicines, the nurse should remain near the patient in case there is a need for assistance with the bedpan, or to walk to the bathroom. If a suppository is expelled within the first few minutes of insertion, the tip should be relubricated and reinserted. Medicated enemas that are expelled immediately may need to be repeated, using fresh solution. Directions provided with a prepared enema should be followed, but the physician may need to be consulted. To assist the patient with retaining the medicine, the nurse can apply gentle pressure to the rectal opening, using a 4x4 gauze pad or by squeezing the buttocks together after rectal medicine instillation. A 4x4 gauze pad should also be tucked between the buttocks to collect seepage; this may help the patient feel more secure. After the procedure is completed, the patient should be covered and instructed to remain still for 10–15 minutes (30 minutes if a suppository was inserted). This period will allow time for medication absorption. Items that can be reused, such as enema pouches, tubing, and applicator tips, should be cleaned with warm running water and allowed to air-dry. Ointments and creams need to be recapped and returned to the medicine boxes. Disposable items and gloves should be placed in an appropriate trash bag that can be sealed and discarded.

Complications

Rectal medicines can cause tissue irritation or allergic reactions. If irritation, swelling, redness, bleeding or prolapse of the rectal tissue is apparent, or if the patient complains of pain or burning, the medication should be stopped and the physician notified.

Results

When given correctly, rectal medications work within 30–60 minutes to relieve pain, nausea, constipation, or fever. Rectal ointments for swelling and irritation of hemorrhoids may reverse the condition within several days. Because of their liquid state, rectal enemas are absorbed quickly and work rapidly. Retention enemas are meant to be held for 30 minutes to achieve full therapeutic effect.

Health care team roles

Rectal medicines are administered by a licensed nurse (R.N. or L.P.N.) in the health care setting. An alert and cooperative patient may be allowed to apply external and internal rectal ointments and suppositories under the direction of the nurse. The nurse, however, should assess the site and the effectiveness of the medicine. The patient or members of the patient's family can be taught to administer rectal medicines in the home setting.

Red blood cell indices

Definition

Red **blood** cell (RBC) indices are calculations derived from the **complete blood count** that aid in the diagnosis and classification of anemia. Measurements needed to calculate indices are the red blood cell count, hemoglobin, and **hematocrit**. The hematocrit is the percentage of blood by volume that is occupied by the red cells. The three RBC indices are:

- Mean corpuscular volume (MCV). The average size of the red blood cells expressed in femtoliters. MCV is calculated by dividing the hematocrit (as percent) by the RBC count in millions per microliter of blood, then multiplying by 10.
- Mean corpuscular hemoglobin (MCH). The average amount of hemoglobin inside an RBC expressed in picograms. The MCH is calculated by dividing the hemoglobin concentration in grams per deciliter by the RBC count in millions per microliter, then multiplying by 10.
- Mean corpuscular hemoglobin concentration (MCHC). The average concentration of hemoglobin in the RBCs expressed as a percent. It is calculated by dividing the hemoglobin in grams per deciliter by the hematocrit, then multiplying by 100.

Purpose

Red blood cell indices help classify types of anemia, a decrease in the oxygen carrying capacity of the blood. Healthy people have an adequate number of correctly sized red blood cells containing enough hemoglobin to carry sufficient oxygen to all the body's tissues. Anemia is diagnosed when either the hemoglobin or hematocrit of a blood sample is too low.

The mechanisms by which anemia occurs will alter the RBC indices in a predictable manner. Therefore, the RBC indices permit the physician to narrow down the possible causes of an anemia. The MCV is an index of the size of the RBCs. When the MCV is below normal, the RBCs will be smaller than normal and are described as microcytic. When the MCV is elevated, the RBCs will be larger than normal and are termed macrocytic. RBCs of normal size are termed normocytic. Failure to produce hemoglobin results in smaller than normal cells. This occurs in many diseases, including **iron deficiency anemia**, thalassemia (an inherited disease in which globin chain production is deficient), and **anemias** associated with chronic **infection** or disease. Macrocytic cells occur when division of RBC precursor cells in the bone marrow

is impaired. The most common causes of macrocytic anemia are **vitamin B₁₂** deficiency, folate deficiency, and **liver** disease. Normocytic anemia may be caused by decreased production (e.g. malignancy and other causes of bone marrow failure); increased destruction (hemolytic anemia); or blood loss. The RBC count is low, but the size and amount of hemoglobin in the cells are normal.

A low MCH indicates that cells have too little hemoglobin. This is caused by deficient hemoglobin production. Such cells will be pale when examined under the **microscope** and are termed hypochromic. **Iron** deficiency is the most common cause of a hypochromic anemia. The MCH is usually elevated in macrocytic anemias associated with vitamin B₁₂ and folate deficiency.

The MCHC is the ratio of hemoglobin mass in the RBC to cell volume. Cells with too little hemoglobin are lighter in color and have a low MCHC. The MCHC is low in microcytic, hypochromic anemias such as iron deficiency, but is usually normal in macrocytic anemias. The MCHC is elevated in hereditary spherocytosis, a condition with decreased RBC survival caused by a structural protein defect in the RBC membrane.

Cell indices are usually calculated from tests performed on an automated electronic cell counter. However, these counters measure the MCV, which is directly proportional to the voltage pulse produced as each cell passes through the counting aperture. Electronic cell counters calculate the MCH, MCHC, hematocrit, and an additional parameter called the red cell distribution width (RDW). The RDW is a measure of the variance in red blood cell size. It is calculated by dividing the standard deviation of RBC volume by the MCV and multiplying by 100. A large RDW indicates abnormal variation in cell size, termed anisocytosis. The RDW aids in differentiating anemias that have similar indices. For example, thalassemia minor and iron deficiency anemia are both microcytic and hypochromic anemias, and overlap in MCV and MCH. However, iron deficiency anemia has an abnormally wide RDW but thalassemia minor does not.

Precautions

Certain prescription medications may affect the test results. These drugs include zidovudine (Retrovir), phenytoin (Dilantin), and azathioprine (Imuran). When the hematocrit is determined by centrifugation, the MCV and MCHC may differ from those derived by an electronic cell counter, especially in anemia. Plasma trapped between the RBCs tends to cause an increase in the hematocrit, giving rise to a somewhat higher MCV and lower MCHC.

RBC indices require 3-5 mL of blood collected by venipuncture. A nurse or phlebotomist usually collects

KEY TERMS

Anemia—A variety of conditions in which a person's blood can't carry as much oxygen as is needed by the tissues.

Hypochromic—A descriptive term applied to a red blood cell with a decreased concentration of hemoglobin.

Macrocytic—A descriptive term applied to a larger than normal red blood cell.

Mean corpuscular hemoglobin (MCH)—A calculation of the average weight of hemoglobin in a red blood cell.

Mean corpuscular hemoglobin concentration (MCHC)—A calculation of the average concentration of hemoglobin in a red blood cell.

Mean corpuscular volume (MCV)—A measure of the average volume of a red blood cell.

Microcytic—A descriptive term applied to a smaller than normal red blood cell.

Normochromic—A descriptive term applied to a red blood cell with a normal concentration of hemoglobin.

Normocytic—A descriptive term applied to a red blood cell of normal size.

Red blood cell indices—Measurements that describe the size and hemoglobin content of red blood cells.

Red cell distribution width (RDW)—A measure of the variation in the size of red blood cells.

the sample following standard precautions for the prevention of transmission of bloodborne pathogens.

Aftercare

Discomfort or bruising may occur at the puncture site. Pressure to the puncture site until the bleeding stops reduces bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test.

Results

Normal results for red blood cell indices are as follows:

- MCV: 80-96 fl (femtoliters)
- MCH: 27-33 pg (picograms)
- MCHC: 33-36%
- RDW: 12-15%

Health care team roles

A phlebotomist, or sometimes a nurse, collects the blood; and a clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or clinical laboratory technician, or CLT(NCA)/medical laboratory technician MLT(ASCP) performs the testing. Results are interpreted by a physician.

Reflex tests

Definition

Reflex tests are simple physical tests of nervous system function.

Purpose

A reflex is a simple nerve circuit. A stimulus, such as a light tap with a rubber hammer, causes sensory **neurons** (nerve cells) to send signals to the **spinal cord**. There, the signals are conveyed both to the **brain** and to nerves that control muscles affected by the stimulus.

Without any brain intervention, these muscles may respond to an appropriate stimulus by contracting.

Reflex tests measure the presence and strength of a number of **reflexes**. In so doing, they help to assess the integrity of the nerve circuits involved. Reflex tests are performed as part of a neurological exam, either a “mini-exam” done to quickly confirm integrity of the spinal cord, or a more complete exam performed to diagnose the presence and location of a **spinal cord injury** or neuromuscular disease.

Deep tendon reflexes are responses to muscle stretch. The familiar “knee-jerk” reflex is an example of a reflex. This tests the integrity of the spinal cord in the lower back region. The usual set of deep tendon reflexes tested, involving increasingly higher regions of the spinal cord, includes:

- ankle
- knee
- abdomen
- forearm
- biceps
- triceps
- patellar

Another type of reflex test is called the Babinski test, which involves gently stroking the sole of the foot to assess proper development and function of the spine and cerebral cortex.

Precautions

Reflex tests are entirely safe, and no special precautions are needed.

Description

The examiner uses a reflex hammer or rubber mallet to strike different points on the examinee’s body, and observes the response. The points chosen for eliciting reflexes are the tendons of specific muscles. Tapping specific sites is intended to provide a quick stretch to the muscle. Muscle spindles, or receptors, mediate the reflex lying within the muscle—not the site of the hammer strike. The examiner may position, or hold, one of the limbs during testing, and may require exposure of the ankles, knees, abdomen, and arms. Reflexes can be difficult to elicit if the individual being examined is paying too much attention to the stimulus. To compensate for this, that person may be asked to perform some **muscle contraction**, such as clenching teeth or grasping and pulling the two hands apart. When performing the

A doctor tests a patient’s reflex during a physical examination. (Photograph by Will & Deni McIntyre. Science Source/Photo Researchers. Reproduced by permission.)

Babinski reflex test, the examiner will gently stroke the outer soles of the person’s feet with the mallet while checking to see whether or not the big toe extends out as a result.

Preparation

The examiner positions the person to be examined in a comfortable position, usually seated on the examination table with legs hanging free. There is no other preparation.

Aftercare

A reflex examination is not invasive. No care after the examination is required.

Complications

The pressure exerted by a reflex hammer is minimal and does not hurt the person being examined. A reflex

Muscle stretch (deep tendon) reflexes

Reflex	Stimulus	Response
Biceps	Tap biceps tendon	Contraction of biceps
Brachioradialis (periosteradial)	Tap styoid process of radius (insertion of brachioradialis)	Flexion of elbow and pronation of forearm
Jaw (maxillary)	Tap mandible in half-open position	Closure of jaw
Patellar	Tap patellar tendon	Extension of leg at knee
Tendocalcaneus	Tap Achilles tendon	Plantar flexion at ankle
Triceps	Tap triceps tendon	Extension of elbow
Wrist extension	Tap wrist extensor tendons	Extension of wrist
Wrist flexion	Tap wrist flexor tendon	Flexion of wrist

examination is not invasive. There are no complications from performing the examination.

Results**Normal results**

The strength of the response depends partly on the strength of the stimulus. For this reason, an examiner will attempt to elicit the response with the smallest stimulus possible. Learning the range of normal responses requires some clinical training. Responses should be the same on both sides of the body. A normal response to the Babinski reflex test depends upon the age of the person being examined. In children under the age of one and a half years, the big toe will extend out with or without the other toes. This is due to the fact that the fibers in the spinal cord and cerebral cortex have not been completely covered in myelin, the protein and lipid sheath that aids in processing neural signals. In adults and children over the age of one and a half years, the myelin sheath should be completely formed; and as a result, all the toes will curl under (plantar flexion reflex).

Abnormal results

Weak or absent response may indicate damage to the nerves outside the spinal cord (peripheral neuropathy), damage to the motor neurons just before or just after they leave the spinal cord (motor neuron disease), or muscle disease. Excessive response may indicate spinal cord damage above the level controlling the hyperactive response. Different responses on the two sides of the body may indicate early onset of progressive disease, or localized nerve damage, as from trauma. An adult or older child who responds to the Babinski with an extended big toe may have a lesion in the spinal cord or cerebral cortex.

Health care team roles

A reflex examination is usually conducted by a physician. Neurologists (doctors with specialized training in neurology) often perform reflex tests. Physician assistants, physical therapists, and nurses may also test reflexes as they examine or evaluate individuals.

Reflexes

Definition

Reflexes are the body's automatic reaction to some type of sensory stimuli. They involve nerve impulses passing from a receptor to a nerve center and then outward to, for example, a nerve or a gland.

Description

Reflexes are classified as unconditioned and conditioned.

Unconditioned reflexes

Unlike most human behaviors, unconditioned reflexes occur without specific learning or experience. They are considered involuntary acts, because a response occurs automatically when a stimulus (for example, a pinprick) takes place.

Unconditioned reflexes that protect us from harm are called nociceptive reflexes. For example, sneezing, coughing, and gagging are automatic responses to **foreign bodies** in the nose and throat. Eye blinking or winking helps protect the eye from harm. Reacting quickly to touching a hot stove is yet another example of a nociceptive reflex.

Most reflex acts are very complicated. However, in simple reflexes four events are involved: reception, conduction, transmission, and response. The stimulation is received by receptors, or sensitive nerve endings. These may be in the eye, ear, nose, tongue, or skin. Energy from the stimulus is changed into nerve impulses and conducted from the receptor to the **central nervous system**. From there, the nerve impulses are transmitted to the motor nerves, which control muscle action. The motor nerves conduct the impulses to the muscles and glands, causing them to respond or act. For example, touching a hot stove stimulates receptors in the skin of the finger. This creates a nerve impulse that travels along a sensory nerve to the **spinal cord**. In the spinal cord, the sensory nerve fibers interlace with motor nerve fibers. The nerve impulse passes from the sensory fibers to the motor fibers, which relay it to the muscles, causing them to contract. When the muscles contract, the person's hand jerks back.

People have many reflex reactions to such emotional stimuli as anger or fear, including changes in **blood pressure** and respiration. Lie detectors measure specific physical reactions to emotional stimuli.

Conditioned reflexes

Conditioned reflexes are acquired as the result of experience. When an action is performed repeatedly, the nervous system learns to react automatically. Walking, running, and typing are examples of learned conditioned activities that require a large number of complex muscular coordinations.

Conditioned reflexes work by association. For example, a dog's mouth begins to water when the animal smells food. The Russian physiologist Ivan P. Pavlov showed that the flow of saliva, originally an automatic reaction to the **smell** of food, may become a conditioned reflex. Pavlov rang a bell each time he brought food to a dog. Eventually, the dog's mouth began to water when Pavlov merely rang the bell without food being present. The dog associated the ringing of the bell with the food, just as it associated the odor with the food.

Function

In a simple reflex, a sensory receptor initiates a nerve impulse in an afferent sensory nerve fiber that conducts it to the spinal cord. In the gray matter of the spinal cord, the afferent nerve impulse is fired over the synaptic gap to an efferent motor fiber that passes along the impulse to the appropriate muscle, producing the reflex.

KEY TERMS

Afferent—Conveying impulses toward a nerve center, such as the brain or spinal cord.

Efferent—Conveying nervous impulses away from the central nervous system to nerves or neurons.

Nociceptive—A stimulus that causes pain or injury.

Synaptic gap—The space between neurons across which a nerve impulse is transmitted by a neurotransmitter. Also referred to as a synaptic cleft.

Role in human health

Nerve cells are sensitive to disturbances caused by tumors, trauma, circulatory problems, metabolic disorders, and a host of other diseases that can be diagnosed by determining which reflexes show abnormalities. Abnormal reflexes may suggest the presence of significant central nervous system or peripheral nerve problems.

Reflex tests measure the presence and strength of a number of reflexes to help assess the integrity of the nerve circuits involved. Reflex tests are performed as part of a neurological exam to quickly confirm the integrity of the spinal cord, or to diagnose the presence and location of **spinal cord injury** or neuromuscular disease.

Common diseases and disorders

Some of the more common reflex-related diseases and disorders include stroke, traumatic **brain** or spinal cord tumors or injury, **multiple sclerosis**, Wernicke-Korsakoff syndrome, **cerebral palsy**, and diabetic neuropathy.

Stroke

Stroke is a brain disorder involving loss of brain functions due to interruption of the brain's **blood** supply.

Brain and spinal cord injury

Brain and spinal cord injuries most commonly result from motor vehicle accidents, **falls**, **sports injuries**, industrial accidents, gunshot **wounds**, and criminal assault. Damage to the spinal cord affects all nerve function at and below the level of the injury, including muscle control and sensation.

Brain and spinal tumors

Brain and spinal cord tumors are abnormal growths of tissue found inside the **skull** or the spinal column. The

word tumor is used to describe both abnormal growths that are new (neoplasms) and those present at birth (congenital).

Multiple sclerosis

Multiple sclerosis involves inflammation within the central nervous system, followed by demyelination, which is a loss of the protective myelin sheaths that surround nerve fibers. When the myelin is damaged, nerve impulses are not transmitted quickly and efficiently. As a result of the inflammatory process, lesions develop in the brain and spinal cord, causing a variety of neurologic symptoms, such as **vision** loss, numbness or tingling, weakness, unsteady gait, double vision, fatigue, heat intolerance, partial or complete **paralysis**, and electric shock sensations when bending the neck. These symptoms may cease or may persist after an attack. Symptoms may become progressively worse over time. For individuals with progressive forms of multiple sclerosis, these symptoms may gradually worsen over time without rapid or abrupt changes.

Wernicke-Korsakoff syndrome

Wernicke-Korsakoff syndrome usually affects people between 40 and 80 years old. The onset is gradual. The syndrome is actually two disorders that may occur independently or together. Wernicke's disease involves damage to multiple nerves in both the central nervous system and the peripheral nervous system. It may also include symptoms caused by alcohol withdrawal. The cause is generally attributed to malnutrition—especially lack of vitamin B₁ (**thiamine**), which commonly accompanies habitual alcohol use or **alcoholism**.

Korsakoff syndrome, or Korsakoff psychosis, involves impairment of **memory** and such intellectual/cognitive skills as problem-solving or learning, along with multiple symptoms of nerve damage. The most distinguishing symptom is confabulation (fabrication), during which the person makes up detailed, believable stories about experiences or situations to cover the gaps in their memory. Korsakoff psychosis involves damage to areas of the brain.

Cerebral palsy

Cerebral palsy is a persistent qualitative motor disorder caused by nonprogressive damage to the brain. Although manifested primarily by motor dysfunction, the disorder also may involve sensory deficits and impairment of the intellect. The majority of cases are caused during labor and delivery or during the first month of infancy. Cerebral palsy may be caused by premature birth, prolonged labor, or traumatic delivery. Any situa-

tion that interferes with fetal oxygen supply can produce brain damage and cerebral palsy.

Diabetic neuropathy

Diabetic neuropathy is a nerve disorder caused by diabetes. Symptoms of neuropathy include numbness and sometimes **pain** in the hands, feet, or legs. Nerve damage caused by diabetes can also lead to problems with such internal organs as the digestive tract, **heart**, and sexual organs, causing indigestion, **diarrhea** or constipation, dizziness, bladder infections, and impotence.

Refractive eye surgeries

Definition

Refractive eye surgeries are medical procedures used to correct such refractive errors as **myopia**, **hyperopia**, and **presbyopia**. The three most widely utilized refractive surgeries approved by the U.S. Food and Drug Administration (FDA) are photorefractive keratectomy (PRK); laser-assisted in-situ keratomileusis (LASIK); and laser thermal keratoplasty (LTK). PRK and LASIK use an excimer laser to correct myopia by reshaping the cornea. The two techniques differ in how the surface layer of the cornea is treated.

Purpose

Refractive surgeries are performed to correct hyperopia, myopia, and presbyopia in patients who don't want to wear eyeglasses or **contact lenses**. After refractive surgery, most patients are able to see well enough to pass a driver's license exam without glasses or contact lenses. Some patients will still need corrective lenses, but the lenses won't need to be as strong or thick.

Precautions

Medical history is important in determining the appropriate refractive surgery patients. Patients for LASIK and PRK must be older than 18 years of age, have healthy corneas, and have **vision** that has been stable for the past year. People who may not be good candidates are pregnant women or women who are breastfeeding; patients with very small or very large refractive errors; those with low contrast sensitivity; people with scarred corneas or macular disease; or those with autoimmune diseases or diabetes. Patients with **glaucoma** should not have LASIK because the intraocular pressure (IOP) of the eye is raised during the procedure. A patient with persistent lid infections (i.e., blepharitis) may not be a good candidate because of an increased **infection** risk.

LTK patients must be at least 40 years old; have stable vision for at least six months; fall in the low-to-moderate range of hyperopia (+0.75–+2.50 diopters); and have no more than 0.75 diopters of **astigmatism**. Pregnant or nursing women, patients with clinically significant corneal dystrophy or scarring in the 6 mm or 7 mm central zone, patients with a history of herpetic keratitis, patients with an autoimmune disease, collagen vascular disease, clinically significant atopic syndrome, insulin-dependent diabetes, or an immune-compromised status should not have LTK.

Description

Refractive surgeries that correct myopia are similar in nature. PRK and LASIK are both performed with an excimer laser, which uses a cold beam of ultraviolet light to reshape the cornea so that light will focus properly on the retina. In myopia, the cornea is either too steep or the eye is too long for a clear image to be focused on the retina. PRK and LASIK flatten the cornea so that the image will focus more precisely on the retina.

In PRK, the surface of the cornea is removed by the laser. In LASIK, the outer layer of the cornea is sliced, lifted, and moved aside while the cornea is reshaped with the laser. The outer layer is then replaced to speed healing. For LASIK and PRK, the patient's eye is numbed with anesthetic drops. No injections are necessary.

Before LASIK, the cornea's surface is marked with a dye marker so that the flap of cornea can be precisely aligned when it is replaced. The ophthalmologist places a suction ring from a microkeratome, a lathe-like surgical instrument, on the corneal limbus (where the clear cornea meets the white of the eye). When the device is properly positioned, the surgeon applies suction by using a foot pedal, causing the eye's pressure to elevate to 80 mmHg from a minimum of 65 mmHg. During this time, the microkeratome lathes the top 10% of the total corneal thickness, which creates a thin flap of tissue. The thin layer is folded back, the cornea is reshaped with the laser beam, and the flap layer is replaced. Because the flap is not permanently removed, patients have a faster recovery time and experience far less discomfort than with PRK. A physician or ophthalmic assistant administers antibiotic drops, and the eye is patched until the following day's checkup.

In PRK, a small area of the surface layer of the cornea is vaporized. It takes about three days for the surface cells to grow back, and vision will be blurred.

PRK and LASIK take only a few minutes. Patients are usually able to return home immediately after surgery.

The LTK system resembles a slit lamp used in a general eye exam, so it is non-threatening to patients. Before the procedure, an ophthalmic assistant administers three sets of anesthetic eyedrops with three minutes between each set. Ophthalmologists use a retractor to keep the eyelids open, and the other eye is patched. There is a three-minute waiting period after insertion of the laser to evaluate the tear film for irregularities or uneven dry spots on the cornea. The patient focuses on a fixating light, and the 16-spot nomogram for the degree of correction is programmed into the LTK unit's computer. The laser is applied for three seconds.

After the procedure, the ophthalmic assistant or physician will give the patient topical antibiotic drops. There is no postoperative patching. Some patients may experience a foreign-body sensation for a few hours after LTK. It sometimes takes a few weeks for vision to stabilize. Patients are usually seen one day postoperatively.

The cost of refractive surgery can vary with geographic area and the surgeon. In general, the procedure costs \$1,350–\$2,500 per eye for PRK and about \$500 more per eye for LASIK. LTK is slightly more expensive than LASIK, at about \$3,000 per eye. Refractive surgery usually isn't covered by insurance.

Preparation

Refractive eye surgery patients should be carefully screened by an ophthalmic assistant or physician before surgery is approved to avoid some possible complications. This screening should include a comprehensive eye exam, either completed by the ophthalmologist or a co-managing optometrist at least a few days before the surgery. At this time, the physician or ophthalmic assistant should chart any dry eye or corneal disease that may hinder surgery. They should also perform corneal topography, which creates a topographical map of the patient's eye.

Assistants need to advise patients to discontinue wearing contact lenses prior to the visual exams to make sure vision is stable, and advise the doctor of contact lens wear.

Before surgery, ophthalmic staff administer eye-drops and a sedative to the patient. The physician tests the patient's vision, and the patient rests while waiting for the sedative to take effect. Immediately before the surgery, ophthalmic staff administer local anesthetic eye-drops.

Ophthalmic staff also will check the microkeratome settings before surgery and test their accuracy. Some complications from refractive surgery result from a faulty microkeratome.

Aftercare

The patient returns to the surgeon for a follow-up visit the next day. After that, postoperative treatment may be handled by a co-managing optometrist. The doctor usually prescribes antibiotic and anti-inflammatory eye-drops. PRK patients have a longer recovery time and may need steroidal eye-drops for months. After LASIK, antibiotic and anti-inflammatory drops are prescribed for one week.

LTK patients are treated similarly, with antibiotic drops and an over-the-counter **pain** reliever. Patients may have a foreign-body sensation for a few hours. It may take a few weeks for the eye to stabilize.

The attending physician will require the patient to return for a few months so that the patient's eye health and vision stability can be monitored. After that, yearly checkups are recommended.

Complications

There is a risk of under- or over-correction with LASIK and PRK. If vision is under-corrected, a second procedure can be performed to achieve results that may

be closer to 20/20 vision. About 5–10% of PRK patients return for an enhancement, as do 10–25% of LASIK patients. Patients with very high myopia (over -15.00 diopters) may experience improvement after LASIK, but are not likely to achieve 20/40 vision or better without glasses.

Severe dry eye syndrome is a possible complication of LASIK, and has been reported more often as the number of procedures performed has increased. The condition may be permanent. Physicians may prescribe intensive artificial tear therapy; and the use of punctal plugs or other procedures may be required.

Haze is another possible side effect, and is more likely to occur after PRK. Corneal scarring, halos, glare at night, or an irritating bump on the cornea are other side effects. Infection and vision loss are also possible with these procedures, but are extremely rare.

Most LASIK complications are related to the creation and realignment of the flap. The microkeratome must be in good working order and sharp. LASIK requires surgical skill and the complication rate is related to the experience level of the surgeon. In one study, the rate of LASIK complications declined from 3% for surgeons during their first three months using this technique, to 1% after a year's experience in the technique, to 0% after 18 months of experience.

Because LTK was approved in mid-2000, many of its complications have not yet been identified. Potential complications include corneal infiltrate or ulcer, uncontrolled intraocular pressure, late onset of haze, decrease in best spectacle-corrected visual acuity, or retinal detachment. In some cases the procedure is not successful at all.

Results

Most patients experience vision improvement immediately after refractive surgery. Vision tends to become sharper a few days after surgery and then stabilizes. Final visual acuity is achieved within three to six months with LASIK and six to eight months with PRK.

LASIK is more complicated than PRK because of the microkeratome procedure. However, LASIK generally has faster recovery time, less pain, and less chance of halos and scarring than PRK. LASIK can treat higher degrees of myopia (-5.00–25.00 diopters). LASIK also requires less use of steroids.

An LTK patient's vision will be overcorrected (improvement will be initially dramatic) for one to three months. The effect of improved near vision may diminish over time as distance vision improves.

KEY TERMS

Blepharitis—An inflammation of the eyelid.

Cataract—A condition in which the lens of the eye turns cloudy and interferes with vision.

Cornea—The clear, curved tissue layer in front of the eye. It lies in front of the colored part of the eye (iris) and the black hole in the center of the iris (pupil).

Diopter (D)—A unit of measure of the power or strength of a lens.

Excimer laser—An instrument that is used to vaporize tissue with a cold, coherent beam of light with a single wavelength in the ultraviolet range.

Hyperopia—The inability to see near objects as clearly as distant objects, and the need for accommodation to see objects clearly.

Intraocular lens (IOL) implant—A small plastic device (IOL), usually implanted in the lens capsule of the eye to correct vision after the lens of the eye is removed. This is the implant that is used in cataract surgery.

Macular degeneration—A condition usually associated with age, in which the area of the retina called the macula is impaired. This condition interferes with vision.

Microkeratome—A precision surgical instrument that can slice an extremely thin layer of tissue from the surface of the cornea.

Myopia—A vision problem in which distant objects appear blurry. Myopia results when the cornea is too steep or the eye is too long and the light doesn't focus properly on the retina. People who are myopic or nearsighted can usually see near objects clearly, but not far objects.

Refractive surgery—A surgical procedure that corrects visual defects.

Retina—The sensory tissue in the back of the eye that is responsible for collecting visual images and sending them to the brain.

There regression has been noted with LTK. The LTK mean rate of change decreases progressively, reaching only .02 diopters per month between 18 and 24 months. If the regression continues at the expected rate, the corrective effect would dissipate no sooner than 11 years after the procedure.

Health care team roles

Allied health professionals play an important role in preparing patients for refractive surgery. Advanced and intermediate-level ophthalmic technicians perform refractions and help determine the patient's eligibility for refractive surgery. These professionals also may perform corneal topography.

Specially trained ophthalmic nurses assist during the surgery. They check the microkeratomes and administer eyedrops. Advanced ophthalmic technologists, who are specially trained for such additional duties as taking ophthalmic photographs and using ultrasound, may administer eye medications, perform ophthalmologic tests, maintain ophthalmic surgical equipment and assist in refractive surgery.

Patient education

Refractive surgeons should carefully screen patients for these procedures and make sure the patients are aware of possible complications before the procedure begins. Some highly myopic patients expecting "perfect" vision will be disappointed when they discover they still need eyeglasses for distance vision.

Ophthalmic staff also need to stress that while LTK vision improvements may be startling at first, those changes are likely to fade. These patients should be advised they may still need glasses for fine print. Aging and the onset of presbyopia will still affect their vision.

Training

Ophthalmologists are advised to observe other surgeons perform these procedures before they begin. Laser companies offer seminars to help doctors perfect their techniques. Other groups, such as the American Society of Cataract and Refractive Surgery, keep physicians informed of the latest advances. Co-managing optometrists are advised to observe surgeries and attend seminars to learn more about follow-up treatments.

Ophthalmic assistants who want to assist in these surgeries can receive additional training from certified education programs.

Registered nurse

Definition

Registered nurses, or RNs, are health care professionals who work as part of health care teams to promote health and prevent and treat disease. They are patient advocates and health care educators working to teach not only patients but also families and the community.

Description

With about 2.1 million positions in the field, RNs make up the largest health care occupation. More than half of all health professions students are nursing students, and there are four times as many RNs in the United States as physicians. Most nurses as of 2001 are women; only 5-7% of all nurses are men.

Nurses work collaboratively with physicians and other health care providers, although the nursing profes-

sion is independent of medicine and other health disciplines. RNs' roles span from direct patient care to case management. Nurses are an integral part of the health care system. In fact, most health care services involve nursing care in some form.

In the area of direct patient care, RNs have many responsibilities:

- They observe, assess, and record patients' symptoms, responses to treatment, and progress.
- They provide assistance to physicians and other health care providers during examinations and treatments.
- They administer medications and take vital signs.
- They help patients to rehabilitate and heal.
- They educate patients and families about appropriate care after treatment, as well as long-term health.
- They develop and manage plans for nursing care.

In hospitals, RNs often work as staff nurses, providing care at the bedside and managing patients' medical needs. In some cases, RNs in hospitals supervise licensed practical nurses and aides.

RNs who work in office settings, for physicians or in clinics, assist administratively in the office and help the medical staff with patient preparation and examination. They administer medications, perform some lab tests and injections, as well as dress **wounds** and incisions. RNs also assist with minor surgery techniques and record-taking.

Nurses in the nursing home setting provide a variety of care to elderly or sickly patients who cannot care for themselves because of age or illness. RNs in nursing home settings spend a good deal of their time developing treatment plans and performing other administrative duties, including supervising LPNs and nursing aides. They also provide direct patient care, assessing residents' medical conditions, monitoring treatment, and performing more advanced tasks, such as starting intravenous fluids. Nurses in this setting might concentrate on an area of specialization, such as long-term rehabilitation, in which they would care for stroke and **head injury** patients.

Home health nurses are often RNs who provide periodic at-home care for patients who might be recovering from illness or suffering from a chronic condition. While home health nurses work independently during their time in the home, the care they provide is prescribed by a physician or nurse practitioner.

RNs in **public health** nursing work in a variety of government and community organizations, including as school nurses and in public health clinics. The focus in this area of nursing is to make health care accessible to populations, including the underserved and those in rural

areas. The goal is to improve overall health care in a community. Public health nurses work with community members to plan and implement programs to enhance community health care and educate groups about good health practices, such as disease prevention, child care and **nutrition**. They work in partnership with families, schools and other public organizations to help educate members about health. And these RNs make arrangements for such health screenings as immunizations and **blood pressure** and cholesterol testing.

Occupational health or industrial nurses provide health care services on-site in different environments. These nurses might work at a company's headquarters providing nursing care to employees or at a resort providing nursing care to tourists. RNs in this environment provide emergency care, prepare accident reports and make arrangements for any necessary additional care. Especially in the employee environment, they might coordinate health screenings, health counseling and assess work environments for safety.

In 1998, RNs' median annual income was \$40,690. The median income that year of RNs working in hospitals was \$39,900; home health care services \$39,200; offices and clinics run by MDs \$36,500; and nursing and personal care facilities \$36,300.

The job market has been changing for RNs, making them more in demand. Much of this growth in opportunity is due to changing demographics. As more people become elderly, more will need nursing care and many more will need long-term care. The expansion of managed care has led to an increased emphasis on primary care. Another factor in the growth of the need for RNs is advancing technology, which requires the knowledge of RN or higher-level nurses. Essentially, the world is open to RNs because of opportunity and need now and in the future.

Work settings

The largest group of nurses work in hospitals, where they usually focus on a particular area of care, such as emergency room, intensive care, critical care, maternity, oncology, or pediatrics; or rotate throughout the hospital.

Nurses also work caring for patients on an outpatient basis in doctors' offices, clinics, surgery centers and emergency medical clinics. Some also work in **nursing homes**; public health facilities, such as government or private agencies and schools; on-site work environments in the occupational health or industrial nursing field; or in administrative positions within a corporate or organizational setting overseeing other nurses.

Nurses who work in hospitals generally work in fast-paced, pressure-filled environments. Many hospitals today are short-staffed due to budget cuts and the nursing shortage. Nurses in these and other environments spend considerable time standing and perform tasks that are hard on the body, such as lifting patients. Nurses often work all types of shifts, including daytime, weekend, and night shifts. Many nurses see the flexibility in scheduling as a positive factor—especially if they juggle childcare responsibilities. Nursing can be a dangerous occupation. They often care for people with infectious diseases, such as hepatitis, and are near radiation, chemicals used for instrument sterilization, and anesthetics. To avoid possible hazards, nurses must adhere to rigid safety guidelines. There is also an emotional toll involved with the job, as nurses often have close daily contact with patients who are severely ill or dying.

Education and training

RNs must graduate from a nursing program and pass a national examination to become licensed. They must periodically renew their licenses and, depending on which state they work, must also take continued education courses for license renewal.

There were more than 2,200 entry-level RN programs in the United States in 1998. RNs can pursue one of three educational options. They can complete an associate degree in nursing, which is usually offered at community and junior colleges and is about two years long; a bachelor of science degree in nursing, taken at colleges and universities and usually taking from four to five years; or a diploma program, which is given in hospitals and lasts about two to three years. Licensed graduates at any of these levels usually qualify to start work at the staff nurse level. Most RNs graduate with either an associate's or bachelor's degree. Today an increasing number of nurse executives are saying that they want a majority of their hospital staff nurses to have bachelor's degrees because of the more complex demands of patient care. In 1996, 27% of RNs reported have a diploma, 31% had a bachelor's degree and 32 percent held an associate's degree. There have been discussions in some states of requiring an RN to obtain a bachelor's degree or higher; however, this trend would not affect current associate degree RNs and would probably take place on a state-by-state basis. Most agree that there are more opportunities for advancement for RNs with bachelor's degrees in nursing. A bachelor's degree is often necessary for administrative positions and is required for admission to graduate nursing programs of all types, including research, consulting, teaching and clinical specialization.

Students in nursing programs take courses in anatomy, physiology, microbiology, nutrition, psychology, chemistry, nursing, and other behavioral sciences. In addition to classroom instruction, nursing students receive supervised clinical experience in hospitals and other health care facilities. Nursing students receive a variety of clinical experience in settings such as hospital maternity, psychiatric, pediatric and surgical wards. They also gain experience in public health departments, home health agencies, and ambulatory clinics.

Advanced education and training

RNs can go on to become **advanced practice nurses**, which include nurse practitioners, clinical nurse specialists, certified registered nurse anesthetists, and certified nurse-midwives. Advanced practice nurses generally have master's degrees or certificates. Nurse practitioners deliver front-line primary and acute care. They can prescribe medications, and diagnose and treat common acute illnesses and injuries. Nurse practitioners provide immunizations, conduct physical exams, and provide care to manage chronic diseases, such as diabetes. Certified nurse-midwives are trained to provide prenatal and gynecological care to healthy women. They also deliver babies in all types of settings, including the patient's home, and provide **postpartum care**. Clinical nurse specialists specialize in such areas as cardiology, oncology and pediatrics. Certified registered nurse anesthetists administer anesthetics to patients in in-patient, outpatient and in-office settings. They are often the sole providers of anesthesia.

RNs can also go on to careers in teaching, research, or administration. These areas require master's degrees in nursing or PhD or doctorate-level degrees. Doctorally-prepared RNs tend to go into education or research.

Future outlook

Registered nursing is projected to among the 10 top occupations in the United States to have the largest number of new jobs. Many areas of the country are suffering from severe nursing shortages and the problem is expected to get worse as baby boomers age. It is estimated that if current trends continue, demand for nurses will outweigh their supply by the year 2010. It is projected that by 2015, some 114,000 jobs for full-time equivalent RNs will go unfilled in the United States. In sum, nurses will be able to pick and choose the paths of their careers. It is expected that job growth in nursing will be faster than average, largely because of technical advances in patient care. These advances will diagnose disease earlier and improve upon current treatments. With the median age of nurses over 40, many nurses will be retiring. Many of the

positions in the future will come from openings left by these aging nurses. Areas that are expected to experience significant growth in nursing are ambulatory care settings, nursing homes, and home health care.

While hospitals will continue to need a tremendous number of nurses, hospitals are expected to grow more slowly than other health care environments. This is because the number of inpatients is expected to remain somewhat steady; patients are being released earlier and more procedures are being done outside hospitals. Nurses will find more opportunity in the hospital's specialty areas, including outpatient services, such as **chemotherapy** and rehabilitation. Home health employment for nursing will probably grow rapidly. A growing number of elderly who need nursing care but do not want to leave their homes will stimulate the expansion of this area of nursing. Nurses who are able to perform complex procedures in the home will be at the forefront of those able to take advantage of the home health opportunity. Nurses who want to work in nursing homes will find much faster than average growth in opportunities due to the growing number of people who are too old to live on their own.

Relaxation

Definition

Relaxation therapy is a broad term used to describe a number of techniques that promote **stress** reduction, the elimination of tension throughout the body, and a calm and peaceful state of mind.

Origins

Relaxation therapy has been around for thousands of years in the forms of transcendental **meditation** (TM), **yoga**, **t'ai chi**, **qigong**, and vipassana (a Buddhist form of meditation meaning insight and also known as mindfulness meditation). Progressive relaxation, a treatment that rids the body of **anxiety** and related tension through progressive relaxation of the muscle groups, was first described by Dr. Edmund Jacobson in his book *Progressive Relaxation*, published in 1929. And in 1975, Dr. Herbert Benson published his groundbreaking work *The Relaxation Response*, which described in detail the stress-reduction mechanism in the body that short-circuits the "fight-or-flight" response and lowers **blood pressure**, relieves muscle tension, and controls **heart rate**. This work gave further credence and legitimacy to the link between mind and body medicine. A number of today's commonly used relaxation techniques, such as cue-controlled relaxation, are a direct result of Benson's work in this area.

Benefits

Stress and tension have been linked to numerous ailments, including heart disease, high **blood pressure**, atherosclerosis, irritable bowel syndrome, ulcers, anxiety disorders, insomnia, and substance abuse. Stress can also trigger a number of distinct physical symptoms, including nausea, headache, hair loss, fatigue, and muscle **pain**. Relaxation therapies have been shown to reduce the incidence and severity of stress-related diseases and disorders in many patients.

Description

There are a number of different relaxation methods available. Some of the most widely taught and practiced by health care providers include progressive relaxation, cue-controlled relaxation, breathing exercises, guided imagery, and biofeedback.

Progressive relaxation

Progressive relaxation is performed by first tensing, and then relaxing, the muscles of the body, one group at a time. Muscle groups can be divided a number of different ways, but a common method is to use the following groupings: 1) Hands and arms; 2) head, neck, and shoulders; 3) torso, including chest, **stomach** and back; and 4) thighs, buttocks, legs, and feet. The patient lies or sits in a comfortable position, and then starts with the first muscle group, focusing on the feeling of the muscles and the absence or presence of tension. The patient then tenses the first muscle in the group; holds the tension for

approximately five seconds; and releases and relaxes for up to 30 seconds. The contrast allows the individual to notice the difference between feelings of tension and feelings of relaxation. The procedure is repeated with the next muscle in the group, and so on, until the first group is completed. The patient then starts on the next muscle group.

Progressive relaxation can be guided with verbal cues and scripts, either memorized by the patient or provided on instructional audiotapes. The procedure remains the same, but the individual is prompted on which muscles to flex and relax, and given other cues about noticing the difference between the tense and relaxed state. Some individuals may prefer progressive relaxation that is prompted with a tape, because it allows them to completely clear their minds and to just follow the given instructions.

Deep breathing exercises

Individuals under stress often experience fast, shallow breathing. This type of breathing, known as chest breathing, can lead to shortness of breath, increased muscle tension, and inadequate oxygenation of blood. Breathing exercises can both improve respiratory function and relieve stress and tension.

Before starting to learn breathing exercises, individuals should first become aware of their breathing patterns. This can be accomplished by placing one hand on the chest and one hand on the abdomen, and observing which hand moves further during breathing. If it is the hand placed on the chest, then chest breathing is occurring and breathing exercises may be beneficial.

Deep breathing exercises are best performed while lying flat on the back, usually on the floor with a mat. The knees are bent, and the body (particularly the mouth, nose, and face) is relaxed. Again, one hand should be placed on the chest and one on the abdomen to monitor breathing technique. The individual takes a series of long, deep breaths through the nose, attempting to raise the abdomen instead of the chest. Air is exhaled through the relaxed mouth. Deep breathing can be continued for up to 20 minutes. After the exercise is complete, the individual checks again for body tension and relaxation. Once deep breathing techniques have been mastered, an individual can use deep breathing at any time or place as a quick method of relieving tension.

Release-only relaxation

Like progressive relaxation, release-only relaxation focuses on relieving feelings of tension in the muscles. However, it eliminates the initial use of muscle tensing as practiced in progressive relaxation, focusing instead solely

on muscle relaxation. Release-only relaxation is usually recommended as the next step in relaxation therapy after progressive relaxation has been mastered.

In release-only relaxation, breathing is used as a relaxation tool. The individual sits in a comfortable chair and begins to focus on breathing, envisioning tension leaving the body with each exhalation. Once even, deep, abdominal breathing is established, the individual begins to focus on releasing tension in each muscle group until the entire body is completely relaxed.

Cue-controlled relaxation

Cue-controlled relaxation is an abbreviated tension relief technique that combines elements of release-only relaxation and deep breathing exercises. It uses a cue, such as a word or mental image, to trigger immediate feelings of muscle relaxation. The cue must first be associated with relaxation in the individual's mind. This is accomplished by choosing the cue and then using it in breathing and release-only relaxation exercises repeatedly until the cue starts to automatically trigger feelings of relaxation outside of the treatment sessions. Cues can be as simple as the word "relax," and are frequently used on relaxation audiotapes. They can also be a visual cue, such as a mental image of a white-sand Caribbean beach, a flower-filled meadow, or other relaxing images. Guided imagery also uses such visualization exercises to produce feelings of relaxation.

Guided imagery

Guided imagery is a two-part process. The first component involves reaching a state of deep relaxation through breathing and muscle relaxation techniques. During the relaxation phase, the person closes his eyes and focuses on the slow in-and-out of his breathing. Or, they might focus on releasing the feelings of tension from their muscles, starting with the toes and working up to the top of the head. Relaxation tapes often feature soft music or such tranquil, natural sounds as rolling waves and chirping birds in order to promote feelings of relaxation.

Once complete relaxation is achieved, the second component of the exercise is the imagery, or visualization itself. Relaxation imagery involves conjuring up pleasant, relaxing images that rest the mind and body. These may be experiences that have already happened, or new situations.

The individual may also use mental rehearsal. Mental rehearsal involves imagining a situation or scenario and its ideal outcome. It can be used to reduce anxiety about an upcoming situation, such as **childbirth**, surgery, or even such a critical event as an important

competition or a job interview. Individuals imagine themselves going through each step of the anxiety-producing event and then successfully completing it.

Biofeedback

Biofeedback, or applied psychophysiological feedback, is a patient-guided treatment that teaches an individual to manipulate muscle tension through relaxation, visualization, and other cognitive techniques. The name biofeedback refers to the biological signals that are fed back, or returned, to the patient in order for the patient to develop techniques of controlling them.

During biofeedback, one or more special sensors are placed on the body. These sensors measure muscle tension, **brain** waves, heart rate, and body temperature; and translate the information into a visual and/or audible readout, such as a paper tracing, a light display, or a series of beeps. While the patient views the instantaneous feedback from the biofeedback monitors, he begins to recognize what thoughts, fears, and mental images influence his physical reactions. By monitoring this relationship between mind and body, he can then use thoughts and mental images deliberately to manipulate heart beat, brain wave patterns, body temperature, and other bodily functions, and to reduce feelings of stress. This is achieved through relaxation exercises, mental imagery, and other cognitive therapy techniques.

As the biofeedback response takes place, the patient can actually see or hear the results of his efforts instantly through the sensor readout on the biofeedback equipment. Once these techniques are learned and the patient is able to recognize the state of relaxation or visualization necessary to alleviate symptoms, the biofeedback equipment itself is no longer needed. The patient then has a powerful, portable, and self-administered treatment tool to deal with problem symptoms.

There are dozens of other effective therapies that promote relaxation, including hypnosis, meditation, yoga, aromatherapy, **hydrotherapy**, t'ai chi, massage, **art therapy**, and others. Individuals should choose a type of relaxation therapy based on their own unique interests and lifestyle requirements.

Preparations

If an individual is considering relaxation therapy to alleviate such physical symptoms as nausea, headache, high blood pressure, fatigue, or gastrointestinal problems, he or she should consult a doctor first to make sure there isn't an underlying disorder or disease causing the symptoms. A complete **physical examination** and comprehensive medical history will be performed, and even

if an organic cause for the symptoms is found, relaxation exercises may still be recommended as an adjunctive, or complementary, treatment to relieve discomfort.

Relaxation therapy should always take place in a quiet, relaxing atmosphere where there is a comfortable place to sit or recline. Some people find that quiet background music improves their relaxation sessions. If an instructional audiotape or videotape is to be used, the appropriate equipment should be available.

The relaxation session, which can last anywhere from a few minutes to an hour, should be uninterrupted. Taking the phone off the hook and asking family members for solitude can ensure a more successful and relaxing session.

Precautions

Most commonly practiced relaxation techniques are completely safe and free of side effects.

Relaxation techniques that involve special exercises or body manipulation such as massage, t'ai chi, and yoga should be taught or performed by a qualified health care professional or instructor. These treatments may not be suitable for individuals with certain health conditions such as arthritis or **fibromyalgia**. These individuals should consult with their health care professional before engaging in these therapies.

Biofeedback may be contraindicated (not recommended) in some individuals who use a pacemaker or other implantable electrical devices. These individuals should inform their biofeedback therapist before starting treatments, as certain types of biofeedback sensors have the potential to interfere with their use.

Relaxation therapy may not be suitable for some patients. Patients must be willing to take a very active role in the treatment process, and to practice techniques learned in treatment at home.

Some relaxation therapies may also be inappropriate for cognitively impaired individuals (e.g., patients with organic brain disease or a traumatic brain injury) depending on their level of functioning. Given the wide range of relaxation therapies available, if one type of relaxation treatment is deemed inappropriate for these patients, a suitable alternative can usually be recommended by a qualified health care professional.

Side effects

Relaxation therapy can induce sleepiness, and some individuals may fall asleep during a session. Relaxation therapy should not be performed while operating a motor vehicle or in other situations where full and alert atten-

KEY TERMS

Qigong—An exercise practice derived from traditional Chinese medicine that is designed to facilitate energy flow throughout the body.

T'ai chi—A martial art that uses exercise to balance the body's energy flow to the body center in order to promote physical well-being.

tion is necessary. Other than this, there are no known adverse side effects to relaxation therapy.

Research and general acceptance

Relaxation therapies have been successfully used in relieving stress and anxiety for many years, and are generally well-accepted by the medical community for this purpose.

Recent research published in 1999 has also indicated that relaxation therapy may be useful in reducing the incidence of **preterm labor** in women at risk for delivering prematurely. The study also found that women who discontinued relaxation exercises for whatever reasons delivered earlier and had lower birth-weight babies than those who continued the treatment.

Training and certification

Relaxation therapy techniques are used by many licensed therapists, counselors, psychologists, psychiatrists, and other health care professionals. There are many self-help books, audiotapes, and videos available that offer instruction in relaxation techniques.

Reproductive health

Definition

A person's reproductive health is the maintenance of the health of his or her reproductive systems, which include respectively the penis and the testes, and the vagina, uterus, and breasts. The reproductive health spectrum also includes **pregnancy** and **infertility**.

Description

The reproductive systems

The **female reproductive system** comprises ovaries, fallopian tubes, uterus, vagina, breasts, and external genitalia. The ovaries hold the eggs and release them during ovulation. When an egg is fertilized, it travels through the fallopian tubes and is implanted in the uterus. The uterus, through the placenta and umbilical cord, nurtures the fetus for approximately 40 weeks, at which time the woman delivers.

The **male reproductive system** consists of the testes, epididymis, vas deferens, urethra, seminal vesicles, prostate, and penis. During intercourse, the penis—the copulating organ—becomes engorged with **blood** and becomes erect. Upon ejaculation, mature sperm cells are ejected into the vagina after moving through the vas deferens, passing the seminal vesicles and prostate gland. After the semen is deposited in the vagina, the sperm swim through the cervix, into the uterus, and up into the fallopian tubes. The egg is fertilized in the fallopian tubes, if indeed an egg is present.

Infertility

A person is infertile when he or she is unable to perform the function of reproduction. Infertility is considered a disease and affects more than six million men and women in the United States, according to the American Society for Reproductive Medicine (ASRM).

Infertility disorders in men include azoospermia, in which no sperm cells are produced; and oligospermia, in which few sperm cells are produced. Although the number of cases is rare, infertility can be caused by a genetic disorder. Typically, male infertility rests with the testes, responsible for the production of sperm. Disorders of the thyroid, adrenal and pituitary glands, **liver**, and kidneys—as well as infections and trauma to the testes—can contribute to male infertility.

Further, hazards in a man's workplace can affect his ability to have healthy children. These are called reproductive hazards, and include radiation, chemicals, drugs (legal and illegal), heat, and lead. Still, every man does not suffer the effects of workplace hazards; frequency, length, and method of exposure (inhalation, skin contact, ingestion) are a few of the factors that affect whether the man is exposed to any dangerous degree. These hazards, unfortunately, can arrest or slow the production of sperm. If there are fewer sperm to fertilize the egg, there will be fewer chances that the egg will be fertilized; if there are no sperm produced, the man is termed "sterile." If the workplace hazard has prevented sperm from being produced at all, the man is permanently sterile.

As of 2001, it is projected that reproductive issues will be the focus of greater attention in the United States in years to come. Reproductive issues are already included in the National Occupational Research Agenda (www.cdc.gov/niosh.com) coordinated by the National Institute of Occupational Safety and Health (NIOSH).

In women, infertility can be caused by an ovulation disorder, blocked fallopian tubes, pelvic inflammatory disease (PID), or endometriosis.

The vast majority of individuals suffering from infertility—85 to 90%—can be treated with medication or surgery. The remaining percentage of persons may turn to in vitro fertilization, in which conception takes place outside the body and the embryo is implanted in the uterus by a physician.

Viewpoints

Abortion

One of the most explosive and controversial aspects of reproductive health is abortion. Issues of morality, religion, and politics are often part of these discussions.

Worldwide, it is estimated that nearly half of all human pregnancies are unplanned. Many result from incorrect use or failure of contraceptives. Women may also become pregnant because they do not have access to family planning alternatives or are pressured by a partner not to use contraceptives.

Abortion became legal in 1973 following the landmark U.S. Supreme Court decision in *Roe vs. Wade*. Since then, the Court has heard at least 20 major cases challenging the law. The Supreme Court, however, has upheld *Roe vs. Wade* as of 2001.

Most abortions are performed within the first trimester, or the first three months of pregnancy. Fewer than 9% of abortions are performed in the second trimester; and in only rare cases when there is serious health concern are abortions performed in the final trimester.

Contraception

The purpose of contraceptives is to avoid pregnancy by preventing the likelihood of fertilization or implantation of a fertilized egg. Women can use devices that fit into either the vagina or uterus; these are known as barrier methods. There are advantages and disadvantages to each method. Sometimes they can cause such serious side effects as excessive menstrual bleeding. Barrier contraceptive devices, in addition to preventing pregnancy, also can help prevent sexually transmitted diseases (STDs) and the human **immunodeficiency** virus (HIV), the virus that causes the acquired immunodeficiency syndrome (**AIDS**). Male barrier methods include latex condoms.

Female barrier methods include the diaphragm, female condom, cervical cap, sponge, and intrauterine device (IUD). These devices can also be used with a chemical combination known as a spermicide, which helps to kill sperm during intercourse.

A diaphragm is a dome-shaped flexible barrier with a rim that fits into the vagina and prevents sperm from reaching the cervix. Health professionals recommend that diaphragms be used with spermicide to achieve an 82–94% effectiveness rate against pregnancy. Instruction is required on how to insert and remove the diaphragm. This device, which can be inserted up to six hours before intercourse, must remain in the vagina for six hours after intercourse. There are two disadvantages to the diaphragm. The diaphragm may be dislodged during sex. There is also an increased risk of bladder and urinary tract infections.

The female condom is designed to line the inside of the vagina. Made from polyurethane, unlike male condoms (which are made from latex), and used without a

spermicide, the female condom can be inserted up to eight hours before intercourse.

The cervical cap is a small dome, but is not as flexible as the diaphragm. It is placed tightly on the cervix one-half hour to 48 hours prior to intercourse, and is used with spermicide. When used alone, the cervical cap provides an 82–94% effectiveness rate. With spermicide, the cervical cap provides an even greater degree of confidence against unwanted pregnancy. There are several reasons that cervical caps are not widely used. Some women have difficulty with their insertion, which must be done at least one-half hour before intercourse. There is some discomfort when they are being inserted. Cervical caps can also be difficult to remove, and repeated intercourse dictates reapplication of the unit. There is some risk of irritation and allergic reaction. Last, because of the risks of toxic shock syndrome (TSS), women should not wear the cervical cap more for more than 48 hours after intercourse.

The contraceptive sponge also acts as a barrier and is used with a spermicide. The sponge is available without a prescription, and the woman does not need training to insert and remove it. However, the spermicide used with the sponge may be irritating and cause allergic reactions. The sponge should not be used more than once, and should be left in the vagina for six hours after intercourse. If left in for more than six hours, the woman is at risk for toxic shock syndrome.

The IUD, inserted by a health professional, blocks the fallopian tubes so that sperm have fewer chances of passing through the tubes to fertilize the woman's egg. In the event that sperm do pass through the tubes and an egg is fertilized, the IUD can prevent the fertilized egg from becoming implanted in the uterus. An IUD, however, can cause cramping and bleeding in women, and can be spontaneously expelled. This device has also been known to increase a woman's risk of developing PID, may increase her menstrual flow, and cause cramping. The rate of effectiveness with the IUD is greater than 99%.

Birth control pills (also called "combined pills") are more than 99% effective against pregnancy. They do not offer any protection against sexually-transmitted diseases (STDs). While they have some other disadvantages for women, such as possible dizziness, nausea, menstruation changes, and weight and mood fluctuations, there are also advantages. These include continuous contraceptive protection, if taken as prescribed. They are reversible. When one stops taking them, the pills stop working, and another method of birth control must be used immediately. Birth control pills must be taken daily, and are contraindicated for smokers over 35 years of age. They also increase blood clot risk.

The minipill, which is progestin only, has a 95% estimated effectiveness rate. It can also cause irregular bleeding, breast tenderness, weight gain, and a slightly increased chance of ectopic pregnancy; it does provide some protection against PID. It is completely ineffective as a barrier to STDs.

With a greater than 99% rate effectiveness and continuous protection against pregnancy for up to five years, the woman who has had a subdermal implant does not need to be bothered remembering to take a pill. An in-office procedure is required, though, to surgically introduce the implant. The patient may suffer from side effects, which may include menstrual bleeding irregularities and weight change.

Another birth control method with a greater than 99% effectiveness rate is the contraceptive injection (depot medroxyprogesterone acetate). One has three months' of protection, with no need to remember to do anything related to birth control on a daily basis. The woman requires quarterly injections at the doctor's office by the doctor or nurse. As with the implant, there may be side effects, which also include changes in menstrual bleeding and weight.

Tubal ligation, performed surgically by a physician, is a procedure that is irreversible. After a woman has undergone this procedure, she has a greater than 99% guarantee against becoming pregnant.

Men have far fewer choices in barrier contraceptives, but condoms remain the most popular choice. They are easy to obtain and the best means of protection from STDs and HIV. Made from latex, condoms are placed over the penis before intercourse to prevent the ejaculation of sperm into the woman's vagina. They can be used with or without spermicides. Without a spermicide, condoms are 88–98% effective against pregnancy. With spermicide, condoms may provide even higher protection against pregnancy. The disadvantages of using a condom are possibly reduced feeling by the man. There may also be less sexual spontaneity—and, of course, condoms can break.

The man also has the option of having a vasectomy. A surgical procedure that is permanent, the vasectomy provides continuous contraceptive protection. It is over 99% effective, and has no side effects.

Spermicide may be used alone, but it must be inserted within one hour before intercourse; requires reapplication for repeated intercourse; must be left in place for six to eight hours afterward; and is often messy. It may give some protection against chlamydia and gonorrhea. Spermicide's effectiveness rate against pregnancy is 79–97% when properly used. It provides a greater measure of safety when used with a condom.

Abortion rights supporters march through Washington. (UPI/Corbis-Bettmann. Reproduced by permission.)

Lastly, there is periodic abstinence, which requires no equipment, foams, or gels. It does, however, necessitate extremely careful planning, motivation, and patience. When a couple is practicing abstinence, intercourse during half of the menstrual cycle is prohibited. If a woman has an irregular cycle, the couple cannot use this method, as fertile periods cannot be determined with any degree of confidence.

Family planning

Couples trying to control the frequency and number of pregnancies can do so through family planning. Women may want to increase their chances of getting pregnant or determine the most infertile times to have intercourse so that they can prevent pregnancy. Women may choose to use barrier methods or oral contraceptives to prevent pregnancy, and men may use condoms.

In “natural family planning,” women chart their menstruation and ovulation to determine fertile and infertile periods—but without actually having to use artificial **contraception**. Typically, women ovulate on the 14th day of their monthly cycle, which is the best time to become pregnant—although a woman is fertile over a range of days because sperm can remain viable inside the

genital tract for up to 48 hours. Basal body temperatures and the texture of cervical mucus should be recorded. These data will aid in the determination of the woman’s fertile days.

In 1970, President Richard Nixon signed into law Title X of the **Public Health Service Act**, referred to as “America’s family planning program.” The program provides funding for low-income women who need contraceptives to prevent pregnancy. The program set a minimum standard of care that requires women to have options among contraceptive methods, and prohibits coercion of women to choose one method over another. Individuals are charged fees for service based on their income and ability to pay. Title X monies do not fund abortions. The program provides for pelvic exams, Pap tests, breast examinations, safe-sex counseling, infertility screening, and referrals to specialized health care when needed.

Professional implications

There is a variety of health disciplines that serves the needs of individuals seeking reproductive health services. Gynecologists treat women seeking services that

KEY TERMS

Azoospermia—In infertile men, it refers to the lack of sperm being produced.

Cervix—The lowest part of the uterus that connects the vagina to the uterus.

Contraceptives—Devices or medications designed to prevent pregnancy by either suppressing ovulation, preventing sperm from passing through the cervix to fertilize an egg, or prevent implantation of a fertilized egg.

Diaphragm—A barrier form of contraception that is a flexible, dome-shaped device with a rim that blocks sperm from passing through the cervix.

Endometriosis—The presence and growth of functioning endometrial tissue in places other than the uterus that often results in severe pain and infertility.

Epididymis—Elongated cordlike structure along the posterior border of testes.

Fallopian tubes—Tubes that are part of a woman's reproductive system that extend from the uterus to the ovaries and carry a fertilized egg to the uterus for implantation.

Infertility—When a person is unable to perform the function of reproduction because of a physical, mental, or hormonal problem.

In vitro fertilization—When an egg is fertilized by sperm outside of the body.

Oligospermia—Low sperm count in men.

Ovulation—The discharge of a mature ovum, or egg, from the ovary.

Prostate—A gland made up of muscular and glandular tissue that surrounds the urethra at the bladder in men.

Testes—Male gonads; the paired egg-shaped glands normally located in the scrotum where sperm develop.

Urethra—Membranous canal through which urine is released from the bladder to the outside of the body.

Vas deferens—The tube cut in a vasectomy.

include Pap exams, breast exams, and pelvic exams; obstetricians provide medical care for women who are pregnant and planning to carry their babies to term.

These professionals can refer women to specialists for further care as necessary—such as radiologists (who perform mammograms and a variety of ultrasound procedures) and oncologists (in cases of possible or confirmed diagnoses of gynecological cancers). In lieu of an obstetrician, a pregnant woman may consult a midwife. Women may also consult their primary care doctors for basic reproductive health questions. Primary care physicians typically can perform routine Pap and pelvic exams and give advice on contraception.

Similarly, men can consult their primary care doctors for reproductive health care. For further problems and follow-up, however, urologists should be consulted.

For other issues related to reproductive health—particularly those of an emotional nature—licensed social workers, psychologists, psychiatrists, and sex therapists may be helpful.

Reproductive system, female

Definition

The female reproductive system is composed of organs that produce female eggs (called female gametes or ova); provide an environment for fertilization of the egg by a male sperm (male gamete); and support the development and expulsion of a fetus in **pregnancy** and **childbirth**.

Description

The normal female reproductive system is composed of external and internal genitals (genitalia).

External genitals

The external genitals (together, they are called the “vulva”) are composed of the genital structures visible from outside the body: the greater lips (labia majora); the lesser lips (labia minora); the clitoris; and the opening of the vagina to the outside (the other end of the vagina opens inside the body to the womb). The labia majora are two large lips that protect the other external genitals. The outer surface of these lips is covered with oil-secreting (sebaceous) glands; their inner surface has hair. The lesser lips (labia minora) are found just inside the greater lips and protect the immediate opening to the vagina (this opening is called the “introitus,” Latin for “entrance”) and the opening to the urethra (which carries urine from the bladder out of the body). The clitoris is a small structure found at the top of the lesser lips; it is very sensitive to stimulation and may become erect. The perineum is the area between the vagina and the anus in the female (in the male, the perineum is the area between the scrotum and the anus). Two glands, one located on either side of the introitus, are called Bartholin’s glands; they secrete a mucus that provides lubrication during sexual intercourse.

Internal genitals

The internal genitals are the vagina, the womb (uterus), the fallopian tubes, and the ovaries. The vagina extends approximately 3 to 4 inches (7 to 10 cm) from the outside of the body to the opening of the womb. The lower third of the vagina (closest to the outside) is encircled by muscles that control its opening and closing. The womb is the organ found at the top of the vagina and consists of two main parts: the neck (cervix) and the body (corpus). The neck is the opening of the womb to the vagina that allows sperm to enter the womb and allows menstrual fluid to exit. The neck is an important means of protecting the body of the womb from disease-causing

germs; a thick mucus normally covers the neck of the womb but changes in consistency during ovulation to allow sperm to penetrate. The body of the womb is the main part of the womb—the womb in the narrower sense of the word. It can enlarge to hold a developing fetus during pregnancy. The inner lining of the body of the womb is called the endometrium, which thickens and then sheds menstrual fluid during each menstrual period if fertilization does not occur.

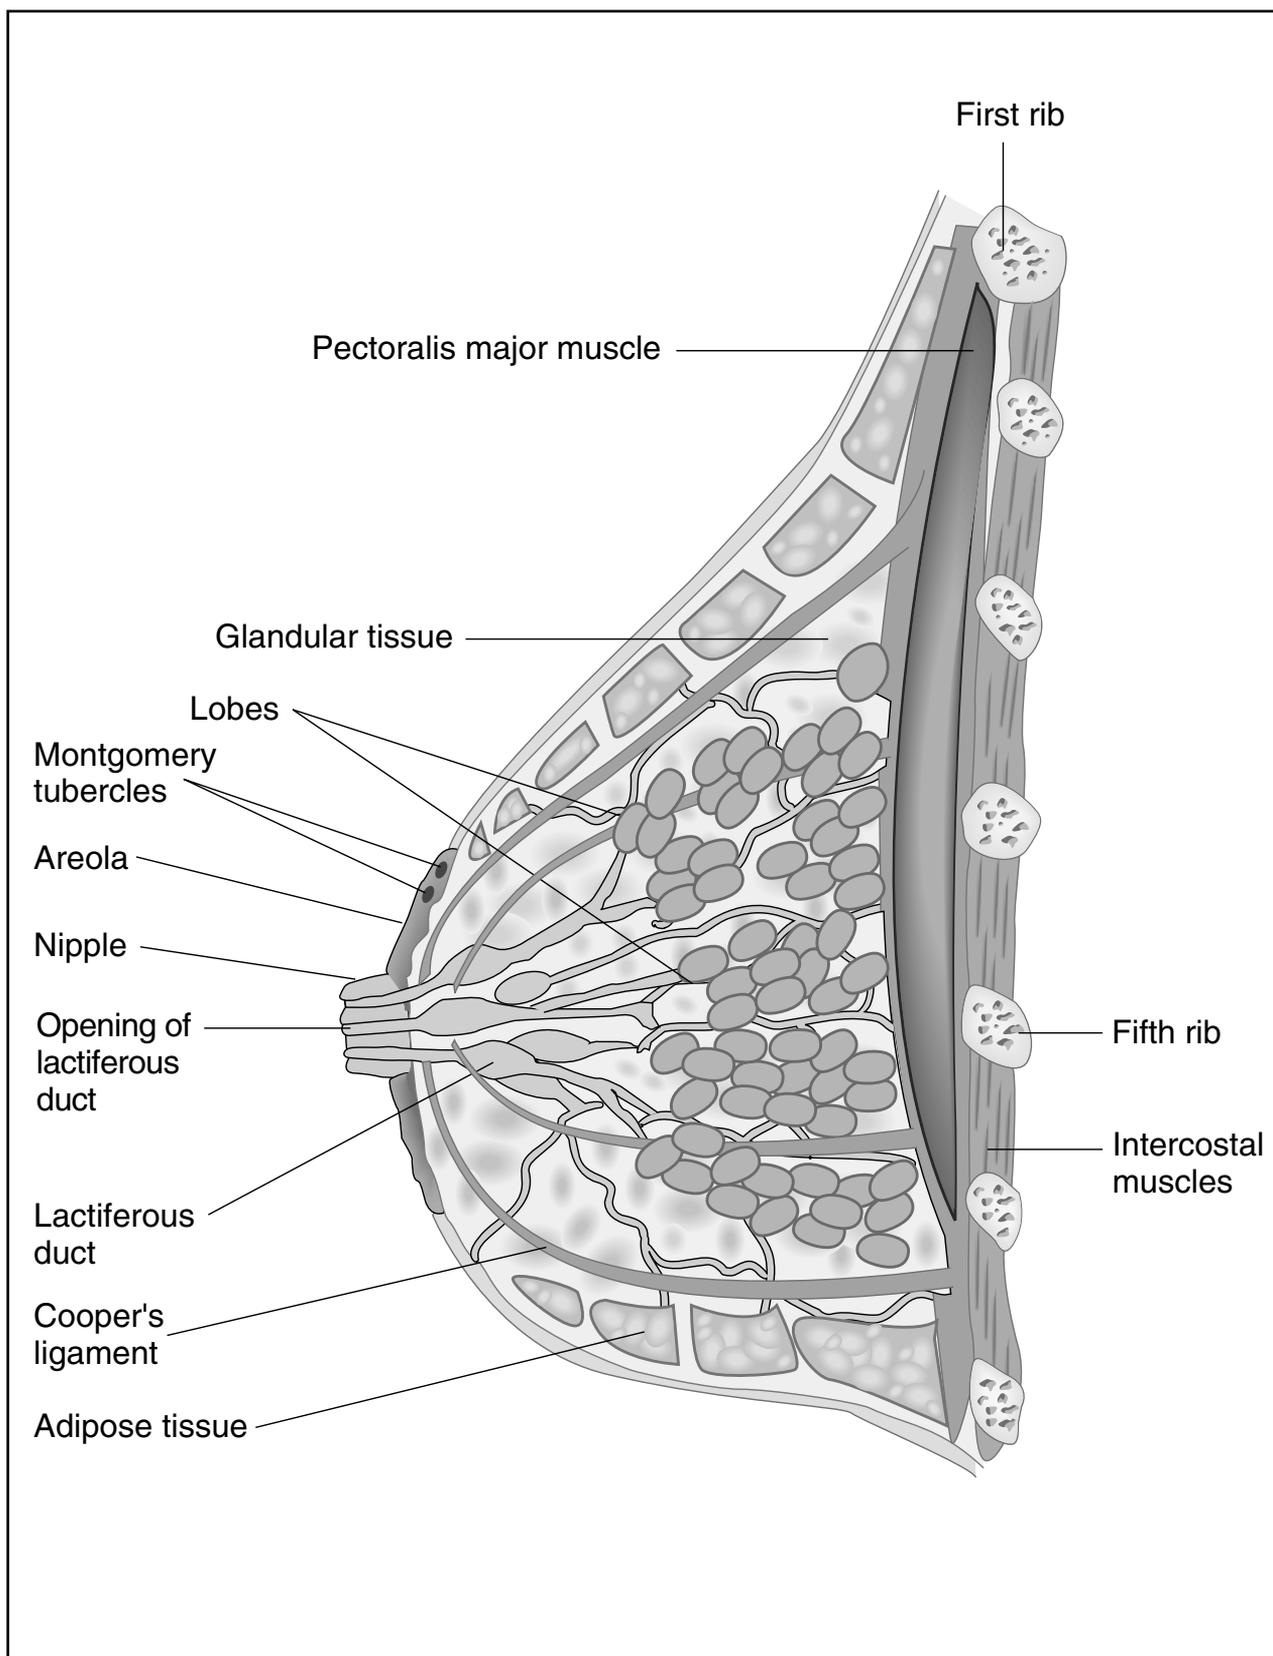

The fallopian tubes (also called the oviducts or uterine tubes) are muscular structures that extend from the upper edges of the womb to the ovaries. The fallopian tubes facilitate the transfer of a mature egg from one of the two ovaries to the body of the womb. A fallopian tube is the site of normal fertilization. The ovaries are a pair of small oval-shaped structures and are suspended near the fallopian tubes by ligaments. A female human being will not produce any new developing eggs (oocytes) after she is born; although she is born with approximately two million eggs, only about 300,000 to 400,000 remain at onset of **puberty**, and only about 300 of these will develop fully and enter a fallopian tube for possible fertilization. The eggs start as oocytes and develop in what are called ovarian or Graafian follicles, small spherical sacs that burst when the mature egg (called an ovum) is ready to be released into a fallopian tube for possible fertilization, or for discharge in the menstrual fluid if fertilization does not take place.

The human egg is a round cell that, when mature, is surrounded by a number of protective layers (the oolemma, zona pellucida, and zona radiata). It contains half the number of chromosomes of a human cell that is not egg or sperm (that is, 23 instead of 46 chromosomes) and is therefore called a haploid (one-fold) cell. When the egg is fertilized by sperm, the resulting cell will have the full number of forty-six chromosomes and will be considered a diploid (two-fold) cell.

Function

Menstruation

The menstrual cycle ranges from 21 to 40 days in most women, with an average cycle lasting 28 days. The first time a girl has a period (the onset of menstruation) is called “menarche”; the permanent cessation of menstruation some decades later is called “menopause” and marks the traditional end of a woman’s ability to reproduce. In the 1990s, women past **menopause** have been impregnated with another woman’s egg after it has been fertilized by artificial insemination, and these older women have successfully given birth to healthy babies.

Cross section of the female breast. (Delmar Publishers, Inc. Reproduced by permission.)

Menstruation occurs when the lining of the womb begins to shed menstrual fluid; the first day of bleeding is the first day of the menstrual cycle. The menstrual cycle has two phases. The follicular phase extends from the first day of the cycle until immediately before a mature egg gets released from the ovary.

In the second phase of the menstrual (ovulatory) cycle, called the “luteal” phase, the mature follicle bursts and releases an egg, a process called ovulation. The second phase of the menstrual cycle lasts approximately fourteen days until the first day of the next period (using as an example the average 28 day menstrual cycle). The ruptured empty follicle collapses to form the corpus luteum.

Fertilization

During the ovulatory phase of the menstrual cycle, the mature egg is released from the ovary and swept into the fallopian tube. If sperm cells are present in the fallopian tube, fertilization may occur. Pregnancy begins at the moment of fertilization (also called conception), when the sperm penetrates the egg. The fertilized egg, also called a zygote, then begins to move down the fallopian tube into the womb, where it implants itself in the thick tissue of the lining of the womb. In the womb, this replicating cluster of cells is called a blastocyst; after two weeks of development, it is called an embryo; eight weeks after conception, it is called a fetus.

Hormones

A complex balance of hormones is required for reproduction. There are two main groups of hormones that are necessary for normal functioning of the female reproductive system.

The first group contains hormones of the **central nervous system (CNS)**. A part of the **brain** called the hypothalamus is the main area of hormonal control; it secretes so-called releasing hormones that travel to the **pituitary gland** located at the base of the brain. Gonadotropin-releasing hormone (GnRH) secreted by the hypothalamus triggers the release of gonadotropic hormones from the anterior pituitary gland. Gonadotropin refers to any hormone that stimulates the gonads (the structures capable of producing eggs or sperm; that is, the ovaries or the testicles); regulates their development and their hormone-secreting functions; and contributes to the production of eggs or sperm.

There are two gonadotropic hormones secreted by the anterior pituitary gland: the follicle-stimulating hormone (FSH) and the luteinizing hormone (LH). The development of the ovarian follicles is dependent upon these hormones. FSH (as its name suggests) stimulates

the development of several follicles in each cycle. During the first half of the follicular phase, increasing levels of FSH cause maturation of ovarian follicles (only one follicle will mature completely). It is the LH that begins the second phase of the menstrual cycle, when a surge of LH causes the mature follicle to burst and release an egg. FSH and LH also control the production of ovarian hormones (the second group of hormones regulating the female reproductive system).

The ovarian hormones in turn are divided into two groups: ovarian peptide hormones and ovarian steroid hormones.

There are two ovarian peptide hormones, inhibin and relaxin. Inhibin is secreted by the granulosa cells of the follicles. It inhibits the releasing of FSH from the anterior pituitary gland and also inhibits the release of GnRH from the hypothalamus. Thus inhibin has a role in controlling further follicular development. Relaxin is produced near the end of pregnancy by the corpus luteum and promotes relaxation of the birth channel.

There are two biologically extremely active ovarian steroid hormones: estrogen and progesterone. Estrogen is produced by the granulosa cells of developing follicles and by the corpus luteum following ovulation. This production of estrogen is dependent upon luteinizing hormone (LH). The most potent estrogenic hormone in human beings is estradiol. It is synthesized and secreted by ovarian follicles, specifically by the theca interna cells (these cells synthesize androstenedione, which is then converted into estradiol and estrone). Estradiol can also be synthesized by the fetoplacental unit and, perhaps, by the adrenal cortex. It has the following biological functions: to promote the growth and maturation of the female secondary sex characters; to induce estrus; in conjunction with progesterone to prepare the endometrium for implantation of a fertilized ovum; and to support pregnancy.

Progesterone is a hormone produced by the corpus luteum. (It can also be secreted by the placenta and by the adrenal cortex.) Together with estrogen, it prepares the endometrium for implantation of the fertilized ovum, it maintains the uteroplacental unit, and it promotes the development of the fetus.

Another important endocrine organ secreting the steroid hormones (estrogen and progesterone) is the placenta. It helps maintain the uterine mucosa during pregnancy. The placenta also produces and secretes chorionic gonadotropic hormone. The actions of human chorionic gonadotropin (hCG) resemble those of LH. The presence of hCG in urine in early pregnancy is the basis of most pregnancy tests. Human chorionic gonadotropic hor-

one maintains the secretory integrity of the corpus luteum.

Common diseases and disorders

Infertility

Infertility is diagnosed when a sexually active couple is unable to get the woman pregnant (or she is unable to carry a pregnancy to a successful childbirth) after one year of attempts. There are numerous reasons why infertility may occur:

- low number or lack of sperm cells produced by the male
- lack of ovulation (no eggs released from ovaries)
- abnormal fallopian tubes
- occurrence of what would normally be the lining of the womb somewhere else than in the womb (endometriosis), such as in the fallopian tubes
- problems with thick mucus in the neck of the womb (hence, sperm are not able to enter the womb)

A number of techniques may be used to assist a couple in getting the woman pregnant. These include fertilization in a dish (in vitro fertilization, IVF; *in vitro* is Latin for “in glass”). Eggs are removed from the woman, placed in a culture dish, and fertilized by sperm, then inserted into the womb for implantation. An alternate technique is gamete intrafallopian transfer, or GIFT.

Male and female reproductive cells are removed from the man and woman and then transferred to the fallopian tube where fertilization may take place naturally.

Cancer

Cancer (uncontrolled and abnormal new growth of cells) may occur in any of the structures of the reproductive system, male or female. Common types of cancer in women include the following:

- Cancer of the womb (uterine carcinoma). It is the most common cancer of the female reproductive system.
- Cancer of the neck of the womb (cervical carcinoma). It may be caused by the sexually transmitted human papillomavirus or HPV.
- Cancer of the ovaries (ovarian carcinoma). It has the highest death rate of all cancers of the female reproductive system.
- Cancer of the external genitals (vulvar carcinoma). It is usually a type of skin cancer.
- Cancer of the vagina (vaginal carcinoma). It may be caused by the sexually transmitted human papillomavirus (HPV).
- Cancer of the fallopian tubes. It is the rarest cancer of the female reproductive system.
- Tumors that form in the womb during or after pregnancy (hydatidiform moles).

Other

The absence or abnormal stopping of menstrual periods (amenorrhea). A number of factors may abnormally stop menstruation. They include abnormal production of LH and FSH; excessive **exercise**; extreme **stress**; and near-starvation.

Painful menstruation, that is, menstruation with severe cramps or aches (dysmenorrhea). It may be caused by excessive production of prostaglandins (the hormones that cause the womb to contract forcefully at childbirth, thus squeezing the fetus into the vagina) or by diseased genitals.

Premenstrual syndrome (PMS) occurs during the luteal phase of the menstrual cycle and is characterized by numerous symptoms. These include changes in mood and behavior, cramps, headaches, fluid retention, and fatigue. Approximately 40% of menstruating women complain of some sort of PMS.

Toxic shock syndrome (TSS) is a rare but devastating disease associated with tampon use. Although the exact cause of the disease is not known, it has been linked to **infection** by *Staphylococcus aureus*. If *S.*

KEY TERMS

Amenorrhea—Abnormal absence or stopping of menstrual cycles.

Dysmenorrhea—Painful menstruation.

Endometrium—The inner lining of the womb.

External genitals—The greater lips (labia majora), the lesser lips (labia minora), the clitoris, and the opening of the vagina.

Follicle—A small spherical sac located in an ovary in which an oocyte develops and matures; when the follicle bursts, the mature egg (ovum) is released into the fallopian tube. Only about 300 follicles burst during a woman's lifetime.

Gamete—A one-fold (haploid, that is, having 23 instead of 46 chromosomes) cell involved in sexual reproduction; the male gamete is the sperm; the female gamete is the egg.

Internal genitals—The vagina, womb, fallopian tubes, and ovaries.

Menarche—The first menstrual cycle in a girl's life.

Menopause—The permanent stopping of menstrual cycles, traditionally marking the end of a woman's ability to reproduce.

Menstruation—The discharge of the lining of the womb (endometrium) as it sheds during the menstrual cycle when pregnancy does not take place.

Zygote—A two-fold (diploid, that is, having 46 chromosomes) cell resulting from fertilization of the female egg by a sperm.

aureus enters the vagina, it is possible that tampon use could promote the growth of these deadly **bacteria**. *S. aureus* may then secrete poisons (toxins) that enter the bloodstream and lead to TSS. Symptoms start with **fever**, vomiting, **diarrhea**, and low **blood pressure**, but may eventually involve multiple organ systems and result in death.

Reproductive system, male

Definition

The male reproductive system is composed of organs that work together to produce sperm and deliver them to the female reproductive tract for fertilization of the ovum.

Description

The normal male reproductive system is composed of numerous anatomical structures, including the testis, the excretory ducts, the auxiliary glands, the penis, and the various hormones that control reproductive functions.

Testis

The testis is responsible for the production and maturation of sperm in a process called spermatogenesis. It is also the site of synthesis and secretion of androgens (male sex hormones). The testes (plural) develop in the abdomen and descend into the scrotum in the normal male. The scrotum is a muscular sac in which the testes hang from the spermatic cord.

The testis is subdivided into the tubular compartment and the interstitial compartment. The tubular compartment is composed of up to 900 seminiferous tubules, which are populated by three main types of cells: germ cells, peritubular cells, and Sertoli cells. Germ cells become mature sperm in the spermatogenic process. Peritubular cells produce various factors that aid in the

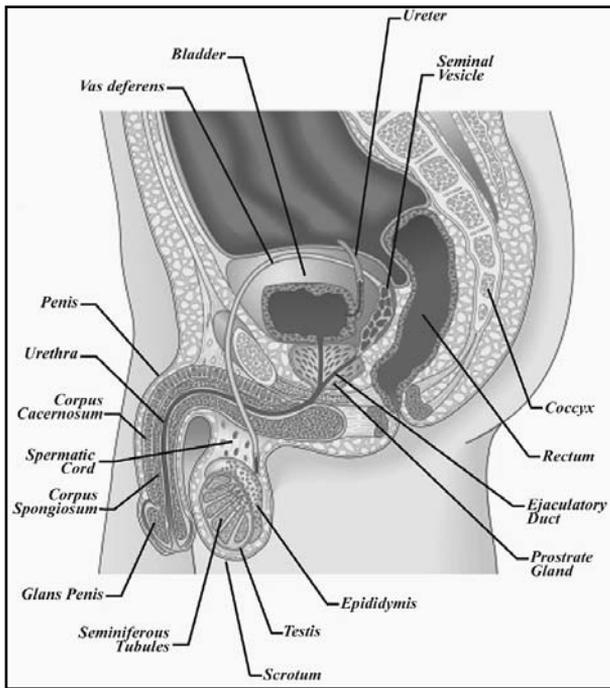

Illustration of the male reproductive system. (Kopp Illustration, Inc. Reproduced by permission.)

transportation of mature sperm to the epididymis. Sertoli cells secrete various factors that determine the sperm production and testis size of an adult male.

Androgens are produced in the interstitial compartment of the testis. Leydig cells are responsible for the production and secretion of testosterone. Immune cells such as macrophages and lymphocytes are also found in the interstitial compartment, and aid in the proliferation and hormone production of Leydig cells.

Sperm cells are composed of a head (containing the nucleus and acrosome); the body (containing the mitochondria, or energy-producing organelles); and the tail. The nucleus contains the cell's genetic material (chromatin) while the acrosome contains enzymes that are capable of penetrating the protective layers around the egg. The mitochondria provide energy for tail motility; this is essential for movement of the sperm through the female reproductive tract.

Excretory ducts

The excretory ducts are responsible for the transfer of sperm from the seminiferous tubules of the testis to the urethra, and include the epididymis, the vas deferens, and intratesticular ducts. The epididymis is a tubular structure through which sperm exiting the seminiferous tubules pass. Testicular sperm are not fully mature and would not be able to fertilize an ovum (egg). Complete maturation

occurs in the epididymis in the two to twelve days that sperm are typically stored before being passed to the vas deferens. The vas deferens functions to carry mature sperm from the epididymis to the urethra; it is also called the ductus deferens. Secretions from the auxiliary glands are mixed with sperm in the vas deferens to form semen.

Auxiliary glands

The auxiliary glands include two bulbourethral glands, one prostate, and two seminal vesicles. These glands contribute the secretions that compose semen. The bulbourethral glands (also called the glands of Cowper) secrete a fluid that lubricates the urethra prior to ejaculation. The prostate secretes a fluid rich in **zinc**, citric acid, choline, and various **proteins**. The secretions of the seminal vesicle are high in fructose (an energy source for sperm) and prostaglandins (fatty acid derivatives).

Penis

The penis is the male organ of sexual reproduction and consists of three elongated bodies that cause erection, the two corpora cavernosa and the corpus spongiosum. These tissues become engorged with **blood** when stimulated by the nervous system during arousal. Blood is supplied by the superficial and deep arterial systems (which carry blood to the penile skin and erectile tissue, respectively). The urethra runs through the corpus spongiosum to the glans penis (distal end of the penis). The organ is covered with loose skin that forms the prepuce (foreskin) over the glans penis.

Function

Endocrine control

Normal reproductive function is dependent on complex interactions between various hormones. A portion of the **brain** called the hypothalamus secretes releasing hormones that travel to the **pituitary gland**, located at the base of the brain. The secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus triggers the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary gland. LH stimulates testosterone production by Leydig cells in the testis, and FSH promotes spermatogenesis.

Male sexual act

The male sexual act can be divided into three main steps: erection, emission, and ejaculation. Erection is the result of increased blood flow to the erectile tissues of the penis; stimulation of the nervous system during arousal causes a release of acetylcholine (a neurotransmitter) that

in turn causes vasodilation (increase in the diameter of **blood vessels**). Emission is the passage of sperm and secretions into the urethra mediated by release of the hormone adrenaline. Ejaculation occurs when the sperm are forced from the urethra by contraction of the bulbocavernosus muscles. A release of noradrenaline causes the blood vessels in the penis to contract, decreasing blood flow and resulting in detumescence (loss of erection).

Fertilization

In order to fertilize the ovum, ejaculated sperm must move into the vaginal tract, pass through the cervix, survive in the uterus, and enter the fallopian tubes. Usually only healthy, motile sperm will reach the ovum and have the opportunity to fertilize it. Numerous protective layers (including the oolemma, the zona pellucida, and the zona radiata) surround the ovum, and sperm cells must penetrate each of these layers for fertilization to occur. Binding of a sperm cell to the zona pellucida induces the acrosome reaction, which permits the sperm to penetrate the zona pellucida and reach the egg membrane. The sperm and egg membranes fuse to form a zygote, and subsequent reactions prevent the binding of additional sperm cells to the egg membrane.

Common diseases and disorders

Diseases of the male reproductive system are classified based on the localization (e.g. testis, pituitary gland, etc.) and cause (e.g. congenital malformation, cancerous tumor, etc.) of the disorder. Some common examples of andrological disorders include:

- **Infertility:** Male infertility may be the symptom of multiple disorders. A blockage in both of the vasa deferentia or a testicular disorder may result in the complete absence of sperm (azoospermia). Low sperm counts might result from a prolonged increase in scrotal temperature—as in the case of a varicocele, a disturbance in testicular blood circulation. Retrograde ejaculation is another cause of male infertility; semen travels in the wrong direction, up the urethra to the bladder instead of down toward the penis.
- **Hypogonadism:** This describes a condition in which there is decreased sexual development and growth of the testes. Hypogonadism may result from tumors, hormone imbalances, or chromosomal abnormalities. Its symptoms (after **puberty**) include voice alteration, decreased size of testes, gynecomastia (enlargement of mammary glands), an infantile penis, or osteoporosis.
- **Erectile dysfunction:** It is estimated that the incidence of erectile dysfunction (ED) is twice as high as that of coronary **heart** disease. ED may result from reduced

KEY TERMS

Acrosome—A compartment in the head of the sperm that contains enzymes that allow the sperm to penetrate the protective layers of an egg.

Androgen—A male sex hormone.

Azoospermia—The complete absence of sperm in ejaculate.

Gynecomastia—Enlargement of the male mammary gland; a symptom of hypogonadism.

Hypogonadism—A condition in which there is decreased sexual development and growth of the testes.

Leydig cells—Found in the interstitial compartment of a testis; responsible for the production and secretion of testosterone.

Sertoli cells—Found in the tubular compartment of a testis; aids in the process of spermatogenesis.

Spermatogenesis—The process of the formation of sperm.

Varicocele—An abnormal swelling of veins in the scrotum.

Zygote—The cell resulting from the fusion of the male and female gametes.

penile blood flow, low serum levels of testosterone, use of psychotropic drugs, alcohol abuse, such metabolic disorders as **diabetes mellitus**, or muscle cell impairment.

- **Prostate cancer:** The prostate surrounds the urethra and secretes seminal fluids. Prostate **cancer** is the second most common cause of cancer death of men in the United States, and the second most commonly diagnosed form of cancer (after skin cancer).

Respiratory distress syndrome

Definition

Respiratory distress syndrome (RDS) of the newborn, known as infant RDS, is an acute lung disease present at birth. RDS usually affects premature babies who weigh less than 5.5 pounds (2.5 kg). In these babies, the lack of a pulmonary substance called surfactant allows layers of tissue called hyaline membranes to develop in the **lungs**. This development prevents the oxygen that is inhaled from passing into the **blood vessels** (capillaries) and thereby into the bloodstream. The lungs are said to be airless. Untreated, the infant will die within a few days after birth. RDS in newborns used to be called hyaline membrane disease.

Description

To breathe properly, the alveoli (small air sacs in the lungs) of a newborn infant must remain open so that oxygen in the air can enter the capillaries that surround the alveoli. Normally, during the last months of **pregnancy**, cells in the alveoli produce a substance called surfactant that maintains a low surface tension inside the alveoli. This allows the sacs to expand at the moment of birth, enabling the infant to breathe. Surfactant is produced starting at about 34 weeks of pregnancy and, by the time the fetal lungs mature at 37 weeks, a normal amount is present; after this point, it can be detected in the amniotic fluid.

When an infant is born prematurely without enough surfactant in the alveoli, the lungs may collapse, making it very difficult for the baby to get enough oxygen. Sometimes a layer of glassy, fibrous tissue called a hyaline membrane forms in the air sacs, making it even harder for oxygen to pass through the membrane to the capillaries.

Causes and symptoms

RDS nearly always occurs in **premature infants**, and the earlier the birth, the greater the chance that RDS will develop. The syndrome is also seen in some infants whose mothers have diabetes. Paradoxically, RDS is less likely to occur in the presence of conditions that are equally harmful: abnormally slow fetal growth, toxemia, and early rupture of the amniotic sac.

An infant with RDS may struggle to breathe as soon as it is born, or difficulty may develop within a few hours. Breathing becomes rapid and shallow, the nostrils flare, and the infant grunts with each breath. Muscles around the ribs and structures in the neck strain inward with each breath, showing the extreme effort that is being exerted. Before long, the intercostal muscles that move the ribs and diaphragm to draw air into the lungs become fatigued, making the breaths even more shallow. This shallow breathing diminishes the oxygen level in the **blood** so severely that the infant becomes cyanotic (the skin turns bluish). Tiny, very premature infants may not even have signs of trouble breathing. Their lungs may be so filled with hyaline membrane that when they are born they cannot even start breathing without assistance.

There are two major complications of RDS. One is pneumothorax, which means "air in the chest." When the infant itself or a ventilator breathing for the infant forces air into the lungs in an attempt to expand them, a lung may rupture, causing air to leak into the chest cavity. This air puts pressure on the lung, collapsing it and making breathing even more labored. Because pneumothorax interferes with blood flow in the pulmonary arteries, the infant's **blood pressure** may drop suddenly, diminishing blood supply to the **brain**. The other complication is intraventricular hemorrhage (bleeding into the ventricles of the brain), which can be fatal.

Diagnosis

When a premature infant has obvious trouble breathing at birth or within a few hours of birth, RDS is a possible diagnosis. If premature birth is expected, or there is some condition that calls for delivery prior to term, the amount of surfactant in the amniotic fluid indicates the extent to which the lungs have matured. If little surfactant is found in an amniotic fluid sample obtained via **amniocentesis**, then there is a definite risk of RDS. In some cases where delivery is essential to maternal or fetal survival, amniocentesis is performed at regular intervals so that the infant may be delivered as soon as the lungs are sufficiently mature. If the amniotic sac has ruptured, surfactant levels may be easily measured using a sample of vaginal fluid.

KEY TERMS

Alveoli—The small air sacs located at the ends of the breathing tubes of the lung, where oxygen normally passes from inhaled air through the membranes into the capillaries and the bloodstream.

Amniocentesis—Analysis of amniotic fluid, extracted surgically by a hollow needle from the uterus of a pregnant woman, to determine the health or other characteristics of a fetus.

Amniotic fluid—The fluid cushioning the fetus inside the uterus, which may be sampled to determine whether the fetus is making enough surfactant to breathe independently.

Endotracheal tube—A metal or plastic tube inserted in the windpipe, which may be attached to a ventilator. It may also be used to deliver such medications as surfactant.

Hyaline membranes—A fibrous layer that develops in the alveoli of many premature infants, which prevents oxygen from passing through the alveolar sac into the capillaries.

Pneumothorax—Air in the chest outside the lung,

which compresses the lung. It occurs as a result of the lung rupture, often caused by oxygen delivered under too high a pressure.

Steroids—Also known as corticosteroids or glucocorticoids, these naturally occurring substances are often given to women before they deliver a very premature infant to stimulate the fetal lungs to produce surfactant; this treatment is intended to prevent or minimize RDS.

Surfactant—A substance normally produced in fetal lungs after the 34th week of pregnancy that helps the air sacs to open up at the time of birth so that the infant can breathe independently.

Toxemia—A disease of pregnancy in which the mother's blood pressure is elevated; it is associated with both maternal and fetal complications, and sometimes with fetal death.

Ventilator—A machine that breathes for an infant with RDS until its lungs are producing enough surfactant and are able to function normally.

RDS can also be diagnosed by **chest x ray**. The syndrome has a recognizable radiologic image, and an x ray will also reveal pneumothorax (if this has occurred), as well. This test may be ordered if the infant suddenly becomes worse while on ventilation.

Treatment

If only a mild degree of RDS is present at birth, then placing the infant in an oxygen hood may be sufficient to sustain them until they can breathe independently. Nurses must closely monitor infants receiving oxygen, however, to prevent excessive oxygen saturation, which can damage the retina. This condition, called retinitis of prematurity, causes blindness. The oxygen level in the blood may be tested by analyzing the levels of arterial gases present, or more easily, by using a device called a **pulse oximeter**, which is clipped to an earlobe. A laboratory technologist usually performs all necessary blood work.

In more severe cases, a drug that mimics the action of natural surfactant (Exosurf Neonatal or Survanta), may be dripped into the lungs through an endotracheal tube. Typically, the infant will be able to breathe more easily within a few days, and such complications as lung rupture are less likely to occur. The drug is continued

until the infant starts producing its own surfactant. There is a risk of bleeding into the lungs from surfactant treatment; this affects about 10% of the smallest infants.

Infants with severe RDS may also be placed on a ventilator, a machine that delivers air under pressure through a tracheal tube to the lungs. This is performed as an emergency procedure for infants who do not breathe when born. Assisted ventilation must be closely supervised, as too much pressure can cause further lung damage, injure vocal cords, and increase the baby's risk of pulmonary **infection**. A gentler way to assist breathing is continuous positive airway pressure (CPAP), which delivers an oxygen mixture through nasal prongs or a tube placed through the nose rather than an endotracheal tube. CPAP may be tried before resorting to a ventilator, or after an infant placed on a ventilator begins to improve. Drugs that stimulate breathing may speed the recovery process.

Pneumothorax, which is a possible complication of assisted ventilation, is a medical emergency requiring immediate intervention. Air may be removed from the chest using a needle and syringe. A tube is then inserted into the lung cavity, and suction applied.

Prognosis

If an infant born with RDS is not treated promptly, lack of an adequate oxygen supply will damage the body's organs. They will eventually stop functioning, after which death follows. The **central nervous system** in particular—made up of the brain and spinal cord—is very dependent on a steady oxygen supply and is one of the first organ systems to feel the effects of RDS. On the other hand, if the infant's breathing is supported immediately after birth until the lungs mature and make their own surfactant, complete recovery within three to five days is the rule.

Health care team roles

Premature infants with respiratory disorders are usually cared for in a neonatal intensive care unit by a neonatologist, certified neonatal intensive care nurse specialist, anesthesia provider (to maintain the airway), and respiratory therapist. Once the infant has recovered, a pediatrician, family practice physician, and a pediatric nurse practitioner may provide continuing medical care. Parents and siblings of critically ill newborns may require additional support from social workers, pastoral counselors, self-help support groups, or other mental health professionals.

Prevention

The best way to prevent RDS is to delay delivery until fetal lungs have matured and are producing enough surfactant—generally at about 37 weeks of pregnancy. If delivery cannot be delayed, the mother may be given a steroid hormone, similar to a natural substance produced in the body, which crosses the placental barrier and helps the fetal lungs produce surfactant. The steroid should be given at least 24 hours before the expected delivery. If the infant does develop RDS, this treatment sharply reduces the risk of cerebral hemorrhage.

If a very premature infant is born without symptoms of RDS, it may be wise to deliver surfactant to its lungs anyway. This treatment may prevent RDS, or make it less severe if it does develop. An alternative is to wait until the first symptoms of RDS appear and then give surfactant immediately. Pneumothorax may be prevented by frequently monitoring blood oxygen content, and limiting oxygen treatment under pressure to the minimum.

Respiratory failure

Definition

Respiratory failure occurs when the lungs' ability to either add oxygen to the bloodstream or remove carbon dioxide from it is impaired. Respiratory failure can have any one of several causes, such as lung disease or **infection**, electrolyte imbalance, interruption of the nerve signals that regulate breathing or nervous system damage, structural (rib cage) collapse, or airway obstruction.

Description

During respiration, the **lungs** extract oxygen from inhaled air, oxygenate the bloodstream, and eliminate carbon dioxide (CO₂) from the **blood** into exhaled air. In respiratory failure, the level of oxygen in the blood becomes dangerously low, and/or the level of CO₂ becomes dangerously high. This result can happen if the gas-exchange process breaks down or if ventilation is inhibited.

There are two main types of respiratory failure. Hypoxemic failure occurs when normal **gas exchange** is interrupted, causing a condition called hypoxemia. When this happens, there is too little oxygen in the blood, and all of the body's organs and tissues suffer as a result. One common type of hypoxemic respiratory failure, which occurs in both adults and **premature infants**, is **respiratory distress syndrome**, a condition in which fluid or tissue changes or physical immaturity prevent oxygen from passing out of the lungs' air sacs into the circulating

blood. Hypoxemia is also caused by exposure to high altitudes, where there is less oxygen in the air; lung diseases that impair the transfer of oxygen into the blood through the alveolar capillaries; severe anemia; and blood vessel disorders that shunt blood away from the lungs, thus preventing the lungs from picking up oxygen.

Ventilatory failure occurs when the body cannot exhale CO₂ properly. The resulting buildup in the blood is called hypercapnia. Ventilatory failure can result when the respiratory center in the brainstem fails to drive breathing, when muscle disease prevents the chest wall from expanding during inhalation, or when a patient has chronic obstructive pulmonary disease that impairs exhalation. Many of the diseases and conditions that produce respiratory failure can cause both hypoxemia and hypercapnia simultaneously.

Causes and symptoms

Respiratory failure can have a variety of causes; all of them inhibit breathing in some way.

- *Airway obstructions*: chronic bronchitis with heavy secretions, **emphysema**, **cystic fibrosis**, **asthma**, and obstructive sleep apnea, in which patients stop breathing for short periods during sleep.
- *Depressed respiration*: weakened breathing that is caused by drug abuse (especially narcotics or opiates) and/or alcohol intoxication, both of which depress the respiratory center. Extreme **obesity** can also be a factor, because it restricts chest wall expansion during inhalation, diminishing the body's ability to acquire enough oxygen.
- *Muscle weakness*: this can be caused by such neuromuscular diseases as myasthenia gravis, **muscular dystrophy**, **multiple sclerosis**, polio, and amyotrophic lateral sclerosis (ALS or Lou Gehrig's disease), as well as strokes that paralyze respiratory muscles and **spinal cord** injuries.
- *Lung diseases and disorders*: severe **pneumonia**, respiratory distress syndrome, pulmonary fibrosis and other scarring diseases of the lung, radiation exposure, burn injury from smoke inhalation, and widespread **lung cancer**. Pulmonary **edema**, often a result of **heart** disease, can also cause respiratory failure.
- *Chest wall abnormalities*: these can be caused by **scolio**sis or severe thoracic injuries, including trauma to the phrenic nerve, which supplies the lungs and diaphragm.
- *Cellular disorders*: any interruption of the Krebs cycle can impede respiration, as can such electrolyte disorders as hypokalemia.

Patients with respiratory failure often have a rapid, weak, or shallow pulse; they are also usually short of breath, restless, and may become confused and disoriented when normal blood gas levels are altered. High blood CO₂ levels can cause headaches and, in time, a semi-conscious state, or even **coma**. Low blood oxygen causes **cyanosis**, and can produce arrhythmias. Lung disease may cause abnormal breath sounds that are audible through a **stethoscope**: wheezing in asthma, rales in pneumonia, or distant breath sounds in obstructive lung disease. A patient with ventilatory failure is prone to gasp for breath, and may use the neck and shoulder muscles to help expand the chest.

Diagnosis

The signs and symptoms of respiratory failure depend on the underlying condition causing it. The key to diagnosis and treatment is measuring the levels of oxygen, carbon dioxide, and acid in the blood at regular intervals. Generally, laboratory technologists and respiratory therapists perform all needed blood work and lung-function testing.

Treatment

Nearly all patients are given oxygen as the first treatment. Then the underlying cause of respiratory failure must be addressed. **Antibiotics** are used to fight a lung infection; bronchodilators, like albuterol, and steroid therapy are commonly prescribed for patients with asthma.

Nurses and respiratory therapists have a number of methods to help patients overcome respiratory failure. These include:

- Suctioning the lungs through a small plastic tube passed through the nose. This treatment removes secretions from the airway that the patient is unable to cough up.
- Postural drainage therapy, in which the patient's position is adjusted frequently to help secretions drain into the central airways. Chest percussion and mechanical vibrators are also applied to help loosen deep secretions. The patient is then encouraged to cough up the secretions; if the patient isn't strong enough to do this, they are suctioned out.
- Deep-breathing exercises, which are often prescribed after the patient recovers, help strengthen the muscles that aid breathing. One technique has the patient breathe out against pursed lips to increase pressure in the airways, preventing them from collapsing. A device called a volumetric incentive spirometer is also used to encourage deep breathing while giving visual feedback. The patient inhales slowly through a plastic tube

KEY TERMS

Arrhythmia—Abnormal heart rhythm.

Chest percussion—A method of loosening deep lung secretions by rhythmically beating the chest with a cupped hand or mechanical vibrator directly over the affected lung areas.

Chronic obstructive pulmonary disease—Lung diseases, such as emphysema and chronic bronchitis, in which airflow is obstructed, causing labored breathing and impairing gas exchange.

Cyanosis—A bluish tinge to the skin caused by low oxygen levels in the blood.

Gas exchange—The process by which oxygen is extracted from inhaled air into the bloodstream; and, at the same time, carbon dioxide is eliminated from the blood and exhaled.

Hypokalemia—Potassium deficiency in the blood.

Hypoxemia—An abnormally low amount of oxygen in the blood, one of the the major consequences of respiratory failure.

Krebs cycle—One of a series of chemical reactions in which the body's cells metabolize glucose for energy.

Pulmonary edema—Fluid accumulation in the lungs; it is frequently a complication of heart disease and other medical disorders.

Pulmonary fibrosis—The conversion of inflamed lung tissue to scarred, fibrotic tissue that cannot carry out gas exchange. Pulmonary fibrosis is caused by such occupational toxins as asbestos and silica, connective tissue diseases like rheumatoid arthritis and lupus, and exposure to some types of medications, including bleomycin and methotrexate.

Pulmonary hypertension—Potentially life-threatening condition in which blood pressure in the pulmonary artery increases to abnormal levels. Primary pulmonary hypertension, which is rare, occurs without any known cause. Secondary pulmonary hypertension is often a complication of lung diseases like emphysema and bronchitis.

Ventilation—The movement of air in and out of the lungs.

attached to a clear plastic cylinder; the cylinder contains a piston and a ball that rests on top of it. Inhalation

raises the ball; the patient has to inhale deeply enough to move it to a predetermined mark.

Patients whose breathing remains very poor may require a ventilator until the lungs can resume their function. Although ventilation is a life-saving treatment, it is very important to use no more pressure than necessary to provide sufficient oxygen; otherwise ventilation may cause further lung damage. Drugs are administered to keep the patient calm, and the amount of fluid in the body is carefully monitored so that the heart and lungs can function as normally as possible. Steroids, which combat inflammation, may sometimes be helpful but can cause complications, including weakening of the muscles of respiration.

Prognosis

The outlook for patients with respiratory failure depends chiefly on the underlying cause. If it can be effectively treated and the patient's breathing supported during treatment, the outlook is usually promising. Good general health and some degree of lung function improve the prognosis considerably.

When respiratory failure develops slowly, secondary pulmonary **hypertension** may develop. This condition may damage the **blood vessels**, worsen hypoxemia, and eventually cause the heart to fail. If it is not possible to provide enough oxygen to the body, complications involving either the **brain** or the heart may prove fatal.

If the **kidneys** fail or the patient's lungs become infected, the prognosis worsens. In some cases, the primary disease causing the lungs to fail is irreversible. The patient, family, and physician must then decide whether to prolong life by ventilator support.

Health care team roles

Patients with respiratory failure are often cared for in the intensive care unit by critical care or intensive care physicians and nurses. Depending on the underlying cause of respiratory failure, patients may be treated by pulmonologists, cardiologists, internists, surgeons, or oncologists. The treatment team also may include respiratory therapists, laboratory technologists, radiology technologists, and physical therapists. Patients and families facing decisions about end-of-life or hospice care may benefit from counseling from social workers, religious counselors, or mental health professionals.

Prevention

Because respiratory failure is not a disease itself, but the result of another disorder, the best prevention is to

treat any lung disease promptly and effectively, and to ensure that patients whose blood electrolyte chemistry is out of balance receive supplemental therapy. Patients with lung problems should, to every extent possible, also avoid exposure to pollutants. Once respiratory failure is present, it is best for a patient to receive treatment in an intensive care unit, where specialized personnel and equipment are available. Close supervision of treatment, especially mechanical ventilation, help to minimize the risk of complications.

Respiratory system

Definition

The respiratory system consists of organs that deliver oxygen to the circulatory system for transport to the all the cells of the body. The respiratory system also assists in the removal of carbon dioxide (CO₂), thus preventing a deadly buildup of this waste product in the body.

Description

The respiratory system consists of the upper and lower respiratory tracts, extending from the nose to the **lungs**.

The upper respiratory tract encompasses the:

- nose
- pharynx, more commonly called the throat

The lower respiratory tract includes the:

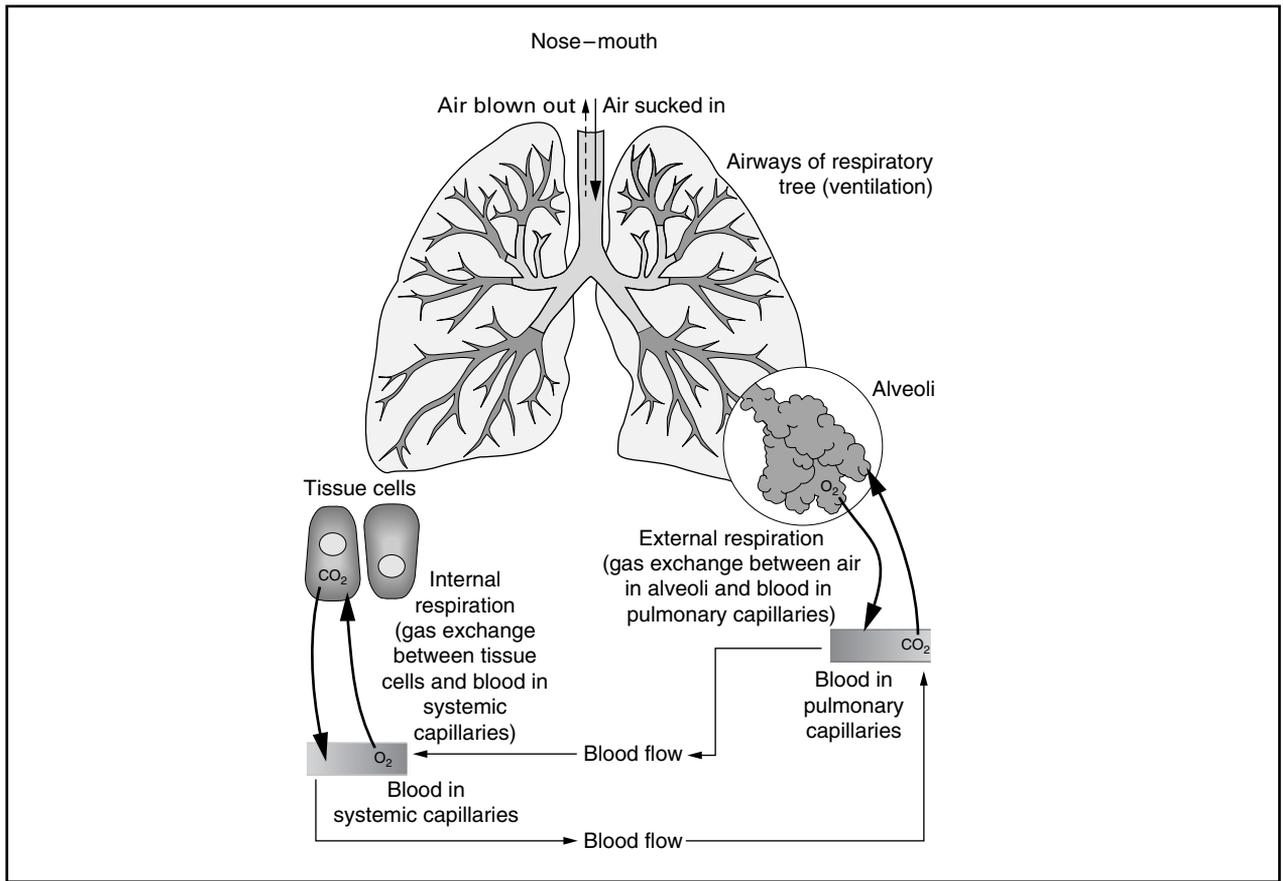

- larynx, also called the voice box
- the trachea or windpipe, which splits into two main branches called bronchi
- tiny branches of the bronchi called bronchioles
- the lungs

These organs all work together to provide air to and from the lungs. The lungs then operate in conjunction with the circulatory system to deliver oxygen and remove carbon dioxide.

Nasal passages

The flow of air begins in the nose, which is divided into the left and right nasal passages and ends in the lungs. The nasal passages are lined with epithelial cells, a mucous membrane composed mostly of a layer of flat, closely packed cells. Each epithelial cell is fringed with thousands of tiny fingerlike extensions of the cells called cilia. Goblet cells are specialized cells that produce mucus, and are among the epithelial cells. Mucus is a thick, moist fluid that coats epithelial cells and cilia. Beneath the mucous membrane, near the surface of the nasal passages, are many tiny **blood vessels** called capillaries. The nasal passages play two critical roles in transporting air to the pharynx. First, the nasal passages filter air to remove potentially disease-causing particles. Secondly, they moisten and warm the air to protect the respiratory system.

Filtering air through the nasal passage prevents airborne **bacteria**, **viruses**, smog, dust particles, and other potentially disease-causing substances from entering the lungs or the bronchioles. Just inside the nostrils are

The functions of ventilation and respiration in the respiratory system. (Delmar Publishers, Inc. Reproduced by permission.)

coarse hairs that assist in trapping airborne particles as they are inhaled. The particles then drop down onto the mucous membranes in the lining of the nasal passages. The particles are then propelled out of the nose or downward to the pharynx by the wave of mucus created by the cilia in the mucous membranes. From the pharynx, mucus is swallowed and travels to the **stomach** where the particles are subsequently destroyed by stomach acid. If there are more particles in the nasal passages than the cilia can cope with, a reflex will be triggered, producing a sneeze. The sneeze, designed to flush out the polluted air, is due to particles building up on the mucus and irritating the membrane below it.

Pharynx

As air leaves the nasal passages, it flows to the pharynx, which is a short, funnel-shaped tube about 13 cm (5 inches) long. The pharynx is also lined with a mucous membrane and ciliated cells that filter air from the nasal passages. The pharynx also includes the tonsils, which are lymphatic tissues that contain white

blood cells. If any impurities escape the hairs, cilia, and mucus of the nasal passages and pharynx, the white blood cells attack the disease-causing organisms. To prevent these organisms from moving further into the body, the tonsils are strategically located. One pair of growths of lymphoid tissue referred to as the adenoids is located high in the rear wall of the pharynx. A pair of tonsils called the palatine tonsils are positioned on either side of the tongue at the back of the pharynx. Another pair called the lingual tonsils are found deep in the pharynx at the base of the tongue. The tonsils may become swollen with **infection** during their fight against disease-causing organisms.

Larynx

Air passes from the pharynx to the larynx, which is approximately 5 cm (2 inches) long and situated near the middle of the neck. The larynx is comprised of several layers of cartilage, a tough and flexible tissue.

In addition to transporting air to the trachea, the larynx serves such other functions as:

- It prevents food and fluid from entering the air passage which would cause choking.
- Its mucous membranes and cilia-bearing cells help filter air.
- It plays a primary role in producing sound.
- The cilia in the larynx move airborne particles up toward the pharynx to be swallowed.

A thin, leaflike flap of tissue called the epiglottis prevents food and fluids from entering the larynx from the pharynx. The epiglottis is held in a vertical position, like an open trap door when a person is breathing. When swallowing, a reflex forces the larynx and the epiglottis to move toward each other. This reflex diverts food and fluids to the esophagus. The swallowing reflex may not work if one eats or drinks too rapidly, or laughs while swallowing. Food or fluid enters the larynx and a coughing reflex is initiated to clear the obstruction. This situation may cause life-threatening choking if coughing does not clear the larynx of the obstruction.

Trachea, bronchi, and bronchioles

Air is passed from the larynx into the trachea, the largest airway in the respiratory system. The trachea is a tube located just below the larynx, approximately 12 to 15 cm (5 to 6 inches) long. Fifteen to twenty C-shaped rings of cartilage form the trachea. Air passes freely at all times because the trachea is held open by the rings of sturdy cartilage. The open part of the C-shaped cartilage rings is situated at the back of the trachea with the ends connected by muscle tissue. The trachea branches into two tubes at its base, located just below where the neck meets the trunk of the body. These two tubes are called the left and right bronchi and they deliver air to the left and right lungs, respectively. The bronchi branch into smaller tubes called bronchioles within the lungs. The trachea, bronchi, and the first few bronchioles are lined with mucous membranes and ciliated cells; thus they contribute to the cleansing action of the respiratory system by moving mucus upward to the pharynx.

Alveoli and lungs

The bronchioles divide many more times in the lungs into an upside-down tree-like structure with progressively smaller branches. Tiny air sacs called alveoli are at the end of the branches. Some of the bronchioles are no larger than 0.5 mm (0.02 inches) in diameter. The alveoli comprise most of the lung tissue, with about 150 million alveoli per lung, and resemble bunches of grapes. The alveoli send oxygen to the circulatory system while removing carbon dioxide. Alveoli have thin elastic walls, thus allowing air to flow into them when they expand;

they collapse when the air is exhaled. Alveoli are arranged in clusters, and each cluster is surrounded by a dense network of capillaries. The walls of the capillaries are very thin; thus the air in the wall of the alveoli is very near to the blood in the capillaries (only about 0.1 to 0.2 microns). Carbon dioxide is a waste product that is dumped into the bloodstream from the cells. It flows throughout the body in the bloodstream to the **heart**, and then to the alveolar capillaries. The oxygen diffuses from the alveoli to the capillaries since the concentration of oxygen is much higher in the alveoli than in the capillaries. From the capillaries, the oxygen flows into larger vessels and is then carried to the heart where it is pumped to the rest of the body. The forces of exhalation cause the carbon dioxide to go back up through the respiratory passages and out of the body. Numerous macrophages are interspersed among the alveoli. Macrophages are large white blood cells that remove foreign substances from the alveoli that have not been previously filtered out. The presence of the macrophages ensures that the alveoli are protected from infection; they are the last line of defense of the respiratory system.

The lungs are the largest organ in the respiratory system and resemble large pink sponges. The left lung is slightly smaller than the right lung since it shares space with the heart, which is also located in the left side of the chest. Each lung is divided into lobes, with two in the left lung and three in the right. A slippery membrane called the pleura covers the lungs and lines the inside of the chest wall. It helps the lungs move smoothly during each breath. Normally, the two lubricated layers of the pleura have very little space between them. They glide smoothly over each other when the lungs expand and contract.

The diaphragm is the most important muscle involved in respiration. It lies just under the lungs and is a muscle shaped like a large dome. The sternum (or breastbone), ribs, and spine protect the lungs and the other organs in the chest. Twelve pairs of ribs curve around the chest and are joined to the vertebrae of the spine. The intercostal muscles are also important for respiration. They lie between the ribs and assist in breathing by helping to move the rib cage.

Function

The main function of the respiratory system is the delivery of oxygen and removal of carbon dioxide. To achieve this purpose, the nervous system controls the flow of air in and out of the lungs while maintaining a regular rate and pattern of breathing. Regulation is controlled by the respiratory center, a cluster of nerve cells in the **brain** stem. These cells simultaneously send signals to the muscles involved in inhalation: the diaphragm and

rib muscles. The diaphragm flattens out when stimulated by a nervous impulse. The thoracic or chest cavity contains the lungs. The volume of the cavity expands with the downward movement of the diaphragm, thus expanding the lungs. The rib muscles also contract when stimulated, which pulls the rib cage up and out, at the same time expanding the thoracic cavity. This movement reduces pressure in the chest. When the volume is increased in the thoracic cavity, air rushes into the lungs to equalize the pressure. This nervous stimulation is quick, and when it is over, the diaphragm and rib muscles relax and a person exhales.

Working in conjunction with the circulatory system, the oxygen-rich blood travels from the lungs through the pulmonary veins into the left side of the heart. From there, blood is pumped to the rest of the body. Blood that is oxygen-depleted, but carbon dioxide-rich, returns to the right side of the heart through two large veins called the superior and inferior venae cavae. This blood is then pumped through the pulmonary artery to the lungs, where oxygen is picked up and carbon dioxide is released. This process is repeated continually under normal circumstances.

Other functions the respiratory system assist in just by normal respiration are the regulation of acid–base balance in the body, a critical process for normal cellular function. It also protects the body against toxic substances inhaled as well as against disease–causing organisms in the air. The respiratory system also assists in detecting **smell** using the olfactory receptors located in the nasal passages. Furthermore, it aids in producing sounds for speech.

Role in human health

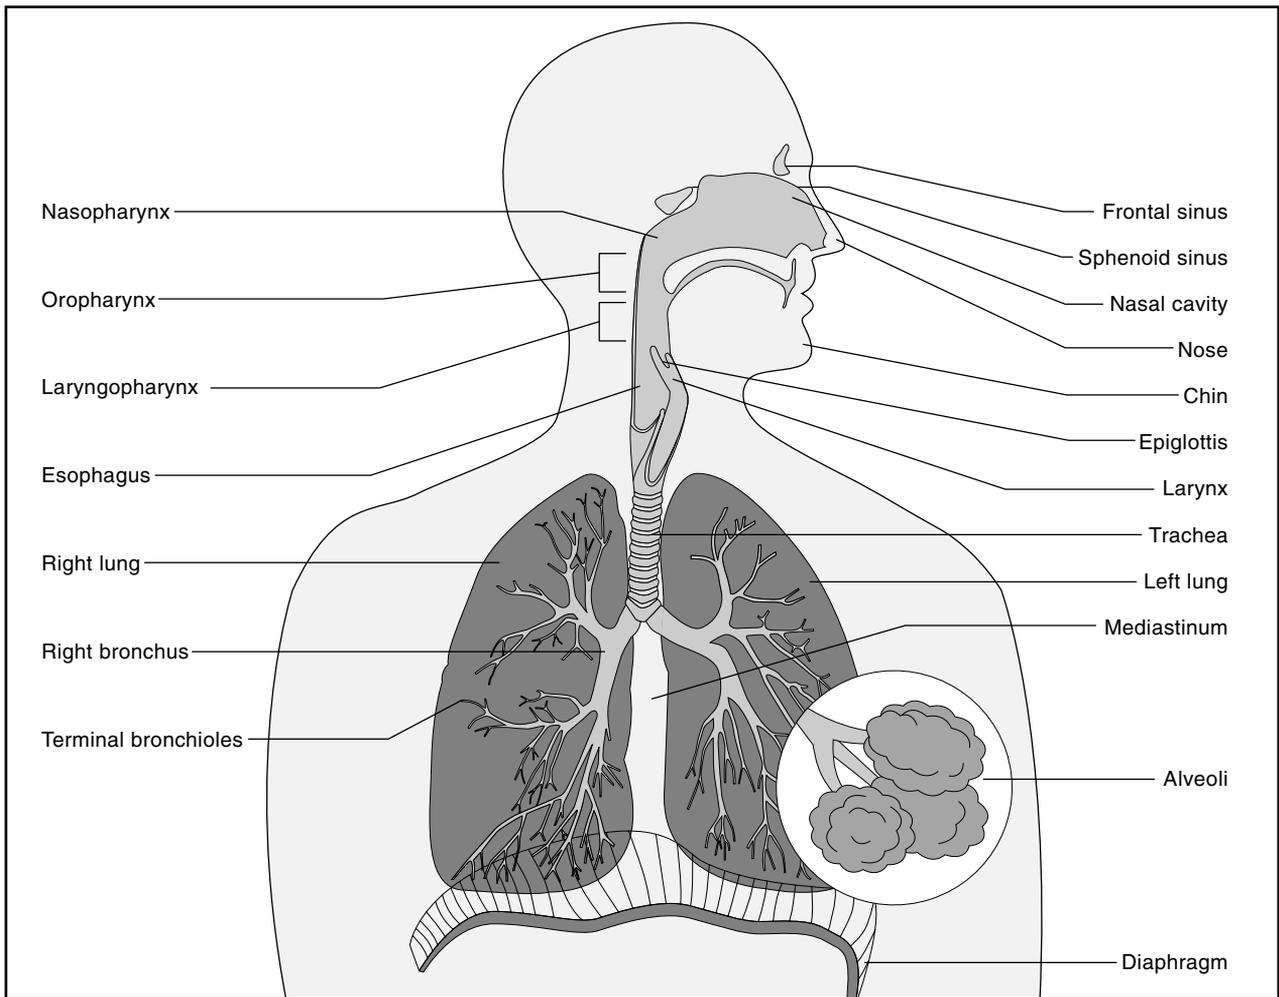

Breathing is an unconscious process carried out on a constant basis and is necessary for survival. Under normal conditions, a person takes 12–20 breaths per minute, although newborns breathe at a faster rate, at approximately 30–50 breaths per minute. The breathing rate set by the respiratory center can be altered by conscious control, for example, by holding the breath. This alteration occurs when the part of the brain involved in thinking, the cerebral cortex, sends signals to the diaphragm and rib muscles to momentarily ignore the signals from the respiratory center. If a person holds his or her breath too long, carbon dioxide accumulates in the blood, which then causes the blood to become more acidic. The increased acidity interferes with the action of enzymes, which are specialized **proteins** that coordinate all biochemical reactions in the body. To prevent too much acid from building up in the blood, special receptors located in the brain stem and in the blood vessels of the neck

called chemoreceptors monitor the acid level in the blood. These chemoreceptors send nervous signals to the respiratory center when acid levels are too high, which overrides the signals from the cerebral cortex, forcing a person to exhale and then resume breathing. The blood acid level is brought back to normal levels by exhalation, which expels the carbon dioxide. Irreversible damage to tissues occurs, followed by the failure of all body systems, and ultimately, death if the respiratory system's tasks are interrupted for more than a few minutes.

Common diseases and disorders

The diseases and disorders of the respiratory system can affect any part of the respiratory tract and may range from mild to life-threatening conditions such as:

- **Colds**—A virus that targets the nasal passages and pharynx. Symptoms include a stuffy and runny nose.
- **Hay fever** and **asthma**—Allergic reactions that may occur when the **immune system** is stimulated by pollen, dust, or other irritants. A runny nose, watery eyes, and sneezing characterizes hay fever. In **asthma**, because the bronchi and bronchioles are temporarily constricted and inflamed, a person has difficulty breathing.
- **Bronchitis**—Characterized by inflamed bronchi or bronchiole membranes, resulting from viral or bacterial infection or from chemical irritants.
- **Emphysema**—A non-contagious disease that results from multiple factors including: smog, cigarette smoke, infection, and a genetic predisposition to the condition. **Emphysema** partially destroys the alveolar tissue and leaves the remaining alveoli weakened and enlarged. When a person exhales, the bronchioles collapse, trapping air in the alveoli. This process eventually impedes the ability to exchange oxygen and carbon dioxide, leading to breathing difficulties.
- **Pneumonia**—Infections caused by bacteria or viruses can lead to this potentially serious condition. The alveoli become inflamed and fill with fluid, impairing the flow of oxygen and carbon dioxide between the capillaries and the alveoli.
- **Tuberculosis**—A condition caused by a bacterium that attacks the lungs and occasionally other body tissues. Left untreated, the disease destroys lung tissue.
- **Laryngitis**—An inflammation of the larynx caused by such irritants as cigarette smoke, overuse of the voice, or a viral infection. A person with laryngitis may become hoarse, or they may be able only to whisper until the inflammation is reduced.

Structures of the respiratory system. (Delmar Publishers, Inc. Reproduced by permission.)

- **Lung cancer**—Occurs in those individuals who are exposed to such cancer-causing agents as tobacco smoke, asbestos, or uranium; or who have a genetic predisposition to the disease. Treatments are very effective if the **cancer** is detected before the cancer has spread to other parts of the body. About 85% of cases are diagnosed after the cancer has spread; thus the prognosis is very poor.
- **Respiratory distress syndrome (RDS)**—Refers to a group of symptoms that indicate severe malfunctioning of the lungs affecting adults and infants. Adult respiratory distress syndrome (ARDS) is a life-threatening condition that results when the lungs are severely injured, for example, by poisonous gases, in an automobile accident, or as a response to inflammation in the lungs.
- **Wheezing**—A high-pitched whistling sound produced due to air flowing through narrowed breathing tubes. It may have many causes such as asthma, emphysema, **pneumonia**, bronchitis etc.
- **Shortness of breath or dyspnea**—This condition may have multiple causes such as asthma, emphysema, hyperventilation, **obesity**, cigarette smoking, lung disease, excessive **exercise**, etc.
- **Chronic respiratory insufficiency (or chronic obstructive pulmonary disease; COPD)**—A prolonged or persistent condition characterized by breathing or respiratory dysfunction resulting in reduced rates of oxygenation or the ability to eliminate carbon dioxide. These rates are insufficient to meet the requirements of the body and may be severe enough to impair or threaten the function of vital organs (**respiratory failure**).

Some of the most common symptoms of respiratory disorders are a cough, shortness of breath, chest **pain**, wheezing, **cyanosis** (bluish discoloration), finger clubbing, stridor (a crowing sound when breathing), hemoptysis (coughing up of blood), and respiratory failure. These symptoms do not necessarily signify a respiratory

KEY TERMS

Acidosis—A dangerous condition in which the blood and body tissues are less alkaline (or more acidic) than normal.

Alkalosis—Excessive alkalinity of the blood and body tissue.

Bronchi—The trachea branches into two tubes at the base of the trachea called the left and right bronchi, which extend from the trachea to deliver air to the left and right lungs, respectively. The bronchi branch into smaller tubes called bronchioles within the lungs.

Bronchioles—The bronchioles are no larger than 0.5mm (0.02 inches) in diameter and divide many times in the lungs to form a tree-like structure; they have progressively smaller branches and tiny air sacs called alveoli at the end.

Capillaries—Tiny blood vessels that lie beneath the mucous membrane near the surface of the nasal passages.

Carbon dioxide (CO₂)—A gaseous waste product that is dumped into the bloodstream from the cells; a byproduct of respiration, it is released upon exhalation of air from the body.

Cilia—Each epithelial cell is fringed with thousands of these tiny fingerlike extensions of the cells.

Diaphragm—The diaphragm is involved in inhalation. It lies just under the lungs and is a muscle shaped like a large dome.

Epiglottis—A thin, leaflike flap of tissue that prevents food and fluids from entering the larynx from the pharynx.

Mucus—A thick, moist fluid that coats epithelial cells and cilia.

pH—the negative logarithm of H⁺ (hydrogen) concentration. Acid-base balance can be defined as homeostasis (equilibrium) of the body fluids at a normal arterial blood pH ranging between 7.37 and 7.43.

Thoracic cavity—Also called the chest cavity, it is the portion of the ventral body cavity located between the neck and the diaphragm. It is enclosed by the ribs, the vertebral column, and the sternum. It is separated from the abdominal cavity by the diaphragm.

problem, but can be a sign of another problem. For example, chest pain may be due to a heart or a gastrointestinal problem.

Cystic fibrosis is a genetic disease that causes excessive mucus production and clogs the airways.

Acidosis is a condition resulting from higher than normal acid levels in the body fluids. It is not a disease but may be an indicator of disease. Respiratory acidosis is due to a failure by the lungs to remove carbon dioxide, therefore reducing the pH in the body. Several conditions such as chest injury, block of the upper air passages, and severe lung disease may result in respiratory acidosis. Blockage of the air passages may be due to bronchitis, asthma, or airway obstruction resulting in mild or severe acidosis. Regular, consistent retention of carbon dioxide in the lungs is referred to as chronic respiratory acidosis. This disorder results in only mild acidosis because of an increased bicarbonate (alkali) production by the **kidneys**.

Alkalosis is a condition resulting from a higher than normal level of base or alkali in the body fluids. Respiratory alkalosis results from decreased carbon dioxide levels caused by such conditions as hyperventilation (a faster breathing rate), **anxiety**, and fever. The pH becomes elevated in the body. Hyperventilation causes the body to lose excess carbon dioxide in expired air and can be triggered by altitude or a disease that reduces the amount of oxygen in the blood. Symptoms of respiratory alkalosis may include dizziness, lightheadedness, and numbing of the hands and feet. Treatments include breathing into a paper bag or a mask that induces rebreathing of carbon dioxide.

Respiratory therapy

Definition

Respiratory therapy is a therapeutic treatment for respiratory diseases and conditions. A respiratory therapist (RT) is a health care professional who usually provides these treatments and evaluates the patient's response to the treatments.

Purpose

The purpose of respiratory therapy is to maintain an open airway for trauma, intensive care, and surgical patients; assist in **cardiopulmonary resuscitation** and support; provide life support for patients who cannot breathe on their own; provide assistance to the anesthesiologist in the operating room; provide inhaled drugs and **medical gases**, provide results from the testing of measuring lung function; and assist with **patient education**.

Description

Respiratory therapy is performed in hospitals, in neonatal, emergency, intensive care, surgical and cardiac units, and various other health care facilities. Respiratory therapy treats many kinds of patients, and provides temporary relief to patients suffering from respiratory ailments. The therapies most commonly administered are oxygen and aerosol medications, and ventilator support after intubation. RTs are assigned to patients during their shift and continuously monitor those patients and respiratory equipment.

It is essential to assess a patient's respiratory function if he/she has a known or suspected pulmonary con-

dition. Therapists perform procedures that are both diagnostic and therapeutic.

Diagnostic therapy includes:

- Obtaining and analyzing sputum and breath specimens. **Blood** specimens are also obtained and analyzed for levels of oxygen, carbon dioxide, and other gases.
- Interpreting data obtained from these specimens.
- Measuring the capacity of a patient's **lungs** to determine if there is impaired function.
- Performing other studies of the cardiopulmonary system.
- Studying disorders of people with disruptive sleep patterns.

Treatment therapy includes:

- Operating and maintaining various types of highly sophisticated equipment to administer oxygen or assist with breathing.
- Employing mechanical ventilation for treating patients who cannot breathe adequately on their own.
- Monitoring and managing therapy that will help a patient recover lung function.
- Administering medications in aerosol form to help alleviate breathing problems and to help prevent respiratory infections.
- Monitoring equipment and patient response to therapy.
- Maintaining the patient's artificial airway.

The following are the most commonly performed procedures in respiratory therapy:

- Oxygen therapy—Oxygen therapy involves the administration of oxygen at concentrations greater than that in ambient air, with the intent of treating or preventing the symptoms and manifestations of hypoxia. Indications include documented hypoxemia, severe trauma, acute **myocardial infarction**, and short-term therapy as in post-anesthesia recovery. The need for **oxygen therapy** is determined by measurement of inadequate oxygen saturations, by invasive or noninvasive means or the presence of clinical indicators. Low-flow oxygen therapy systems deliver 100% oxygen at flows lower than the patient's inspiratory flow rate. The concentration inhaled may be low or high, depending on the specific device and the patient's inspiratory flow rate. Nasal cannulas can provide 24-40% oxygen with flow rates up to 6L/min in adults. In infants and newborns, flow should be limited to a maximum of 2L/min. If the oxygen supplied to adults via nasal cannula is at a flow rate lower than or equal to 4L/min, it does not have to be humidified. Simple oxygen masks can provide 35%-50% oxygen at flow rates of 5-10 L/min. Rates should

KEY TERMS

Artificial airway—A passage for respiration that is created and maintained by a device, such as tubing. Artificial airways are usually established for patients who are at risk of having their own natural airways collapse because of trauma or another medical condition.

Mechanical ventilation—The process of maintaining respiration in a patient who cannot breathe naturally by means of a respiratory device.

be maintained at 5L/min or more to avoid rebreathing exhaled CO₂ that may be retained in the mask. Masks with reservoir bags (partial and non-rebreathers) provide FIO₂s (fraction-inspired oxygen, or the concentration of oxygen as delivered to the patient) of 0.5 or greater. High-flow systems deliver a prescribed gas mixture—either high or low FDO₂—at flow rates that exceed patient demand. Aerosol masks, tracheostomy collars, T-tube adaptors and face tents can be used with high-flow supplemental oxygen systems. O₂ therapy should be administered continuously unless needed only in specific situations, as with **exercise** or sleep.

- **Pulse oximetry**—Indications for pulse oximetry include the need to monitor the adequacy of arterial oxyhemoglobin saturation, gauge the response of O₂ saturation to therapeutic interventions, and complying with regulations. SpO₂ (a measure of oxygen saturation) is used for continuous and prolonged monitoring as in during sleep, exercise or surgical procedures. Results of SpO₂ tests validate the basis for ordering the test by reflecting the patient's clinical condition. Documentation of results should be noted in the patient's chart.
- **Incentive spirometry**—I.S. encourages patients to take long, slow, deep breaths. It is a device that provides patients with positive feedback during inhalation at a predetermined flow rate or volume and sustains the inflations for a minimum of three seconds. I.S. is used to increase transpulmonary pressure and inspiratory volumes; improve inspiratory muscle performance; and reestablish or simulate the normal pattern of pulmonary hyperinflation. Airway patency is maintained and atelectasis prevented and/or reversed if the procedure is performed on a repeat basis. It is not effective unless performed as ordered, so that proper teaching is mandatory. I.S. is used in post-surgical procedures, especially those involving the thorax or upper abdomen; or condi-

tions that portend atelectasis, as in immobility, abdominal binders, and less than optimal **pain** control.

- **Selection of aerosol delivery devices**—for delivery of aerosol to the lower airways. Devices include metered dose inhalers (MDIs), dry powder inhalers, and nebulizers. Drugs used in delivery include beta-adrenergic agents, anticholinergics, anti-inflammatory agents, and mucokinetics. For maximum success, the technique is important—for instance, coordination, breathing pattern, and inspiratory hold. Patient compliance may be a limiting factor in the procedure.
- **Arterial blood gases (ABGs)**—for arterial **blood gas analysis**. Blood is drawn from a peripheral artery (radial, brachial, femoral) via a single percutaneous needle puncture or from an indwelling arterial cannula, for a direct measurement of partial pressures of carbon dioxide (PaCO₂) and oxygen (PaO₂), hydrogen ion activity (pH), total hemoglobin (Hbtot), oxyhemoglobin saturation (HbO₂). The procedure is performed by trained health care personnel (usually the RT). ABGs are utilized to quantify the patient's response to therapeutic interventions and/or diagnostic evaluation and to monitor disease severity or progression. The sampling of arterial blood must be done according to protocol or test results may be rendered invalid.
- **Nasotracheal suctioning (NTS)**—to remove secretions, blood or vomitus from the trachea, especially if the patient is unable to cough spontaneously to maintain a patent airway. To accomplish NTS, a suction catheter is inserted through the nasal passage and pharynx into the trachea to aspiration secretions or foreign material.
- **Patient-ventilator system checks**—documented evaluation of a mechanical ventilator and of the patient's response to ventilatory support. Objectives of ventilator checks include: evaluating the patient's response to mechanical ventilation; assuring proper operation of the ventilator, that it is functioning properly and alarms are activated; verifying that inspired oxygen concentration is measured with every change in FIO₂ and that ventilator settings comply with physician orders. All of the above are documented in the patient's chart. Clinical observations of the patient's response to ventilation are also charted in narrative form.

In order for respiratory therapy to be effective, RTs have to evaluate, document, and report all of the above procedures so that appropriate action can be taken by other members of the health care team.

Aftercare

Another important part of respiratory therapy is planning and implementing safe and effective care after

discharge from the medical institution. The patient must be successfully transferred from the health care facility to another care site. Patient evaluation involves assessing the patient's current medical condition and ascertaining the type of respiratory care and support needed. Should it be invasive or noninvasive? The patient's physical, functional and psychological ability is assessed, as well as the family's psychosocial condition. The goals of care for the patient and family are also evaluated.

Complications

- Pulse oximetry is usually considered a safe procedure. Device limitations and false-negative results for hypoxemia, though, may lead to inappropriate treatment of the patient. At times, tissue injury at the monitoring site may occur due to misuse of the probe.
- Incentive spirometry. Unless closely supervised, pulse oximetry may be ineffective. It is also inappropriate as a sole treatment for major lung collapse. There may be discomfort secondary to inadequate pain control. Hyperventilation and fatigue may also occur.
- Aerosol delivery devices. Malfunction of the device or improper technique may result in underdosing or overdosing. There may be complications of specific pharmacologic agents; and repeated aerosol exposure may produce asthmatic symptoms in caregivers.
- Arterial blood gases. Dangers encountered during this procedure include air or clotted-blood emboli, introduction of contagion at sampling site and **infection**, hemorrhage, trauma to the vessel, arterial occlusion, pain.
- Nasotracheal suctioning. Mechanical trauma (laceration of nasal turbinates, perforation of pharynx, nasal irritation, mucosal hemorrhage) are hazards of this procedure. Other complications of NTS include hypoxia, cardiac dysrhythmias, hyper- or hypotension, respiratory arrest, coughing, gagging or vomiting, bronchoconstriction, atelectasis, misdirection of catheter, increased intracranial pressure.
- Patient-ventilator system checks. Disconnecting the patient from the ventilator during system checks may result in hypoventilation, hypoxemia, bradycardia, and hypotension.

Health care team roles

Physicians, registered nurses, respiratory therapists, and pulmonologists all work to maintain respiratory health in the patient. Physicians diagnose respiratory illnesses and determine which kinds of therapy will be most effective in alleviating them. Registered nurses monitor

the effects of the therapy on the patient, administer tests, and make recommendations for any needed changes to the therapy program. Respiratory therapists are trained in the use of therapy equipment and are responsible for maintaining the welfare of patients while they are undergoing therapy. Pulmonologists specialize in the study of the heart-lung system and may also recommend or adjust therapy.

Respiratory therapy apparatus

Definition

Respiratory therapy apparatus refers to a group of different inhalation devices and equipment used to treat a variety of respiratory ailments.

Purpose

Respiratory therapy apparatus is used to aid a patient's breathing or heal damage to a patient's **lungs** and bronchial tubes due to **infection** and disease.

Description

Simply put, respiratory therapists help patients breathe better. Patients may have mechanical difficulties

A therapist helps a patient with his respiratory therapy.
(Photograph by Will & Deni McIntyre. Science Source/Photo Researchers. Reproduced by permission.)

within the lungs and trachea that make it difficult to get enough oxygen. Often these instances are life-threatening and must be treated immediately. Obstructions (e.g. a child swallowing an object) and injury (automobile accidents, **sports injuries**, natural disasters, etc.) are common situations in which breathing assistance is necessary. In these cases, intubation (the insertion of a tube into the trachea) is necessary to open the airway so that oxygen can be administered. **Ventilators** regulate the amount of oxygen that the patient receives and even how often the patient breathes. Disease and atrophy of the lungs may require the use of a ventilator to help a patient breathe.

Premature infants and some other newborns may not have lungs that are mature enough to allow them to breathe on their own. Oxygen is often administered as a life-support measure. In some cases, oxygen is given to ease the burden on the lungs until the baby is strong enough to breathe on its own.

Some patients may be suffering from chronic obstructive pulmonary disease (COPD), a group of diseases that affect the lungs, which includes **emphysema**, bronchitis, and **asthma**. Other patients may have **cystic fibrosis**, **lung cancer**, **pneumonia**, or **AIDS**. In these

cases, the respiratory therapist may administer medications through an inhaler or a hand-held nebulizer.

Other patients may have **heart** disease. The therapist may administer oxygen and also provide rehabilitation devices and techniques to increase lung capacity.

Nebulizers and inhalers

Nebulizers and inhalers provide medications in a fine mist that the patient breathes. Inhalers provide metered doses of medication and come prepackaged. They are portable and can be tucked into a pocket or handbag. So-called “rescue” inhalers are often carried by people with asthma and used when they have an episode. Special dry powder inhalers provide medications that do not work well in liquid form. These inhalers deliver the medication in fine, dry particles that are inhaled.

Metered-dose inhalers dispense specific medications and can be grouped according to type of medication. They are usually bronchodilators, inhaled steroids, cromolyn, nedrocromil, and ipratropium bromide.

Nebulizers are hand-held machines with an airflow meter that measures oxygen flow. These machines administer a variety of medications. The respiratory therapist must prepare a mixture of medication and saline solution according to the physician’s written order. Nebulizers vaporize this mixture and deliver it as a fine mist or steam. Nebulizers are usually used in the hospital or nursing home setting. Disposable nebulizers are often sent home with a patient and are cleaned and reused for a limited time. There are three types of nebulizers: large-volume, small-volume, and ultrasonic.

Intubation catheters and ventilators

Intubation catheters are inserted into the airway and fill the lungs with oxygen at a specific respiratory rate. Ventilators provide mechanical breathing through the catheters and are said to “breathe” for the patient. The amount of oxygen can be varied as well as the breathing rate.

Oxygen masks, nasal cannulas, and oxygen tanks

Oxygen masks, nasal cannulas, and oxygen tanks provide **oxygen therapy** and assistance in maintaining specific oxygen levels within the lungs. Oxygen masks fit over the mouth and nose, whereas cannulas are thin tubes inserted into the nasal openings. Tubing connects the mask or cannula to the oxygen tank from which oxygen is delivered.

Oxygen masks come in a variety of sizes. There are very small ones used to fit premature infants faces. Adult-size masks come in small, medium, and large.

Masks usually provide high flow and a high concentration of oxygen within a range to the patient. Ventilator masks come with a series of different adaptors that allow a specific percentage of oxygen flow. These adaptors are preset and can be installed on the mask to provide oxygen at a specific rate (e.g. 50% oxygen).

Nasal cannulas provide low flow and a lower concentration of oxygen. Cannulas deliver oxygen within a range. These are usually used in home health situations because of their ease of use.

Operation

The respiratory therapist will need to make sure that the equipment is running efficiently and that the medication formula is properly mixed. Masks must be of the correct size and must fit the patient snugly. Since therapy often involves patient cooperation, the therapist should instruct conscious patients clearly about the procedure and what is expected of them during treatment. For example, when using inhalers, the patient should be instructed in creating a tight seal around the inhaler nozzle with the lips and to hold the inhalation for a few seconds.

For unconscious patients, the therapist will need to make sure oxygen masks fit properly, or that intubation and ventilation is done correctly.

Maintenance

Most respiratory therapy devices are one-use only and disposable. Only in the case of pocket inhalers and take-home nebulizers does the therapist need to instruct the patient in proper cleaning of the devices. Inhalers often need just rinsing with soap and water and drying after use. Nebulizers will need to be cleaned with distilled water and vinegar, or other approved disinfectant solution. Even in hospital settings, nebulizers are changed every day, though they may be reused several times during that day. Some nebulizers may be cleaned by running them through a cycle in a dishwasher, but the therapist should check with the manufacturer first.

Intubation catheters need to be as sterile as possible in order to prevent infection or sepsis. Therefore, they are one-use disposable products.

Nebulizers will need to be inspected for wear to insure their proper working. Machines with an air compressor or motor often have air filters; these filters will need to be replaced regularly.

KEY TERMS

Bronchodilators—Medications that expand the bronchial tubes so that patients can breathe better.

Intubation—The insertion of a tube into the trachea.

Nasal cannula—A tube placed inside the nostrils to bring oxygen to the patient's lungs.

Nebulizer—A hand-held device that distributes medication to the lungs via a steam or mist derived from a mixture of medication and saline solution. The respiratory therapist prepares the mix per the physician's written order.

Trachea—Windpipe; the airway by which oxygen passes to the lungs and carbon dioxide is expelled out of the body.

Health care team roles

The respiratory therapist is a member of a large medical team that treats a patient's specific diseases and injuries; and can work in hospitals, **nursing homes**, outpatient clinics, physicians' offices, and in homes. Since respiratory therapy requires trust and cooperation from the patient, the therapist will need to be able to instruct patients clearly and in a friendly manner. The therapist will also need to be adaptable and able to deal with a variety of people across a wide age range.

The respiratory therapist is responsible for maintaining the respiratory therapy equipment, cleaning it if necessary, and requisitioning parts and apparatus (masks, catheters, etc.). The therapist also administers treatment via this equipment and monitors patient performance and response.

Training

Formal training and licensure by the state in which the therapist works is necessary for this profession. Training programs graduate registered or certified respiratory therapists. The Committee on Accreditation for Respiratory Care identified 327 registered programs and 134 certified programs in 1999. Registered respiratory therapists usually study for two years and earn an associate degree, though some receive a bachelor's degree after four years of course work. Respiratory therapists take courses in physiology and anatomy, chemistry, microbiology, physics, and mathematics. They are also trained in the use and maintenance of respiratory therapy apparatus. Apart from formal education, many therapists are receive-

ing additional on-the-job training to administer **stress** tests and electrocardiograms, or draw **blood**.

Restorative dental materials

Definition

Restorative dental materials are substances that are used to repair, replace, or enhance a patient's teeth. These materials include metals, porcelains, and composite resins (often made from plastics).

Purpose

Restorative dental materials are used to create fillings, bridges, crowns, and inlays in order to restore a tooth's appearance, structure, or function.

Description

The end of the twentieth century witnessed a dramatic decline in **dental caries** and an increased interest in dental health and enhancement. Smaller cavities are being discovered in the general population and in children, with over half of those aged five to 17 having no tooth decay at all. At the other end of the spectrum, older Americans are retaining more and more of their natural teeth and are beginning to seek out dentists for restorative work.

Visits to prosthodontists (dentists who specialize in mouth reconstructions, such as crowns, fixed bridges, dentures, and implants) and cosmetic or esthetic dentists (those who repair and enhance teeth through whitening, veneer application, or attachment of permanent restora-

tions) increased from the 1990s into the twenty-first century. An American Dental Association (ADA) survey in 2000 indicated that 84% of responding dentists reported offering some form of cosmetic services to their patients.

In 2001, dentists have more tools with which to diagnose a patient's unique problems, and they are able to find more creative, conservative solutions for them. The dentistry of the 1970s provided limited options. A patient had a tooth filled or extracted, had teeth straightened with braces, or had a crown or bridge installed. Often, the crown cracked and had to be replaced, or the bridge that was fitted was a plastic tooth set in a maze of wires.

Thirty years later, dentists can whiten teeth, alter their shape, fill gaps between them, or build up a tooth that is cracked. Dentists can fill a cavity with a tooth-colored filling that appears invisible to the naked eye. They can replace a missing tooth with a porcelain bridge or a resin implant. Even crooked teeth can be greatly improved with veneers and bonding or invisible plastic braces.

Cosmetic dentists and prosthodontists create restorations in order to repair, replace, or enhance a patient's tooth or teeth.

Restoration types

All restorations perform one of three main functions. They repair, replace, or enhance. Among the types of restorations that repair are fillings. These are used to restore tooth damage that occurs as a result of dental caries (tooth decay). Metal amalgams or composite resins are used to fill cavities and restore the function and esthetics of a tooth. Inlays and crowns, used to repair damage to the teeth, replace tooth structure lost to decay or injury, protect what remains, and restore the tooth's shape and function. Inlays are more durable than amalgam fillings.

Crowns may be necessary when a tooth cracks, has its entire structure weakened by decay, or becomes brittle after a root canal. Crowns can also cover dental implants or abutment (adjacent) teeth when fitting a bridge.

Bonding and contouring

Bonding is a low-cost alternative to crowns or veneers. A tooth-colored composite resin is molded over the tooth, exposed to a special light, and then polished. It is used to restore chipped or slightly ill-shaped teeth. It is less durable and subject to chipping. Bonding is also limited to areas of the mouth that do not experience strong chewing forces, such as the front teeth.

Contouring is done to correct the shape of a tooth. This is mainly an extractive procedure because small amounts of tooth enamel are removed. This technique can be combined with bonding or veneer application.

Restorations that replace

BRIDGES. Bridges fill in a gap left by missing teeth, preventing the remaining teeth from shifting and providing a more stable surface for chewing. Bridges consist of a metal framework and one or more artificial teeth anchored to adjacent teeth (abutment teeth). Sometimes, a two-implant bridge is required. It is then cemented into place.

IMPLANTS, DENTURES, AND PARTIAL DENTURES. Implants, dentures, and partial dentures also replace missing teeth. Individual artificial teeth may be implanted or inserted into the patient's jaw. Partial dentures are dental appliances that have more than one artificial tooth inserted into a metal framework. They are usually removable and can be designed for one or both sides of the mouth.

Restorations that enhance

Crowns are used less frequently to enhance stained or damaged teeth. Newer techniques, such as bleaching or veneer application, are less invasive, save more original tooth structure, and cost less than crowns.

Veneers are ultra-thin coatings used to close gaps between teeth or cover discolored teeth. They are also used to fill in spaces between teeth, repair broken or chipped teeth, and straighten out misshapen or crooked teeth.

Materials used in fillings

The dentist cleans out the decayed part of the tooth and fills the opening with an artificial material (a filling) to protect the tooth's structure and restore the beauty and utility of the tooth.

METALS. The most common and strongest filling material is amalgam. It is a silver filling that is usually placed on the rear molars, which endure more stress during chewing. Amalgam fillings are strong and very resistant to wear, and are used for large, deep fillings. Amalgam has been in use since 1833. It is a mixture (an amalgam) of several metals, including liquid mercury (35% silver, 15% tin or tin and **copper**, 50% mercury, and a trace of **zinc**). When it is prepared, it has a malleable consistency that can easily be shaped to fit the prepared tooth. It hardens to a durable metal.

Despite its durability, many dentists and patients avoid using amalgam fillings. They have found that

amalgam has a tendency to expand with time. As a result, teeth become fractured from the inside and often split. Patients are not choosing amalgam, but this is strictly for aesthetic reasons. They darken over time and make teeth decayed. There has also been a question about the safety of amalgam since it contains mercury; also the ADA has maintained that it is safe to use as a restorative material.

Gold fillings or inlays are created outside of the mouth by a dental technician, then cemented into place. They are also used to fill the back molars and are very durable. Like amalgam, however, they are not as aesthetically pleasing as tooth-colored fillings. Still, gold has been a good source for foundation materials for porcelain over metal crowns.

Alloys of palladium, nickel, or chromium are frequently used for inlays and overlays, as well as for some base material for porcelain over metal crowns. In 2001, palladium is the metal of choice for porcelain-to-metal reconstructions. It is strong and generates fewer allergic reactions. Low-fusing porcelain allows lab technicians to add onto existing restorations.

PORCELAINS. Implants, partial dentures, dentures, crowns, and veneers are usually made from porcelain. Thin veneers made from porcelain are quite durable. All-porcelain products in the twenty-first century tend to fracture less than those of the past. Some crowns and implants are made with porcelain-covered metals. They are extremely durable, but sometimes recede from the gums, exposing the metals. Porcelain-over-gold crowns often have a golden glow that is caused by the metal beneath. This glow creates a more aesthetically pleasing crown, but it is more expensive than a crown made of other materials.

When inlays are required for teeth exposed by a smile, tooth-colored composites and porcelains are used. Reinforced porcelain and lucite porcelain are durable, but still may not be suitable for patients who grind their teeth because metal fillings withstand the stress of grinding better.

COMPOSITE RESIN. Composite fillings, often called white fillings, are made of a plastic resin and finely ground glass. They must be applied to the tooth surface in thin layers. Dentists try to match the color of composites with neighboring teeth for a more natural look, making the fillings appear invisible. Composite resin fillings are often made smaller than amalgam fillings and require less tooth preparation, thereby saving more natural tooth surface.

The composite filling is bonded to the tooth so that the tooth becomes stronger than it was before. A composite filling is also less sensitive to temperature changes in the mouth, which can damage the tooth. Thus, there is

KEY TERMS

Abutment tooth—A crowned tooth that stabilizes a bridge or partial denture.

Amalgam—A mixture of metals, primarily mercury and silver, used to make large, durable fillings. Also called silver fillings.

Composite filling—A resin material that is tooth colored and used to fill a tooth after decay has been removed. It is used most often in front teeth, but may be used in any tooth for aesthetic reasons.

Crown—A protective shell that fits over the tooth.

Denture—A dental prosthetic device consisting of a full set of teeth to fill the upper or lower jaw or both. Also called false teeth.

Enamel—The hard outermost surface of a tooth.

Impression—An exact copy of the teeth and mouth using materials that will set sufficiently so that a more durable cast of the mouth can be made from plaster, dental stone, or other casting materials.

Inlay—A filling that is made outside the tooth and then cemented into place.

Onlay—A restoration like an inlay that wraps over the crown and sides of a tooth.

Partial dentures—A dental prosthetic of two or more teeth used to replace missing teeth.

Porcelain—A strong, translucent ceramic material.

Prosthodontist—A dentist who specializes in such mouth reconstructions as crowns, fixed bridges, dentures, and implants.

Restoration—Any prosthetic device or process used to replace or improve the structure or appearance of a tooth or teeth.

less chance that the tooth will shatter because of the filling.

The major drawback of the composite resin filling is cost. The average cost is 1.5 to 2 times greater than the price of an amalgam filling. The composite resin filling can be stained by coffee and tea. Further, the large composite filling tends to wear out sooner than the large amalgam filling. However, the composite combined with porcelain is an excellent material for thin veneers. Finally, the light-cured composite's flexibility allows restorations to be repaired directly in the mouth. They are not abrasive and feel much like a natural tooth.

Operation

Crowns

The dentist first removes the decayed portion of the tooth. The tooth is then prepared for a crown. It may be tapered on the outside edges to a peg, reinforced with a cast metal core, or rebuilt with both a cast metal core and a post. An impression is made of the prepared tooth and its adjacent teeth. A retraction cord is placed around the tooth to get the impression medium under the gum, where the crown will be fitted.

A new crown will be created by the dental technician, who will use a cast made from this impression. The technique the technician uses is called lost-wax casting. A wax model is made of the crown. Another mold is made around the wax model and both are fired in a kiln. The wax melts, leaving an opening into which a restorative material can be poured. The crown may be made of gold or stainless steel alone; metal with a veneer of tooth-colored porcelain or resin; or of porcelain or resin alone. The finished crown is then placed over the prepared tooth, adjusted, and cemented into place.

When a tooth has had a root canal procedure and the root has been filled, the tooth may not be strong. In these cases, post crowns are used. The tooth is leveled at the gum line and a stainless steel or gold post is fitted into the root canal. This post can then receive the new crown and hold it in place.

For other patients, it may be necessary to implant the crown. In this case, a steel post is embedded in the patient's jawbone. It is left in place until the bone adheres to the post. The post is exposed and the crown is made and fitted.

Inlays

After the decay is removed and the cavity walls are shaped, the dentist makes a wax pattern of the space. A mold is cast from the wax pattern. An inlay is made from this mold and sealed into the tooth with dental cement.

When a restoration is cemented in place, the dentist and the dental assistant clean off all uncured restorative materials left on the tooth. Pumice or another mild abrasive is more effective in removing leftover materials than air or water spray, or even a roll of cotton.

Partial dentures, dentures, and implants

Partial dentures, dentures, implants, and veneers are created in much the same way as crowns and inlays. Teeth may already be absent, or they may need to be extracted. Impressions of the patient's mouth are taken and restorations are created from a variety of materials in

a dental laboratory. The final product is fitted and/or cemented into place at the dentist's office. For a veneer, the tooth is etched and a strong bonding agent is applied. The veneer is then cemented to the tooth.

Bonding

For bonding, thin layers of enamel are removed. The bonding material is laid over the tooth and shaped. It is cured with a special light and then polished.

Maintenance

Restoration materials are durable. Composite and amalgam fillings can last seven to ten years. They should be maintained with good **oral hygiene** and replaced as necessary. Some of the composite resins are sensitive to staining from coffee and tea. Amalgam fillings have a tendency to expand over time. As a result, teeth become fractured from the inside, and they often split. When a fracture occurs, a crown is needed. Unfortunately, amalgam fillings also darken over time and make teeth look as if they are decayed.

Cracks can occur in materials used for dentures and partial dentures, but far less frequently in older porcelain materials.

Composite resins are used to bond teeth, but they may not stand up to the patient who eats hard candy, popcorn kernels, or ice. They may require repair or touch-ups. Porcelain—a strong, translucent ceramic material—is used to make veneers, which can change the shape of teeth and fill in unsightly gaps. Porcelain veneers can become chipped or otherwise damaged, and may need to be replaced every five to twelve years.

Health care team roles

Dentists are assisted by dental assistants, who prepare patients for prosthodontic procedures. These usually involve taking x rays, making impressions of patients' teeth, making casts from the impressions, preparing restorative materials, and assisting the dentist in installing dental **prosthetics** or applying restorative materials. Cleaning and disinfecting of instruments and the treatment area are also the responsibility of the dental assistant. They take an active role in educating patients about the care and maintenance of their restorations, and instruct patients in proper aftercare, especially if there has been some invasive procedure (such as extraction or surgery). Dental assistants must be well trained in the preparation of dental materials and their applications, and must also have good communication skills, as they need to instruct patients and have the ability to reassure those who may be uncomfortable in a dentist's office.

In the laboratory, dental technicians are responsible for the creation of dental prosthetics. They must possess excellent manual dexterity and some creative skill. With recent advances in digital dentistry, the technician will require computer skills as well as manual ones.

Restraint use

Definition

A restraint, or physical restraint, is a piece of equipment or device that restricts a patient's ability to move. Restraints may keep a patient from getting out of bed or moving arms and legs excessively.

Proper use of restraints helps patients avoid harming themselves or others. (Delmar Publishers, Inc. Reproduced by permission.)

Purpose

Restraints are used to control a patient who is in danger of harming the self or others. It is sometimes necessary to restrain children who may not be capable of remaining still when they are frightened or in **pain** during some procedures. The use of physical restraints in the health care arena should be used as a last-resort option.

Precautions

Many safety measures should be considered before applying restraints. According to federal law, first and foremost is the need to try other methods to promote safety and avoid the use of physical restraints. Some examples of alternative methods are patient reorientation to physical surroundings; discussion with family and friends about staying with the patient; moving the patient's room nearer to staff members; teaching **relaxation** techniques in order to decrease **anxiety** and fear; and decreasing overstimulation. Documentation of these methods is extremely important.

Description

Several types of medical manufacturers have different names for the same types of physical restraints. The most common names and types of physical restraints are:

- soft wrist and ankle restraints
- strap fastening vest (posey jacket)
- seat belt with buckle (restraint belt)
- mittens (restraint mitts)
- leather wrist and ankle restraints

The most common reasons for the use of physical restraints are:

- When a confused patient roams through the health care facility endangering him/herself.
- When a confused patient tries to remove medically necessary tubes, intravenous lines, or protective dressings.
- When a patient has an unsteady gait (walk) and is at risk for falls.
- When a patient needs to be kept from inflicting self-harm or injury (suicidal).
- When a patient needs to be kept from inflicting harm upon health care workers, other patients, and/or visitors (homicidal).
- When a professional is performing minor surgical procedures on a child that is not able to remain still.

Preparation

Before restraint application, the health care provider should be familiar with the restraint device that will be used. Also, if a patient is violent, a five-person team is optimal for the restraining process. Each person will be responsible for one extremity, with the fifth person supervising and positioning the patient's head.

Each restraint device will have different directions for application. However, there are some universal standards for proper application. When using any type of restraining device, it is extremely important to tie or lock the restraint to the bed frame and not the bed rails, thus allowing for proper movement. With soft restraints, posey jackets, and restraint belts, a quick-release slipknot should be used to allow immediate release if needed. When leather restraints are used and applied to both arms and legs, one arm should be positioned above the patient's head while the other is positioned by the patient's side. This will decrease the possibility of the patient's rocking or tipping over the bed.

Aftercare

The nurse has to reassess restraints at least every 30 minutes. Neurovascular assessment (circulation to hands, fingers, feet, toes); skin assessment (bruising of restrained area); and meeting a patient's activities of daily living such as toileting, eating, and drinking are all aspects of restraint reassessment and care. Documentation of these interventions must be clearly identified on the patient's chart.

Complications

Most common restraint complications include:

- accidental or intentional removal of restraints by patient, family, or staff, resulting in possible removal of tubes, intravenous lines, injury to patient or others
- injury to restrained extremity (arm or leg)
- fracture or muscle strains during application with violent patient
- dislocation or contusion of extremity
- exposure to blood or body fluid while restraining violent patient (biting, spitting, urinating, etc.)
- numbness and/or tingling in restrained extremity

Results

The end results of using physical restraints are the maintenance of safety to the patient and others and the administration of medically necessary interventions.

Health care team roles

The **registered nurse (RN)** or **licensed practical nurse (LPN)** has a tremendous responsibility when caring for a patient in physical restraints. Many times restraints are needed immediately and violent attacks on health care workers can happen. The emphasis on proper documentation of alternative methods is an absolute must. Obtaining a physician's order for physical restraints is a top priority as well. Rationale for the application of restraints must be discussed with the patient and family. Adequate explanation of the interference with medical treatment or the diversion of suicidal or homicidal acts is important. Reassessment of proper restraint positioning and re-evaluation of the patient's continued need for physical restraints are also aspects of complete nursing care.

Paramedics and **emergency medical technicians (EMTs)** are confronted with the need to use physical restraints in the field (outside of the hospital). In these cases, they are allowed to use a "reasonable amount of

Retinopathies

Definition

The retinopathies are a group of retinal diseases that cause vascular and neurological changes in the retina of the eye. They are reflective of such ongoing systemic diseases as diabetes, arteriosclerosis, **hypertension**, and sickle cell anemia.

Description

The retina is an outward extension of the **central nervous system** that lines the inside of the eye. It has 10 layers and is comprised of the photoreceptor rods and cones and such support cells as Mueller cells. The retinal pigment epithelium (RPE) is a single cell layer located behind the retina, which services the photoreceptors. Bruch's membrane is a basement membrane found between the RPE and the choroid, a highly vascular layer that includes the choriocapillaris, which supplies nutrients to the RPE and to the photoreceptors. The central retinal artery and its branches supply **blood** to the rest of the retina. The cilio-retinal artery that emerges from the optic nerve supplies the macula. The macula is located temporal to the optic nerve and is the part of the retina that contains the highest concentration of photoreceptors, especially cones. The part of the macula with the highest concentration of cones is the fovea. The vitreous humor is a gelatinous body that is located between the retina and the lens of the eye. The optic nerve is a large nerve in the posterior part of the eye through which the central artery and vein pass. It is actually formed from the axons of cells in the retina. It is through the optic nerve that visual stimuli leave the eye for the occipital lobe of the **brain**, where **vision** is processed. Hemoglobin is a molecule in red blood cells responsible for the transport of oxygen.

The presentation and pathogenesis of each of these retinal diseases are unique; and the signs can be seen by an ophthalmologist or an optometrist upon dilation of the eye. All of these retinopathies can lead to blindness.

Causes and symptoms

Diabetic retinopathy

Diabetic retinopathy is the leading cause of blindness in the United States for people between 20 and 74 years of age. Risk factors for diabetic retinopathy include hypertension, elevated HgA1C (a **hemoglobin test**), a history of smoking, and number of years as a diabetic. Within 10 years of diagnosis, over 70% of type I diabetics will have some retinopathy, and within 16 years diagnosis, 60% of type II diabetics will have retinopathy. A

diabetic may have normal vision, yet still have severe retinopathy.

The underlying pathogenesis of diabetic retinopathy is hypoxia, a decreased oxygen supply that is caused by elevated blood sugar or hyperglycemia. Glucose is needed in the cells of the body for energy, and oxygen and insulin are required for entry of the glucose molecules. The diabetic, because of insufficient insulin or because of cellular resistance to insulin, cannot absorb glucose into the cell effectively. The pathologic response of the retina to a decreased oxygen supply is first a thickening of, and then a breakdown of the retinal capillary basement membrane. Pericytes, cells that surround the capillaries and produce an inhibitor for angiogenesis, also degenerate. In the absence of this inhibitor, retinal neovascularization, or new vessel formation, is stimulated by vascular endothelial growth factor (VEGF). The new vessels that form are very fragile and can easily rupture, causing bleeding in the vitreous and subsequently leading to vitreous traction. Degeneration of retinal neural cells precedes the vascular changes of diabetic retinopathy.

Diabetic retinopathy is a condition that initially affects only the posterior pole of the retina. The peripheral retina is affected only in the extreme cases. Diabetic retinopathy is divided into two phases: nonproliferative and proliferative. In the nonproliferative phase the retina has microaneurysms, dot and blot hemorrhages, hard lipid exudates, a beading pattern of some of the venules, areas of local ischemia where there is little or no oxygen perfusion (called cotton-wool spots), or macular **edema**. The macular edema is called clinically significant macula (CSME) when there are hard exudates and macular thickening or edema, close to the fovea. In the proliferative phase of diabetic retinopathy, neovascularization of the retina and of the optic nerve can be observed. A fibrous substance that materializes when the new retinal vessels form adheres to the vitreous, causing retinal traction and retinal detachments. The newly formed **blood vessels** can invade the anterior part of the eye, causing neovascular **glaucoma**. Vitreous hemorrhaging occurs when the blood vessels attach to the vitreous. Venous and arterial occlusions are also seen in diabetic retinopathy.

Arteriosclerotic retinopathy

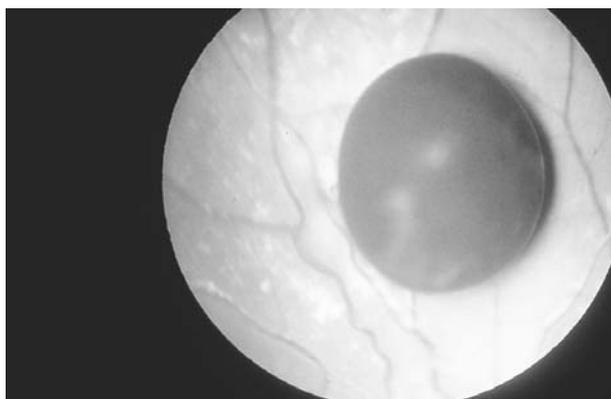

Arteriosclerotic retinopathy is the ocular manifestation of arteriosclerosis, a systemic condition in which the arterial walls thicken and harden. The risk factors for arteriosclerotic retinopathy include **heart** disease and elevated serum cholesterol. Arteriosclerotic retinopathy can be involved in hypertensive retinopathy. One of the first ophthalmoscopic signs of arteriosclerotic retinopathy is an increased arterial reflex due to thickening of the

retinal arterial walls. As the arteriosclerosis progresses, the vessels undergo color changes to a copper-wire and then to a silver-wire appearance. Arteriovenous or A-V crossing defects are also synonymous with arteriosclerotic retinopathy. In advanced arteriosclerosis, banking—a type of A-V crossing that completely cuts off distal venous circulation, forming a large dilated vein—occurs.

Arterial occlusion can occur as a result of arteriosclerotic retinopathy. An embolus from the carotid artery or from the aortic arch of the heart can travel to the retina, occluding either the central retinal artery (CRAO) or one of its branches (BRAO). An embolus from the carotid artery usually is a cholesterol plaque; and that from the heart is usually fibrotic in appearance. Immediately after a CRAO, the retina becomes ischemic and then edematous. Due to the surrounding ischemia, the fovea takes on a characteristic cherry-red appearance. A pupil abnormality, called an afferent pupillary defect (APD), may be noted. The vision loss in a CRAO is severe, sudden and painless, although the patient may have a history of amaurosis fugax. After resolution of the CRAO the retina takes on a normal appearance, but the retinal blood vessels are narrowed and the optic nerve shows pallor. Macular function will be intact if there is cilioretinal circulation. Patients with a BRAO may be asymptomatic if there is no macular involvement, but usually there is field loss in the affected quadrant as well as decreased visual acuity.

Hypertensive retinopathy

Hypertensive retinopathy is an ocular presentation of the effects of systemic hypertension, defined as systolic pressure over 140 mm/Hg and diastolic pressure over 90 mm/Hg. This type of retinopathy is usually bilateral. There is narrowing of retinal arterioles in systemic hypertension. Constriction of vessels in older hypertensive patients may not be observed because of involutational sclerosis of the arteries, which occurs during aging. When the integrity of the retinal vessels is compromised because of long-term hypertension, leakage of blood occurs; and flame-shaped hemorrhages, characteristic of hypertensive retinopathy can be observed in the retina. Also, a star-shaped pattern of exudation appears in the macula. In the advanced stages of hypertensive retinopathy there will be cotton-wool spots close to the optic nerve. In malignant hypertension the optic nerve will become swollen and the patient will often experience blurred vision; and, if the **blood pressure** is extremely elevated, encephalopathy can develop.

A close-up view of a human eye following retinal hemorrhage. (Custom Medical Stock Photo. Reproduced by permission.)

Retinal vein occlusions

Retinal vein occlusions block the drainage of the retina. They can be either central (CRVO) or branched (BRVO). They are usually seen in older patients who have arteriosclerosis, hypertension or diabetes. Vein occlusions can also strike patients with sickle-cell anemia. Papillophlebitis is a form of retinal vein occlusion that is inflammatory in nature and seen in younger patients. A hemi-central vein occlusion is similar to a CRVO, but affects only one-half of the retina. A CRVO occurs when the central retinal artery compresses the central vein as it leaves the lamina cribosa. A BRVO occurs when there is constriction of a venule by a sclerotic artery that affects only one quadrant, usually the superior temporal one.

A CRVO can be either ischemic (characterized by decreased blood flow) or nonischemic. Approximately 80% of CRVO events are nonischemic. In the nonischemic CRVO, hemorrhages are evident throughout the retina, but usually there are no cotton-wool spots. The optic nerve swelling is usually mild and macular edema is not always present. The visual acuity may be only mildly reduced. Months after such an occlusion, collateral blood vessels may appear on the optic nerve. Up to 20% of individuals with a nonischemic CRVO may progress to an ischemic event. The hallmark of ischemic CRVO is extensive capillary nonperfusion. Ophthalmoscopic examination following an ischemic event reveals extensive venous tortuosity and enlargement of the retinal veins. Edema of the macula and optic nerve are always present and cotton-wool spots are common. Visual acuity is usually less than 20/200. Neovascularization of the iris and neovascular glaucoma are common complications of CRVO. There can be optic nerve neovascularization, bleeding into the vitreous, and vitreal traction, which

KEY TERMS

Exudation—Leakage of cells, proteins, and fluids through the blood vessel wall into the surrounding tissue.

Ischemia—Lack of blood supply to a tissue or organ.

Neovascularization—Formation of new blood vessels.

Proliferative retinopathy—Retinopathy with neovascularization.

increases the risk of a retinal detachment. The signs of a BRAO are similar, but present in just one quadrant.

Sickle-cell retinopathy

The underlying cause of sickle-cell retinopathy is different from that of the other retinopathies. Sickle-cell anemia is a genetically inherited condition, seen primarily in persons of African descent. Close to 10% of African Americans carry one of the sickle-cell traits. Sickle-cell anemia is caused by mutant hemoglobin molecules which form either because of an amino acid substitution of valine for glutamic acid, causing a structural defect in the hemoglobin molecule, or because of a deficiency in the synthesis of one of the hemoglobin peptide chains. A normal red blood cell has a biconcave appearance and can easily pass through the capillary bed. A “sickle” cell does not have this biconcave shape, is less pliable than a normal red blood cell, and thus does not move well through the capillaries, triggering retinal microvascular occlusions and then ischemia.

Sickle-cell retinopathy can be non-proliferative or proliferative and affects primarily the peripheral retina. In the nonproliferative stage the retinal vessel walls begin to deteriorate. The ophthalmoscopic signs of non-proliferative sickle-cell retinopathy include: venous tortuosity; intraretinal “salmon patch” hemorrhages, found near a vessel occlusion; “black sunburst” lesions, that develop when a vascular occlusion damages the RPE; silver-wired arterioles; and breaks in Bruch’s membrane, called angioid streaks. Sickle-cell retinopathy becomes proliferative when neovascularization, in the form of arteriovenous anastomoses or connections between veins and arteries, appears in a sea-shaped formation. These vessels can adhere to the vitreous, but usually regress, forming a characteristic white tuft. Vitreous traction and retinal detachments are not common in sickle-cell retinopathy.

Diagnosis

The ophthalmologist or optometrist uses fluorescein **angiography** to determine the extent of vessel leakage and perfusion in the retinopathies. The fluorescein dye is injected into the body through a vein in the hand. Rarely does a patient have a reaction to the dye, but a localized redness at the injection site is occasionally observed. The fluorescein molecule binds to **proteins** in the blood and it is excited by light of 490 nanometers (blue light). A retinal camera filters the light, such that only blue light enters the eye. Photos taken in rapid succession reveal the extent of perfusion, leakage, and ischemia in the retina. The results of this angiography help the doctor to determine if laser photocoagulation can benefit the patient.

Treatment

In laser treatment of retinopathy, the light energy of the laser is absorbed by certain cells in the retina, destroying them and thus reducing the oxygen demand of the area, while leaving the surrounding tissue intact. Pan-retinal photocoagulation (PRP) treats neovascularization following a BRAO or hemi-retinal arterial occlusion and the neovascularization of the optic nerve in diabetic retinopathy. The macular edema of arterial occlusions and diabetic retinopathy is treated by focal argon photocoagulation. **Laser surgery** is not performed close to the fovea. Often the edema that develops during an arterial occlusion will dissipate without treatment. Laser treatment is not usually beneficial in CRAO. Peripheral scatter photocoagulation treats the neovascularization of sickle-cell retinopathy.

The vitreous hemorrhaging of diabetes and sickle-cell retinopathy may require either a vitrectomy, which is a surgical removal of part or all of the vitreous, or cryopexy, the use of low-temperature probes to kill the blood vessels. Vitrectomy has been especially beneficial in restoring vision in diabetic patients in whom retinopathy has already affected visual acuity.

There is little that can be done to treat a CRAO. Massage of the globe to dislodge the embolus, the use of carbogen to increase blood carbon dioxide levels, and anterior chamber **paracentesis** have all been employed with limited success. Hyperbaric **oxygen therapy** has been successful in treatment of CRAO in one study.

In treatment of the patient with malignant hypertension it is important to slowly lower the blood pressure in order to reduce the risk of ischemic optic neuropathy.

The intraocular pressure must be lowered in the patient with a CRAO.

Nonmedical treatments may include changes in diet and **exercise** regimens.

Prognosis

Except when vitrectomy is performed (when indicated), and once the retinopathies have had an effect on vision, there is little that can be done to restore it. The goal of many of the treatments is to prevent further damage. If the proliferative phases of these retinopathies are treated early enough, normal vision is possible. The prognosis for patients with nonproliferative retinopathy is better than for patients with proliferative disease.

Health care team roles

The role of the allied health professional in diagnosis and treatment of retinopathy is to assist the ophthalmologist or optometrist in diagnosis. Ophthalmic technicians or nurses may instill the drops for dilation of the eye, inject the fluorescein dye used in angiography. The ophthalmic technician or a retinal photographer takes the photos needed for analysis of retinopathy. Dieticians assist diabetics, hypertensives, and those with heart disease.

Prevention

The first line in prevention of the retinopathies is an annual dilated eye exam performed by an ophthalmologist or an optometrist. Patients with systemic disease that can cause retinopathy must understand the ocular complications of their disease and the consequences if medical therapy is not followed as recommended by a physician.

Depending on the type of retinopathy, other preventive measures need to be taken. All patients with retinal emboli need a cardiac workup, including analysis of blood lipid levels. This is the case even in the absence of an occlusion. Older patients need testing for temporal arteritis once CRAO is detected. Over 65% of patients with temporal arteritis will have a CRAO in the fellow eye within days of the initial event. Since 70% of patients with BRAO have hypertension, all patients with such occlusions need to be evaluated for hypertension. Since sickle-cell anemia can cause a BRVO, African Americans need a Sickledex test. In the event of unilateral hypertensive retinopathy, a carotid artery obstruction should be suspected and a carotid workup is imperative. Finally, the best prevention of the retinopathies is management of the underlying systemic diseases.

Retrograde cystography

Definition

A retrograde cystogram is a radiographic study of the bladder, made after a direct injection of a radiopaque contrast material by means of a urethral catheter.

Purpose

A retrograde cystogram is performed to evaluate the structure of the bladder and identify such bladder disor-

KEY TERMS

Bladder—A balloon-like organ located in the lower pelvis that stores urine.

Catheter—A thin tube used to inject fluids into or withdraw fluids from the body.

Fluoroscope—An under-table x-ray tube used in conjunction with a television monitor that allows immediate visualization of the x-ray image.

Hematuria—The presence of blood in the urine.

Stones—Also known as calculi, stones result from an excessive build-up of mineral crystals in the kidney. Symptoms of stones include intense pain in the lower back or abdomen, urinary tract infection, fever, burning sensation on urination, and/or blood in the urine.

Ureter—The tube that carries urine from the kidney to the bladder.

Urethra—The tube that empties urine from the bladder to the outside of the body.

ders as cystitis, polyps, stones, and tumors. It may also be used to diagnose recurrent urinary tract infections due to urine reflux (backward flow) into the ureters. This examination is commonly performed as an emergency procedure on patients with gross hematuria (**blood** in urine) due to a pelvic fracture or severe trauma to the abdomen, in order to detect rupture of the bladder. Retrograde cystography is frequently done on children being evaluated for a congenital abnormality, obstruction, or urethral stricture. When the urethra is also being evaluated, the study is called a cystourethrogram. If the bladder or urethra is evaluated while the patient is voiding (urinating), the study is called a voiding cystourethrogram or VCUG. A voiding cystourethrogram is often performed when the bladder is full to check for any reflux or other problems during urination.

Complications

The physician should be alerted to any previous history of an allergic reaction to an iodine-based contrast material. Since the contrast medium is injected directly into the bladder instead of the venous circulation, allergic reactions are extremely rare. A retrograde cystogram should not be performed, however, on patients who have had recent bladder surgery or an obstruction that interferes with the placement of a urinary catheter. Patients

with an active urinary tract **infection** or who may be pregnant should not be given a retrograde cystogram.

Description

To administer a retrograde cystogram, a doctor or nurse will insert a thin tube-like instrument called a Foley catheter through the patient's urethra and into the bladder. The contrast medium is then injected through the catheter into the bladder. The catheter can be inserted in an outpatient clinic before the patient is taken to the radiology department. It may also be inserted by an emergency physician when a retrograde cystogram is ordered on a severe trauma patient. The cystogram can be performed in the emergency department using a portable x-ray machine.

After the Foley catheter is inserted, 250–300 mL of a water-soluble contrast medium is injected into the bladder and the catheter is clamped. A diluted contrast agent (usually 30% sodium iodide) is used since the contrast medium is not injected intravenously. An AP (anteroposterior) view of the full bladder is taken with the tube angled 10–15 degrees caudal (in the direction of the patient's feet) to project the pubic symphysis away from the base of the bladder. The patient is turned 45 degrees onto each side for two oblique views of the bladder and completely sideways for a true lateral view. The films are reviewed by the radiologist. If no other films are needed the catheter will be removed and a post-void film is taken. If the patient is unable to urinate, the clamp will be removed, the contrast medium will then empty from the bladder through the tube, and a post-drainage film will be taken. During a voiding cystogram, films are taken by the radiologist under fluoroscopy while the patient is voiding in order to image any urethral abnormalities or urinary reflux.

A retrograde cystogram usually takes from 30 minutes to one hour, depending on how many films are requested by the radiologist.

This examination can also be performed with a radioactive tracer (isotope) in the nuclear medicine department. A cystogram performed with a tracer is known as a radionuclide retrograde cystogram.

A CT scan of the bladder may also be ordered after the injection of a radiopaque contrast material.

Preparation

Laxatives or **enemas** are sometimes given before the procedure to eliminate gas and fecal material that may prevent proper visualization of the bladder. The patient will be given a hospital gown. The x-ray technologist will explain the procedure and take a detailed

patient history concerning **allergies**, the possibility of **pregnancy**, and current medical problems. The patient is usually requested to sign a consent form.

Aftercare

The patient may have some burning on urination for a few hours after the test, due to the irritation of the urethra from the catheter. The discomfort can be reduced by a liberal fluid intake, which will dilute the urine.

Results

A normal result reveals no anatomical or functional abnormalities of the bladder.

Abnormal results may indicate:

- calculi (stones)
- inflammation (cystitis)
- blood clots
- polyps
- injury (bladder tear)
- diverticula
- cystocele (prolapse of the bladder into the vaginal cavity, common after childbirth)
- ruptures (imaged as flame-like leakages of the contrast material superior or lateral to the bladder)
- tumors (visualized in the bladder or in an adjacent structure such as the vagina or prostate)
- reflux (urine passing backward from the bladder into the ureters, causing infection)

Health care team roles

The procedure is ordered by the physician. The patient may be catheterized by a physician or nurse. The x-ray technologist prepares the contrast medium for injection and takes all the overhead views of the bladder. If the portable x-ray machine is used to perform the cystogram, all staff members remaining in the room must be shielded. The x-ray technologist works closely with the doctors and nurses to make sure the patients are catheterized before arriving in the radiology department and that an enema or laxative has been administered.

Patient education

The x-ray technologist must explain to the patient that it is necessary to fill the bladder completely to see a detailed image of the bladder outline. The patient may experience some discomfort with a full bladder; however, the films are taken at once and the catheter is removed

or unclamped. If a film must be taken while the patient is voiding, the lights can be dimmed and the water tap turned on to help the patient relax. The radiology technologist must be certified and registered with the American Society of Radiologic Technologists.

Rh factor

Definition

Rh (Rhesus) factor is a **blood** protein that plays a critical role in some pregnancies. People without Rh factor are known as Rh negative, while people with the Rh factor are Rh positive. If a woman who is Rh negative is pregnant with a fetus who is Rh positive, her body may make antibodies against the fetus’s blood. This can cause Rh disease in the baby, also known as hemolytic disease of the newborn, or erythroblastosis fetalis. In severe cases, Rh disease leads to **brain** damage and even death. Since 1968 a vaccine has existed to prevent the mother’s body from making antibodies against the fetus’s blood.

Description

Rh factor is an antigen found on the red blood cells of most people. Rh factor, like the blood types A, B, and O, is inherited from one’s parents. A simple blood test can determine blood type, including the presence of the

Rh factor incompatibility. (Delmar Publishers, Inc. Reproduced by permission.)

Rh factor. About 85% of white Americans and 95% of African-Americans are Rh positive. A person's own health is not affected by the presence or absence of Rh factor.

Rh factor is important only during a **pregnancy** in which an Rh negative woman is carrying a fetus who might be Rh positive. This can occur when an Rh negative woman conceives a baby with an Rh positive man. The gene for Rh positive blood is dominant over the gene for Rh negative blood, so their baby will be Rh positive. If the Rh positive father also carries the gene for Rh negative blood, his babies have a 50% chance of inheriting Rh negative blood and a 50% chance of inheriting Rh positive blood. If both parents are Rh negative, their babies will always be Rh negative. In order to protect their future babies from Rh disease, all women of child-bearing age should know their Rh status before becoming pregnant.

Role in human health

Rh factor in pregnancy

The danger of Rh disease begins when the mother's Rh negative blood is exposed to the baby's Rh positive

blood. This mixing of blood can occur at the time of birth, and after an abortion or **miscarriage**. It may also happen during prenatal tests such as **amniocentesis** and **chorionic villus sampling**. More rarely, blood from the mother and fetus may mingle during pregnancy, before birth. When this contact occurs, the mother's body responds by building antibodies to fight the foreign Rh blood protein. The mother's blood is now said to be "sensitized" against Rh factor blood.

Common diseases and disorders

Rh incompatibility

Once a mother's blood has become sensitized, her antibodies will attack the blood of any Rh positive fetus that she carries. The antibodies will destroy the fetus's red blood cells. If this happens, the infant will suffer from Rh factor incompatibility. It will become anemic, a condition caused by a reduction in red blood cells and marked by weakness and fatigue. Severe anemia can lead to **heart failure** and death. The breakdown of red blood cells will also cause the formation of a reddish-yellow substance known as bilirubin. An infant with high levels of bilirubin will look yellowish. This is known as **jaun-**

dice. Brain damage can occur if the bilirubin level gets high enough. However, Rh incompatibility occurs in varying degrees of severity, with brain damage at the far end of a spectrum.

Rh disease is usually not a problem during a first pregnancy. This is because the Rh negative mother probably will not become sensitized until her blood mixes with the baby's blood during birth. Her baby will be born before her blood can produce antibodies against the baby's Rh positive blood. Once a mother is sensitized, however, any future babies with Rh positive blood will be at risk for Rh disease.

PREVENTION AND TREATMENT. Since 1968 a vaccine has existed to prevent sensitization from occurring. This is the best way to eliminate Rh disease. Available as an injection, the vaccine is called Rh immune globulin (brand name RhoGAM). It blocks the action of the antibodies and prevents the mother's blood from attacking the baby's blood. To be effective, the vaccine must be given any time fetal blood mixes with maternal blood: after birth, abortion, miscarriage, or prenatal tests like amniocentesis and chorionic villus sampling. The vaccine is typically given within 72 hours of any of these events. Since mixing of the blood may also occur during the last three months of pregnancy, the vaccine is also administered at 28 weeks of pregnancy.

A pregnant woman who has already been sensitized from a previous pregnancy will want her doctor to carefully monitor the level of antibodies in her blood throughout her pregnancy. As long as the antibody levels remain relatively low, no problem exists. But if those levels rise, the fetus will need special attention. High antibody levels mean that the fetus's red blood cells are being attacked and destroyed.

A fetus whose red blood cells are being destroyed will need a blood transfusion while it is still in the uterus. Two or three transfusions may be necessary before the baby is born. If the fetus shows signs of illness close to its anticipated birth, the physician may elect to deliver the baby early, either by inducing birth or by cesarean section. The baby will then receive a transfusion after birth.

ELIMINATING RH DISEASE. Until the introduction of the Rh immune globulin vaccine, Rh disease could not be prevented. About 45 babies per 10,000 births developed the disease each year before widespread use of the vaccine in the early 1970s. Use of the Rh immune globulin vaccine has reduced the chances of the mother becoming sensitized from approximately 12-13% to 1-2%.

Nevertheless, the disease is not completely eradicated. Further steps must be taken, since this is a preventa-

KEY TERMS

Amniocentesis—A procedure in which a sample of the fluid in the amniotic sac is removed with a needle for genetic testing.

Antigen—A substance, usually a protein or carbohydrate, that stimulates a response from the immune system.

Bilirubin—Reddish-yellow substance formed by the breakdown of red blood cells.

Chorionic villus sampling—A procedure in which a sample of the membrane surrounding the fetus is taken for genetic testing.

Prenatal test—Procedure done to determine the presence of disease or defect in a fetus.

Sensitization—Occurs when a mother's blood produces antibodies against the blood of her Rh positive fetus.

ble disease. The majority of cases of Rh disease are the result of women not receiving the vaccine at the appropriate time. Poor women without health insurance, who are likely to lack adequate **prenatal care**, are especially vulnerable to this oversight. Older women may have become sensitized before the vaccine was available; foreign-born women may not have had access to the vaccine.

Riboflavin

Description

Riboflavin, also known as Vitamin B₂, has many functions in common with the other members of the B complex family. These include support of the immune and nervous systems, and formation of healthy red **blood** cells. Riboflavin provides essential factors for the production of cellular enzymes that turn **proteins, fats, and carbohydrates** into energy. It also participates in cell reproduction, and keeps skin, hair, nails, eyes, and mucous membranes healthy. **Folic acid** (vitamin B₉) and pyridoxine (vitamin B₆) are activated by riboflavin.

General use

The RDA of riboflavin for infants under six months is 0.4 milligrams (mg). It goes up incrementally with age and caloric intake. Babies from six months to one year of age require 0.5 mg. Children need 0.8 mg at one to three years of age, 1.1 mg at four to six years, and 1.2 mg at seven to ten years. Women need 1.3 mg from 11-50 years, and 1.2 mg thereafter. Slightly more is required during **pregnancy** (1.6 mg) and **lactation** (1.7-1.8 mg). Men require 1.5 mg from 11-14 years of age, 1.8 mg from 15-18 years, 1.7 mg from 19-50 years, and 1.4 mg at 51 years and older. Riboflavin is water-soluble, and is not stored in significant quantities in the body.

High doses of riboflavin, as much as 400 mg per day, have been shown to reduce the frequency of migraine headaches by half in susceptible people. The severity of the events was also reportedly decreased. This may be an effect of improved use of cellular energy in the **brain**. It is theorized that riboflavin may help decrease the odds of getting **cataracts**, but the evidence for this protection is not definitive. One large study had a group taking both **niacin** (vitamin B₃) and riboflavin, and while the group had a significantly lower total incidence of cataracts, they had a somewhat higher than average incidence of a specific cataract subtype. **Memory** may be improved by these supplements, according to some research done on older people. Riboflavin and **vitamin C** both help boost the body's level of glutathione, which is an antioxidant with many beneficial effects. There is not enough evidence to support the effectiveness of riboflavin for sickle-cell anemia, canker sores, or as an athletic performance aid.

Preparations

Natural sources

Beef **liver** is a very rich source of riboflavin, but dairy products also supply ample amounts. Higher-fat

sources contain less than those with low fat. Many processed grain products are fortified with riboflavin, as well as other **B vitamins**. Good vegetable choices include avocados, mushrooms, spinach, and other dark green, leafy vegetables. Nuts, legumes, nutritional yeast, and brewer's yeast contain riboflavin as well. Cooked foods provide as much of this vitamin as raw ones do, since the substance is heat stable. Light, however, does break down riboflavin. To preserve it, be sure to either store dairy and grain products in something opaque or keep them away from light.

Supplemental sources

Riboflavin is available as an oral single vitamin product. Consider taking a balanced B complex supplement rather than high doses of an individual vitamin unless there is a specific indication to do so. Store supplements in a cool, dry place, away from light, and out of the reach of children.

Deficiency

Ariboflavinosis is the term for the condition of vitamin B₂ deficiency. Since small amounts can be stored in the liver and **kidneys**, a dietary inadequacy may not become apparent for several months. Insufficient levels of riboflavin have noticeable effects on several areas of the skin. Commonly the corners of the mouth are cracked. Facial skin and scalp tend to itch and scale, as does the scrotal skin. The eyes fatigue easily and are sensitive to light, and may also become watery, sore, or bloodshot. Trembling, neuropathy, dizziness, insomnia, poor digestion, slow growth, and **sore throat** and tongue have also been reported. Anemia may develop if the deficiency is severe. People who are deficient in riboflavin are likely to be lacking in other B vitamins, and possibly additional nutrients as well.

Risk factors for deficiency

Riboflavin deficiency is uncommon, but some populations may need more than the RDA in order to maintain good health. Vegans, and others who do not use dairy products, would do well to take a balanced B vitamin supplement. Those with increased need for riboflavin and other B vitamins may include people under high **stress**, including those experiencing surgery, chronic illnesses, liver disease, or poor nutritional status. Diabetics may have a tendency to be low on riboflavin as a result of increased urinary excretion. Athletes and anyone else with a high-energy output will need additional vitamin B₂. This includes anyone who exercises with some regularity. The elderly are more likely to suffer from nutritional inadequacy as well as problems with absorption.

KEY TERMS

Antioxidant—Any one of a group of substances that function to destroy cell-damaging free radicals in the body.

Migraine—A very severe headache, often accompanied by nausea and vomiting. It is usually experienced on one side of the head, and may be preceded by visual symptoms.

Neuropathy—Abnormality of the nerves, which may be manifested as numbness, tingling, or weakness of the affected area.

Smokers and alcoholics are at higher risk for deficiency, as tobacco and alcohol suppress absorption. Birth control pills may possibly reduce riboflavin levels, as can phenothiazine tranquilizers, tricyclic antidepressants, and probenecid. Consult a health care professional to determine if supplementation is appropriate.

Precautions

Riboflavin should not be taken by anyone with a B vitamin allergy or chronic renal disease. Other populations are unlikely to experience any difficulty from taking supplemental B₂.

Side effects

Taking supplemental riboflavin causes a harmless intense orange or yellow discoloration of the urine.

Interactions

Probenecid (a drug treating **gout**) impairs riboflavin absorption, and propantheline bromide (a drug treating peptic ulcers) reportedly both delays and increases absorption. Phenothiazines (**antipsychotic drugs**) increase the excretion of riboflavin, thus lowering serum levels; and oral contraceptives may also decrease serum levels. Supplementation should be discussed with a health care provider if these medications are being used. Absorption of riboflavin is improved when taken together with other B vitamins and vitamin C.

Rinne and Weber tests

Definition

Both the Rinne and the Weber tests employ the use of metal tuning forks to provide a rough assessment of a patient's **hearing** level at various frequencies. A tuning fork is a metal instrument with a handle and two prongs, or tines. Tuning forks, made of steel, aluminum, or magnesium alloy, will vibrate at a set frequency to produce a musical tone when struck. The vibrations produced can be used to assess a person's ability to hear different sound frequencies.

Purpose

A vibrating tuning fork held next to the ear or placed against the **skull** will stimulate the inner ear to vibrate, and can help determine if there is **hearing loss**. The Rinne tuning fork test helps evaluate a patient's hearing ability by air conduction compared to that of bone conduction. The Weber tuning fork test helps determine a patient's hearing ability by bone conduction only, and is useful when hearing loss is asymmetrical.

Precautions

No special patient precautions are necessary when tuning forks are used to conduct hearing tests.

Description

Two types of hearing tests using tuning forks are typically conducted. In the Rinne test, the vibrating tuning fork is held against the skull, usually on the bone behind the ear (mastoid process) to cause vibrations through the bones of the skull and inner ear. It is also held next to, but not touching, the ear, to cause vibrations in

KEY TERMS

Asymmetrical—Unbalanced, disproportionate, or unequal.

Mastoid process—The protrusions of bone behind the ears at the base of the skull.

Rinne test—A hearing test using a vibrating tuning fork that is held near the ear and held at the back of the skull.

Weber test—A hearing test using a vibrating tuning fork that is held at various points along the midline of the skull and face.

the air next to the ear. The patient is asked to determine which sound is louder, the sound heard through the bone or through the air. For the Weber test, the stem or handle of the vibrating tuning fork is placed at various points along the midline of the skull and face. The patient is then asked to identify which ear hears the sound created by the vibrations. Tuning forks of different sizes produce different frequencies of vibrations and can be used to establish the range of hearing for an individual patient.

Preparation

No special patient preparation is required for either of these hearing tests.

Aftercare

No special patient aftercare is required following the hearing tests. If hearing loss is detected using either tuning-fork test, the patient may require further testing to determine the cause and extent of hearing loss.

Complications

There are no known complications associated with the use of tuning forks to screen for hearing loss.

Results

With the Rinne test, a patient with normal hearing will hear the tone of the vibration longer and louder when the tuning fork is held next to the ear, as opposed to when it is held against the mastoid bone. Conversely, the test detects a hearing loss when a patient hears a louder and longer tone when the vibrating tuning fork is held against the mastoid bone, than when it is held next to the ear. This result is often referred to as “reversed Rinne.”

For the Weber test, the patient is considered to have normal hearing if the tone produced when the tuning fork is placed along the center of the skull or face sounds about the same volume in each ear. The volume of sound vibrations conducted through parts of the skull and face during the Weber test can indicate which ear may have a hearing loss, if the patient hears louder sound vibrations in one ear compared to sounds picked up by the opposite ear.

If either method of testing reveals abnormal results, the patient will require further evaluation.

Health care team roles

Nurses should explain the procedure to patients and answer any questions.

Patient education

Patients should be instructed to listen carefully to directions for either test and be reassured that there are no **pain** or complications associated with either test.

Training

No special training is required.

Root canal therapy

Definition

Root canal therapy, also known as endodontic treatment, is a dental procedure in which the diseased or damaged pulp (nerve) of a tooth is removed and the inside

Root canal treatment is a dental procedure in which the diseased pulp of a tooth is removed and the inside areas are filled and sealed. In figure A, the infection can be seen above the pulp cavity. The dentist drills into the enamel and the pulp cavity is extracted (Figure B). Finally, the dentist fills the pulp cavity with antibiotic paste and a temporary filling (Figure C). (Illustration by Electronic Illustrators Group.)

areas of the nerve chambers or root canals are filled and sealed.

Purpose

Root canal therapy has become a common dental procedure. More than 14 million are performed each year, with a success rate of 95%, according to the American Association of Endodontists. Inflamed or infected pulp (pulpitis), often causing a toothache, is removed to relieve the **pain** and prevent further complications for the patient.

Precautions

Once root canal therapy is finished and the nerve is removed, the tooth becomes brittle over time and can fracture and break easily. Therefore the tooth requires extra protection and will need a crown.

Description

Root canal therapy may be performed by a general dentist or by an endodontist, a dentist who specializes in

endodontic procedures. The pulp of the tooth consists of soft tissue containing the **blood** supply from which the tooth gets its nutrients and by which the tooth senses hot and cold. This tissue is vulnerable to damage from deep dental decay, accidental injury, tooth fracture, or trauma from repeated dental procedures (such as multiple fillings over time). **Infection** may produce pain that is severe, constant, or throbbing, as well as prolonged sensitivity to heat or cold. Swelling in and around the surrounding gums along with facial swelling may be seen. However, in some cases, the pulp may die so gradually that there is little noticeable pain or swelling.

Root canal therapy is performed under **local anesthesia**. A thin sheet of rubber, called a rubber dam, is placed in the mouth to isolate the tooth. The endodontist makes an opening through the natural crown of the tooth into the pulp chamber. He will then determine the length of the root canal, usually with a series of x rays. Small wire-like files, called broaches, are used to clean the entire canal space of diseased pulp tissue and **bacteria**. The debris is flushed out (irrigated) with sterile water. The canals are also slightly enlarged and shaped to receive an inert (non-reactive) filling material called

KEY TERMS

Abscess—Gum tissue filled with pus as the result of infection. This swelling exerts pressure on the surrounding tissues, causing pain.

Apicoectomy—Also called root resectioning. The root tip of a tooth is accessed in the bone and a small amount is taken off away. A small filling is placed to reseal the canal.

Crown—The natural crown of a tooth is that part of the tooth covered by enamel. Also, a restorative crown is a protective shell that fits over a tooth.

Endodontic—Pertaining to the inside structures of the tooth, including the dental pulp and tooth root, and the periapical tissue surrounding the root.

Endodontist—A dentist who specializes in the diagnosis and treatment of disorders affecting the inside structures of the tooth.

Extraction—The surgical removal of a tooth from its socket in the bone.

Gutta-percha—An inert latex-like substance used for filling root canals.

Pulp—The soft innermost layer of a tooth, containing blood vessels and nerves.

Pulp chamber—The area within the natural crown of the tooth occupied by dental pulp.

Pulpitis—Inflammation of the pulp of a tooth involving the blood vessels and nerves.

Root canal—The space within a tooth that runs from the pulp chamber to the tip of the root.

Root canal treatment—The process of removing diseased or damaged pulp from a tooth, then filling and sealing the pulp chamber and root canals.

gutta-percha. However, the tooth is not filled and permanently sealed until it is completely free of the active infection and/or bacteria. The endodontist will place a temporary seal, or leave the tooth open to drain, and prescribe an antibiotic to counter any spread of infection from the tooth. The patient may need a number of return visits to the dental office while the root canal is being treated, and the infection brought under control.

Preparation

There is no typical preparation for root canal therapy, as the treatment is done on an emergency basis due to sudden injury or pain. The reasons why root canals are thought to be so painful are due to the sudden injury and build-up of infection in the tooth. Normal doses of local anesthetic used by the dentist are not always effective against the degree of pain the patient is already feeling. Occasionally, even high amounts of anesthesia aren't effective until the infection can be drained and brought under control.

Aftercare

The tooth may be sore for several days after filling. Such pain relievers as ibuprofen (Advil, Motrin) may be taken to ease the soreness. Ibuprofen is an effective anti-inflammatory drug and can help reduce the inflammation caused by the infection. The tissues surrounding the tooth may also be irritated due to the infection, but also due to the rubber dam used to isolate the tooth during the root canal treatment. Rinsing the mouth with warm salt-water

rinses several times a day is helpful. The patient should avoid chewing on the treated tooth for several days. A follow-up appointment should be scheduled with the dentist for six months after treatment to make sure the tooth and surrounding structures are healthy.

Risks

There is the possibility that the root canal treatment will not be successful the first time. If infection and inflammation recur and an x ray indicates re-treatment is feasible, the old filling material is removed and the canals are thoroughly cleaned out. The dentist will try to identify and correct problems with the first root canal treatment before filling and sealing the tooth a second time.

In cases in which an x ray indicates that re-treatment cannot correct the problem, endodontic surgery may be performed. An apicoectomy, or root resectioning, is the procedure by which the root portion of the tooth is accessed through the gum tissue above or below the tooth in the bone. A small portion of the root tip is taken off and a small filling is placed to reseal the canal.

In some cases, root canal treatment, re-treatment, and apicoectomy surgery are not effective and the tooth must be extracted.

Results

With successful root canal treatment, the restored tooth can last a lifetime.

Salivary gland scan

Definition

A salivary gland scan is a nuclear medicine test that establishes the function of the salivary glands. The salivary glands include the parotid glands and submandibular glands, which are located on both sides of the neck below the ears and jaw. Salivary gland function is determined by the pattern of uptake and secretion of a radioactive tracer, usually Tc99m (Technium 99). The scan also demonstrates the relative size and shape of the salivary glands.

Purpose

A salivary gland scan is indicated when a patient has recurring salivary gland swelling due to either **infection**, inflammation, or obstruction. Salivary gland scans can detect salivary gland tumors, and can help evaluate the glands of patients with persistent dry mouth.

Precautions

Salivary gland scans are a safe, effective way to diagnose salivary gland pathology. The level of radioactivity used to obtain the images is low, however, pregnant patients are cautioned not to have this test unless necessary. Women who are breastfeeding are advised to stop breastfeeding for a specific period of time, depending on the dose administered. Other recent nuclear medicine tests may affect the results of this scan, and it may be necessary to wait until previously administered radiopharmaceuticals have been cleared from the body before undergoing this test.

Description

A salivary gland scan, also called a parotid gland scan, is a non-invasive test. It is typically performed in a hospital radiology or nuclear medicine department or

out-patient radiology facility. The patient is injected with a low-level radioactive marker and is positioned in front of or under a gamma scintillation camera, which detects the radiation and produces an image. In some facilities, imaging begins immediately after the injection to observe the progressive accumulation of the radioactive tracer in the glands. If indicated, an additional procedure can be done after the initial images are obtained. The patient is given a sour substance, known as a sialogogue, such as a lemon drop or some lemon juice, to stimulate the emptying of the salivary glands. Another set of images is then made for comparison purposes. The entire process takes about 30 to 45 minutes.

Preparation

No special preparations are needed for this test. It is not necessary to fast or to restrict medications before testing. Any **blood** to be drawn for other tests may need to be taken before the radiopharmaceutical is injected. Patients must remove any metal objects from the face and neck and may be asked to remove dentures.

Images of the **thyroid gland** is typically included when imaging the salivary glands. Therefore, it should be noted if the patient is taking any medication that inhibits the uptake of the radiopharmaceutical in the thyroid gland.

Aftercare

Patients can return to normal activities immediately.

Complications

A salivary gland scan is a safe test, and there are generally no complications associated with it.

Results

A normal study reflects a normal position, size, and shape of the salivary glands, and will also demonstrate proper emptying of the glands after the oral administra-

KEY TERMS

Radiopharmaceutical—A radioactive chemical used for diagnostic or therapeutic purposes.

Sjogren’s syndrome—A disease, often associated with rheumatoid arthritis or lupus, that causes dry mouth, dry eyes, and swollen salivary glands.

Warthin’s tumor—A benign tumor of the parotid gland.

tion of the sialogogue. Abnormally functioning salivary glands, due to conditions such as Sjögren’s syndrome, fail to exhibit a normal uptake and secretion pattern. Some tumors, such as a Warthin’s tumor, prevent the emptying of the salivary gland and are seen as areas of increased concentration of radionuclide. Metastatic lesions, cysts, and abscesses are seen as areas of decreased concentration of radionuclide. This test does not differentiate between benign and malignant lesions. This requires other diagnostic imaging tests such as CT, MRI, or ultrasound.

Health care team roles

The radionuclide is administered by a nuclear medicine technologist, who is specially trained to handle radioactive materials and operate the equipment in a nuclear medicine department. The technologist may obtain pertinent patient medical history and describe the testing procedure to the patient. All data collected is interpreted by a radiologist or nuclear medicine specialist. Results of the test are sent to the referring physician.

Sarcomas

Definition

A sarcoma is a malignant tumor (neoplasm), or **cancer**. Certain sarcomas characteristically spread throughout the body. The word “sarcoma” has its etiology in a Greek word whose definition is “fleshy.” Tumors come from the mesenchymal tissue, from which connective tissues, **blood**, lymphatics, bone, and cartilage come. The blood carries sarcomas throughout the body into neighboring tissue, or via the bloodstream. Frequent sites of extension of the tumors are the lung, the **liver**, and the **brain**.

Description

When the original site of the cancer is the bone, there is a primary bone cancer. The tumor originates in or near a bone. Most primary bone tumors are benign, and the cells that compose them do not metastasize (spread) to nearby tissue or to other parts of the body.

Sarcomas account for fewer than 1% of all cancers diagnosed in the United States. They can infiltrate nearby tissues, enter the bloodstream, and metastasize to other bones, tissues, and organs far from the site of the original malignancy. Malignant primary bone tumors are characterized as either:

- cancers that originate in the hard material of the bone
- soft-tissue sarcomas that begin in **blood vessels**, nerves, or tissues containing muscles, fat, or fiber

Types of bone tumors

Osteogenic sarcoma, or osteosarcoma, is the most common form of primary bone cancer, accounting for about 5% of all cancers in children. Every year, 900 new cases of osteosarcoma are diagnosed in the United States. The disease usually affects teenagers and young adults, and is almost twice as common in males as in females.

Osteosarcomas grow very rapidly. Although they can develop in any bone, but they are most often seen along the edge or on the end of one of the fast-growing long bones that support the arms and legs. Approximately 80% of all osteosarcomas develop in the distal femur or in the proximal tibia (parts of the upper and lower leg nearest the knee). The next likely location for an osteosarcoma is the proximal humerus (the bone of the upper arm closest to the shoulder).

Ewing’s sarcoma is the second most common form of childhood bone cancer. Accounting for less than 5% of bone tumors in children, Ewing’s sarcoma usually begins in the soft tissue or nerves. It rapidly metastasizes to the

lungs, and may metastasize to bones in other parts of the body.

Ewing's sarcoma occurs most frequently in children aged 11–15. It is more often diagnosed in taller teens. Slightly more males than females develop common bone cancer—but this type is the most frequently found carcinoma in children. The disease is rarely diagnosed in children younger than five and adults older than 30. It primarily affects Caucasians, and rarely occurs in African Americans and native Chinese persons.

Chondrosarcomas are cancerous bone tumors that most often appear in middle age. Usually originating in cartilage in ribs, leg, or hip bones, chondrosarcomas grow slowly. They rarely metastasize to the lungs. It takes years for a chondrosarcoma to metastasize to other parts of the body, and some of these tumors never spread.

Parosteal osteogenic sarcomas, fibrosarcomas, and chordomas are rare. Parosteal osteosarcomas generally involve both the bone and the periosteum, the membrane that covers bones. Fibrosarcomas originate in the ends of the bones in the arm or leg, and then spread to soft tissue. Chordomas develop on the **skull** or **spinal cord**.

Osteochondromas, which usually develop between persons aged 10–20 years, are the most common non-cancerous primary bone tumors. Giant cell tumors generally develop in a section of the femur near the knee. Giant cell tumors are originally benign, but sometimes become malignant.

Causes and symptoms

The cause of bone cancer is unknown, but the tendency to develop it may be inherited. Children who develop bone tumors are often tall for their age, and the disease seems to be associated with growth spurts during childhood and adolescence. Injuries can make the presence of tumors more apparent, but do not cause them.

A bone that has been broken or exposed to high doses of radiation that has been used to treat other cancers is more likely than other bones to develop osteosarcoma. It should be noted, however, that the amount of radiation in diagnostic x rays poses little or no danger of bone cancer development. A history of noncancerous bone disease also increases bone cancer risk.

Cancer of the eye (retinoblastoma) is a rare tumor of the eye that develops in the cells of the retina, and occurs mostly in patients under five years of age. It is known to be hereditary—the condition is an autosomal-dominant trait.

Both benign and malignant bone tumors can distort and weaken bone, causing **pain**, but benign tumors are generally painless and asymptomatic.

Patients may feel a lump or mass, but pain in the affected area is the most common early symptom of bone cancer. Pain is not constant in the initial stages of the disease; it is aggravated by activity and may be worst at night. If the tumor is located on a leg bone, the patient may limp. Swelling and weakness of the limb may not be noticed until weeks after the pain began.

Other symptoms of bone cancer include:

- a bone that breaks with minimal trauma, also known as a pathologic fracture
- difficulty moving the affected part of the body
- fatigue
- fever
- a lump or swelling on the trunk, an arm or leg, or another bone
- persistent, unexplained back pain
- weight loss

Diagnosis

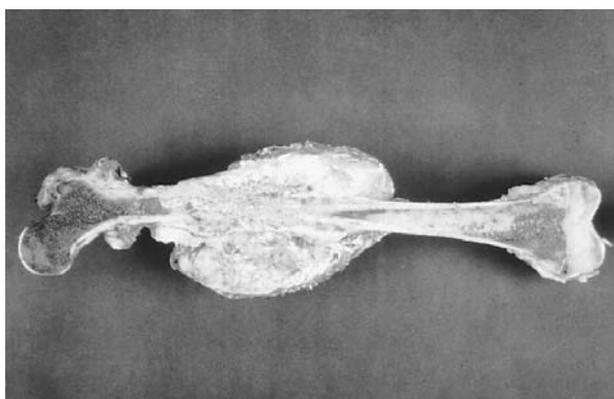

Physical examination and routine x rays may provide enough evidence to diagnose benign bone tumors, but biopsy (removal of tumor tissue for microscopic analysis) is the only definitive way to determine the nature of the tumor.

A needle biopsy involves using a fine, thin needle to remove small bits of tumor, or a thick needle to extract tissue samples from the innermost part (the core) of the growth. An excisional biopsy is the surgical removal of a small, accessible tumor and a margin of surrounding normal tissue. An incisional biopsy is performed on tumors too large or inaccessible to be completely removed. A portion of the tumor is removed by the surgeon performing an incisional biopsy. Performed under local or **general anesthesia**, biopsy reveals whether a tumor is benign or malignant, and ideally identifies the type of cancer cells the malignant tumor contains.

Primary bone cancer is usually diagnosed about three months after symptoms first appear. Twenty percent of these malignant tumors will have already metastasized to the lungs or to other parts of the body.

Imaging techniques

The following procedures are used, in conjunction with biopsy, to diagnose bone cancer:

A specimen of a femur bone indicating the cancerous growth around the knee. Osteosarcoma is the most common primary cancer of the bone. (Photo Researchers, Inc. Reproduced by permission.)

- Plain x rays. These x rays usually provide a clear image of osteosarcomas.
- The computerized tomography (CAT) scan, or computed tomographic scanning (CT), is a specialized x ray that uses a rotating beam to obtain detailed information about an abnormality and its physical relationship to other parts of the body.
- A CAT scan can show differentiation between osteosarcomas and other types of bone tumors, reveal if tumor cells have spread to other tissues, and help surgeons decide which portion of a growth is best to biopsy. Since malignant bone tumors frequently metastasize to the lungs, a CAT scan of the chest should also be performed. The CAT scan can provide information about other organs that may have been affected. Chest and abdominal CAT scans are used to determine whether Ewing's sarcoma has spread to the lungs, liver, or lymph nodes.
- Magnetic resonance imaging (MRI) is a specialized scan that relies on radio waves and powerful magnets to reflect energy patterns created by tissue abnormalities and specific diseases. MRI provides more detailed information than a CAT scan about tumors and marrow cavities of the bone, and can sometimes detect clusters of cancerous cells that have separated from the original tumor. This valuable information helps physicians select the best approach for treatment.
- Radionuclide bone scans involve the injection of a small amount of radioactive material into a vein. Primary tumors, or cells that have metastasized, absorb the radioactive material and present as dark spots on the scan.

Cytogenic and molecular genetic studies, which assess the structure and composition of chromosomes

and genes, may also be used to diagnose osteosarcoma. These tests sometimes help to determine the most appropriate form of treatment.

Laboratory studies

A **complete blood count** (CBC) reveals abnormalities in the blood, and may indicate whether bone marrow has been affected. A blood test that measures levels of the enzyme lactate dehydrogenase (LDH), can be used determine the prognosis for the survival of a given patient.

Immunohistochemistry involves adding special antibodies and chemicals, or stains, to tumor samples. This technique effectively helps the pathologist to identify cells that are found in Ewing's sarcoma, but that are not present in other malignant tumors.

Reverse transcription polymerase chain reaction (RT-PCR) relies on chemical analysis of RNA (the substance in the body that transmits genetic information) to:

- Evaluate the effectiveness of cancer therapies.
- Identify mutations consistent with the presence of Ewing's sarcoma.
- Reveal cancer that recurs after treatment has been completed.

Staging

Once bone cancer has been diagnosed, the tumor is staged. This process indicates how far the tumor has spread from its original location. The stage of a tumor helps the oncologist decide which form of treatment is indicated, and to predict how the condition will probably respond to therapy.

An osteosarcoma may be localized or metastatic. A localized osteosarcoma has not spread beyond the bone where it, originated, or beyond nearby muscles, tendons, and other tissues. Metastatic osteosarcoma has spread to the lungs, to bones not directly connected to the bone, or to other tissues or organs.

Treatment

Since the 1960s, when amputation was the only treatment for bone cancer, **chemotherapy** and innovative surgical techniques have improved survival with intact limbs. Because osteosarcoma is rare, treatment is most often sought at a cancer center staffed by specialists familiar with the disease. A treatment plan for bone cancer, which is devised after the tumor has been diagnosed and staged, may include:

- Radiation therapy. Radiation therapy is used often to treat Ewing's sarcoma.

- **Surgery.** Surgery, coordinated with diagnostic biopsy, enhances the probability that limb-salvage surgery can be used to remove the cancer, while preserving nearby blood vessels and bones. A metal rod or bone graft is used to replace the area of bone removed. Subsequent surgery may be needed to repair or replace rods that have become loose or broken. Patients who have undergone limb salvage surgery require intensive rehabilitation. It may take as long as one year for a patient to regain full use of a leg following limb salvage surgery. Some patients who undergo this procedure eventually require amputation.
- **Chemotherapy.** In addition to surgery, chemotherapy is usually administered to kill cancer cells that have separated from the original tumor and spread to other parts of the body. Although chemotherapy can increase the likelihood of future development of another form of cancer, the American Cancer Society maintains that the benefit of chemotherapeutic bone cancer treatment is much greater than its potential risk.
- **Amputation.** Amputation may be the only therapeutic option for large tumors involving nerves or blood vessels that have not responded to chemotherapy. MRI scans demonstrate the extent of disease in the limb, providing information about how much of it must be removed. The treatment, surgery, is designed to create a cuff (formed of muscles and skin) around the amputated bone. Following surgery, a prosthetic (artificial) leg is fitted over the cuff. Patients who actively participate in the rehabilitation may be walking independently as soon as three months after the amputation.
- **Rotationoplasty.** Rotationoplasty, sometimes performed after a leg amputation, involves attaching the lower leg and foot to the femur, so that the ankle replaces the knee. A prosthetic is later added to make the leg as long as it is normally. Prosthetic devices are not used to lengthen limbs that remain functional after amputation to remove osteosarcomas located on the upper arm. When an osteosarcoma develops in the jaw bone, the entire lower jaw is removed. Bones from other parts of the body are later grafted onto remaining bone to create a new jaw.

Follow-up treatments

After a patient completes the final course of chemotherapy, a number of tests—CAT or **CT scans**, bone scans, x rays, and other diagnostic tests—may be repeated to determine if any traces of tumor remain. If none are found, treatment is discontinued, but patients are advised to see their oncologists and orthopedic surgeons every two or three months for the subsequent year.

X rays of the chest and affected bone are taken every four months. An annual echocardiogram is recommended to determine whether there have been any adverse cardiovascular effects of chemotherapy, and CT scans are performed every six months.

Patients who have received treatment for Ewing's sarcoma are examined regularly—at gradually lengthening intervals—after completing therapy. Accurate growth measurements are taken at each visit and blood is drawn to test for side effects of treatment. X rays, CAT or CT scans, bone scans, and/or other imaging studies are generally performed every three months during the first year. If no evidence of tumor growth or recurrence is revealed, these tests are performed less frequently in the following years.

Some benign bone tumors shrink or disappear without treatment. However, regular examinations are recommended to determine whether these tumors have changed in any way.

Alternative treatment

Alternative treatments should never be substituted for conventional anticancer treatments or used without the approval of a physician. Some alternative treatments may be used as adjunctive and supportive therapies during and following conventional treatments.

Many patients find that alternative and complementary therapies help to reduce the **stress** associated with illness, improve immune function and feel better. While there is no evidence that these therapies specifically combat disease, activities such as biofeedback, **relaxation**, **therapeutic touch**, **massage therapy**, and guided imagery have been reported to enhance well-being.

Some cancer patients find that acupuncture alleviates pain, nausea, and vomiting. It may also be effective in helping to maintain energy and relative wellness during surgery, chemotherapy, and radiation. Massage, reflexology, and relaxation techniques are reported to relieve pain, tension, **anxiety**, and depression.

Claims of effectiveness in fighting cancer have been made for a variety of herbal medicines. These botanical remedies should only be used when prescribed by a practitioner familiar with cancer treatment.

Prognosis

Benign bone tumors rarely recur, but sarcomas can reappear, even after treatment considered effective in eliminating all the cancerous cells.

Likelihood of long-term survival depends on:

- the type and location of the tumor

KEY TERMS

Biofeedback—The technique of making unconscious or involuntary bodily processes (as heart-beat or brain waves) perceptible to the senses in order to manipulate them by conscious mental control.

CAT scan (CT scan)—Computerized axial tomography, or computed tomography, tomographic scanning; a specialized x ray that uses a rotating beam to obtain detailed information about an abnormality and its physical relationship to other parts of the body.

Chondrosarcoma—A malignant tumor derived from cartilage cells or their precursors.

Chordoma—Malignant tumor composed of remnants of the embryonic notochord—a flexible rod of cells that in the embryos of higher vertebrates forms the supporting axis of the body—and is found along the spine, attacking especially the bones at the base of the skull, or near the coccyx.

Echocardiogram (ECHO)—The use of beeps of ultrasonic waves directed through the chest wall to record the position and motion of the heart walls or internal structures of the heart.

Ewing's sarcoma—A tumor that invades the shaft of a long bone and that tends to recur, but metastasizes infrequently.

Fibrosarcoma—A sarcoma of relatively low malignancy, consisting mostly of spindle-shaped cells that generally form collagenous fibers of connective tissue.

Magnetic resonance imaging (MRI)—A specialized scan that uses radio waves and powerful magnets to reflect energy created by abnormal tissue and specific diseases.

Metastasis—Transfer of disease from one organ of the body to another not directly connected with it, as a result of transfer of pathogenic microorganisms or to transfer of cells.

- how much the tumor has metastasized, and the organs, bones, or tissues affected

More than 85% of patients survive for more than five years after complete surgical removal of low-grade osteosarcomas (tumors that arise in mature tissue and contain a small number of cancerous cells). About 25–30% of patients diagnosed with high-grade osteosar-

comas (tumors that develop in immature tissue and contain a large number of cancer cells) will die of the disease.

Two-thirds of all children diagnosed with Ewing's sarcoma live for more than five years after the disease is detected. The outlook is most favorable for children under age 10, and least favorable in patients whose cancer is not diagnosed until after it has metastasized: fewer than three of every 10 of these patients remain alive five years later. More than 80% of patients whose Ewing's sarcoma is confined to a small area, and surgically removed live for at least five years. Postsurgical radiation and chemotherapy add years to their lives. More than 70% of patients live five years or more with a small Ewing's sarcoma that cannot be removed, but only three out of five patients with large, unremovable tumors survive that long. Patients with tumors that do not respond to treatment and those who suffer recurrences have poor outlooks for long-term survival.

Health care team roles

Like other cancer patients, patients with sarcoma are usually cared for by a multidisciplinary team of health professionals. The patient's family physician or primary care provider collaborates with other physician specialists, such as surgeons and oncologists. Radiologic technicians perform x ray, CT, and MRI scans; nurses and laboratory technicians may obtain samples of blood, urine and other laboratory tests.

Before and after any surgical procedures, including biopsies, the procedures may be explained by nurses or physicians, who are also called upon to help prepare patients and families. Depending on the tumor location and treatment plan, patients may also benefit from rehabilitation therapy with physical therapists, nutritional counseling from dietitians, and counseling from social workers or other mental health professionals.

Prevention

Since the causes of most sarcomas are not known, there are no formal recommendations about how to prevent their development. Among families with an inherited tendency to develop soft tissue sarcomas, careful monitoring may help to ensure early diagnosis and treatment of the disease.

In 1999 and 2000, there were a number of studies that reported both genetic and biologic factors in sarcomas. The reports generated by these studies provide evidence that more and more sarcomas possess the same

chromosome abnormalities. The reports also point to the high complexity of these genetic changes; which further complicate identifying any single abnormality associated with sarcomas. Despite their limitations, continuing studies can yield new, therapeutic treatment modalities. These approaches will be experimental, yet they will facilitate advancement in this arena toward even better disease management.

Schizophrenia

Definition

Schizophrenia is a psychotic disorder (or a group of disorders) marked by severely impaired thinking, emotions, and behaviors. Schizophrenic persons are typically unable to filter sensory stimuli and may have enhanced perceptions of sounds, colors, and other features of their environment. Most schizophrenics, if untreated, gradually withdraw from interactions with other people, and lose their ability to take care of personal needs and grooming.

Description

The course of schizophrenia in adults can be divided into three phases or stages. In the acute phase, a person has an overt loss of contact with reality (psychotic episode) that requires intervention and treatment. In the second or stabilization phase, the initial psychotic symptoms have been brought under control but the person is at risk for relapse if treatment is interrupted. In the third or maintenance phase, an individual is relatively stable and can be kept indefinitely on antipsychotic medications. Even in the maintenance phase, however, relapses are not unusual and people do not always return to full functioning.

The term schizophrenia comes from two Greek words that mean split mind. It was first used by a Swiss doctor named Eugen Bleuler in 1908 to describe the splitting apart of mental functions that he regarded as the central characteristic of schizophrenia.

Recently, some psychotherapists have begun to use a classification of schizophrenia based on two main types. People with Type I, or positive schizophrenia, have a rapid (acute) onset of symptoms and tend to respond well to drugs. They also tend to suffer more from so-called positive symptoms, such as delusions and hallucinations. People with Type II, or negative schizophrenia, are usually described as poorly adjusted before their schizophrenia slowly overtakes them. They have predominantly negative symptoms, such as withdrawal from others and a slowing of mental and physical reactions (psychomotor retardation).

The fourth (1994) edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* specifies five subtypes of schizophrenia.

PARANOID. The key feature of this subtype of schizophrenia is the combination of false beliefs (delusions) and hearing voices (auditory hallucinations), with more nearly normal emotions and cognitive functioning (cognitive functions include reasoning, judgment, and mem-

ory). The delusions of paranoid schizophrenics usually involve thoughts of being persecuted or harmed by others or exaggerated opinions of their own importance, but may also reflect feelings of jealousy or excessive religiosity. The delusions are typically organized into a coherent framework. Paranoid schizophrenics function at a higher level than other subtypes, but are at risk for suicidal or violent behavior under the influence of their delusions.

DISORGANIZED. Disorganized schizophrenia (formerly called hebephrenic schizophrenia) is marked by disorganized speech, thinking, and behavior by an affected person, coupled with flat or inappropriate emotional responses to a situation (affect). An individual may act silly or withdraw socially to an extreme extent. Most people in this category have weak personality structures prior to their initial acute psychotic episode.

CATATONIC. Catatonic schizophrenia is characterized by disturbances of movement that may include rigidity, stupor, agitation, bizarre posturing, and repetitive imitations of the movements or speech of other people. These people are at risk for malnutrition, exhaustion, or self-injury. This subtype is presently uncommon in Europe and the United States. Catatonia as a symptom is most commonly associated with mood disorders.

UNDIFFERENTIATED. Persons in this category have the characteristic positive and negative symptoms of schizophrenia but do not meet the specific criteria for the paranoid, disorganized, or catatonic subtypes.

RESIDUAL. This category is used for persons who have had at least one acute schizophrenic episode but do not presently have strong positive psychotic symptoms, such as delusions and hallucinations. They may have negative symptoms, such as withdrawal from others, or mild forms of positive symptoms, which indicate that the disorder has not completely resolved.

Genetic profile

The risk of schizophrenia among first-degree biological relatives is 10 times greater than that observed in the general population. Furthermore the presence of the same disorder is higher in monozygotic (identical) twins than in dizygotic (non-identical) twins. Research concerning adoption studies and identical twins also supports the notion that environmental factors are important, because not all relatives have the disorder or express it. There are several chromosomes and loci (specific areas on chromosomes that contain mutated genes) that have been identified. Research is ongoing to elucidate the causes, types and variations of these mutations.

Demographics

A number of studies indicate that about 1% of the world's population is affected by schizophrenia, without regard to race, social class, level of education, or cultural influences. The outcome may vary from culture to culture, depending on the familial support of an affected person. Most people are diagnosed in their late teens or early twenties, but the symptoms of schizophrenia can emerge at any age in the life cycle. The male to female ratio in adults is about 1.2:1. Males typically have their first acute episode in their early twenties, while females are usually closer to age 30 when they are recognized with active symptoms.

Schizophrenia is rarely diagnosed in preadolescent children, although individuals as young as five or six have been reported. Childhood schizophrenia is at the upper end of the spectrum of severity and shows a greater gender disparity. It affects one or two children in every 10,000; the male to female ratio is 2:1.

Causes and symptoms

Theories of causality

One of the reasons for the ongoing difficulty in classifying schizophrenic disorders is incomplete understanding of their causes. As of 2001, it is thought that these disorders are the end result of a combination of genetic, neurobiological, and environmental causes. A leading neurobiological hypothesis emphasizes the connection between the disease and excessive levels of dopamine, a chemical that transmits signals in the **brain** (neurotransmitter). The genetic factor in schizophrenia has been underscored by recent findings that first-degree biological relatives of schizophrenics are 10 times more likely to develop the disorder than are members of the general population.

Prior to recent findings of abnormalities in the brain structure of schizophrenic persons, several generations of psychotherapists advanced a number of psychoanalytic and sociological theories about the origins of schizophrenia. These theories ranged from hypotheses about a person's problems with **anxiety** or aggression to theories about **stress** reactions or interactions with disturbed parents. Psychosocial factors are now thought to influence the expression or severity of schizophrenia, rather than directly cause it.

Another hypothesis suggests that schizophrenia may be caused by a virus that attacks the hippocampus, a part of the brain that processes sense perceptions. Damage to the hippocampus would account for a schizophrenic person's vulnerability to sensory overload. As of mid-2001,

researchers are testing antiviral medications on schizophrenics.

Symptoms of schizophrenia

People with a possible diagnosis of schizophrenia are evaluated on the basis of a set or constellation of symptoms. There is no single symptom that is unique to schizophrenia. In 1959, the German psychiatrist Kurt Schneider proposed a list of so-called first-rank symptoms, which he regarded as diagnostic of the disorder.

These symptoms include:

- delusions
- somatic hallucinations
- hallucinations
- hearing voices commenting on a person's behavior
- thought insertion or thought withdrawal

Somatic hallucinations refer to sensations or perceptions concerning body organs that have no known medical cause or reason, such as the notion that one's brain is radioactive. Thought insertion and/or withdrawal refer to delusions that an outside force (for example, the FBI, the CIA, Martians, etc.) has the power to put thoughts into one's mind or remove them.

POSITIVE SYMPTOMS. The positive symptoms of schizophrenia are those that represent an excessive or distorted version of normal functions. Positive symptoms include Schneider's first-rank symptoms as well as disorganized thought processes (reflected mainly in speech) and disorganized or catatonic behavior. Disorganized thought processes are marked by such characteristics as looseness of association, in which a person rambles from topic to topic in a disconnected way; tangentiality, which means that an individual gives unrelated answers to questions; and flights of ideas or "word salad," in which a person's speech is so incoherent that it makes no grammatical or linguistic sense. Disorganized behavior means that a person has difficulty with any type of purposeful or goal-oriented behavior, including personal self-care or preparing meals. Other forms of disorganized behavior may include dressing in odd or inappropriate ways, sexual self-stimulation in public, or agitated shouting or cursing.

NEGATIVE SYMPTOMS. The *DSM-IV* definition of schizophrenia includes three so-called negative symptoms. They are called negative because they represent the lack or absence of behaviors. The negative symptoms that are considered diagnostic of schizophrenia are a lack of emotional response (affective flattening), poverty of speech, and absence of volition or will. In general, the

negative symptoms are more difficult for doctors to evaluate than the positive symptoms.

Diagnosis

A doctor must make a diagnosis of schizophrenia on the basis of a standardized list of outwardly observable symptoms, not on the basis of internal psychological processes. There are no specific laboratory tests that can be used to diagnose schizophrenia. Researchers have, however, discovered that persons with schizophrenia have certain abnormalities in the structure and functioning of the brain compared to normal test subjects. These discoveries have been made with the help of imaging techniques such as computed tomography scans (**CT scans**).

When a psychiatrist assesses an individual for schizophrenia, the doctor will begin by excluding physical conditions that can cause abnormal thinking and some other behaviors associated with schizophrenia. These conditions include organic brain disorders (including traumatic injuries of the brain), temporal lobe epilepsy, Wilson's disease, Huntington's chorea, and encephalitis. The doctor will also need to rule out substance abuse disorders, especially amphetamine use.

After ruling out organic disorders, a clinician will consider other psychiatric conditions that may include psychotic symptoms or symptoms resembling psychosis. These disorders include mood disorders with psychotic features; delusional disorder; dissociative disorder not otherwise specified (DDNOS) or multiple personality disorder; schizotypal, schizoid, or paranoid **personality disorders**; and atypical reactive disorders. In the past, many individuals were incorrectly diagnosed as being schizophrenic. Some people who were diagnosed prior to the changes in categorization introduced by *DSM-IV* should have their diagnoses, and treatment, reevaluated. In children, a doctor must distinguish between psychotic symptoms and a vivid fantasy life, and also identify learning problems or disorders. After other conditions have been ruled out, a person must meet a set of criteria specified by *DSM-IV*:

- **Characteristic symptoms.** To make a diagnosis of schizophrenia, a person must exhibit two (or more) of the following symptoms during a one-month period: delusions; hallucinations; disorganized speech; disorganized or catatonic behavior; negative symptoms.
- **Decline in social, interpersonal, or occupational functioning,** including self-care.
- **Duration.** The disturbed behavior must last for at least six months.

- Diagnostic exclusions. Mood disorders, substance abuse disorders, medical conditions, and developmental disorders have been ruled out.

Treatment

The treatment of schizophrenia depends in part on an individual's stage or phase. People in the acute phase are hospitalized in most cases, to prevent harm to themselves or to others and to begin treatment with antipsychotic medications. A person having a first psychotic episode should be given a CT (computed tomography) or MRI (**magnetic resonance imaging**) scan to rule out structural brain abnormalities or disease.

Antipsychotic medications

The primary form of treatment of schizophrenia is antipsychotic medication. **Antipsychotic drugs** help to control almost all the positive symptoms of the disorder. They have minimal effect on disorganized behavior and negative symptoms. Between 60–70% of schizophrenics will respond to antipsychotics. In the acute phase of the illness, people are usually given medications by mouth or by **intramuscular injection**. After an affected person has been stabilized, the antipsychotic drug may be given in a long-acting form called a depot dose. Depot medications last for two to four weeks and have the advantage of protecting a person against the consequences of forgetting or skipping daily doses. In addition, some people who do not respond to oral neuroleptic medications have better results with depot form. Persons whose long-term treatment includes depot medications are introduced to the depot form gradually during their stabilization period. Most people with schizophrenia are kept on antipsychotic medications indefinitely during the maintenance phase of their disorder to minimize the possibility of relapse.

As of 2001, the most frequently used antipsychotics fall into two classes: the older dopamine receptor antagonists, or DAs, and the newer serotonin dopamine antagonists, or SDAs. Antagonists block the action of some other substance. For example, dopamine antagonists counteract the action of dopamine. The exact mechanisms of action of these medications are not known, but it is thought that they lower a person's sensitivity to sensory stimuli and so indirectly improve the person's ability to interact with others.

DOPAMINE RECEPTOR ANTAGONIST. The dopamine antagonists include the older antipsychotic (also called neuroleptic) drugs, such as haloperidol (Haldol), chlorpromazine (Thorazine), and fluphenazine (Prolixin). These drugs have two major drawbacks. It is often difficult to find the best dosage level for a given individual, and a dosage level high enough to control psychotic

symptoms frequently produces extrapyramidal side effects, or EPS. EPSs include parkinsonism, in which a person cannot walk normally and usually develops a tremor; dystonia, or painful muscle spasms of the head, tongue, or neck; and akathisia, or restlessness. A type of long-term EPS is called tardive dyskinesia, which features slow, rhythmic, automatic movements. Schizophrenics with **AIDS** are especially vulnerable to developing EPS.

SERATONIN DOPAMINE ANTAGONISTS. The serotonin dopamine antagonists, also called atypical antipsychotics, are newer medications that include clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa). The SDAs have a better effect on the negative symptoms of schizophrenia than do the older drugs and are less likely to produce EPS than the older compounds. The newer drugs are significantly more expensive in the short term, although the SDAs may reduce long-term costs by reducing the need for hospitalization. They are also presently unavailable in injectable forms. The SDAs are commonly used to treat persons who respond poorly to the DAs. However, many psychotherapists now regard the use of these atypical antipsychotics as the treatment of first choice.

Psychotherapy

Most schizophrenics can benefit from **psychotherapy** once their acute symptoms have been brought under control by antipsychotic medication. Psychoanalytic approaches are not recommended. Behavior therapy, however, is often helpful in assisting people to acquire skills for daily living and social interaction. It can be combined with **occupational therapy** to prepare individuals for eventual employment.

Family therapy

Family therapy is often recommended for the families of schizophrenic patients, to relieve the feelings of guilt that they often have as well as to help them understand a schizophrenic's disorder. The family's attitude and behaviors toward the schizophrenic are key factors in minimizing relapses (for example, by reducing stress in an individual's life), and family therapy can often strengthen the family's ability to cope with the stresses caused by the schizophrenic's illness. Family therapy that focuses on communication skills and problem-solving strategies is particularly helpful. In addition to formal treatment, many families benefit from support groups and similar mutual help organizations for relatives of schizophrenics.

KEY TERMS

Affective flattening—A loss or lack of emotional expressiveness. It is sometimes called blunted or restricted affect.

Akathisia—Agitated or restless movement, usually affecting the legs and accompanied by a sense of discomfort. It is a common side effect of neuroleptic medications.

Catatonic behavior—Behavior characterized by muscular tightness or rigidity and lack of response to the environment. In some persons, rigidity alternates with excited or hyperactive behavior.

Delusion—A fixed, false belief that is resistant to reason or factual disproof.

Depot dosage—A form of medication that can be stored in a person's body tissues for several days or weeks, thus minimizing the risk of forgetting daily doses. Haloperidol and fluphenazine can be given in depot form.

Dopamine receptor antagonists (DAs)—The older class of antipsychotic medications, also called neuroleptics. These primarily block the site on nerve cells that normally receives the brain chemical dopamine.

Dystonia—Painful involuntary muscle cramps or spasms. Dystonia is one of the extrapyramidal side effects associated with some antipsychotic medications.

Extrapyramidal symptoms (EPS)—A group of side effects associated with antipsychotic medications. EPS include parkinsonism, akathisia, dystonia, and tardive dyskinesia.

First-rank symptoms—A set of symptoms designated by Kurt Schneider in 1959 as the most important diagnostic indicators of schizophrenia. These symptoms include delusions, hallucinations, thought insertion or removal, and thought broadcasting. First-rank symptoms are sometimes referred to as Schneiderian symptoms.

Hallucination—A sensory experience of something that does not exist outside the mind. A person can experience a hallucination in any of the five senses. Auditory hallucinations are a common symptom of schizophrenia.

Huntington's chorea—A hereditary disease that typically appears in midlife, marked by gradual loss of brain function and involuntary movements. Some of its symptoms resemble those of schizophrenia.

Negative symptoms—Symptoms of schizophrenia that are characterized by the absence or elimination of certain behaviors. DSM-IV specifies three negative symptoms: affective flattening, poverty of speech, and loss of will or initiative.

Neuroleptic—Another name for the older type of antipsychotic medications given to schizophrenic persons.

Parkinsonism—A set of symptoms originally associated with Parkinson's disease that can occur as side effects of neuroleptic medications. The symptoms include trembling of the fingers or hands, a shuffling gait, and tight or rigid muscles.

Positive symptoms—Symptoms of schizophrenia that are characterized by the production or presence of behaviors that are grossly abnormal or excessive, including hallucinations and thought-process disorder. DSM-IV subdivides positive symptoms into psychotic and disorganized.

Poverty of speech—A negative symptom of schizophrenia, characterized by brief and empty replies to questions. It should not be confused with shyness or reluctance to talk.

Psychotic disorder—A mental disorder characterized by delusions, hallucinations, or other symptoms of lack of contact with reality. The schizophrenias are psychotic disorders.

Serotonin dopamine antagonists (SDAs)—The newer second-generation antipsychotic drugs, also called atypical antipsychotics. SDAs include clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa).

Wilson's disease—A rare hereditary disease marked by high levels of copper deposits in the brain, eyes and liver. It can cause psychiatric symptoms resembling schizophrenia.

Word salad—Speech that is so disorganized that it makes no linguistic or grammatical sense.

Prognosis

One important prognostic sign is a person's age at onset of psychotic symptoms. People with early onset of schizophrenia are more often male, have a lower level of functioning prior to onset, a higher rate of brain abnormalities, more noticeable negative symptoms, and worse outcomes. Persons with later onset are more likely to be female, with fewer brain abnormalities and thought impairment, and more hopeful prognoses.

The average course and outcome for schizophrenics are less favorable than those for most other mental disorders, although as many as 30% of people diagnosed with schizophrenia recover completely and the majority experience some improvement. Two factors that influence outcomes are stressful life events and a hostile or emotionally intense family environment. Schizophrenics with a high number of stressful changes in their lives, or who have frequent contacts with critical or emotionally over-involved family members, are more likely to relapse. Overall, the most important component of long-term care for schizophrenic individuals is complying with their regimen of antipsychotic medications.

Health care team roles

Physicians such as a family doctor or internist often make an initial diagnosis of schizophrenia. Psychiatrists, psychologists, or other therapists may also provide an initial diagnosis. Psychiatrists, clinical psychologists, or other trained professionals provide intervention treatment and therapy. Counselors may provide support during and after treatment. Nurses often administer medications.

Prevention

With present levels of understanding about schizophrenia, there does not appear to be any way to prevent the disease. Better understanding holds the promise of prevention if specific causal factors are environmental, chemical or viral.

Sciatic nerve pain *see* **Sciatica**

Sciatica

Definition

Sciatica describes **pain** or discomfort in the distribution of the sciatic nerve or its components. This nerve runs from the lower part of the **spinal cord**, down the back of the leg, to the foot. Injury to, or pressure on, the sciatic nerve can cause the characteristic pain of sciatica—a sharp or burning pain that radiates from the lower back or hip, following the path of the sciatic nerve to the foot.

Description

The sciatic nerve is the largest and longest nerve in the body. It supplies sensation from the lower back to the foot. The nerve originates in the lumbar region of the spinal cord. As it branches off from the spinal cord, it passes between the bony vertebrae (the component bones of the spine) and runs through the pelvic girdle (hip-bones). The nerve passes near the hip joint and continues down the back of the leg to the foot.

Sciatica is a fairly common disorder. Approximately 40% of the population suffers from it at some point in their lives; however, only about 1% experience any sensory or motor deficits. Sciatic pain has several root causes, and its treatment is directed to the underlying problem.

Of the identifiable causes of sciatic pain, lumbosacral (LS) radiculopathy and back strain are the most

frequently suspected. The LS area is the lower part of the spine, and radiculopathy describes pain radiating from pressure on a spinal nerve roots. This area between the vertebrae (hard bones) is cushioned with a disk of shock-absorbing tissue. The spinal canal, comprising the spinal cord and other nerve roots, is hollow and lies in the middle of the spinal column. It is the disks between the vertebrae that enable the back to bend or flex.

A “ring” of cartilage, gristle-like in character, is found the outer edge of the disk (the annulus). The disk’s center (nucleus) is a substance like gel. When a disk ruptures, or herniates, it does so because of wear-and-tear, excessive weight, poor posture, injury (perhaps due to improper lifting), or disease. The center nucleus pushes the outer edge of the disk into the spinal canal, putting pressure on the nerves. The spinal nerve root may become compressed by the shifted tissue or the vertebrae. This compression of the nerve root sends a pain signal to the **brain**. Although the injury is actually suffered by the nerve roots, the pain may be perceived as originating anywhere along the sciatic nerve. Further, if fragments of the disk lodge in the spinal canal, the nerves that control bowel and urinary functions may be damaged. Incontinence may result.

Sciatica is largely a symptom of a **herniated disk**. However, compression of the sciatic nerve can also present as muscle spasms in the lower back (back strain). In this case, pressure is placed on the sciatic nerve. In rare cases, **infection**, **cancer**, bone inflammation, or other diseases may cause pressure. Another possible cause of sciatica is piriformis syndrome.

As the sciatic nerve passes behind the hip joint, it shares the space with several muscles. One of these muscles, the piriformis muscle, is closely associated with the sciatic nerve. In some people, the nerve actually runs through the muscle. If this muscle is injured or has a spasm, it places pressure on the sciatic nerve, in effect, compressing it.

In many sciatica cases, the specific cause is never identified. About half of affected individuals recover from an episode within a month. Some cases persist and may require aggressive treatment. In other cases, the pain returns or becomes chronic.

Causes and symptoms

Patients with sciatica may experience low back pain, but the most common symptom is pain that radiates through one buttock and down the back of the leg. The most frequently identified cause of pain is compression or pressure on the sciatic nerve. The extent of the pain varies. Some patients describe pain that centers in the

area of the hip; others feel discomfort all the way to the foot. The quality of the pain also varies; it may be described as tingling, burning, prickly, aching, or stabbing.

Onset of sciatica may be sudden, but it might also develop gradually. The pain may be intermittent or continuous. Certain activities (such as bending, coughing, sneezing, or sitting) can worsen the pain.

Sudden loss of bowel or bladder control, weakness in the legs, buttocks, or torso, as well as numbness that goes upwards from the toes or the feet, may indicate a sciatic condition.

Chronic pain may arise from more than simple compression of the nerve root. Discogenic pain, the result of injury to the innervated portions of the annulus fibrosus, is a common cause of sciatica. Pain is generally felt in the buttocks and in the posterior thigh.

According to some pain researchers, physical damage to a nerve is only half of the equation. A theory developed in 2001 proposes that some nerve injuries result when certain neurotransmitters and **immune system** chemicals that exacerbate and sustain a pain message. Even after the injury has healed or the damage has been repaired, the pain lingers. Effective management of this type of pain is difficult. Another theory that has been put forward is that back problems may be inherited. This theory presupposes that a genetic abnormality is responsible for a number of cases of spinal disk disease cases. This defect makes people susceptible to rupture when the back is strained. The investigators claimed that 25% of all cases of sciatica, lower back problems, and discomfort higher in the spine, might be attributable to this gene defect. When classic symptoms are absent, identification of the defect could enable diagnosis of disease, thereby facilitating the therapeutic process.

Diagnosis

Establishing the diagnosis requires taking a thorough medical history and performing a focused **physical examination**. The patient is asked about the location, nature, and duration of the pain, and the details of any accidents, injuries or unusual activities that may have occurred prior to the onset of sciatica. This information provides clues that may point to back strain or injury to a specific location.

Back pain from disk disease, piriformis syndrome, and back strain must be differentiated from more serious conditions, such as cancer or infection. In spring 2001, Dr. T. S. J. Elliott, professor of microbiology at University Hospital in Birmingham, England, conducted a new study—the results of which were published in *The*

Lancet. The doctor found hidden infections in 43 of 140 sciatica (30.7%) patients who suffered from persistent pain originating in the sciatic nerve. (The sciatic nerve of the leg is the largest nerve in the body.) Dr. Elliott believes that when the spine suffers a minor trauma, an organism enters the body. This organism causes sciatica that is continuous, with the resulting inflammation being caused by the infection. Further, he postulated that if imaging studies do not show injury, then there may be something to the physician's study.

More investigations need to be done, however, evaluating the success of **antibiotics** (used to fight infections) in treating sciatica. Lumbar spine stenosis, an overgrowth of the covering layers of the vertebrae that narrows the spinal canal, must also be considered.

A straight leg-raising test is often performed. The patient lies supine, and the health care provider raises the affected leg to various heights. This test pinpoints the location of the pain and may reveal whether it is caused by a disk problem. Other tests, such as observing the patient rotate the hip joint, may provide information about involvement of the piriformis muscle if the patient experience pain. Piriformis weakness is tested with additional leg-strength maneuvers.

Further tests may be conducted depending on the patient's history, results of the physical examination, and response to initial treatment. Diagnostic tests may include traditional x rays, **magnetic resonance imaging** (MRI), and computed tomography scans (**CT scans**). Other tests include **electromyography** (studies of the electrical activity generated as muscles contract), nerve conduction velocity testing, and evoked potential testing. **Myelography**, a more invasive test, involves injecting a contrast medium into the spinal subarachnoid space between the vertebrae and taking x-ray images of the spinal cord. Myelography is usually ordered when surgical treatment is considered. Since the advent of MRI, however, myelography is very rarely used. The MRI does not use ionizing radiation. Noninvasive, it produces excellent computerized images of soft tissues, such as seen in herniated discs and tumors. The MRI is based on nuclear magnetic resonance of atoms within the body; the atoms are generated by the use of radio waves. All these tests can reveal problems with the vertebrae, the disk, or the nerve itself.

Treatment

Pharmacological therapy—initial treatment for sciatica—focuses on pain relief. Regardless of the cause of the pain, **analgesics** (such as acetaminophen) may help relieve pain. **Muscle relaxants** are also used, but it hasn't been proved whether they really work. Furthermore,

the side effects of muscle relaxants may be greater than their benefits, particularly in the elderly. Generally, pain relief is accomplished with nonsteroidal anti-inflammatory drugs (NSAIDs). It should be noted, however, that anti-inflammatory medications should be administered generally for only two to four weeks, and only if no medical contraindications are present. As of 2001, the Food and Drug Administration (FDA) had also approved labeling two newer drugs for the relief of pain; they are rofecoxib (Vioxx), a NSAID with selective cyclo-oxygenase 2 inhibition; and celecoxib (Celebrex). Both have fewer gastrointestinal side effects, but must be taken advisedly by the patient at risk for peptic ulcer disease.

If the pain is unremitting, opioids may be prescribed for short-term use or a local anesthetic may be injected directly into the lower back. Massage and heat application may be suggested as adjunct therapies.

If the pain is chronic, different pain relief medications are used to avoid long-term dosing of NSAIDs, muscle relaxants, and opioids. **Antidepressant drugs**, which have been shown to be effective in treating pain, may be prescribed in conjunction with a short-term course of a muscle relaxant or a NSAID. Local anesthetic injections, or epidural steroids, are used in selected cases.

As pain permits, **physical therapy** is introduced into the treatment regime. Stretching exercises that focus on the lower back, buttocks, and hamstring muscles are suggested. The exercises may also include identifying and practicing comfortable, pain-reducing positions. Corsets and braces may be useful in some cases, but there is not any clinical evidence for their general effectiveness as of 2001. However, they may be helpful in the prevention of exacerbation of sciatica as related to certain activities.

With less pain and the success of early therapy, the patient is encouraged to follow a long-term **exercise** program to maintain a healthy back and prevent re-injury. A physical therapist may suggest exercises and regular activity, such as water exercise or walking. Patients are instructed in proper posture and body mechanics as means of minimizing symptoms during light lifting, prolonged sitting or standing, and other activities.

If the pain is chronic and conservative treatment fails—suggesting that a disk fragment has lodged in the spinal canal and is pressing on the nerve (and perhaps causing a loss of function—surgery may be required. A procedure to repair a herniated disk or excise part, or all of the piriformis muscle, may be suggested, particularly if there is neurologic evidence of nerve or nerve-root damage (radiculopathy). It should be noted, however, that as of 2001, newer and minimally invasive procedures are available to relieve the pain of sciatica. A local

anesthetic is used, and surgery is performed on an ambulatory basis. The recovery period is two to six weeks.

Massage is a recommended form of therapy, especially when the sciatic pain arises from muscle spasm. Patients may be able to relieve symptoms by icing the painful area as soon as pain occurs. The physical therapist or nurse may instruct the patient to place ice on the affected area for 20 minutes, several times a day. After two to three days, a hot water bottle or heating pad can replace the ice. Chiropractic or osteopathic therapy may offer solutions for relieving pressure on the sciatic nerve and the accompanying pain. Acupuncture and biofeedback may also be useful as pain control methods.

Prognosis

Most cases of sciatica are treatable with pain medication and physical therapy. After four to six weeks of treatment, the patient should be able to resume normal activities.

Health care team roles

The diagnosis of sciatica is usually made by a PCP or a mid-level practitioner (physician assistant [PA] or nurse practitioner [NP]). Other physician specialists, such as neurologists, orthopedists, and physiatrists (specialists in physical medicine) also may provide consultative services. Radiologic technologists generally perform diagnostic imaging studies.

The treatment plan may involve physical therapists (PTs) and physical therapist assistants (PTAs), who instruct and supervise prescribed exercise programs. Patients also may be referred to specialists in orthotics, who prescribe appliances/apparatuses to support, align, prevent, or correct deformities, improve posture, or ease the function of movable body parts. Sometimes specialists work with ergonomics. The patient may be taught proper body mechanics at home and in the workplace.

Patient education

Patient education focuses on adhering to prescribed treatment, including exercise and body mechanics (above), and preventing future injuries. Nurses, PTs, PTAs, occupational therapists, and exercise physiologists may be involved in helping patients learn how to perform the activities of daily living (ADL) without exacerbating existing injuries.

Prevention

Some sources of sciatica are not preventable, such as disk degeneration, back strain resulting from **pregnancy**,

KEY TERMS

Acupuncture—The Chinese practice of piercing specific areas of the body along peripheral nerves with fine needles to relieve pain, to induce surgical anesthesia, and for therapeutic purposes.

Biofeedback—The process of furnishing an individual with information on the state of one or more physiologic variables, such as heart rate, blood pressure, or skin temperature. The goal is to enable the patient to gain some voluntary control over them.

Disk—Dense tissue between the vertebrae that acts as a shock absorber and prevents damage to nerves and blood vessels along the spine.

Electromyography—A diagnostic test in which a nerve's ability to conduct an impulse is measured.

Lumbosacral (LS)—Referring to the lower part of the backbone or spine.

Myelography—A medical test in which a special dye—a contrast medium—is injected the spinal subarachnoid space (through which cerebrospinal fluid [CSF] circulates, and across which extend delicate connective tissue pass) to make it visible on radiographic visualization.

NSAID—Nonsteroidal anti-inflammatory drugs are medications that produce analgesic and anti-inflammatory effects.

Opioid—A synthetic narcotic that has opiate-like qualities, but is not derived from opium.

Orthotics—Serving to protect or to restore or improve function; relating to the use or application of an orthosis.

Piriformis—A muscle in the pelvic girdle that is closely associated with the sciatic nerve.

Radiculopathy—A condition in which the nerve root of a nerve has been injured or damaged.

Spasm—Involuntary contraction of a muscle.

Spinal subarachnoid space—Space through which which cerebrospinal fluid circulates, and across which extend delicate connective tissue pass.

Vertebrae—The component bones of the spine.

or accidental injuries from **falls**. Other sources of back strain, such as poor posture, overexertion, **obesity**, or

wearing high heels, may be corrected or avoided. Smoking may also predispose patients to pain, as it the supply of **blood** to intervertebral discs, and interferes with healing. An orthopedist with the Gwinnett Health System in Lawrenceville, Georgia, Dr. Walker states that “Smoking leads to drying and stiffness of the discs, making them more susceptible to injury, including herniation, and prolonged recovery time.”

General suggestions for avoiding sciatica or preventing future episodes include sleeping on a firm mattress, using chairs with firm back supports, and sitting with both feet flat on the floor. Habitually crossing the legs while sitting may place excess pressure on the sciatic nerve. Sitting for prolonged periods of time also places pressure on the sciatic nerves, so patients are advised to take short breaks and move around during the workday, when on long trips, or in other situations that require sitting for extended lengths of time. When sitting for long periods, the patient should put his or her feet up on a low stool. If it is required that something be lifted without another person, the back should be kept straight and the legs should provide the lift. The knees should be bent, and the individual should get as close to the object as possible. This will reduce the load on the lower back. To give one a wider base of support and to distribute the weight of the object being lifted, the feet should be kept apart.

Regular exercise, such as swimming and walking, can build stamina, strengthen back muscles, improve flexibility, and improve posture. Exercise also helps to maintain proper body weight and lessens the likelihood of back strain.

Scoliosis

Definition

Scoliosis is a side-to-side (lateral) curvature of the spine of 10 degrees or greater.

Description

When viewed from the rear, the spine usually appears to form a straight vertical line. Scoliosis is a lateral (side-to-side) curve in the spine, usually combined with a rotation of the vertebrae. The lateral curvature of scoliosis should not be confused with the normal set of front-to-back spinal curves visible from the side. While a small degree of lateral curvature does not cause any medical problems, larger curves can cause postural imbalance and lead to muscle fatigue and **pain**. More severe scoliosis can interfere with breathing and lead to arthritis of the spine (spondylosis).

Four out of five cases of scoliosis are idiopathic, meaning their cause is unknown. Children with idiopathic scoliosis appear to be otherwise entirely healthy, and have not had any bone or joint disease early in life. Scoliosis is not caused by poor posture, diet, or carrying a heavy bookbag exclusively on one shoulder.

Idiopathic scoliosis is further classified according to age of onset:

- **Infantile.** Curvature appears before age three. This type is quite rare in the United States, but is more common in Europe.
- **Juvenile.** Curvature appears between ages three and 10. This type may be equivalent to the adolescent type, except for the age of onset.
- **Adolescent.** Curvature appears between ages of 10 and 13, near the beginning of **puberty**. This is the most common type of idiopathic scoliosis.
- **Adult.** Curvature begins after physical maturation is completed.

Causes are known for three other types of scoliosis:

- **Congenital scoliosis** is due to congenital birth defects in the spine, often associated with other structural defects.
- **Neuromuscular scoliosis** is due to loss of control of the nerves or muscles which support the spine. The most common causes of this type of scoliosis are **cerebral palsy** and **muscular dystrophy**.
- **Degenerative scoliosis** may be caused by degeneration of the discs which separate the vertebrae or arthritis in the joints that link them.

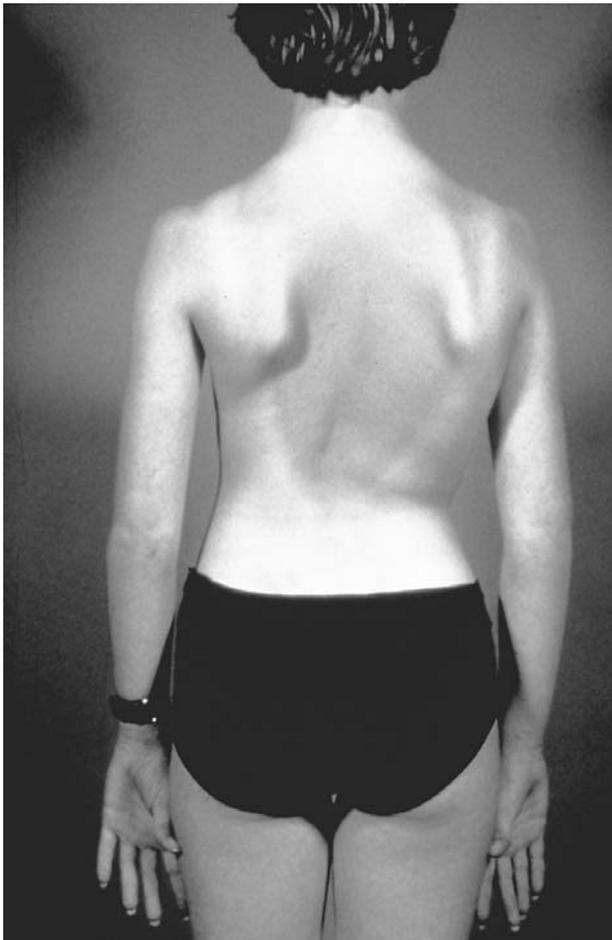

Genetic profile

Idiopathic scoliosis has long been observed to run in families. Twin and family studies have consistently indicated a genetic contribution to the condition. However, no consistent pattern of transmission has been observed in familial cases. As of 2001, no genes have been identified which specifically cause or predispose individuals to the idiopathic form of scoliosis.

There are several genetic syndromes which involve a predisposition to scoliosis. Several studies have investigated whether or not the genes which cause these syndromes may also be responsible for idiopathic scoliosis. Using this candidate gene approach, the genes responsible for Marfan syndrome (fibrillin), Stickler syndrome, and some forms of osteogenesis imperfecta (collagen types I and II) have been shown not to correlate with idiopathic scoliosis.

Attempts to map a gene or genes for scoliosis have not shown consistent linkages to any particular chromosome region.

Most researchers have concluded that scoliosis is a complex trait. As such, there are likely to be multiple genetic, environmental, and potentially additional factors that contribute to the etiology of the condition. Complex traits are difficult to study due to the difficulty in identifying and isolating multiple factors.

Demographics

The incidence of scoliosis in the general population is approximately 2–3%. Among adolescents, however, 10% have some degree of scoliosis, though fewer than 1% have curves that require treatment.

Scoliosis is found in both males and females, but a female's spinal curve is much more likely to progress than a male's. Females require scoliosis treatment about five times as often as males. The reason for these differences is not known with certainty but they may relate to increased levels of estrogen and other hormones in females.

Causes and symptoms

Scoliosis causes a noticeable asymmetry in the torso when viewed from the front or back. The first sign of scoliosis is often seen when a child is wearing a bathing suit or underwear. A child may appear to be standing with one shoulder higher than the other, or to have a tilt in the

waistline. One shoulder blade may appear more prominent than the other due to rotation. In girls, one breast may appear higher than the other, or larger if rotation pushes that side forward.

Curve progression is greatest near the adolescent growth spurt. Scoliosis that begins early in life is more likely to progress significantly than scoliosis that begins later in puberty.

More than 30 states have screening programs in schools for adolescent scoliosis. These are usually conducted by physicians, school nurses or trained physical education teachers.

Diagnosis

Scoliosis is initially noticed during a screening program or during a routine **physical examination** conducted by a pediatrician or family physician. Confirmatory diagnosis of scoliosis is often conducted by an orthopedic surgeon. A complete medical history is taken, including questions about family history of scoliosis. The physical examination includes determination of pubertal development in adolescents, a neurological exam (which may reveal a neuromuscular cause), and measurements of trunk asymmetry. Examination of the trunk is done while the person is standing, bending over, and lying down, and involves both visual inspection and use of a simple mechanical device called a scoliometer.

If a curve is detected, one or more x rays will usually be taken to define more precisely the curve or curves. An x ray is used to document spinal maturity, any pelvic tilt or hip asymmetry, and the location, extent, and degree of curvature. The curve is defined in terms of where it begins and ends, in which direction it bends, and by an angular measure known as the Cobb angle. The Cobb angle is found by projecting lines parallel to the vertebrae tops at the extremes of the curve; projecting perpendiculars from these lines; and measuring their angle of intersection. To properly track the progress of scoliosis, it is important to project from the same points of the spine each time.

Occasionally, **magnetic resonance imaging** (MRI) is used, primarily to look more closely at the condition of the **spinal cord** and nerve roots extending from it if neurological problems are suspected.

Treatment

Treatment decisions for scoliosis are based on the degree of curvature, the likelihood of significant progression, and the presence of pain, if any.

Curves less than 20 degrees are not usually treated, except by regular follow-up for children who are still growing. Watchful waiting is usually all that is required in adolescents with curves of 20–25 degrees, or adults with curves up to 40 degrees or slightly more, as long as there is no pain.

For children or adolescents whose curves progress to 25 degrees, and who have a year or more of growth left, bracing may be required. Bracing cannot correct curvature, but may be effective in halting or slowing its progression. Bracing is rarely used in adults, except where pain is significant and surgery is not an option, as in some elderly patients.

There are two different categories of braces, those designed for nearly 24 hour per day use and those designed for night use. The full-time brace styles are designed to hold the spine in a vertical position, while the night use braces are designed to bend the spine in the direction opposite the curve.

The Milwaukee brace is a full-time brace which consists of metal uprights attached to pads at the hips, rib cage, and neck. Other types of full-time braces, such as the Boston brace, involve underarm rigid plastic molding to encircle the lower rib cage, abdomen, and hips. Because they can be worn out of sight beneath clothing, underarm braces are better tolerated and often lead to better compliance. The Boston brace is currently the most commonly used. Full-time braces are often prescribed to be worn for 22–23 hours per day, though some clinicians believe that recommending brace use of 16 hours leads to better compliance and results.

Night-use braces bend an individual's scoliosis into a correct angle, and are prescribed for eight hours of use during sleep. Some investigators have found that night-use braces are not as effective as the day-use types.

Bracing may be appropriate for scoliosis due to some types of neuromuscular disease, including spinal muscular atrophy, before growth is finished. Duchenne muscular dystrophy is not treated by bracing, since surgery is likely to be required, and since later surgery is complicated by loss of respiratory capacity.

Surgery for idiopathic scoliosis is usually recommended if:

- The curve has progressed despite bracing.
- The curve is greater than 40–50 degrees before growth has stopped in an adolescent.
- The curve is greater than 50 degrees and continues to increase in an adult.
- There is significant pain.

Orthopedic surgery for neuromuscular scoliosis is often done early in life. The goals of surgery are to correct the deformity as much as possible, to prevent further deformity, and to eliminate pain as much as possible. Surgery can usually correct 40–50% of the curve, and sometimes as much as 80%. Surgery cannot always completely remove pain.

The surgical procedure for scoliosis is called spinal fusion, because the goal is to straighten the spine as much as possible, and then to fuse the vertebrae together to prevent further curvature. To achieve fusion, the involved vertebra are first exposed, and then scraped to promote re-growth. Bone chips are usually used to splint together the vertebrae to increase the likelihood of fusion. To maintain the proper spinal posture before fusion occurs, metal rods are inserted alongside the spine, and are attached to the vertebrae by hooks, screws, or wires. Fusion of the spine makes it rigid and resistant to further curvature. The metal rods are no longer needed once fusion is complete, but are rarely removed unless their presence leads to complications.

Spinal fusion leaves the involved portion of the spine permanently stiff and inflexible. While this leads to some loss of normal motion, most functional activities are not strongly affected, unless the very lowest portion of the spine (the lumbar region) is fused. Normal mobility, **exercise**, and even contact sports are usually all possible after spinal fusion. Full recovery takes approximately six months.

Prognosis

The prognosis for a person with scoliosis depends on many factors, including the age at which scoliosis begins and the treatment received. Most cases of mild adolescent idiopathic scoliosis need no treatment, do not progress, and do not cause pain or functional limitations. Untreated severe scoliosis often leads to spondylosis, and may impair breathing.

Health care team roles

A pediatrician or family physician usually makes an initial diagnosis of scoliosis. Orthopedic surgeons may provide surgical treatment. Physical therapists may provide therapeutic exercises for a person with scoliosis.

Prevention

There is no known way to prevent any of the forms of scoliosis.

KEY TERMS

Cobb angle—A measure of the curvature of scoliosis, determined by measurements made on x rays.

Scoliometer—A tool for measuring trunk asymmetry; it includes a bubble level and angle measure.

Spondylosis—Arthritis of the spine.

Scrotal nuclear medicine scan

Definition

Scrotal nuclear medicine scan is a study of the tissues in the scrotum, using a radioactive contrast agent to identify masses, **blood** flow, and areas of **infection**.

Purpose

The scrotal nuclear medicine scan is used to assess blood flow within the testicles and damage caused by injury. It is also used to ascertain the cause of swollen testes (testicles) which may be due to infection or the twisting of the entire tissues of the testicle. This is done in an emergency setting if the testicle swells suddenly and painfully.

This scan can be used to diagnose tumors and cysts (pockets of fluid), but testicular ultrasound has become the diagnostic tool of choice for these growths in 2001.

Precautions

There are no precautions with a scrotal nuclear medicine scan, except that the patient must remain still during the procedure.

Description

A radioisotope, technetium-99, combined with a chemical (pertechnetate) is injected intravenously while the patient is under a gamma camera that detects radiation. This special camera scans the scrotum at one minute intervals for about five minutes, then less often for another 10 or 15 minutes. It then creates pictures (either x ray or Polaroid) that reveal where the isotope is in the scrotum. Since both sides of the scrotum are scanned, even greater accuracy is obtained by comparison.

Some areas accumulate the tracer in greater than normal amounts. These are called “hot” spots and may indicate tumors or other masses. Areas that have less than normal amounts of the tracer or none at all are called “cold” spots and may indicate cysts or infection.

It is important to differentiate infection from twisting torsion and infection. A common infection called epididymitis involves a collection of tubules on top of the testicle called the epididymis that carry sperm. Twisting of the spermatic cord inside the scrotum, outside the testicle often shuts off the testes’ blood supply and is called testicular torsion. Both conditions cause a very painful, swollen testicle on one side of the scrotum. Epididymitis and testicular torsion occur most often in young men, although infection usually occurs at a slightly older age. Infection increases the blood supply, showing up as a “hot” spot on the scan, whereas testicular torsion cuts off the blood supply, appearing as a “cold” spot. The distinction is critically important, because testicular torsion must be untwisted immediately by surgery or the testicle will die. On the other hand, epididymitis responds to **antibiotics**, and surgery might further injure it.

After the patient has changed into gown, he will lie on a scanning table. The penis will be taped to the abdomen to prevent it from shadowing the scan. A towel may be used to support the testicles during the test. The tracer will be injected into a vein on the inside of the elbow, and the camera will begin taking pictures of the testicles. It is important that the patient remain still during the scans.

Two complete passes are made about 15 minutes apart. The total scrotal scan takes about 45 minutes.

Preparation

There is no preparation prior to a scrotal nuclear medicine scan. The day of the test, the patient will need to remove any jewelry, watches, and metal (belts, hair-pins, etc.) and change into a gown.

Aftercare

The patient should be able to go about normal activities after the scan. However, if surgery is performed immediately after the scan, normal post-surgical precautions should be undertaken.

Complications

The risk of complications is minimal due to the small amount of radiation to which the body is exposed. Even sensitive testicular tissue is at minimum risk. The tracer is eliminated from the body within 24 hours, and allergic reactions to the tracer are rare.

Results

Results are usually available in two days. In an emergency, results are made available in one hour. Normal results show unobstructed blood flow with no “hot” or “cold” spots. Abnormal results are shown in the scan images as:

- “Hot” spots, where the tracer accumulates in greater amounts than normal, can indicate epididymitis or a tumor.
- “Cold” spots have no accumulation of the tracer or very little. These may point to cysts, abscesses, or blood clots.
- Blood flow is uneven throughout the testicles. This indicates a narrowing or blockage of the **blood vessels**, including from torsion, or possibly direct damage from injury. Sometimes the blood flow pattern appears in a “donut” shape, which suggests that testicular torsion has occurred but that it has resolved itself within the last few days.

KEY TERMS

Epididymitis—A common infection involving a collection of tubules on top of the testicle called the epididymis that carry sperm.

Radioisotope—An unstable form of an element that gives off radiation to become stable.

Scrotum—The bag of skin below the penis that contains the testes.

Testicular torsion—A condition involving the twisting of the spermatic cord inside the testicle that shuts off its blood supply and can seriously damage the testicle.

Abnormal results may require further investigation through other tests, such as testicular biopsy or ultrasound.

Health care team roles

The nuclear medicine technologist will need to educate the patient about the procedure (for example, how the scan is done, what happens during it, what kinds of information the scan can produce for the doctor, etc.). This is very necessary to keep the patient informed and to ensure cooperation during the procedure. It is crucial that the patient remain still during the scan.

The nuclear medicine technologist who performs the scrotal scan will need to reassure the patient before and during the scan in order to keep the patient relaxed and still during the scan.

Scrotal ultrasound

Definition

Scrotal ultrasound is an imaging technique used for the diagnosis of suspected abnormalities of the scrotum and testes. It uses harmless, high-frequency sound waves to form an image. The sound waves are reflected by scrotal tissue to form a picture of internal structures. It is not invasive and involves no radiation.

Purpose

Ultrasound of the scrotum is the primary imaging method used to evaluate disorders of the testicles and surrounding tissues. It is used when a man has acute **pain** in the scrotum. Some of the medical problems for which the use of scrotal ultrasound is valuable include an absent or undescended testicle, inflammation of the testicle or associated structures, testicular torsion, a fluid collection (hydrocele), abnormal **blood vessels** (varicocele), or a mass (lump or tumor).

A sudden onset of pain in the scrotum is considered a serious problem. Delay in diagnosis and treatment can lead to loss of function. Epididymitis is the most common cause of this type of pain. Epididymitis is an inflammation of the epididymis, a tubular structure that transports sperm from the testes. It is most often caused by bacterial **infection**, but may occur after injury, or arise from an unknown cause. Epididymitis is treatable with **antibiotics**, which usually resolves pain quickly and ice to reduce swelling. Left untreated, this condition can lead to **abscess** formation or loss of **blood** supply to the testicle. The latter condition can cause testicular loss.

Testicular torsion is the twisting of the spermatic cord that containing the blood vessels that supply the testicles. It is caused by abnormally loose attachments of tissues that are formed during **fetal development**. Torsion can be complete, incomplete, or intermittent. Spontaneous detorsion, or untwisting, can occur, making diagnosis difficult. Testicular torsion arises most commonly during adolescence, and is acutely painful. Scrotal ultrasound is used to distinguish this condition from inflammatory problems, such as epididymitis. Testicular torsion is a surgical emergency; it should be operated on as soon as possible to avoid permanent damage to the testes.

A scrotal sac with an absent testicle may be the result of a congenital anomaly (an abnormality present at birth), where a testicle fails to develop. More often, it is due to an undescended testicle. In the fetus, the testicles normally develop just outside the abdomen and descend into the scrotum during the seventh month. Approximately

3% of full term baby boys have undescended testicles. It is important to distinguish between an undescended testicle and an absent testicle, as an undescended testicle has a very high probability of developing **cancer** if left untreated.

Ultrasound can be used to locate and evaluate masses in the scrotum. Most masses within the testicle are malignant or cancerous, and most outside the testicle are benign. Primary cancer of the testicles is the most common malignancy in men between the ages of 20 and 35. Fluid collections and abnormalities of the blood vessels in the scrotum may appear to the physician as masses and need evaluation by ultrasound. A hydrocele, the most common cause of painless scrotal swelling, is a collection of fluid between two layers of tissue surrounding the testicle. An abnormal enlargement of the veins which drain the testicles is called a varicocele. It can cause discomfort and swelling, which can be examined by touch (palpated). Varicocele is a common cause of male **infertility**, and is more common on the left testicle.

Precautions

Clear scrotal ultrasound images are difficult to obtain if a person is unable to remain still. Other than cleaning the surface of the skin upon which a transducer will be placed, there are no special precautions that are associated with ultrasonography.

Description

A transducer (an electronic imaging device) is used to both generate and receive acoustic images. It is placed against the skin over the structure to be examined. The transducer is moved over the area creating images from reflected sound waves, which appear on a monitor screen. There is no discomfort from the study itself. However, if the scrotum is very tender, even the slight pressure involved may be painful.

Preparation

The patient lies on his back on an examining table. The technologist will usually take a history of the problem, then gently palpate the scrotum. A rolled towel is placed between the patient's legs to support the scrotum. The penis is lifted up onto the abdomen and covered. A gel that enhances sound transmission is applied directly on the scrotum. The technologist then gently places a transducer (an electronic imaging device) against the skin.

Aftercare

The transducing gel is removed with soap and water. Any underlying medical condition is treated. There is no aftercare for the scrotal ultrasound examination.

Complications

There are no complications associated with ultrasonography.

Results

A normal study reveals testicles of normal size and shape, with no masses or abnormalities.

An abnormal result of an ultrasound of the scrotum may reveal an absent or undescended testicle, an inflammation problem, testicular torsion, a fluid collection, abnormal blood vessels, or a mass.

Health care team roles

A family physician, pediatrician, urologist, or emergency room doctor usually orders a scrotal ultrasound examination. An ultrasonographer or radiologist performs the examination. A radiologist interprets the images obtained.

Sedimentation rate test

Definition

The sedimentation rate test, also called the erythrocyte sedimentation rate (ESR) or sed rate test, measures the speed at which the red **blood** cells (erythrocytes or RBCs) separate from the liquid part of the blood (plasma) and settle to the bottom in a tube of anticoagulated blood.

Purpose

The sedimentation rate is a non-specific indicator of the presence of inflammation or **infection**. Although newer methods for diagnosing specific diseases have decreased the test's usefulness, it is still an important tool for the diagnosis and monitoring of two diseases: polymyalgia rheumatica and temporal arteritis. Sedimentation rate testing at regular intervals can also be helpful in predicting relapse in patients with chronic diseases such as Hodgkin's disease and other cancers.

Precautions

Patients who have **bleeding disorders** or are taking blood thinners might have trouble with bleeding following a venipuncture. Before having a blood sample drawn, such patients should tell the phlebotomist about their condition.

Description

The sedimentation rate test dates back to the early 1900s. In 1921, Westergren introduced a new method for performing the test that has become the time-honored classic. It is the recommended method of the International Committee for Standardization in Haematology and the National Committee for Clinical Laboratory Science. While automated methods can perform the sed rate in less time and with smaller samples of blood, many labs continue to use the Westergren method because it is simple and inexpensive.

For accurate results, the blood sample should be fresh (within two hours of collection is best). The sample might be rejected because it is too old or because the collection tube is underfilled, not labeled correctly, or contains blood that is hemolyzed or clotted.

The standard Westergren method includes the following steps:

- Diluting whole blood, or blood anticoagulated with EDTA, in citrate (1 volume of citrate to 4 volumes of blood).
- Aspirating the diluted blood to the 200 mm mark of a Westergren tube (30 cm in length and 2.55 mm in diameter with a uniform bore diameter) by means of a mechanical device or teat.
- Placing the tube in a vertical position in a Westergren rack in a location that is free of vibration and that is not exposed to direct sunlight.
- After exactly one hour, reading the distance the erythrocytes have fallen, and recording this value as the sedimentation rate.

Preparation

This test requires no special preparation.

Aftercare

To prevent bruising, pressure should be applied to the site of the venipuncture as soon as the needle is withdrawn. Pressure should be maintained until the bleeding stops.

Complications

No complications are associated with this test other than the possibility of having a slight bruise from having blood drawn from a vein. In very rare cases, vein inflammation or continued bleeding at the puncture site might be a problem.

Results

The sedimentation rate is measured in millimeters per hour (mm/hr). Normal values vary with age and sex, and can vary from lab to lab. A normal result does not rule out a diagnosis of inflammatory disease. An abnormal result does not diagnose any specific disease, and should be evaluated in conjunction with the patient's physical exam, medical history, and other more specific blood tests. In general, an abnormal result correlates with active inflammatory disease, and the sedimentation rate test is a useful way of monitoring disease progression or treatment. If the result is abnormal, the test should be repeated to verify its accuracy. A number of factors (such as medications, hormones, **obesity**, and improper collection or handling of the blood sample) can affect the outcome of this test.

Normal values

- Males under 50: 0–15 mm/hr.
- Males 50 and older: 0–20 mm/hr.
- Females under 50: 0–20 mm/hr.
- Females 50 and older: 0–30 mm/hr.
- Children: 3–13 mm/hr.
- Newborns: 0–2 mm/hr.

Greater than normal values

A greater than normal value can indicate inflammation due to infection, autoimmune disease (such as rheumatoid arthritis), or certain types of **cancer** (such as multiple myeloma and Hodgkin's disease). An elevated sed rate usually occurs when the level of plasma **proteins** in the blood is higher than normal. These plasma proteins (primarily fibrinogen) bind to the red blood cells, reducing the negative surface charge which normally causes the cells to repel each other. The red blood cells stack and settle to bottom of the tube faster than single red blood cells.

Lower than normal values

A lower than normal value can indicate diseases such as congestive **heart failure**, sickle cell anemia, and

KEY TERMS

Arteritis—The inflammation of an artery.

Aspirate (verb)—To draw or move by suction.

Phlebotomist—A person who draws blood from a vein.

Phlebotomy—A procedure in which a vein is punctured to obtain a blood sample.

Polymyalgia rheumatica—A disease that causes aching and stiffness in the neck, shoulder, or pelvis.

Temporal (giant cell) arteritis—A disease caused by arterial inflammation that usually results in headaches and facial pain. The production of giant cells is characteristic of this type of arteritis. If the ophthalmic artery and its branches become involved, it can also cause blindness.

Venipuncture—The puncture of a vein to withdraw a blood sample.

polycythemia (abnormally high numbers of circulating red blood cells).

Health care team roles

A phlebotomist usually draws and labels the blood sample for the sedimentation rate. However, any health care professionals trained in phlebotomy (such as doctors, nurses, clinical laboratory scientists, or medical technologists) can perform this task.

When the blood sample arrives at the lab, a clinical laboratory scientist (CLS [NCA]), medical technologist (MT [ASCP]), clinical laboratory technician (CLT [NCA]), or medical laboratory technician (MLT [ASCP]) will set up the test and record the sedimentation rate after the specified period of time, usually one hour.

Seizure disorder

Definition

A seizure is a sudden disruption of the brain's normal electrical activity accompanied by an alteration in consciousness or other neurological and behavioral manifestations. Epilepsy is a condition characterized by recurrent seizures that may include repetitive muscle jerking called convulsions.

Description

There are more than 20 different seizure disorders. One in 10 Americans will have a seizure at some time, and at least 200,000 have at least one seizure each month.

Epilepsy affects 1% to 2% of the United States population. Although epilepsy is as common in adults over 60 as in children under 10, 25% of all cases develop before the age of five. One in every two cases develops before the age of 25. About 125,000 new cases of epilepsy are diagnosed each year, and a significant number of children and adults that have not been diagnosed or treated have epilepsy.

Most seizures are benign, but a seizure that lasts a long time can lead to status epilepticus, a life-threatening condition characterized by continuous seizures, sustained loss of consciousness, and respiratory distress. Non-convulsive epilepsy can impair physical coordination, **vision**, and other senses. Undiagnosed seizures can lead to conditions that are more serious and more difficult to manage.

Types of seizures

Generalized epileptic seizures occur when electrical abnormalities exist throughout the **brain**. A partial seizure does not involve the entire brain. A partial seizure begins in an area called an epileptic focus, but may spread to other parts of the brain and cause a generalized seizure. Some people who have epilepsy experience more than one type of seizure.

Motor attacks cause parts of the body to jerk repeatedly. A motor attack usually lasts less than an hour and may last only a few minutes. Sensory seizures begin with numbness or tingling in one area. The sensation may move along one side of the body or the back before subsiding.

Visual seizures, which affect the area of the brain that controls sight, cause people to see things that are not there. Auditory seizures affect the part of the brain that controls **hearing** and cause a person to imagine voices, music, and other sounds. Other types of seizures can cause confusion, upset **stomach**, or emotional distress. When such phenomena occur prior to the onset of a seizure, they are called auras.

GENERALIZED SEIZURES. A generalized tonic-clonic (grand-mal) seizure begins with a loud cry before the person having the seizure loses consciousness and falls to the ground. The muscles become rigid for about 30 seconds during the tonic phase of the seizure and alternately contract and relax during the clonic phase, which lasts 30 to 60 seconds. The skin sometimes acquires a bluish tint, and the person may bite the tongue, lose bowel or bladder control, or have trouble breathing.

A grand mal seizure lasts between two and five minutes, and the person may be confused or have trouble talking when consciousness is regained (postictal state). There may be complaints of head or muscle aches or weakness in the arms or legs before falling into a deep sleep.

PRIMARY GENERALIZED SEIZURES. A primary generalized seizure occurs when electrical discharges begin in both halves (hemispheres) of the brain at the same time. Primary generalized seizures are more likely to be major motor attacks than to be absence seizures.

ABSENCE SEIZURES. Absence (petit mal) seizures generally begin at about the age of four and stop by the time the child becomes an adolescent. Absence seizures usually begin with a brief loss of consciousness and last between one and ten seconds. A person having a petit mal seizure becomes very quiet and may blink, stare blankly, roll eyes, or move lips. A petit mal seizure lasts 15 to 20 seconds. When it ends, the person who had the seizure resumes whatever task was being completed before the seizure began. There will be no **memory** of the seizure, and the person may not realize that anything unusual has happened. Untreated petit mal seizures can recur as many as 100 times a day and may progress to grand mal seizures.

MYOCLONIC SEIZURES. Myoclonic seizures are characterized by brief, involuntary spasms of the tongue or muscles of the face, arms, or legs. Myoclonic seizures are most apt to occur when waking after a night's sleep.

A Jacksonian seizure is a partial seizure characterized by tingling, stiffening, or jerking of an arm or leg. Loss of consciousness is rare. The seizure may progress in characteristic fashion along the limb.

Limp posture and a brief period of unconsciousness are features of akinetic seizures, which occur in young children. Akinetic seizures, which cause the child to fall, are also called drop attacks.

PARTIAL SEIZURES. Simple partial seizures do not spread from the focal area where they arise. Symptoms are determined by what part of the brain is affected. The person usually remains conscious during the seizure and can later describe it in detail.

COMPLEX PARTIAL SEIZURES. A distinctive **smell**, **taste**, or other unusual sensation (aura) may signal the start of a complex partial seizure. These seizures start as simple partial seizures but move beyond the focal area and cause loss of consciousness. Complex partial seizures can become major motor seizures. Although a person having a complex partial seizure may appear to be conscious, the person has no knowledge of what is happening and may behave inappropriately. There will be no memory of the seizure and there may be a brief period of confusion after it ends.

Causes and symptoms

The origin of 50–70% of all cases of epilepsy is unknown. Epilepsy is sometimes the result of trauma at the time of birth. Such causes include insufficient oxygen to the brain; **head injury**; heavy bleeding or incompatibility between a woman's **blood** and the blood of her newborn baby; and **infection** immediately before, after, or at the time of birth.

Other causes of epilepsy include:

- head trauma resulting from a car accident, gunshot wound, or other injury
- alcoholism
- brain **abscess** or inflammation of membranes covering the brain or spinal cord
- phenylketonuria (PKU) (A disease that is present at birth, PKU is often characterized by seizures, and can result in mental retardation and other inherited disorders.)
- infectious diseases such as measles, mumps, and diphtheria
- degenerative disease
- lead **poisoning**, mercury poisoning, **carbon monoxide poisoning**, or ingestion of some other poisonous substance
- genetic factors

Status epilepticus, a condition in which a person suffers from continuous seizures and may have trouble breathing, can be caused by:

- suddenly discontinuing anti-seizure medication
- hypoxic or metabolic encephalopathy (brain disease resulting from lack of oxygen or malfunctioning of other physical or chemical processes)
- acute head injury
- blood infection caused by inflammation of the brain or the membranes that cover it

Diagnosis

Personal and family medical history, description of seizure activity, and physical and neurological examinations help primary care physicians, neurologists, and epileptologists diagnose this disorder. Doctors rule out conditions that cause symptoms that resemble epilepsy, including small strokes (transient ischemic attacks or TIAs), fainting (**syncope**), pseudoseizures, and sleep attacks (narcolepsy).

Neuropsychological testing uncovers learning or memory problems. Neuro-imaging provides views of brain areas involved in seizure activity.

An electroencephalogram (EEG) is the main test used to diagnose epilepsy. EEGs use electrodes placed on or within the **skull** to record the brain's electrical activity and pinpoint the exact location of abnormal discharges. A person may be asked to remain motionless during a short-term EEG or to go about normal activities during extended monitoring. Some people are deprived of sleep or exposed to seizure triggers, such as rapid, deep breathing

(hyperventilation) or flashing lights (photic stimulation). In some cases, people may be hospitalized for EEG monitoring that can last as long as two weeks. Video EEGs also document what an individual was doing when the seizure occurred and how the seizure altered behavior.

Other techniques used to diagnose epilepsy include:

- Magnetic resonance imaging (MRI) provides clear, detailed images of the brain. Functional MRI (fMRI), performed while a person does various tasks, can measure shifts in electrical intensity and blood flow and indicate the brain region each activity affects.
- Positron emission tomography (**PET**) and single photon emission tomography (SPECT) monitor blood flow and chemical activity in the brain area being tested. PET and SPECT are very effective in locating the brain region where metabolic changes take place between seizures.

Treatment

The goal of epilepsy treatment is to eliminate seizures or make the symptoms less frequent and less severe. Long-term anticonvulsant drug therapy is the most common form of epilepsy treatment.

Medication

A combination of drugs may be needed to control some symptoms, but most persons who have epilepsy take one of the following medications:

- phenytoin (Dilantin)
- carbamazepine (Tegretol)
- phenobarbital (Barbita)
- primidone (Mysoline)
- valproic acid or sodium valproate (Depakene)
- clonazepam (Klonopin)
- ethosuximide (Zarontin)

Phenytoin, carbamazepine, phenobarbital, and primidone are used to manage or control generalized tonic-clonic and complex partial seizures. Valproic acid (sodium valproate), clonazepam, and ethosuximide are prescribed for persons who have absence seizures. Gabapentin (Neurontin) and lamotrigine (Lamictal) are medications recently approved in the United States to treat adults who have partial seizures or partial and grand mal seizures.

Even a person whose seizures are well controlled should have regular blood tests to measure levels of anti-seizure medication in the blood stream and to check to see if the medication is causing any changes in the blood

or **liver**. A doctor should be notified if any signs of drug toxicity appear, including uncontrolled eye movements; sluggishness, dizziness, or hyperactivity; inability to see clearly or speak distinctly; nausea or vomiting; or sleep problems.

Status epilepticus requires emergency treatment, usually with Ativan (Valium), phenytoin, or phenobarbital. An intravenous dextrose (sugar) solution is given to persons whose condition is due to low blood sugar, and a vitamin B₁ preparation is administered intravenously when status epilepticus results from chronic alcohol withdrawal. Because dextrose and **thiamine** are essentially harmless and because delay in treatment can be disastrous, these medications are given routinely, as it is usually difficult to obtain an adequate history from a person suffering from status epilepticus.

Intractable seizures are seizures that cannot be controlled with medication or without sedation or other unacceptable side effects. Surgery may be used to eliminate or control intractable seizures.

Surgery

Surgery can be used to treat people whose intractable seizures stem from small focal lesions that can be removed without endangering them, changing their personality, dulling their senses, or reducing their ability to function.

Each year, as many as 5,000 new people may become suitable candidates for surgery, which is most often performed at a comprehensive epilepsy center. Potential surgical candidates include people with:

- partial seizures and secondarily generalized seizures (attacks that begin in one area and spread to both sides of the brain)
- seizures and childhood **paralysis** on one side of the body (hemiplegia)
- complex partial seizures originating in the temporal lobe (the part of the brain associated with speech, hearing, and smell) or other focal seizures (However, the risk of surgery involving the speech centers is that a person will lose speech function.)
- generalized myoclonic seizures or generalized seizures featuring temporary paralysis (akinetic) or loss of muscle tone (atonic)

A **physical examination** is conducted to verify that a person's seizures are caused by epilepsy, and surgery is not used to treat people with severe psychiatric disturbances or medical problems that raise risk factors to unacceptable levels.

Surgery is never indicated unless:

- The best available anti-seizure medications have failed to control the person's symptoms satisfactorily.
- The origin of a person's seizures has been precisely located.
- There is good reason to believe that surgery will significantly improve the person's health and quality of life.

Every person considering epilepsy surgery is carefully evaluated by one or more neurologists, neurosurgeons, neuropsychologists, and/or social workers. A psychiatrist, chaplain, or other spiritual advisor may help an affected individual and family members family cope with the stresses that occur during and after the selection process.

TYPES OF SURGERY. Surgical techniques used to treat intractable epilepsy include:

- **Lesionectomy.** Removing the lesion (diseased brain tissue) and some surrounding brain tissue is very effective in controlling seizures. Lesionectomy is generally more successful than surgery performed on persons whose seizures are not caused by clearly defined lesions, but removing only part of the lesion lessens the effectiveness of the procedure.
- **Temporal resections.** Removing part of the temporal lobe and the part of the brain associated with feelings, memory, and emotions (the hippocampus) provides good or excellent seizure control in 75–80% of properly selected individuals with appropriate types of temporal lobe epilepsy. Some people experience post-operative speech and memory problems.
- **Extra-temporal resection.** This procedure involves removing some or all of the frontal lobe, the part of the brain directly behind the forehead. The frontal lobe helps regulate movement, planning, judgment, and personality, and special care must be taken to prevent post-operative problems with movement and speech. Extra-temporal resection is most successful in people whose seizures are not widespread.
- **Hemispherectomy.** This method of removing brain tissue is restricted to persons with severe epilepsy and abnormal discharges that often extend from one side of the brain to the other. Hemispherectomies are most often performed on infants or young children who have had an extensive brain disease or disorder since birth or from a very young age.
- **Corpus callosotomy.** This procedure, an alternative to hemispherectomy in persons with congenital hemiplegia, removes some or all of the white matter that connects the two halves of the brain. Corpus callosotomy is performed almost exclusively on children who are

This patient's brain is exposed during surgery in order for surgeons to resect the mass responsible for his epilepsy.
(Custom Medical Stock Photo. Reproduced by permission.)

frequently injured during falls caused by seizures. If removing two-thirds of the corpus callosum doesn't produce lasting improvement in a person's condition, the remaining one-third will be removed during another operation.

- Multiple subpial transection. This procedure is used to control the spread of seizures that originate in or affect the "eloquent" cortex, the area of the brain responsible for complex thought and reasoning.

Other forms of treatment

KETOGENIC DIET. A special high-fat, low-protein, low-carbohydrate diet is sometimes used to treat persons whose severe seizures have not responded to other treatment. Calculated according to age, height, and weight, the ketogenic diet induces mild starvation and **dehydration**. This forces the body to create an excessive supply of ketones, natural chemicals with seizure-suppressing properties.

The goal of this controversial approach is to maintain or improve seizure control while reducing medication. The ketogenic diet works best with children between the ages of one and 10. It is introduced over a period of several days, and most children are hospitalized during the early stages of treatment.

If a child following this diet remains seizure-free for at least six months, increased amounts of **carbohydrates** and protein are gradually added. If the child shows no

improvement after three months, the diet is gradually discontinued.

Introduced in the 1920s, the ketogenic diet has had limited, short-term success in controlling seizure activity. Its use exposes people to such potentially harmful side effects as:

- staphylococcal infections
- stunted or delayed growth
- low blood sugar (hypoglycemia)
- excess fat in the blood (hyperlipidemia)
- disease resulting from **calcium** deposits in the urinary tract (urolithiasis)
- disease of the optic nerve (optic neuropathy)

VAGUS NERVE STIMULATION. The United States Food and Drug Administration (FDA) has approved the use of vagus nerve stimulation (VNS) in persons over the age of 16 who have intractable partial seizures. This non-surgical procedure uses a pacemaker-like device implanted under the skin in the upper left chest, to provide intermittent stimulation to the vagus nerve. Stretching from the side of the neck into the brain, the vagus nerve affects swallowing, speech, breathing, and many other functions, and VNS may prevent or shorten some seizures.

First aid for seizures

A person having a seizure should not be restrained, but sharp or dangerous objects should be moved out of reach. Anyone having a complex partial seizure can be warned away from danger by someone calling out his or her name in a clear, calm voice.

A person having a grand mal seizure should be helped to lie down. Tight clothing should be loosened. A soft, flat object like a towel or the palm of a hand should be placed under the person's head. Forcing a hard object into the mouth of someone having a grand mal seizure could cause injuries or breathing problems. If the person's mouth is open, placing a folded cloth or other soft object between the teeth will protect the tongue. Turning the head to the side will help breathing. After a grand mal seizure has ended, the person who had the seizure should be told what has happened and reminded of the present location.

Alternative treatment

Stress increases seizure activity in 30% of people who have epilepsy. **Relaxation** techniques can provide some sense of control over the disorder, but they should never be used instead of anti-seizure medication or used without the approval of a person's doctor. **Yoga, medita-**

tion, and favorite pastimes help some people relax and more successfully manage stress. Biofeedback can teach adults and older adolescents how to recognize an aura and what to do to stop its spread. Children under 14 are not usually able to understand and apply principles of biofeedback. Acupuncture treatments (acupuncture needles inserted for a few minutes or left in place for as long as half an hour) make some people feel pleasantly relaxed. **Acupressure** can have the same effect on children or on adults who dislike needles.

Aromatherapy involves mixing aromatic plant oils into water or other oils and massaging them into the skin or using a special burner to waft their fragrance throughout the room. Aromatherapy oils affect the body and the brain, and undiluted oils should never be applied directly to the skin. Ylang ylang, chamomile, or lavender can create a soothing mood. People who have epilepsy should not use rosemary, hyssop, sage, or sweet fennel, which seem to make the brain more alert.

Dietary changes that emphasize whole foods and eliminate processed foods may be helpful. Homeopathic therapy also can work for people with seizures, especially constitutional homeopathic treatment that acts at the deepest levels to address the needs of an individual.

Prognosis

People who have epilepsy have a higher-than-average rate of suicide; sudden, unexplained death; and drowning and other accidental fatalities.

Benign focal epilepsy of childhood and some absence seizures may disappear in time, but remission is unlikely if seizures occur several times a day, several times in a 48-hour period, or more frequently than in the past.

Seizures that occur repeatedly over time and always involve the same symptoms are called stereotypic seizures. The probability that stereotypic seizures will abate is poor.

About 85% of all seizure disorders can be partially or completely controlled if a person takes anti-seizure medication according to directions; avoids seizure-inducing sights, sounds, and other triggers; gets enough sleep; and eats regular, balanced meals.

Health care team roles

First aid may be provided by trained individuals. Physicians make the initial diagnosis of seizure disorders. Endocrinologists and radiologists may assist in refining a diagnosis. Neurologists, neurosurgeons, neuropsychologists, and social workers may assess persons

prior to receiving surgery for a seizure disorder. Neurosurgeons may perform surgery to remove structures in the brain that are known to cause seizures. Psychiatrists, chaplains, or other spiritual advisors may help an affected individual and relations cope with the stresses that occur during and after surgery. Nurses also teach family and friends about emergency care of patient when having a seizure, as well as **home care** following a seizure and hospitalization.

Prevention

Eating properly, getting sufficient sleep, and controlling stress and fevers can help prevent seizures. A person who has epilepsy should be careful not to hyperventilate. A person who experiences an aura should find a safe place to lie down and stay there until the seizure passes. Anticonvulsant medications should not be stopped suddenly; and, if other medications are prescribed or discontinued, the doctor treating the seizures should be notified. In some conditions, such as severe head injury, brain surgery, or subarachnoid hemorrhage, anticonvulsant medications may be given to a person to prevent seizures. Seizures that are caused by ingesting substances such as alcohol or drugs can be prevented by discontinuing use of the offending substance.

KEY TERMS

Acupressure—An ancient Chinese method of relieving pain or treating illness by applying pressure to specific areas of the body.

Acupuncture—An ancient Chinese method of relieving pain or treating illness by piercing specific areas of the body with fine needles.

Akinetic seizure—Seizure characterized by limp posture and a brief period of unconsciousness; also called a drop attack.

Aura—A distinctive smell, taste, or other unusual sensation that precedes the onset of a seizure.

Biofeedback—A learning technique that helps individuals influence automatic (autonomic) body functions.

Clonic—Referring to clonus, a series of muscle contractions and partial relaxations that alternate in some nervous diseases in the form of convulsive spasms.

Epileptologist—A physician who specializes in the treatment of epilepsy.

Hyperlipidemia—A condition characterized by high serum triglyceride and lipid levels.

Hypoglycemia—A condition characterized by low serum glucose (blood sugar) levels.

Lesionectomy—Removal of a lesion and surrounding tissue. The term is applied to brain tissue when trying to control seizures.

Myoclonic seizures—Brief, involuntary spasms of the tongue or muscles of the face, arms, or legs.

Petit-mal seizure—Absence seizure.

Post-ictal state—A period of disorientation usually followed by sleep that occurs after a seizure.

Tonic—Characterized by tonus, a state of partial contraction that is maintained at least in part by a continuous bombardment of motor impulses.

Semen analysis

Definition

A semen analysis is the examination of freshly ejaculated seminal fluid. Seminal fluid is a viscous, turbid fluid produced mainly from secretions of the seminal vesicles (45–80% of volume) and prostate gland (15–30% of the volume). About 1% of the total volume is spermatozoa and testicular fluid produced by the testes. A routine analysis of seminal fluid includes the measurement of fluid volume, viscosity, pH, and fructose and measurement of sperm concentration, count, motility, viability, and morphology. Additional tests are performed as indicated. These are usually performed by andrology laboratories and include testing for sperm autoantibodies, zona free hamster oocyte penetration, cervical mucus penetration, the acrosomal reaction test, and computer assisted sperm analysis (CASA).

Purpose

In the United States, the **infertility** rate for married couples is approximately 15%. A semen analysis is the examination of a male's ejaculate, performed to determine if the cause of a couple's infertility is attributed to the male's inability to fertilize the ovum. It is also used to confirm the absence of sperm following vasectomy. In addition, a microscopic exam for sperm is performed on vaginal swabs and clothing taken in suspected rape cases as part of the crime scene investigation. This is used along with tests for acid phosphatase and prostate specific antigen to determine the presence of seminal fluid.

Precautions

The patient should abstain from intercourse for three days prior sample collection and refrain from drinking alcoholic beverages for at least 24 hours before testing. Antineoplastic agents and estrogen may lower test results. Additionally, several herbal supplements have been found to affect sperm counts and/or characteristics.

A semen specimen to investigate infertility must kept at room temperature. It should be collected by masturbation into a disposable sterile, wide-mouth container. A room close to the testing site is preferred for collection, since specimen quality deteriorates rapidly. If possible, examinations for motility and viability should be performed and smears prepared within one hour of collection. Timing is not as critical for postvasectomy testing. Physiological and environmental factors can increase the variability of semen analysis, and the World Health Organization (WHO) recommends the evaluation of two

ejaculates collected at least seven days but not more than three months apart.

Description

Male infertility may be caused by many conditions that affect the production of functional sperm. The most common cause is varicocele (hardening of the veins that drain the testes) which accounts for about 40% of cases and is treated surgically. Testicular failure accounts for approximately 10% of cases and may result from numerous causes including malignancy, mumps, Klinefelter's syndrome, injury, and radio- or **chemotherapy**. Hyperspermia, increased seminal fluid volume, also accounts for about 10% of cases. Endocrine diseases affecting spermatogenesis account for approximately 9% of cases and usually involve pituitary or adrenal hypoplasia or hyperthyroidism. Obstruction of the ejaculatory duct accounts for about 5% of cases and sperm autoantibodies for 1–2%.

Physical characteristics of the semen sample that are evaluated include volume, gross appearance (color, turbidity), viscosity, and liquifaction. Seminal fluid will coagulate within five minutes of collection due to coagulating protein secreted by seminal vesicles. The seminal fluid should liquefy within one hour at room temperature, due to the action of prostatic secretions. Failure to do so inhibits motility. After liquifaction, viscosity may be measured by observing the fluid as it drains from the tip of a 5 mL serological pipet. The fluid should flow from the tip in discrete droplets. Formation of a thread of two or more centimeters at the tip indicates abnormally high viscosity. Volume is determined by determining the amount of fluid that can be drawn into a 10 mL serological pipet.

Sperm counting methods

The sperm concentration is usually performed using a 1:20 dilution of seminal fluid in a diluent containing formalin which immobilizes the sperm. Usually five of the 0.2 x 0.2 mm squares of a hemacytometer grid are counted. The number of cells counted is equal to the sperm concentration in millions per mL. All 25 squares are counted if there are less than 10 sperm (spermatozoons) per square. A Mackler chamber, a grid consisting of 1 square millimeter divided into 100 equal squares, (0.1 x 0.1 mm, 0.01 mm deep) can be used in place of a hemacytometer. Undiluted seminal fluid is heated to 50–60°C to immobilize the sperm. Heads are counted in 10 of the squares and the total is equal to the sperm concentration in millions per milliliter. A sperm concentration less than 20 million per milliliter is termed oligozoospermia, and often results from ductal obstruction, regurgita-

KEY TERMS

Autoantibody—An antibody formed in response to, and reacting against, an antigenic constituent of the individual's own tissues.

Infertility—The diminution of absence of ability to produce offspring.

Morphology—The biological study of the form and function of living organisms.

Motility—The ability to move spontaneously.

Semen—Fluid discharged at ejaculation in the male, consisting of secretion of glands associated with the urogenital tract and containing spermatozoa.

Sperm—Vernacular term for spermatozoon, which is a mature male germ cell, the specific output of the testes, which impregnates the ovum in sexual reproduction.

Vasectomy—An operation done to sterilize a man by stopping the release of sperm into semen.

tion of sperm into bladder, or testicular failure. The total sperm count is determined by multiplying the sperm concentration per mL by the seminal fluid volume.

Motility and viability evaluation

Sperm motility should be performed within one hour of ejaculation. During this portion of the analysis, 10 microliters of semen are placed on a standard microscopic slide, and a coverglass is applied. Ten random fields are then examined at 250x to 400x magnification using phase contrast or brightfield microscopy. Two hundred sperm are graded for motility using a scale ranging from zero to four, with zero signifying no motility, and four describing sperm that exhibit rapid, progressive movement. A more detailed analysis of sperm motility is obtained using CASA. This procedure produces a computer analysis of video camera generated microscopic images of sperm movements. Various aspects of sperm movement such as curvilinear and straight-line velocity are measured and analyzed statistically.

Sperm viability is measured when the motility test is abnormal. The test is based upon the fact that living sperm exclude the dye eosin Y, but dead sperm do not. A slide is prepared by mixing a sample of the seminal fluid and the dye, and 200 sperm are counted under the **microscope**. The percentage of living sperm (unstained sperm) is recorded.

Morphology evaluation

The morphology of sperm is also assessed from a stained smear. To prepare a stained specimen, a drop of semen is placed on a glass slide and a second slide is used to spread the drop over the slide surface. The smear is air dried and fixed using ethanol-ether. The slide is stained with Papanicolaou or other suitable stain (Wright stain is not recommended). Two hundred mature sperm are evaluated for head, neck, and tail defects. Any white **blood** cells (WBCs) or immature sperm cells (round cells) are also counted per 200 mature sperm. WBCs and round cells are estimated from the average number seen per 400x field. When more than one WBC or five round cells are seen on average per field, the respective cell count should be performed. Each cell per field equates to approximately one million cells per mL of seminal fluid. There are two alternative ways of classifying sperm that give very different results. The majority of clinical labs use nonstrict criteria. This process identifies only gross abnormalities of the sperm. The alternative method, strict criteria, is used by andrology and some clinical labs. For example, the WHO criteria for the normal sperm head is as follows: length 4.0–4.5 microns, width 2.5–3.5 microns, length:width ratio 1.5–1.75, acrosomal area 40–70%, vacuolization less than 20% of head area. Studies have shown that the probability of successful fertilization via assisted reproductive technology diminishes significantly when less than 15% of the sperm are normal by strict criteria. There are several strict criteria in use, including those developed by WHO.

Other tests

Chemical tests routinely performed on seminal fluid include pH and fructose. pH is measured with pH paper, and fructose may be measured quantitatively using an enzymatic assay.

Antibodies to sperm have the potential to impair fertility. While sperm agglutinins (antibodies) may be detected in the male or female partner of up to 10% of infertile couples, they are not always responsible for infertility. There are several tests for sperm agglutinins including direct microscopic observation, the mixed antiglobulin test, and the immunobead test.

Preparation

Sterile, wide-mouth containers should be used for specimen collection. The best quality sperm are obtained when the specimen is collected after three days of sexual abstinence, but not more than five to seven days. Because the initial portion of the ejaculate contains the majority of the sperm cells, and the volume of ejaculate may provide

clues regarding infertility, *coitus interruptus* should not be used as the method of collection.

The specimen should be examined in the laboratory within one hour of collection. Typically, two to three specimens are examined over a period of several weeks. When results from two testing days are different, additional specimens collected over a two- to three-month period should be analyzed.

Aftercare

There are no aftercare requirements.

Complications

There are no complications associated this test.

Results

Each laboratory defines its own set of normal values. Many follow the recommendation of WHO. The values below are representative for the procedures described above.

- Volume: 2.0–5.0 mL.
- pH: 7.2–8.0.
- Sperm concentration: greater than or equal to 20 million per mL.
- Sperm count: greater than or equal to 40 million per ejaculate.
- Motility: Greater than or equal to 50% demonstrating forward progressive movement or 25% or more demonstrating rapid progressive movement. Prolonged abstinence may depress sperm motility. Frequent sperm agglutination suggests the presence of antisperm antibodies.
- Morphology: Nonstrict criteria: greater than 60% normal sperm. Strict criteria: 15–40 % normal sperm.
- White blood cells: less than 1 million per mL.
- Round cells: less than 5 million per mL.
- Viability: equal to or greater than 75%.
- Viscosity: droplets to threads less than 2 cm.

Post-vasectomy

Semen analysis to confirm the success of a vasectomy is concerned only with the absence or presence of sperm. Semen is collected six weeks after surgery, or after at least 20 ejaculations. Sperm should not be seen. If sperm are seen, another specimen is collected two to four weeks later. The test should be repeated several

months later to ensure that the vas deferens have not reattached.

Health care team roles

Physicians, nurses, or laboratory scientists provide collection and delivery instructions. Laboratory tests are performed by clinical laboratory scientists CLS(NCA)/medical technologists MT(ASCP), or pathologists.

Sensory reeducation

Definition

Sensory reeducation is a therapeutic program using sensory stimulation to help sensory-impaired patients recover functional sensibility in the damaged area and learn adaptive functioning.

Purpose

Following disease, such as stroke, or accident, sensory reeducation helps patients with various forms of sensory loss and impairment retrain their sensory pathways, adapt to changed abilities, and regain function.

Precautions

There may be contraindications related to particular modalities used in sensory reeducation or related to coexisting conditions. For example, some coexisting conditions that may contraindicate electrical stimulation include thrombophlebitis, cardiac demand pacemaker, disturbances in cardiac rhythm, local inflammation or **infection**, or **cancer**. Extreme caution should be used when applying heat, cold, or electrical stimulation to sensory impaired areas to avoid possible damage due to the patient's inability to feel symptoms that may indicate dangerous temperature or stimulation levels.

A thorough medical history and examination should be conducted and any coexisting conditions noted and taken into consideration during treatment design and implementation. The patient should be educated and monitored to help prevent further damage to the sensory-impaired area.

Description

Sensory reeducation uses a variety of therapeutic, rehabilitation, and educational techniques to help sensory-impaired patients recover sensibility, fine discrimination abilities, and the ability to perform other tasks involved in daily living and work activities. In addition to actual loss of sensibility and related functional ability, paresthesias (abnormal sensations), such as numbness, tingling, or burning sensations, may be present. Some of the many possible causes of sensory impairment may include nerve damage, nerve repair surgery, stroke, aneurysm, other forms of **central nervous system** damage, and diabetes-related nerve impairment.

Many techniques of sensory stimulation are used to provide input to sensory receptors and pathways. Some forms of stimulation used include electrical stimulation; stroking the skin with textured, friction-producing items such as Velcro; and the use of specially modified tools and instruments (Dannenbaum). Other procedures and modalities that may be used include massage, vibration, pressure, biofeedback, various forms of movement and tactile stimulation, or other activities that require use of and attention to the senses. Sensory reeducation may be delivered in indirect ways as part of a larger therapeutic program, rather than being an independent, distinct therapy.

In addition to loss of tactile sensibility and related inability to distinguish heat, cold, textures, shapes, and other types of stimulation on the skin, losses related to other senses may also be addressed. One example is visual field impairment that may be caused by a stroke. Patients with visual field impairments might be taught to

attend to the neglected side, or helped to use other senses to compensate for sensory impairment and loss.

Another form of impairment that may be treated with sensory reeducation is hypersensitivity, a condition in which a patient overreacts to mild forms of stimulation. One such condition is called regional **pain** syndrome. When treating such conditions tactile stimulation, weight bearing activities, and other forms of sensory reeducation are used to desensitize the patient's sensory responses and reduce perceived discomfort.

Among the goals of sensory reeducation is the retraining of neural pathways and responses to stimuli in order to restore the patient's sensory perception. Increased sensory input and activity may help to stimulate nerve regeneration and growth. In addition, previously unused neural connections may be trained to take over for damaged pathways. This neural plasticity can be used to the advantage of the patient with nerve damage or impairment.

Some scientists believe it may be possible for a remapping to occur in the **brain** so that connections between areas of the brain and certain parts of the body, as represented on Penfield maps, can adapt and change after nerve injury or amputation, causing new connections that relay sensation.

In general, in addition to actually retraining the senses and nervous system activities, much of sensory reeducation may focus on teaching the patient functional adaptation—new ways of using the abilities they have to compensate for sensory impairments and other disabilities. Adaptation may be used to help the patient function until full rehabilitation is achieved, but it may also be a permanent adaptation when full rehabilitation is not possible.

Preparation

The patient will be interviewed and examined by the therapist to determine the types and extent of sensory impairment. An individualized rehabilitation and sensory reeducation program will be designed in accord with the patient's needs, abilities, and goals.

Aftercare

Patients may continue to see their physician and therapist for follow-up exams and treatment after completion of initial sensory reeducation to record and maintain progress made.

Complications

The therapist should be alert to any possible complications related to the primary and coexisting conditions and associated with any of the modalities used. With careful diagnosis, treatment planning, and monitoring, complications should be minimal. Special caution and supervision should be used when working with sensory-impaired patients.

Results

The patient should be helped to regain sensibility and related functions such as two-point discrimination and object recognition, and minimize discomfort. To the degree that full recover of sensibility is not possible, the patient should learn adaptive behaviors that will aid in function.

Health care team roles

The surgeon, neurologist, or primary physician may prescribe and monitor the therapy. Physical or occupational therapists and their assistants may perform sensory reeducation. Nurses and other hospital personnel may also be involved in the general rehabilitation and sensory reeducation of the patient, along with social workers, speech therapists, cognitive therapists, and other allied health care providers.

Sensory testing

Definition

Sensory testing involves the evaluation of a patient's perception in an effort to assess the integrity of the peripheral nervous system. There are many sensory receptors in the human body that provide information to the **brain** concerning an individual's surroundings. The information from sensory receptors helps the human being move and interact within the environment. For example, information from various sensory organs such as the eyes, vestibular (inner ear), and light touch are all integrated and organized by the brain to help the body complete safe and efficient movement. If sensory impairment is present, the patient's movement will likely be affected, making common tasks cumbersome and even dangerous. Therefore, individuals with possible sensory

impairment need to have a full sensory evaluation to assess the integrity of sensation.

Purpose

There are many pathologies that can cause impairments in sensation. Injury or disease can compromise the integrity of a nerve and thus impair sensory function. Peripheral neuropathy is a broad classification that describes disease or dysfunction of a peripheral nerve. A peripheral neuropathy can be acquired or inherited.

Acquired peripheral neuropathy

A common acquired peripheral neuropathy is Guillain-Barre syndrome. This syndrome is usually considered an autoimmune disorder, but the etiology (cause) is unknown. Guillain-Barre syndrome is classified as a myelinopathy where the myelin sheath (an insulating wrapping which surrounds the axons of many nerves) disintegrates. In this disorder there is marked weakness and sensory impairment on both sides of the body. Two other types of acquired peripheral neuropathy are alcoholic and diabetic neuropathies. Alcoholic neuropathy is due to **alcoholism** and diabetic neuropathy is due to diabetes, a metabolic disease. In alcoholic neuropathy, sensory and motor losses are typical, especially in the feet and lower legs. The actual cause is unknown, but may be due to the toxic effects of alcohol on the nervous system. In diabetic neuropathy sensory loss also is prominent, especially in the lower limbs. Other acquired neuropathies can be caused by laceration (i.e., knife injury), crushing injuries to the nerve, or ischemia (a condition characterized by a decreased supply of oxygenated **blood**). All can lead to sensory and/or motor impairment by compromising the integrity of the nerve.

Inherited peripheral neuropathy

The most common inherited peripheral neuropathy is Charcot-Marie-Tooth disease. It is a genetic disorder that is categorized by weakness or atrophy of the lower limbs, especially the lower leg and foot.

There are many sensory receptors corresponding to various sensations within the human body. The purpose of sensory receptors is to gather pertinent information on the surrounding environment. Sensory receptors respond to stimuli in the environment, and thus provide valuable information on a person's surroundings. Therefore, the disorders categorized as peripheral neuropathies can impair the gathering and transmission of information. The purpose of sensory testing is to evaluate the proficiency and integration of information from sensory

receptors in individuals who have known disease or injury.

Precautions

Sensory testing gives valuable information to the clinician on an individual's sensation and perception. Care must be taken when performing sensory tests if sensory loss is suspected. Applying increased pressure or heat on an individual who has a sensory deficit may injure the patient. For example, if a patient cannot sense the application of heat, there is a risk that the patient will be burned.

Description

Sensory testing should be done on both sides of the body so that comparisons can be made between sides, i.e., affected side versus non-affected side. If there is a deficit noted, it is usually termed absent, diminished, or exaggerated. If there is no deficit, sensation is termed intact.

There are seven common tests used to evaluate sensation and perception. They are: stereognosis, touch and pressure, kinesthesia, proprioception, touch localization, two-point discrimination, and recognition of textures.

Stereognosis

Stereognosis refers to the ability of an individual to identify objects placed in his/her hand, while his/her eyes are closed. The individual should be able to identify objects based on size, shape, and texture.

Touch and pressure

Touch can be assessed by gently rubbing a ball of cotton on the surface of the skin to be tested. The clinician's finger can be used to apply pressure to various locations in order to assess pressure sensation. While touch and pressure are being assessed, the subject's eyes should be closed.

Proprioception

This test evaluates the individual's perception of movement specifically related to the limbs. In this test the individual's eyes are closed while the examiner moves the unaffected limb into a position and holds the position. The examiner then asks the individual to move the affected side into the same position.

Kinesthesia

This test assesses the individual's perception of joint movement rather than position (proprioception). In this test, the examiner moves the unaffected limb and, as the

limb is moved, the individual being tested must copy the movement and follow the path with the affected or involved side. This test also is done with the individual's eyes are closed.

Touch localization

While the subject's eyes are closed, the examiner touches different areas on the skin and asks the subject, "Where am I touching?" The subject must verbally identify the location of the examiner's touch.

Two-point discrimination

This test evaluates an individual's ability to discern two points at the same time. While the subject's eyes are closed, the examiner applies point pressure in two spots separated by one to two inches. The examiner asks the subject, "Can you feel two points?" If the subject can discern two points, the examiner moves the points closer together and the test is repeated. This continues until two points cannot be discerned. These results are compared with results from the opposite side.

Recognition of textures

Various textures are placed in the individual's hand, while his/her eyes are closed. The individual must verbally identify the texture. Cotton and sandpaper are examples of items used in this test.

Another testing device, the Weinstein Enhanced Sensory Test or WEST, is primarily used to assess touch sensation. It is a precision instrument that uses hair-like filaments to record pressure or force. The instrument is a safe, valid, and reliable way of recording sensory loss.

Results

Results or outcomes of treatment are variable. Usually the initial severity of the deficit reflects the possible outcome. The greater the deficit, the greater the likelihood of long-term or total impairment.

Health care team roles

Nurses and other allied health team members need to be aware of potential sensory and perceptive disorders and their relationship to function. Early identification of sensory or perceptive impairments may minimize further complications. Physicians, nurses, and allied health professionals, such as occupational and physical therapists, usually perform sensation testing. Nurses are now becoming more familiar with the WEST device and this technology is now available for assessing the feet. This is especially useful for patients with diabetic neuropathy.

KEY TERMS

Kinesthesia—The ability to perceive where a limb or the body is moving in space. Information about the surrounding environment is processed in the brain and received from muscles, tendons, and joints.

Proprioception—The ability to perceive where a limb or the body is in space. Usually refers to a static situation.

Sensation—Awareness (as of heat or pain) due to stimulation of a sense organ.

Sepsis syndrome see **Septic shock**

Septic shock

Definition

Septic **shock** is a syndrome in which a potentially lethal drop in **blood pressure** occurs as a result of an overwhelming bacterial **infection**.

KEY TERMS

Bacteremia—Invasion of the bloodstream by bacteria.

Description

Septic shock is a possible consequence of bacteremia, which is also called sepsis. Bacterial toxins, and the immune system's response to them, can cause a dramatic drop in **blood** pressure and may result in under-perfusion to various organs. Septic shock can lead to multiple organ failure, including **respiratory failure**, and may cause rapid death. Toxic shock syndrome is one type of septic shock.

Causes and symptoms

During an infection, certain **bacteria** can release complex molecules, called endotoxins, that may provoke a dramatic response by the body's **immune system**. Endotoxins are particularly dangerous; as they become widely dispersed, they cause arteries and the smaller arterioles to dilate. At the same time, the walls of the **blood vessels** become leaky, allowing fluid to seep into the tissues, lowering intravascular volume (the amount of fluid left in circulation). This combination, of arterial dilation and decreased intravascular volume, causes a dramatic decrease in blood pressure and impaired blood flow to multiple organs. Other changes seen in septic shock are disseminated intravascular coagulation (DIC), which can further impair organ perfusion (blood flow).

Septic shock is seen most often in patients with impaired host defenses (patients who are immunosuppressed), and is often due to nosocomial (hospital-acquired) infections. The immune system is suppressed by drugs used to treat **cancer**, **autoimmune disorders**, organ transplants, and diseases of immune deficiency such as **AIDS**. Malnutrition, chronic drug abuse, and long-term illness also increase the likelihood of succumbing to bacterial infection. Bacteremia is more likely with preexisting infections such as urinary or gastrointestinal tract infections, or skin ulcers. Bacteria may be introduced to the blood stream by surgical procedures, catheters, or intravenous equipment.

Toxic shock syndrome (TSS) is a potentially fatal disorder resulting from infection with *Staphylococcus aureus*, a toxin-producing strain of a bacteria. When it was first reported about 25 years ago, toxic shock syndrome was associated with menstruation and linked to super-absorbent tampon use. Today, it is recognized that

use of super-absorbent tampons does increase the risk of TSS, as does use of a contraceptive sponge or diaphragm. Postpartum patients (women who have just given birth) and patients with wound infections, or recovering from nasal surgery also are at risk for TSS. The illness appears suddenly, with **fever**, rash, low blood pressure, and episodes of fainting. Survival has improved since the 1980s, approximately 2–5% of patients die from this disorder. Patients recovering from TSS face increased risk of recurrence. To prevent TSS, menstruating women are advised to avoid use of super-absorbent tampons.

Symptoms

Septic shock is usually preceded by bacteremia, which causes fever, malaise, chills, and nausea. The first sign of shock is often confusion and decreased consciousness. In this beginning stage, the extremities are usually warm. Later, as the blood pressure drops, they may become cool, pale, and cyanotic (bluish). Fever may subside to normal temperatures later on in sepsis.

Other symptoms include:

- rapid heartbeat
- shallow, rapid breathing
- decreased urination
- reddish patches in the skin

Septic shock may progress to cause “adult respiratory distress syndrome,” (also called non-cardiogenic pulmonary **edema**) in which the pulmonary capillaries become leaky and the **lungs** fill with fluid. This can lead to respiratory failure. When this occurs the patient can no longer breathe without mechanical ventilation and supplemental oxygen.

Diagnosis

Diagnosis of septic shock is made when a patient with a severe infection has hypotension (low blood pressure) for which other causes such as major bleeding, **dehydration**, or massive **myocardial infarction** have been excluded. Pulmonary artery pressure may be monitored with a Swan-Ganz catheter, a catheter inserted into the pulmonary artery. Blood, urine, sputum, and cultures from other possible sites of infection determine the type of bacteria responsible for the infection. Arterial **blood gases** are also monitored to assess changes in respiratory function.

Treatment

Septic shock is treated initially with a combination of **antibiotics** and fluid replacement. The antibiotic is cho-

sen based on the bacteria known or suspected to be present. Usually, two or more types of antibiotics are started until the organism is identified. Intravenous fluids replete the intravascular fluid lost by leakage. Impaired coagulation and hemorrhage may be treated with transfusions of plasma, platelets, or red blood cells. Dopamine may be given to increase blood pressure further if necessary.

Respiratory distress is treated with mechanical ventilation and supplemental oxygen, either using a nose-piece or a tube into the trachea through the throat. The mainstay of therapy is to treat the underlying infection that caused the septic shock.

Prognosis

Septic shock is most likely to develop in the hospital, since it frequently results from hospital-acquired infection. Close monitoring and early, aggressive therapy can minimize the likelihood of progression. Nonetheless, death occurs in at least 25% of all cases.

The likelihood of recovery from septic shock depends on many factors, including the degree of immunosuppression of the patient, underlying disease, timeliness of treatment, and type of bacteria responsible. Mortality is highest in the very young and the elderly, those with persistent or recurrent infection, and those with compromised immune systems.

Health care team roles

Generally, care for the septic patient is delivered by hospital-based health care professionals in the hospital ICU (intensive care unit). Physicians, intensive care nurses, and other nursing personnel closely monitor patients' **vital signs** and administer antibiotics and fluids. Laboratory technologists perform necessary blood tests, and respiratory therapists may provide oxygen to patients in respiratory distress.

Prevention

The risk of developing septic shock can be minimized through treatment of underlying bacterial infections and prompt attention to signs of bacteremia. In the hospital, scrupulous **aseptic technique** on the part of medical professionals reduces the risk of introducing bacteria into the bloodstream.

Sex hormones tests

Definition

Sex hormones tests include tests that measure levels of estrogen (estradiol and estriol), progesterone, and testosterone (total and free).

Purpose

In non-pregnant women, a test of estradiol (E2) levels is ordered to evaluate delayed sexual maturity, precocious **puberty**, menstrual problems, and **infertility**, and ovarian failure. It is also used to test for tumors in both males and females that secrete estrogen. The test is also used to measure estrogen secretion in males who present with gynecomastia and feminization in male children.

Estriol (E3), another estrogen, is only ordered for pregnant women (typically at 15–18 weeks gestation). The test is used as part of the triple marker screen (in association with alpha fetoprotein and chorionic gonadotropin) for **Down syndrome**.

A progesterone test is ordered to evaluate women for anovulation, and to investigate precocious puberty. Progesterone may be measured in those persons with ovarian or adrenal **cancer** that secrete progesterone.

The testosterone test (free testosterone and/or total testosterone) is used to evaluate delayed sexual development, male sexual precocity, testicular failure, virilism in females, infertility, and tumors that secrete testosterone.

Precautions

Both the estrogen and testosterone test are most often measured by radioimmunosassay and results can be

affected by radioactive scans. When RIA is used the estradiol or estriol tests should not be performed on a patient who has received radioactive dye within 48 hours prior to the test. For RIA testosterone tests, the period between the scan and the test should be at least seven days. Oral contraceptives may interfere with progesterone and estradiol results. Tetracycline, some phenothiazines, diazepam, clomiphene, and some **vitamins** may interfere with estradiol results.

Estradiol and progesterone results vary with the phase of the menstrual cycle, and this must be taken into account when interpreting the results of these tests.

Sex hormone tests are performed on **blood** collected by venipuncture. The nurse or phlebotomist performing the procedure should observe **universal precautions** for the prevention of transmission of bloodborne pathogens.

Description

The sex hormones control the development of primary and secondary sexual characteristics and regulate the sex-related functions of the body, such as the menstrual cycle, and the production of eggs or sperm. Because of their normally low concentration in plasma the sex hormones are typically measured by radioimmunoassay (RIA), chemiluminescence immunoassay, or fluorescent immunoassay.

Estradiol

While there have been more than 30 of these hormones identified, only estradiol (E2) is necessary to evaluate ovarian function. Estradiol is the most potent of the estrogens, but it accounts for only one-third of the total estrogen in premenopausal females. In the nonpregnant female the ovaries are responsible for almost all estradiol production. In **pregnancy**, some estradiol is also produced by the placenta. Estradiol is produced from cholesterol, androstenedione, and testosterone. In males, estradiol is mainly produced from testosterone by the testes, but a small amount is also made by the adrenal cortex.

In **menopause**, the ovaries stop producing estradiol and estrone (E1) becomes the principal estrogen. A small amount of estradiol is formed from adrenal conversion of androstenedione, but this accounts for only about 15% of total estrogens. Plasma estradiol will be low in menopause, and FSH and LH will usually be increased. The measurement of estrone is seldom needed, but may be used to investigate vaginal bleeding after menopause or when estrone secreting ectopic hormone production is suspected.

Prior to menopause, estradiol is most often measured to evaluate amenorrhea and ovarian failure. In primary ovarian failure the ovaries may either fail to develop (as in Turner syndrome) or fail to produce estrogens as a result of autoimmune, metabolic, or endocrine disease. The plasma estradiol will be low, but the plasma levels of both LH and FSH are elevated. If secondary sexual characteristics are undeveloped, and the person is of short stature, chromosomal studies may reveal Turner syndrome as the cause. Primary amenorrhea results in failure to have a menses by age 16. In addition to ovarian failure, primary amenorrhea may be caused by endometriosis, polycystic ovary syndrome, anatomic defects in the vagina or uterus, and other disorders. In secondary ovarian failure, amenorrhea may be caused by pituitary failure or prolactinoma. In the former, both plasma and urinary LH and FSH will be low. In prolactinoma, LH and FSH are low because their release is suppressed by excessive secretion of prolactin which inhibits corticotropin releasing hormone.

An increased plasma level of estrogen indicates ovarian hyperfunction which may occur as a result of an ovarian tumor such as a granulosa-thecal cell tumor or signals the presence of an ectopic estradiol-producing tumor.

Estradiol is also measured to evaluate the response of patients to progesterone challenge and to determine responsiveness to clomiphene. In a person with amenorrhea, estradiol greater than 40 pg/mL following progestin administration excludes estrogen deficiency as a cause of amenorrhea. Clomiphene blocks the hypothalamic response to estrogen and is a treatment for patients with anovulation who have adequate estrogen and normal pituitary function. Use of the drug requires demonstration that the ovaries can produce estradiol.

Estriol (E3)

Estriol (E3) is the principal estrogen produced during pregnancy. Estriol is produced by the placenta from dehydroepiandrosterone sulfate derived from the fetal **liver** and adrenals. Estriol levels are low by approximately 25% (less than 75 MOM) in Down syndrome and other trisomies. Tests on maternal plasma for alpha-fetoprotein, chorionic gonadotropin, and unconjugated estriol are performed at 15–18 weeks gestation. Measurement of unconjugated estriol (uE3) is a better reflection of fetal-derived estriol than is total estriol, and is measured by RIA. Estriol levels are also low for the gestational age in spontaneous abortions and in threatened pregnancy, but are no longer needed for the diagnosis of these conditions.

Progesterone

Progesterone in the nonpregnant female is produced mainly by the ovaries with a small fraction also made by the adrenals. Progesterone levels in plasma are very low prior to ovulation. At ovulation, the level begins to rise due to secretion by the corpus luteum. The progesterone level peaks in the middle of the luteal phase (about one week prior to the next menses). Progesterone causes thickening of the endometrium in order to prepare the ovum for implantation should it be fertilized. In the absence of fertilization, negative feedback of progesterone on the hypothalamus results in suppression of luteinizing hormone and the corpus luteum involutes causing the wall of the uterus to breakdown. If fertilization occurs, the corpus luteum and placenta produce large amounts of progesterone. The most common use of plasma progesterone measurement is to evaluate ovulation. Progesterone is often measured on days 21 and 22 of the menstrual cycle. At this point the progesterone should represent the midluteal peak and levels above 5 ng/L are considered evidence of ovulation. Lower levels indicate a disruption of the normal luteal phase of progesterone production.

Testosterone

In males testosterone is produced by the testes under the control of luteinizing hormone. It is responsible for development of the testes, secondary sexual characteristics, and spermatogenesis. Testosterone is subject to diurnal variation in response to LH and highest plasma levels occur at 6–9 A.M. Approximately 60% of plasma testosterone is bound to sex hormone binding globulin (SHBG) and almost 40% is bound to albumin. Only about 2% of the hormone is in the free form and is physiologically active. Measurement of free hormone levels is more sensitive than total hormone because small changes in SHBG concentration can increase free hormone levels. A reduction in binding of testosterone to SHBG can be caused by drugs or other steroid hormones, and will increase free hormone levels. In males, plasma testosterone is low in hypogonadism and is measured in male children with delayed or absent sexual maturation. Primary testicular failure may result from Klinefelter syndrome, testicular **infection**, injury, and other causes. In these cases the plasma testosterone is low, but the LH and FSH are increased. In secondary testicular failure, plasma testosterone, FSH, and LH are decreased. Testosterone levels are also useful for the differential diagnosis of gynecomastia. In addition to low testosterone, gynecomastia can be caused by drugs that interfere with testosterone action, or ectopic tumors that secrete estrogen or chorionic gonadotropin.

Testosterone levels may be measured in both males and females to identify tumors that secrete the hormone. Testosterone is produced by some testicular and ovarian tumors as well as some others. Overproduction of testosterone caused by testicular, adrenal, or pituitary tumors in the young male may result in precocious puberty. Overproduction in females caused by an ovarian tumor or adrenal adenoma causes virilization and hirsutism (excessive hair growth). In cases of ambiguous sex or virilization in female children, testosterone and adrenal androgens such as androstenedione may be measured. Most cases of congenital adrenal hyperplasia are caused by 21-hydroxylase deficiency which is associated with excessive androgen production. The enzyme deficiency blocks cortisol synthesis and causes intermediate steroids to accumulate that are converted to testosterone and other androgens. Androgens are most often measured by RIA or gas chromatography-mass spectroscopy (GC-MS).

Preparation

Progesterone and testosterone tests require a blood sample; it is not necessary for the patient to restrict food or fluids before the test. However, testosterone specimens should be drawn in the morning, because testosterone levels are highest in the early morning hours. For progesterone tests, the date of the patient's last menstrual cycle or week of gestation should be noted on the test request slip.

The estrogen test can be performed on blood and/or urine. It is not necessary for the patient to restrict food or fluids for either test. If a 24-hour urine test has been requested, the patient should be instructed to discard the first morning specimen, then save all urine voided during the next 24 hours. The blood sample should be placed on ice immediately after it is drawn. It is also important to note the patient's sex, age, and menstrual cycle phase on the test request slip.

Aftercare

Discomfort or bruising may occur at the puncture site. Applying pressure to the puncture site until the bleeding stops helps to reduce bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with these tests.

KEY TERMS

Amenorrhea—Cessation of the menstrual cycle.

Gynecomastia—Excessive development of the male mammary glands, even to the functional state.

Hirsutism—Abnormal hairiness, especially in women.

Hypogonadism—Underactivity of the testes.

Orchiectomy—Removal of one or both testes.

Spermatogenesis—The production of sperm.

Virilism—The presence of male characteristics in women.

Results

Normal values for sex hormone tests are highly dependent upon age and sex and in females the time of the collection relative to the menstrual cycle. Ranges vary from laboratory to laboratory depending upon the method used. Representative values for some patient groups are shown below.

Estradiol: For adult women, estradiol levels range from 20–150 pg/mL during the follicular phase, 100–500 pg/mL during the mid-cycle phase, and 50–150 pg/mL during the luteal phase. Menopausal women have estradiol levels of less than 18 pg/mL. The normal range for adult males is approximately 18–75 pg/mL.

Increased levels of estrogen are found in the following conditions:

- ovarian tumor
- adrenocortical tumor
- some testicular tumors
- pregnancy

Decreased levels of estrogen are found in the following conditions:

- ovarian dysfunction
- interuterine death in pregnancy
- anorexia nervosa
- primary and secondary hypogonadism
- turner syndrome
- infantilism
- menopausal and post-menopausal symptoms
- pituitary insufficiency

- psychogenic stress

Progesterone levels for women during the follicular phase normally range from 0.1–1.5 ng/mL and 2–24 ng/mL during the luteal phase. The normal range for the mid-luteal peak is 4.5–25.5 ng/mL. For post menopause women, results fall below 1.0 ng/mL. Results for pregnant women are as follows:

- first trimester: 9–50 ng/mL
- second trimester: 18–150 ng/mL
- third trimester: 60–260 ng/mL

For men, the normal progesterone value is 0.1–0.3 ng/mL. For children, normal values run from 7–51 ng/mL.

Increased levels of progesterone are seen:

- during ovulation and pregnancy
- with certain types of ovarian cysts
- with a tumor of the ovary known as a choriocarcinoma

Decreased levels of progesterone are seen:

- in toxemia of pregnancy
- with a threatened abortion
- during placental failure
- after fetal death
- with amenorrhea
- due to gonadal dysfunction

Normal ranges for testosterone are generally 300–1,200 ng/dL for men, and 30–95 ng/dL for women. Boys between the ages of six and nine have normal values in the range of 3–30 ng/dL, while for girls of the same age the range is 2–20 ng/dL.

In men, increased levels are found in:

- sexual precocity
- adrenal hyperplasia
- testicular tumor
- hyperthyroidism
- testicular feminization

In men, decreased levels are found in:

- Klinefelter syndrome
- primary and secondary hypogonadism
- Down syndrome
- orchiectomy
- impotence
- gynecomastia

In women, increased levels of testosterone are most commonly associated with ovarian and adrenal tumors and hirsutism.

Health care team roles

Physicians order sex hormone tests and interpret the results often with the assistance of endocrinologists. A nurse or phlebotomist collect the blood samples. Testing is performed by clinical laboratory scientists/medical technologists.

Sexual dysfunction

Definition

Sexual dysfunction is broadly defined as the inability to fully enjoy sexual intercourse. Specifically, sexual dysfunctions are disorders that interfere with a full sexual response cycle. These disorders make it difficult for a person to enjoy or to have sexual intercourse. While sexual dysfunction rarely threatens physical health, it can take a heavy psychological toll, bringing depression, **anxiety**, and debilitating feelings of inadequacy.

Description

Sexual dysfunction takes different forms in men and women. A dysfunction can be life-long and always present; acquired; situational; or generalized, occurring despite the situation. A man may have a sexual problem if he:

- Ejaculates before he or his partner desires.
- Does not ejaculate, or experiences delayed ejaculation.
- Is unable to have an erection sufficient for pleasurable intercourse.
- Feels **pain** during intercourse.
- Lacks or loses sexual desire.

A woman may have a sexual problem if she:

- Lacks or loses sexual desire.
- Has difficulty achieving orgasm.
- Feels anxiety during intercourse.
- Feels pain during intercourse.
- Feels vaginal or other muscles contract involuntarily before or during sex.
- Has inadequate lubrication.

The most common sexual dysfunctions in men include:

- Erectile dysfunction: an impairment of the erectile reflex. The man is unable to have or maintain an erection that is firm enough for coitus or intercourse.
- Premature ejaculation, or rapid ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it.
- Ejaculatory incompetence: the inability to ejaculate within the vagina despite a firm erection and relatively high levels of sexual arousal.
- Retrograde ejaculation: a condition in which the bladder neck does not close off properly during orgasm so that the semen spurts backward into the bladder.

Until recently, it was presumed that women were less sexual than men. In the past two decades, traditional views of female sexuality were all but demolished, and women's sexual needs became accepted as legitimate in their own right.

Female sexual dysfunctions include:

- Sexual arousal disorder: the inhibition of the general arousal aspect of sexual response. A woman with this disorder does not lubricate, her vagina does not swell, and the muscle that surrounds the outer third of the vagina does not tighten—a series of changes that normally prepare the body for orgasm (“the orgasmic platform”). Also, in this disorder, the woman typically does not feel erotic sensations.
- Orgasmic disorder: the impairment of the orgasmic component of the female sexual response. The woman may be sexually aroused but never reach orgasm. Orgasmic capacity is less than would be reasonable for

her age, sexual experience, and the adequacy of sexual stimulation she receives.

- **Vaginismus:** a condition in which the muscles around the outer third of the vagina have involuntary spasms in response to attempts at vaginal penetration.
- **Painful intercourse:** a condition that can occur at any age. Pain can appear at the start of intercourse, midway through coital activities, at the time of orgasm, or after intercourse is completed. The pain can be felt as burning, sharp searing, or cramping; it can be external, within the vagina, or deep in the pelvic region or abdomen.

Causes and symptoms

Many factors, of both physical and psychological natures, can affect sexual response and performance. Injuries, ailments, and drugs are among the physical influences; in addition, there is increasing evidence that chemicals and other environmental pollutants depress sexual function. As for psychological factors, sexual dysfunction may have roots in traumatic events such as rape or incest, feelings of guilt, a poor self-image, depression, chronic fatigue, certain religious beliefs, or marital problems. Dysfunction is often associated with anxiety. If a man operates under the misconception that all sexual activity must lead to intercourse and to orgasm by his partner, and if the expectation is not met, he may consider the act a failure.

Men

With premature ejaculation, physical causes are rare, although the problem is sometimes linked to a neurological disorder, prostate **infection**, or urethritis. Possible psychological causes include anxiety (mainly performance anxiety), guilty feelings about sex, and ambivalence toward women. However, research has failed to show a direct link between premature ejaculation and anxiety. Rather, premature ejaculation seems more related to sexual inexperience in learning to modulate arousal.

When men experience painful intercourse, the cause is usually physical; an infection of the prostate, urethra, or testes, or an allergic reaction to spermicide or condoms. Painful erections may be caused by Peyronie's disease, fibrous plaques on the upper side of the penis that often produce a bend during erection. **Cancer** of the penis or testis and arthritis of the lower back can also cause pain.

Retrograde ejaculation occurs in men who have had prostate or urethral surgery, take medication that keeps the bladder open, or suffer from diabetes, a disease that can injure the nerves that normally close the bladder during ejaculation.

Erectile dysfunction is more likely than other dysfunctions to have a physical cause. Drugs, diabetes (the most common physical cause), **Parkinson's disease**, **multiple sclerosis**, and **spinal cord** lesions can all be causes of erectile dysfunction. When physical causes are ruled out, anxiety is the most likely psychological cause of erectile dysfunction.

Female

Dysfunctions of arousal and orgasm in women also may be physical or psychological in origin. Among the most common causes are day-to-day discord with one's partner and inadequate stimulation by the partner. Finally, sexual desire can wane as one ages, although this varies greatly from person to person.

Pain during intercourse can occur for any number of reasons, and location is sometimes a clue to the cause. Pain in the vaginal area may be due to infection, such as urethritis; also, vaginal tissues may become thinner and more sensitive during breastfeeding and after **menopause**. Deeper pain may have a pelvic source, such as endometriosis, pelvic adhesions, or uterine abnormalities. Pain can also have a psychological cause, such as fear of injury, guilt feelings about sex, fear of **pregnancy** or injury to the fetus during pregnancy, or recollection of a previous painful experience.

Vaginismus may be provoked by these psychological causes as well, or it may begin as a response to pain, and continue after the pain is gone. Both partners should understand that the vaginal contraction is an involuntary response, outside the woman's control.

Similarly, insufficient lubrication is involuntary, and may be part of a complex cycle. Low sexual response may lead to inadequate lubrication, which may lead to discomfort, and so on.

Diagnosis

In deciding when a sexual dysfunction is present, it is necessary to remember that while some people may be interested in sex at almost any time, others have low or seemingly nonexistent levels of sexual interest. Only when it is a source of personal or relationship distress, instead of voluntary choice, is it classified as a sexual dysfunction.

The first step in diagnosing a sexual dysfunction is usually discussing the problem with a health care professional, who will need to ask further questions in an attempt to differentiate among the types of sexual dysfunction. A physical exam of the genitals may be performed, and further medical tests may be ordered, including measurement of hormone levels in the **blood**. Men

may be referred to a specialist in diseases of the urinary and genital organs (urologist), and primary care physicians may refer women to a gynecologist.

In general, causes of sexual dysfunction are either physical or psychological. Physical causes often have an underlying condition that effect sexual function including:

- diabetes
- heart disease
- neurological disorders
- pelvic surgery or trauma
- alcoholism and drug abuse
- chronic disease such as kidney or **liver** failure
- side effects of medicines
- hormone imbalance
- heavy smoking

Psychological factors including the following:

- **stress** or anxiety
- insecurity about sexual performance
- relationship discord
- confusion regarding sexual orientation
- depression
- trauma in previous sexual experiences

The following agents have been associated with sexual dysfunction, so patients should speak to their doctors if they have concerns regarding: Tamoxifen, Luminal, Dilantin, Mysloine, Tegretol, Tricyclic, Anafranil, Prozac, Paxil, Inderal, Lopressor, Corgard, Blocadren, Tenormin, Cimetidine, Tagament, Thorazine, Haldol, Zyprexa, Xanax, Valium, and some progestin-dominant birth control pills. It is important to note that there may be alternate medications available that do not affect sexual function. Other agents may also be available to counteract any sexual dysfunctions experienced with these medications. Prescribed medication should not be discontinued without first speaking with a physician.

Treatment

Treatments break down into two main kinds, physical and behavioral **psychotherapy**.

In many cases, doctors or advance practice nurses may prescribe medications to treat an underlying physical cause or sexual dysfunction. Possible medical treatments include:

- Viagra (Sildenafil) is a treatment for erectile dysfunction in men.

- Papaverine and prostaglandin are used for erectile difficulties.
- MUSE (Medical Urethral System for Erection), a prostaglandin E-1 pellet which can be inserted into the urethra. In addition, Caverject and Edex are prostaglandin E-1 injection medications for erectile dysfunction.
- Surgically implanted inflatable penile prosthesis for erectile dysfunction.
- AndroGel, a topical gel for testosterone/androgen replacement in men. Testosterone injections and patches may also be used in men and women to stimulate sexual desire.
- Clomipramine, fluoxetine, as well as serotonin reuptake inhibitors such as Prozac, Zoloft, and Anafranil for premature ejaculation.
- Hormone replacement therapy for female dysfunctions.
- EROS-CTD, a clitoral therapy device approved by the FDA in May 2000 is designed to enhance lubrication and sensation in women who have arousal disorders. With a gentle suction, it increases blood flow to the clitoris and surrounding area.

New agents not yet FDA approved as of March 2001, but are expected to gain approval are:

- ICOS is an agent for treatment of erectile dysfunction that will likely receive FDA approval in 2001 or 2002.
- Uprima (apomorphine) claims to induce erection in men and arousal in women.
- Vasomax, an oral tablet, is said to facilitate an erection within 10–15 minutes. It is anticipated that Vasomax may aid women as well as men.
- Trials using Viagra in women are ongoing as of 2001.
- SS Cream is a topical agent with natural plant extracts which appears to desensitize the penis and is used to treat premature ejaculation.

In some cases, a specific technique may be used during intercourse to correct a dysfunction. One of the most common is the “squeeze technique” to prevent premature ejaculation. When a man feels that an orgasm is imminent, he withdraws from his partner. Then, the man or his partner gently squeezes the head of the penis to halt the orgasm. After 20–30 seconds, the couple may resume intercourse. The couple may do this several times before the man proceeds to ejaculation.

In cases where significant sexual dysfunction is linked to a broader emotional problem, such as depression or substance abuse, intensive psychotherapy and/or pharmaceutical intervention may be appropriate.

KEY TERMS

Ejaculatory incompetence—The inability to ejaculate within the vagina.

Erectile dysfunction—Difficulty achieving or maintaining an erect penis.

Impotence—The inability to achieve and sustain an erection suitable for intercourse.

Orgasmic disorder—The impairment of the ability to reach sexual climax.

Painful intercourse (dyspareunia)—Generally thought of as a female dysfunction but it also affects males. Pain can occur anywhere.

Premature ejaculation—Rapid ejaculation before the person wishes it, usually in less than one to two minutes after beginning intercourse.

Retrograde ejaculation—A condition in which the semen spurts backward into the bladder.

Sexual arousal disorder—The inhibition of the general arousal aspect of sexual response.

Vaginismus—Muscles around the outer third of the vagina have involuntary spasms in response to attempts at vaginal penetration, not allowing for penetration.

A variety of alternative therapies can be useful in the treatment of sexual dysfunction. Counseling or psychotherapy is highly recommended to address any emotional or mental components of the disorder. Botanical medicine, either western, Chinese, or ayurvedic, as well as nutritional supplementation, can help resolve biochemical causes of sexual dysfunction. Acupuncture and homeopathic treatment can be helpful by focusing on the energetic aspects of the disorder.

Some problems with sexual function are normal. For example, women starting a new or first relationship may feel sore or bruised after intercourse and find that an over-the-counter lubricant makes sex more pleasurable. Simple techniques, such as soaking in a warm bath, may relax a person before intercourse and improve the experience. **Yoga** and **meditation** provide needed mental and physical **relaxation** for several conditions, such as vaginismus. Relaxation therapy eases and relieves anxiety about dysfunction. Massage is extremely effective at reducing stress, especially if performed by the partner.

Prognosis

There is no single cure for sexual dysfunction, but almost all can be controlled. Most people who have a level of sexual dysfunction fare well once they get into a treatment program. For example, a high percentage of men with premature ejaculation can be successfully treated in two to three months. Furthermore, the gains made in sex therapy tend to be long-lasting rather than short-lived. Viagra produces an erection in 75% of men with erectile dysfunction. For men who are not responsive to drug treatment, studies with surgically implanted inflatable penile prosthesis claim a success rate at approximately 98%.

Health care team roles

Nursing and allied health professionals play a critical part in the diagnosis and treatment of sexual dysfunction. Sex therapy, which is ideally provided by a member of the American Association of Sexual Educators, Counselors, and Therapists (AASECT), universally emphasizes correcting sexual misinformation, the importance of improved partner communication and honesty, anxiety reduction, sensual experience and pleasure, and interpersonal tolerance and acceptance. Sex therapists believe that many sexual disorders are rooted in learned patterns and values. These are termed psychogenic. An underlying assumption of sex therapy is that relatively short-term outpatient therapy can alleviate learned patterns, restrict symptoms, and allow a greater satisfaction with sexual experiences.

Registered dietitians and nutritionists can be instrumental in giving dietary guidance and **nutrition** supplementation that may improve overall health and energy levels. Health improvements may impact general well-being and sexual function.

Sexual pain disorders see **Sexual dysfunction**

Sexuality and disability

Definition

Sexuality is a wide term that encompasses more than just the sexual organs or secondary sexual characteristics of a human being. It includes body image, self image, gender identity, beliefs and feelings about sex, capacities for love and friendship, and social behavior as well as overt physical expression of love or sexual desire. A person's sexuality is influenced by ethical, spiritual, cultural, and moral concerns. It can also be greatly impacted by mental, emotional, or physical disabilities.

Description

Simply put, sexuality is a natural part of life, and it should be addressed with sensitivity, but as any other occupation or activity would be by a rehabilitation therapist or other health professional treating a patient. While the sexual activity of persons with disabilities has been studied by medical and mental health researchers for the last thirty years, however, the subject rarely arises in ordinary conversations between persons with disabilities and their health care providers. This silence reflects both the embarrassment that people feel in discussing sexual problems, as well as the social attitude that persons with disabilities are not fully human, that is, they do not have sexual desires.

Sexual activity is a complex set of behaviors that involves most of the systems of the body as well as the mind and emotions. Consequently, a physical or mental disability that interferes with cognition, motor skills, coordination, and/or sensory skills can affect one's sexuality and/or sexual activity. Such physical impairments as **brain and spinal cord injury**, **multiple sclerosis**, arthritis, or seizures produce muscle weakness, loss of endurance, a decreased range of motion, and back **pain**. Such developmental and cognitive disabilities as attention span deficit, **dementia**, mental retardation, and depression affect a person's ability to form healthy relationships with trustworthy sexual partners. Lastly, the damaged self-image that can result from such surgical

procedures as mastectomy or amputation can affect a person's desire to resume or maintain sexual activity.

Health professionals should note that sexuality is a concern of most people in contemporary society, not just of those with some form of disability. The widespread use of sex in advertising to sell consumer goods, the saturation of the mass media with images of physically perfect men and women, and the increased availability of pornography leave many adults confused about "normal" sexual behaviors, "normal" aspects of attractiveness to others, and "normal" levels of sexual desire. It is often helpful to reassure persons with disabilities that "normal" covers a wide range of degrees of interest in sexual relationships or sexual behaviors. Human sexuality is not a "one-size-fits-all" entity in either men or women.

Clients of occupational therapists, physical therapists, social workers, and other health professionals should understand that they can discuss sexual concerns. Clients should be reminded throughout the process of rehabilitation that the return of sexual feelings is a sign of healing and recovery. It is equally important, however, for practitioners to keep in mind that a client with a chronic stressful health problem may not consider sexual activity a high priority. That decision, too, should be respected.

Physical disabilities

SPINAL CORD INJURIES. Sexual function or dysfunction following **spinal cord** injury (SCI) depends on the severity of injury. Sensation can be affected throughout the limbs and body, affecting erectile function in men and lubrication in women. Just below half of studied men have reported they could have erections and achieve orgasm. Most women report that they still can achieve lubrication and orgasm, but sometimes in an altered manner. Males with spinal cord injuries often use their mouths more frequently to arouse and give pleasure to their partners.

STROKE AND TRAUMATIC BRAIN INJURY. Survivors of stroke are often concerned about the impact of changes in their physical appearance on their partner, since strokes often produce such symptoms as drooling or a droop on one side of the mouth. In addition, many persons who have had a stroke worry about having another stroke during sexual activity. Lastly, either emotional depression or medications can cause stroke patients to lose interest in sex. Frank discussion with the partner as well as experimentation with different positions for intercourse are often helpful. In no case, however, should a stroke patient stop taking a prescribed medication without consulting his or her physician.

Not much research exists on the sexual function following traumatic brain injury (TBI). However, sexual activity has been found to decrease following TBI. Existing studies report conflicting evidence regarding men and erectile dysfunction. While many men report no erectile dysfunction, other studies have shown that a majority of men are impotent following TBI. It is also possible, depending on the portion of the brain affected by TBI, for a person to exhibit inappropriate sexual behavior, which is also known as hypersexuality.

NEUROMUSCULAR DISORDERS. Neuromuscular disorders, such as **muscular dystrophy**, can result in underdeveloped genitalia, which in turn, can affect sexual function. Although few studies exist, most experts believe that given the physiology of neuromuscular disorders, people with these disorders still are able to become aroused, have erections, and experience orgasms.

The age at onset of the disorder determines how sexually active a person can be. A client who experiences neuromuscular disorders at an early age may never gain full physical dependence, and that subsequently could hinder sexual function. Physical disability leads to lessened socialization, which also can hinder sexual expression. It is also common for the parents of children with disabilities to never fully acknowledge sexual maturation or the possibility of normal sexual function in their children.

ARTHRITIS. Arthritis causes stiffness in the joints, fatigue, and pain. A decreased desire for sex may result from the tiredness and discomfort themselves, but it may also be a side effect of arthritis medications. Arthritis patients should be assessed for joint range of motion, inflammation and deformity, and muscle strength and flexibility. Because arthritis affects the use of the hands, masturbation can be difficult. Positioning during sex can be difficult because of the body's loss of flexibility. Low back pain is common in clients with **osteoarthritis**, and sexual activity may result in muscle spasms.

Rheumatoid arthritis causes bone erosion and may cause problems with erection. Some persons with rheumatoid arthritis have reported that the symptoms of the disorder become temporarily worse following sexual activity.

DIABETES. Many studies exist examining the effects of diabetes on sexual function and sex drive. Most experts believe that sexual desire in men is virtually unaffected by diabetes. Women, however, are reported to experience a decrease in sexual desire. Diabetic women also experience a higher rate of occurrence of vaginal infections, which results in a decrease in lubrication, discharge, odor, itching, and tenderness, all which affect sexual desire and function.

Diabetes greatly impacts **contraception**, fertility, successful gestation, and the long-term health of women. Diabetic women are less likely than nondiabetic to carry a child full term and have a live birth. There is a risk of **miscarriage**, birth defects, and complications during **childbirth**.

Mental disabilities

Cognitive or mental impairment does not preclude a person's engaging in sexual activity. For a client with mental retardation, information should be presented in simple, short terms. The Association for Retarded Citizens believes that persons with mental retardation have a fundamental right to learn about sexual functions and relationships as well as safe sex, and that they should be able to make informed decisions regarding their sexuality. The Arc, a national organization for people with mental retardation maintains that the retarded should not be involuntarily sterilized nor denied sterilization if they choose it for themselves.

Having a developmental disability does not preclude a person from ever having an appropriate sexual relationship. Although some individuals may be too impaired to have a safe and appropriate sexual relationship, there are many individuals with moderate developmental impairments who can engage in self-stimulation.

The Arc also urges that people with mental retardation be given education and support to protect them from abuse and exploitation while respecting their human dignity.

Children with disabilities

Children with disabilities should not be treated as if they are asexual beings, without sexual feelings and drives. At the same time they, like people with mental retardation, require appropriate protections against exploitation and abuse by adults. These protections are all the more necessary because of the increased emphasis on sexual activity in the mass media and the general culture.

Because masturbation and certain other behaviors that may be related to children's self-discovery are clearly inappropriate if performed in public, it is important for practitioners to point out their inappropriateness to children. Practitioners should not, however, refer to these behaviors as "bad," but rather as improper at certain times.

The elderly

In general, older adults are often regarded as "over the hill" with regard to sexual attractiveness, interest or activity, purely apart from any physical or mental dis-

abilities that may accompany the aging process. This prejudice is particularly strong in the case of postmenopausal women. The National Women's Health Information Center reports that many medical professionals are misinformed about the sexual potential of women of any age with disabilities and consequently do not encourage them to resume normal sexual activities. But many older women also reported to the agency that they do not receive adequate education on sexual function related to disability. It is important for health professionals to inform themselves about the effects of aging on sexuality in the elderly—particularly about the side effects of medications frequently prescribed for older adults—and convey an openness to discussing these matters with their clients.

Viewpoints

The Sexuality Information and Education Council of the United States (SIECUS), which takes stands on issues of sexuality believes that persons with disabilities have a right to sexuality education, sexual health care, and opportunities for sexual expression. It further states that public and private health agencies should ensure that persons with disabilities should be eligible for services dealing with sexuality and sexual function.

Professional implications

Rehabilitation should include advice about resuming sexual activity when such discussion is appropriate. It is important, however, for the practitioner to consider this issue prior to addressing it with a client. The practitioner should first analyze his or her own attitudes about sexuality, and understand that the client may want to discuss an aspect of sexuality or sexual function that the practitioner does not agree with or is uncomfortable discussing. If a practitioner plans to avoid discussion of a particular sexual issue with a client, they should be prepared to refer the client to appropriate counseling or therapy that will meet this need. The practitioner always should remain nonjudgmental with the client when discussing any sexuality issue.

Much like any other activity of daily living, sexuality should be addressed by the practitioner during the normal course of treatment. The issue can easily be raised in the context of such other everyday activities as grooming, bathing, or dressing. Sexual issues can be addressed in the context of communication and intimacy among partners rather than focusing on physical abilities or limitations. Practitioners can bring up the subject with an open-ended question asking the client if he/she has any questions regarding sexual activity. If the practitioner avoids discussion of sexuality, the client may assume that

the subject is inappropriate or that the practitioner is uncomfortable. Practitioners uneasy about the subject should at least put the issue on the table, leave it open for discussion, and give the client the option of declining to address it. It is also appropriate to allow the client to invite their spouse or partner to a treatment session dealing with sexuality.

Sexually transmitted diseases cultures

Definition

Sexually transmitted diseases are infections spread from person to person through sexual contact. A culture is a test in which a laboratory attempts to grow and identify the microorganism causing an **infection**. Laboratory culture is performed to isolate and identify the causes of several sexually transmitted infections.

Purpose

Sexually transmitted diseases (STDs) produce symptoms such as genital discharge, **pain** during urination, bleeding, pelvic pain, skin ulcers, or urethritis. Often, however, they produce no immediate symptoms. Therefore, the decision to test for these diseases must be based not only on the presence of symptoms, but on whether or not a person is at risk of having one or more of the diseases. Activities such as drug use and sex with more than one partner put a person at high risk for these diseases. STD cultures are necessary to diagnose certain types of STDs. Only after the infection is diagnosed can it be treated and further spread of the infection prevented. Left untreated, consequences of these diseases range from discomfort to **infertility** to death. In addition, these diseases in a pregnant woman can be passed from mother to fetus.

Precautions

Some infections, particularly gonorrhea, can be difficult to culture. It may be necessary to culture other sites which may be infected, such as the anus and mouth if the patient has corresponding sexual habits which may put them at risk. Also, health care workers should be aware that testing of anyone who mentions a sexual assault must be done very carefully, following a protocol which is usually best carried out in the emergency room. The physician, nurse, or physician assistant performing sample collection should observe **universal precautions** for the prevention of transmission of bloodborne pathogens.

Description

Gonorrhea, bacterial vaginosis, candidiasis, chancroid, chlamydiosis, herpes, and mycoplasma are common sexually transmitted diseases that can be cultured. The organisms which cause the first three conditions are cultured routinely while those that cause the last four are more difficult to grow and are more frequently identified immunologically or by DNA amplification. **Syphilis**, human **immunodeficiency** virus, and trichomoniasis are sexually transmitted diseases that usually are not cultured because they do not grow on artificial culture medium.

The female patient will be in the dorsal lithotomy position (lying on the back with legs raised and bent) typical for Pap testing. A speculum is moistened with warm water (no lubricant should be used) and inserted into the vagina to secure good visualization of the cervix. Any excess cervical mucous should be removed with a cotton ball (held by ring forceps). A sterile swab is inserted just inside the opening of the cervix (the os) and rotated gently for 30 seconds. Genital swabs are usually placed in a transport medium that contains charcoal to absorb toxins that inhibit the growth of gonococcus.

Care should be taken not to touch the vaginal surfaces with the swab in order to avoid the transfer of normal vaginal flora. For culture, the sample is placed in Stuart or Amies transport medium with charcoal added and delivered to the laboratory at room temperature. Since *Neisseria gonorrhoeae* are very sensitive to drying and temperature changes, plating is performed as soon as possible. For DNA probe or immunological testing (in which organisms are not cultured), the swab is broken off at the top of the sterile tube provided, and the tube is capped and sent to the laboratory. For immediate viewing, a swab sample may be placed in normal saline. One drop can then be placed between a slide and coverslip, and viewed beneath the **microscope**. This is called a “wet prep.” A wet prep is useful for diagnosing yeast infection and trichomoniasis. Pelvic inflammatory disease samples and samples from genital lesions such as chancres are collected by aspiration. Plating for *H. ducreyi* should be done from the chancre aspirate and performed immediately because the organism is fastidious.

In the male patient, a smaller sterile swab is used to remove cells and any discharge from the last 0.75 in (2 cm) of the urethra, and the swab is transported for culture (or DNA probe or immunological testing) as described for the female patient. If visible discharge is present on the surface of the penis, this should be swabbed, and it is unnecessary to enter the urethra. For anal specimens the physician inserts a sterile, cotton-tipped swab about 1 in (2.5 cm) into the anus and rotates the swab for 30 seconds. Stool must not contaminate the swab. For orophar-

ynx (throat) specimens the person’s tongue is held down with a tongue depressor, as a healthcare worker moves a sterile, cotton-tipped swab across the back of the throat and tonsillar region.

Gonorrhea

Neisseria gonorrhoeae, also called gonococcus or GC, causes gonorrhea. It infects the mucosal surfaces of the genitourinary tract, primarily the urethra in males and the cervix in females. When seen on **Gram stain**, *Neisseria gonorrhoeae* are gram-negative diplococci (pairs of round or bean-shaped **bacteria**) often located inside white **blood** cells. The best specimen from which to culture *Neisseria gonorrhoeae* is a swab of the urethra in a male or the cervix in a female. Other possible specimens include the mouth, anus, or a swab of a genital lesion. All swabs are plated on modified Thayer-Martin (MTM) agar or New York City (NYC) agar. These media are selective for the growth of *N. gonorrhoeae*. MTM is chocolate agar (heated sheep blood agar) containing colistin to inhibit the growth of gram negative bacilli, nystatin or anisomycin to inhibit yeast, vancomycin to inhibit growth of gram-positive bacteria, and trimethoprim to inhibit *Proteus spp.* NYC agar contains amphotericin B instead of nystatin and consists of clear proteose-peptone supplemented agar. In addition, the sample is plated on either 5% sheep blood agar or Columbia agar with 5% sheep blood and colistin and nalidixic acid (CNA) to isolate *Candida albicans* which causes a yeast infection in the vagina and *Gardnerella vaginalis* which causes vaginosis as well. Plates are incubated at 96.8°F (36°C) in 5–10% carbon dioxide. MTM or NYC agar are examined for growth at 24 hours and if negative again at 48 hours. After 24 hours, any suspicious colonies are Gram-stained and tested for oxidase which provides presumptive identification of *Neisseria* if positive. The physician can be notified at this point by a preliminary report that gonococcus has been identified presumptively. Further biochemical testing may be performed to differentiate *N. gonorrhoeae* from *N. meningitides* which is sometimes isolated from homosexual males. Isolated colonies should also be tested for penicillin resistance. Plates may be discarded at 48 hours if no growth is seen. Rapid non-culture DNA amplification and enzyme **immunoassay tests** are available to test for *Neisseria gonorrhoeae* and provide results on the same day.

Microscopic analysis should always be included with **genital culture**. Wet preparations can identify yeast, *Trichomonas vaginalis*, and *G. vaginalis*. The latter can be seen as rods attached to large squamous epithelial cells called “clue cells.” A Gram stain of the swab material can identify gram-negative diplococci which is presumptive evidence of gonococcal infection. In males,

a positive finding on the Gram stain obviates the need for culture and the patient can begin antibiotic treatment. In females, the diplococci must be located intracellularly in order to make a presumptive diagnosis of gonorrhea infection, and culture must be performed to confirm the diagnosis. The presence of clue cells, epithelial cells containing gram-negative or gram-variable coccobacilli, can signal the presence of *Gardnerella vaginalis*.

Chancroid

Chancroid is caused by *Haemophilus ducreyi*. It is characterized by genital ulcers with nearby swollen lymph nodes. The specimen is collected by swabbing one of these pus-filled ulcers. The Gram stain cannot differentiate *Haemophilus ducreyi* from other *Haemophilus* species. The physician must request a specific culture for a person who has symptoms of chancroid. Even using special culture, *Haemophilus ducreyi* is isolated from less than 80% of the ulcers it infects. If a culture is negative, the physician must diagnose chancroid based on the person's symptoms, and by ruling out other possible causes of these symptoms, such as syphilis (which is diagnosed by a blood test for antibodies).

H. ducreyi is fastidious and culture media should be inoculated within 10 minutes of sample collection. The swab should be spread over a chocolate (heated sheep blood agar) plate and incubated at 96.8°F (36°C) in 5–10% carbon dioxide. Isolated colonies are Gram-stained to identify the bacteria as small gram-negative bacilli, and a colony is transferred to trypticase soy broth and a suspension is made. This is plated onto Mueller-Hinton or trypticase soy agar and strips of factor X (hemin) and factor V (NAD) are applied. *Haemophilus ducreyi* requires X factor but not V factor for growth. Like other *Haemophilus* species the organism is oxidase positive and reduces nitrate. Unlike most other *Haemophilus* species it does not produce catalase and does not ferment glucose, and these tests can be used for positive identification.

Mycoplasma and Ureaplasma

Three types of mycoplasmal organisms cause sexually transmitted disease: *Mycoplasma hominis*, *Mycoplasma genitalium*, and *Ureaplasma urealyticum*. *M. hominis* causes pelvic inflammatory disease (PID) and pyelonephritis in females but does not cause urethritis, vaginitis, or cervicitis. *Ureaplasma urealyticum* can cause urethritis in males and may cause PID in females but does not cause vaginitis or cervicitis. *M. genitalium* has been implicated as a cause of urethritis and PID. Samples are collected from the cervix in a female, and from the urethra (or urine) in a male. Swabs must be immediately placed in sucrose-phosphate or other

acceptable transport medium and transported to the lab immediately. These organisms will grow on New York City agar and *M. hominis* will also grow on CNA plates, but swabs should be inoculated onto a selective agar or broth such as SP-4 which differentiates *Mycoplasma* from *Ureaplasma* based upon the ability of the latter to hydrolyze urea. Cultures are incubated aerobically at 96.8°F (36°C) and grow for two to four days. Colonies are very small and difficult to see with the unaided eye. When growth is seen, a portion of the agar is removed and stained with Dienes stain. The colonies are examined under a microscope for their characteristic fried egg appearance. They will have a dark blue center and light blue periphery. These organisms cannot be seen with the Gram stain.

Chlamydiosis

Chlamydiosis is caused by the gram-negative bacterium *Chlamydia trachomatis*. It is one of the most common STDs in the United States (approximately three million cases occur each year), and generally appears in sexually active adolescents and young adults. While chlamydiosis often does not have any initial symptoms, it can if left untreated lead to pelvic inflammatory disease and sterility. Samples are collected from one or more of these infection sites: cervix in a female, urethra in a male, or the rectum. Swabs must be immediately placed in sucrose-phosphate or other acceptable transport medium and transported to the lab immediately. Culture is successful in recovering *Chlamydia trachomatis* about 80% of the time. The organism is inoculated onto monolayers of malignant tissue culture cells such as HeLa cells or McCoy cells in shell vials. The cultures are incubated for two to three days at 96.8°F (36°C) in 5–10% carbon dioxide. Following this they are stained with fluorescent-labeled monoclonal antibodies to the major outer membrane protein (MOMP) to identify the characteristic chlamydial inclusions. This technique is expensive and requires a high level of tissue culture expertise. Consequently most labs use non-culture tests such as enzyme immunoassay or DNA amplification methods to diagnose chlamydial infections.

Genital herpes

Herpes is generally diagnosed based on the patient's symptoms and the physical exam. Approximately two-thirds of **genital herpes** is caused by herpes simplex 2 (HSV-2) and the remainder by herpes simplex 1 (HSV-1). Extremely painful blisters around the genital area are classic for initial herpes presentation. However, if questions remain, the herpes virus can be cultured from a vesicle (blister) which has been "unroofed" carefully with a scalpel blade. The base of the vesicle is swabbed

with a sterile cotton applicator, and the virus taken to the laboratory in a tube of viral transport medium. Herpes can be cultured in several cell lines including human diploid fibroblasts (HDF), HEp2 cells (epithelial cancer cells from the larynx), primary monkey kidney cells (PMK), and rabbit kidney cells (RK). Cell cultures are inoculated and allowed to grow for one to three days at 98.6°F (36°C) in 5–10% carbon dioxide. Usually by the end of the first day of culture the cytopathic effect (CPE) can be seen by observing the cells under a microscope. Herpes induces the formation of giant cells.

Antibiotic susceptibility testing

Antibiotic susceptibility is not usually required for organisms isolated from a genital culture. Gonorrhea is treated with penicillin or related drugs. Chlamydiosis and mycoplasmal infections are treated with erythromycin. Herpes is treated with acyclovir or related antivirals. Candida is treated with clotrimazole or other antifungal. Bacterial vaginosis is treated with metronidazole, *Haemophilus ducryi* is treated with ceftriaxone or erythromycin.

Preparation

Cultures should always be collected before the person begins taking **antibiotics**. Men should not urinate within one hour before collection of a urethral specimen. Women should not douche or take a bath within 24 hours of collection of a cervical or vaginal culture.

Aftercare

Patients should be instructed to have no sexual contacts until test results are reported.

Complications

The minor discomforts of genital testing are short lived, and no significant complications are common.

Results

With the exception of *Mycoplasma* and *Ureaplasma*, these microorganisms are not found under normal conditions, so tests should be negative. *M. hominis* can be found in the male urethra and *Ureaplasma urealyticum* can be found in the female genital tract in the absence of disease. Therefore positive cultures for these organisms may indicate colonization without infection and the physician must differentiate these conditions on the basis of the **physical examination** and symptoms. Therefore, these organisms are treated at the discretion of the physician. If a person has a positive culture for any other of

these microorganisms, antibiotic treatment is started and his or her sexual partners should be notified and tested. After treatment is completed, the physician may request a follow-up culture to confirm that the infection is cured.

Health care team roles

Genital cultures are ordered by a physician and collected by a physician, nurse, or physician assistant. Culture, microscopic analysis, immunoassay, and DNA testing are performed by clinical laboratory scientists/medical technologists. Wet preparations may also be performed by the physician or physician assistant or nurse practitioner with appropriate training. Nursing staff have a very important task in educating the patient in what to expect, assisting with obtaining samples, and helping to explain test results to patients. Many patients undergoing genital testing are in need of counseling regarding the risks of careless sexual behavior, and the opportunity should be used by staff for education to reduce risks in the future.

Erika J. Norris

Shiatsu

Definition

Shiatsu is a manipulative therapy developed in Japan and incorporating techniques of *anna* (Japanese traditional massage), **acupressure**, stretching, and Western massage. Shiatsu involves applying pressure to special points or areas on the body in order to maintain physical

and mental well being, treat disease, or alleviate discomfort. This therapy is considered holistic because it attempts to treat the whole person instead of a specific medical complaint. All types of acupressure generally focus on the same pressure points and so-called energy pathways, but may differ in terms of massage technique. Shiatsu, which can be translated as finger pressure, has been described as needle-free acupuncture.

Origins

Shiatsu is an offshoot of anma that developed during the period after the Meiji Restoration in 1868. Traditional massage (anma) used during the age of shoguns was being criticized, and practitioners of *koho anma* (ancient way) displeased with it introduced new practices and new names for their therapies.

During the twentieth century, shiatsu distinguished itself from anma through the merging of Western knowledge of anatomy, *koho anma*, *ampuku* (abdominal massage), acupressure, *Do-In* (breathing practices), and Buddhism. Based on the work of Tamai Tempaku, shiatsu established itself in Japan and worldwide. The Shiatsu Therapists Association was found in 1925 and clinics and schools followed. Students of Tempaku began teaching their own brand of shiatsu, creating branch disciplines. By 1955, the Japanese Ministry of Health and Welfare acknowledged shiatsu as a beneficial treatment and licensing was established for practitioners.

Benefits

Shiatsu has a strong reputation for reducing **stress** and relieving nausea and vomiting. Shiatsu is also believed to improve circulation and boost the **immune system**. Some people use it to treat **diarrhea**, indigestion, constipation, and other disorders of the gastrointestinal tract; menstrual and menopausal problems; chronic **pain**; migraine; arthritis; toothache; **anxiety**; and depression. Shiatsu can be used to relieve muscular pain or tension, especially neck and back pain. It also appears to have sedative effects and may alleviate insomnia. In a broader sense, shiatsu is believed to enhance physical vitality and emotional well being.

Description

Shiatsu and other forms of Japanese acupressure are based on the concept of *ki*, the Japanese term for the all-pervading energy that flows through everything in the universe. (This notion is borrowed from the Chinese, who refer to the omnipresent energy as *qi* or *chi*.) *Ki* tends to flow through the body along special energy pathways called meridians, each of which is associated with

a vital organ. In Asian systems of traditional medicine, diseases are often believed to occur due to disruptions in the flow this energy through the body. These disruptions may stem from emotional factors, climate, or a host of other causes including stress, the presence of impurities in the body, and physical trauma.

The aim of shiatsu is to restore the proper flow of bodily energy by massaging the surface of the skin along the meridian lines. Pressure may also be applied to any of the 600 or so acupoints. Acupoints, which are supposedly located just under the skin along the meridians, are tiny energy structures that affect the flow of *ki* through the body. When *ki* either stagnates and becomes deflected or accumulates in excess along one of these channels, stimulation to the acupoints, which are sensitive to pressure, can unblock and regulate the *ki* flow through toning or sedating treatment.

Western medicine hasn't proven the existence of meridians and acupoints. However, in one study, two French medical doctors conducted an experiment at Necher Hospital in Paris to test validity of theory that energy is being transported along acupuncture meridians. They injected and traced isotopes with gamma-camera imaging. The meridians may actually correspond to nerve transmission lines. In this view, shiatsu and other forms of healing massage may trigger the emission of naturally occurring chemicals called neurotransmitters. Release of these chemical messengers may be responsible for some of the therapeutic effects associated with shiatsu, such as pain relief.

Preparations

People usually receive shiatsu therapy while lying on a floor mat or massage table or sitting up. The massage is performed through the clothing—preferably a thin garment made from natural fibers—and disrobing is not required. Pressure is often applied using the thumbs, though various other parts of the body may be employed, including fingertips, palms, knuckles, elbows, and knees—some therapists even use their feet. Shiatsu typically consists of sustained pressure (lasting up to 10 seconds at a time), squeezing, and stretching exercises. It may also involve gentle holding as well as rocking motions. A treatment session lasts anywhere from 30 to 90 minutes.

Before shiatsu treatment begins, the therapist usually performs a general health assessment. This involves taking a family medical history and discussing the physical and emotional health of the person seeking therapy. Typically, the practitioner also conducts a diagnostic

A woman receiving a shiatsu treatment on her shoulder. (Photo Researchers, Inc. Reproduced by permission.)

examination by palpating the abdomen or back for any energy imbalances present in other parts of the body.

Precautions

While shiatsu is generally considered safe, there are a few precautions to consider. Because it may increase **blood** flow, this type of therapy is not recommended in people with bleeding problems, **heart** disease, or **cancer**. **Massage therapy** should always be used with caution in those with **osteoporosis**, fresh **wounds** or scar tissue, bone **fractures**, or inflammation.

Applying pressure to areas of the head is not recommended in people with epilepsy or high **blood pressure**, according to some practitioners of shiatsu.

Shiatsu is not considered effective in the treatment of **fever**, **burns**, and infectious diseases.

Shiatsu should not be performed right after a meal.

Side effects

When performed properly, shiatsu is not associated with any significant side effects. Some people may expe-

rience mild discomfort, which usually disappears during the course of the treatment session.

Research and general acceptance

Like many forms of massage, shiatsu is widely believed to have a relaxing effect on the body. There is also a significant amount of research suggesting that acupressure techniques can relieve nausea and vomiting associated with a variety of causes, including **pregnancy** and anesthetics and other drugs. In one study, published in the *Journal Of Nurse-Midwifery* in 1989, acupressure was shown to significantly reduce the effects of nausea in 12 of 16 women suffering from morning sickness. Five days of this therapy also appeared to reduce anxiety and improve mood. Another investigation, published in the *British Journal Of Anaesthesia* in 1999, studied the effects of acupressure on nausea resulting from the use of anesthetics. Pressure applied to an acupoint on the inside of the wrist appeared to alleviate nausea in patients who received anesthetics during the course of laparoscopic surgery.

Shiatsu may also produce sedative and analgesic effects. The sedative powers of acupressure were investigated in a study published in the *Journals of Gerontology*

KEY TERMS

Acupressure—An ancient form of Asian healing massage that involves applying pressure to special points or areas on the body in order to maintain good health, cure disease, and restore vitality.

Analgesic—Pain reliever.

Osteoporosis—A disease of the bones due to deficiency of bone matrix, occurring most frequently in postmenopausal women.

Palpate—Feel.

in 1999, which involved over 80 elderly people who suffered from sleeping difficulties. Compared to the people in the control groups, the 28 participants who received acupressure were able to sleep better. They slept for longer periods of time and were less likely to wake up during the night. The researchers concluded that acupressure may improve the quality of sleep in older adults. The use of acupressure in postoperative pain was investigated in a study published in the *Clinical Journal Of Pain* in 1996. In this study, which involved 40 knee surgery patients, one group received acupressure (15 acupoints were stimulated) while the control group received sham acupressure. Within an hour of treatment, members of the acupressure group reported less pain than those in the control group. The pain-relieving effects associated with acupressure lasted for 24 hours.

Shiatsu may benefit stroke victims. The results of at least one study (which did not include a control group) suggest that shiatsu may be useful during stroke rehabilitation when combined with other treatments.

Training and certification

A qualified shiatsu therapist must have completed courses in this form of therapy and should be nationally certified or licensed by the state (most are certified by the American Oriental Bodywork Therapy Association). Asking a medical doctor for a recommendation is a great place to start. It can also be helpful to consult friends and family members who have tried shiatsu. There are several massage-related organizations that offer information on locating a qualified therapist. These include the National Certification Board for Therapeutic Massage and Bodywork, the American Massage Therapy Association, the International School of Shiatsu, and the American Oriental Bodywork Therapy Association.

Shock

Definition

Shock occurs when the body's organs and tissues do not receive an adequate flow of **blood**. Inadequate blood flow deprives the organs and tissues of oxygen and allows the buildup of waste products. Shock is a medical emergency and can result in serious damage or even death.

Description

There are three stages of shock: Stage I (also called compensated, or nonprogressive), Stage II (also called decompensated or progressive), and Stage III (also called irreversible).

In Stage I of shock, when low blood flow (perfusion) is first detected, a number of systems are activated in order to maintain or restore perfusion. The result is that the **heart** beats faster, the **blood vessels** throughout the body become slightly smaller in diameter, and the kidney works to retain fluid in the circulatory system. All this serves to maximize blood flow to the most important organs and systems in the body. A person in this stage of shock has very few symptoms, and treatment can completely halt any progression.

In Stage II of shock, the body's standard methods of compensation begin to fail and are unable to improve perfusion any longer. Oxygen deprivation in the **brain** causes the person to become confused and disoriented, while oxygen deprivation in the heart may cause chest **pain**. With quick and appropriate treatment, this stage of shock can be reversed.

In Stage III of shock, the length of time that poor perfusion has existed begins to take a permanent toll on the body's organs and tissues. The heart's functioning continues to spiral downward, and the **kidneys** usually shut down completely. Cells in organs and tissues throughout the body are injured and dying. The endpoint of Stage III shock is death.

Causes and symptoms

Shock is caused by three major categories of problems: cardiogenic (problems associated with the heart's functioning); hypovolemic (total volume of blood available to circulate is low); and **septic shock** (overwhelming **infection**, usually by **bacteria**).

Cardiogenic shock can be caused by any disease or event which prevents the heart muscle from pumping strongly and consistently enough to circulate the blood in a normal fashion. Heart attack, conditions which cause inflammation of the heart muscle (myocarditis), disturbances of the electrical rhythm of the heart, and any kind of mass or fluid accumulation or blood clot which interferes with flow out of the heart can significantly affect the heart's ability to pump a normal quantity of blood.

Hypovolemic shock occurs when the total volume of blood in the body falls well below normal. This can occur when there is excess fluid loss, as in **dehydration** due to severe vomiting or **diarrhea**, diseases which cause excess urination (diabetes insipidus, **diabetes mellitus**,

and kidney failure), extensive **burns**, blockage in the intestine, inflammation of the **pancreas (pancreatitis)**, or severe bleeding of any kind.

Septic shock can occur when an untreated or inadequately treated infection (usually bacterial) is allowed to progress. Bacteria often produce poisonous chemicals (toxins) which can cause injury throughout the body. When large quantities of these bacteria and their toxins begin circulating in the bloodstream, every organ and tissue is at risk of their damaging effects. The most damaging consequences include poor functioning of the heart muscle; widening of the diameter of the blood vessels; a drop in **blood pressure**; activation of the blood clotting system, causing blood clots, followed by a risk of uncontrollable bleeding; damage to the **lungs**, causing acute **respiratory distress syndrome**; **liver** failure; kidney failure; and **coma**.

Initial symptoms of shock include cold, clammy hands and feet; pale or blue-tinged skin tone; weak, fast pulse rate; fast rate of breathing; low blood pressure. A variety of other symptoms may be present, but they are dependent on the underlying cause of shock.

Diagnosis

Diagnosis of shock is based on a person's symptoms, as well as criteria including a significant drop in blood pressure, extremely low urine output, and blood tests that reveal overly acidic blood with a low circulating concentration of carbon dioxide. Other tests are performed, as appropriate, to try to determine the underlying condition responsible for an individual's state of shock.

Treatment

The most important goals in treating shock include quickly diagnosing a person's state of shock; quickly intervening to halt the underlying condition (stopping bleeding, re-starting the heart, giving **antibiotics** to combat an infection, etc.); treating the effects of shock (low oxygen, increased acid in the blood, activation of the blood clotting system); and supporting vital functions (blood pressure, urine flow, heart function).

Treatment includes keeping a person warm, with legs raised and head down to improve blood flow to the brain, putting a needle in a vein in order to give fluids or blood transfusions, as necessary; giving a person extra oxygen to breathe and medications to improve the heart's functioning; and treating the underlying condition which led to shock.

KEY TERMS

Cardiogenic—Originating with the heart.

Deprivation—A condition of having too little of something.

Hypovolemic—Having a low volume.

Perfusion—Blood flow through an organ or tissue.

Sepsis—An overwhelming infection throughout the body, usually caused by bacteria in the bloodstream.

Prognosis

The prognosis of an individual in shock depends on the stage of shock when treatment was begun, the underlying condition causing shock, and the general medical state of the person.

Health care team roles

First aid is often given by appropriately trained individuals. Physicians supervise the treatment of shock in a hospital setting. Nurses provide bedside management and patient-family education.

Prevention

The most preventable type of shock is caused by dehydration during illnesses with severe vomiting or diarrhea. Shock can be avoided by recognizing that a person who is unable to drink in order to replace lost fluids needs to be given fluids intravenously (through a needle in a vein). Other types of shock are only preventable insofar as one can prevent their underlying conditions or can monitor and manage those conditions well enough so that they never progress to the point of shock.

Sickle cell disease

Definition

Sickle cell disease describes a group of inherited **blood** disorders characterized by chronic anemia, painful events, and various complications due to associated tissue and organ damage.

Description

The most common and well-known type of sickle cell disease is sickle cell anemia, also called SS disease. All types of sickle cell disease are caused by a genetic change in hemoglobin, the oxygen-carrying protein inside the red blood cells. The red blood cells of affected individuals contain a predominance of a structural variant of the usual adult hemoglobin. This variant hemoglobin, called sickle hemoglobin, has a tendency to polymerize into rod-like structures that alter the shape of the usually flexible red blood cells. The cells take on a shape that resembles the curved blade of a sickle, an agricultural tool. Sickle cells have a shorter life span than normally-shaped red blood cells. This results in chronic anemia characterized by low levels of hemoglobin and decreased numbers of red blood cells. Sickle cells are also less flexible and more sticky than normal red blood cells and can become trapped in small **blood vessels** preventing blood flow. This compromises the delivery of oxygen, which can result in **pain** and damage to associated tissues and organs. Sickle cell disease presents with marked variability, even within families.

Demographics

Carriers of the sickle cell gene are said to have sickle cell trait. Unlike sickle cell disease, sickle cell trait does not cause health problems. In fact, sickle cell trait is protective against **malaria**, a disease caused by blood-borne parasites transmitted through mosquito bites. According to a widely accepted theory, the genetic mutation associated with the sickle cell trait occurred thousands of years ago. Coincidentally, this mutation increased the likelihood that carriers would survive malaria **infection**. Survivors then passed the mutation on to their offspring, and the trait became established throughout areas where malaria was common. As populations migrated, so did the sickle cell trait. Today, approximately one in 12 African Americans has sickle cell trait.

Worldwide, it has been estimated that one in every 250,000 babies is born with sickle cell disease. Sickle cell disease primarily affects people with African, Mediterranean, Middle Eastern, and Asian Indian ances-

try. In the United States, sickle cell disease is most often seen in African Americans, in whom the disease occurs in one out of every 400 births. The disease has been described in individuals from several different ethnic backgrounds and is also seen with increased frequency in Latino Americans, particularly those of Caribbean, Central American, and South American ancestry. Approximately one in every 1,000–1,400 Latino births are affected.

Genetic profile

Humans normally make several types of the oxygen-carrying protein hemoglobin. An individual's stage in development determines whether primarily embryonic, fetal, or adult hemoglobins will be made. All types of hemoglobin are made of three components: heme, alpha (or alpha-like) globin, and beta (or beta-like) globin. Sickle hemoglobin is the result of a genetic change in the beta globin component of normal adult hemoglobin. The beta globin gene is located on chromosome 11. The sickle cell form of the beta globin gene results from the substitution of a single DNA nucleotide, or genetic building-block. The change from adenine to thymine at codon (position) 6 of the beta globin gene leads to insertion of the amino acid valine instead of glutamic acid at this same position in the beta globin protein. As a result of this change, sickle hemoglobin has unique properties in comparison to the usual type of adult hemoglobin.

Most individuals have two normal copies of the beta globin gene, which make normal beta globin that is incorporated into adult hemoglobin. Individuals who have sickle cell trait (called sickle cell carriers) have one normal beta globin gene and one sickle cell gene. These individuals make both the usual adult hemoglobin and sickle hemoglobin in roughly equal proportions, so they do not experience any health problems as a result of having the trait. Although traces of blood in the urine and difficulty in concentrating the urine can occur, neither represents a significant health problem due to sickle cell trait. Of the millions of people with sickle cell trait worldwide, a small handful of individuals have experienced acute symptoms. In these very rare cases, individuals were subject to very severe physical strain.

When both members of a couple are carriers of sickle cell trait, there is a 25% chance in each **pregnancy** for their baby to inherit two sickle cell genes and have sickle cell anemia, or SS disease. Correspondingly, there is a 50% chance their baby will have sickle cell trait and a 25% chance that the baby will have the usual type of hemoglobin. Other types of sickle cell disease include SC disease, SD disease, and S/beta thalassemia. These conditions are caused by the co-inheritance of the sickle cell

gene and another altered beta globin gene. For example, one parent may have sickle cell trait and the other parent may have hemoglobin C trait (another hemoglobin trait that does not cause health problems). For such a couple, there would be a 25% chance of SC disease in each pregnancy.

Causes and symptoms

Normal adult hemoglobin transports oxygen from the **lungs** to tissues throughout the body. Sickle hemoglobin can also transport oxygen. However, once the oxygen is released, sickle hemoglobin tends to polymerize (line-up) into rigid rods that alter the shape of the red blood cell. Sickling of the red blood cell can be triggered by low oxygen, such as occurs in organs with slow blood flow. It can also be triggered by cold temperatures and **dehydration**.

Sickle cells have a decreased life span in comparison to normal red blood cells. Normal red blood cells survive for approximately 120 days in the bloodstream; sickle cells last only 10–12 days. As a result, the bloodstream is chronically short of red blood cells and hemoglobin, and an affected individual develops anemia.

The sickle cells can create other complications. Due to their shape, they do not fit well through small blood vessels. As an aggravating factor, the outside surfaces of sickle cells may have altered chemical properties that increases their stickiness. These sticky sickle cells are more likely to adhere to the inside surfaces of small blood vessels, as well as to other blood cells. As a result of the sickle cells' shape and stickiness, blockages form in small blood vessels. Such blockages prevent oxygenated blood from reaching areas where it is needed, causing pain, as well as organ and tissue damage.

The severity of symptoms cannot be predicted based solely on the genetic inheritance. Some individuals with sickle cell disease may develop problems in infancy that affect their health or be life-threatening. Others may experience only mild symptoms throughout their lives. Individuals may experience varying degrees of health at different stages in the life cycle. For the most part, this clinical variability is unpredictable, and the reasons for the observed variability can not usually be determined. However, certain types of sickle cell disease (i.e., SC disease) tend to result in fewer and less severe symptoms on average than other types of sickle cell disease (i.e., SS disease). Some additional modifying factors are known. For example, elevated levels of fetal hemoglobin in a child or adult can decrease the quantity and severity of some symptoms and complications. Fetal hemoglobin is a normally occurring hemoglobin that usually decreases from over 90% of the total hemoglobin to under 1% dur-

ing the first year of life. This change is genetically determined, although some individuals may experience elevated levels of fetal hemoglobin due to variation in the genes that control fetal hemoglobin production. Such individuals often experience a reduction in their symptoms and complications due to the ability of fetal hemoglobin to prevent the polymerization of sickle hemoglobin, which leads to sickling of the red blood cell.

There are several symptoms that warrant immediate medical attention, including the following:

- signs of infection (**fever** above 101°F or 38.3°C, coughs frequently or breathing trouble, unusual crankiness, feeding difficulties)
- signs of severe anemia (pale skin or lips, yellowing of the skin or eyes, very tired, very weak)
- signs indicating possible dehydration (vomiting, **diarrhea**, fewer wet diapers)
- other signs (pain or swelling in the abdomen, swollen hands or feet, screams when touched)

The following can be signs of various complications that occur in sickle cell disease.

Infections and effects on the spleen

Children with sickle cell disease who are under age three are particularly prone to life-threatening bacterial infections. *Streptococcus pneumoniae* is the most common offending **bacteria**, and invasive infection from this organism leads to death in 15% of cases. The spleen, an organ that helps to fight bacterial infections, is particularly vulnerable to the effects of sickling. Sickle cells can impede blood flow through the spleen, causing organ damage, which usually results in the loss of spleen function by late childhood. The spleen can also become enlarged due to blockages and/or increased activity of the spleen. Rapid enlargement of the spleen may be a sign of another complication called splenic sequestration, which occurs mostly in young children and can be life-threatening. Widespread sickling in the spleen prevents adequate blood flow from the organ, removing increasing volumes of blood from the circulation and leading to accompanying signs of severe anemia.

Painful events

Painful events, also known as vaso-occlusive events, are a hallmark symptom of sickle cell disease. The frequency and duration of the pain can vary tremendously from person to person and over an individual's life cycle. Painful events are the most common cause of hospitalizations in sickle cell disease. However, only a small proportion of individuals with sickle cell disease experience frequent and severe painful events. Most painful events

can be managed at home. Pain results when small blood vessel blockages prevent oxygen from reaching tissues. Pain can affect any area of the body, although the extremities, chest, abdomen, and bones are frequently affected sites. There is some evidence that cold temperatures or infection can trigger a painful event, but most events occur for unknown reasons. The hand-foot syndrome, or dactylitis, is a particular type of painful event. Most common in toddlers, dactylitis results in pain and swelling in the hands and feet and is sometimes accompanied by a fever.

Anemia

Sickle cells have a high turnover rate, and there is a deficit of red blood cells in the bloodstream. Common symptoms of anemia include fatigue, paleness, and a shortness of breath. A particularly severe form of anemia called aplastic anemia may occur following infection with parvovirus. Parvovirus infection causes extensive destruction of the bone marrow, bringing production of new red blood cells to a halt. Bone marrow production resumes after seven to 10 days. However, given the short lives of sickle cells, even a brief shut-down in red blood cell production can cause a rapid decline in hemoglobin concentrations.

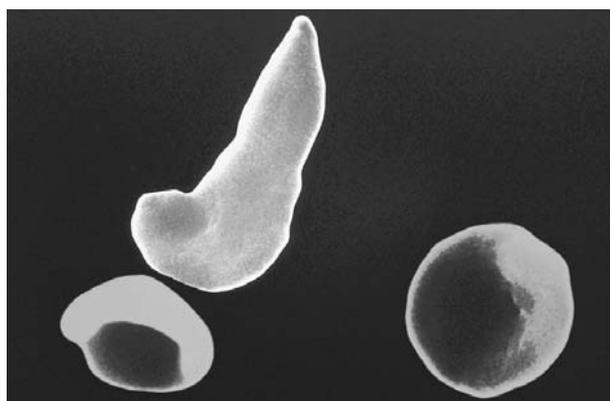

Delayed growth

The energy demands of the bone marrow for red blood cell production compete with the demands of a growing body. Children with sickle cell anemia may have delayed growth and reach **puberty** at a later age than normal. By early adulthood, they catch up on growth and attain normal height. However, their weight typically remains below average.

Stroke

Children with sickle cell disease have a significantly elevated risk of having a stroke, which can be one of the most serious complications of sickle cell disease. Approximately 11% of individuals with sickle cell disease will have a recognizable stroke by the age of 20. **Magnetic resonance imaging** (MRI) studies have found that 17% of children with sickle cell anemia have evidence of a previous stroke or clinically ‘silent’ stroke-like events called transient ischemic attacks. Stroke in sickle cell disease is usually caused by a blockage of a blood vessel. However, approximately one-fourth of the time they may be caused by a hemorrhage (or rupture) of a blood vessel.

Strokes result in compromised delivery of oxygen to an area of the **brain**. The consequences of stroke can

A scanning electron micrograph (SEM) of red blood cells taken from a person with sickle cell anemia. The blood cells at the right are normal; the diseased, sickle-shaped cells appear at the left. (Photograph by Dr. Gopal Murti, Photo Researchers, Inc. Reproduced by permission.)

range from life-threatening, to severe physical or cognitive impairments, to apparent or subtle learning disabilities, to undetectable effects. Common stroke symptoms include weakness or numbness that affects one side of the body, sudden behavioral changes, loss of **vision**, confusion, loss of speech or the ability to understand spoken words, dizziness, headache, seizures, vomiting, or even **coma**.

Approximately two-thirds of children who have a stroke will have at least one more. Transfusions have been shown to decrease the incidence of a second stroke. A recent study showed that children at highest risk to experience a first stroke were ten times more likely to stroke if untreated when compared to high-risk children treated with chronic blood **transfusion therapy**. High-risk children were identified using transcranial Doppler ultrasound technology to detect individuals with increased blood flow speeds due to constricted intracranial blood vessels.

Acute chest syndrome

Acute chest syndrome (ACS) is a leading cause of death for individuals with sickle cell disease, and recurrent attacks can lead to permanent lung damage. Therefore rapid diagnosis and treatment is of great importance. ACS can occur at any age and is similar but distinct from **pneumonia**. Affected persons may experience fever, cough, chest pain, and shortness of breath. ACS seems to have multiple causes including infection, sickling in the small blood vessels of the lungs, fat embolisms to the lungs, or a combination of factors.

Priapism

Males with sickle cell anemia may experience priapism, a condition characterized by a persistent and painful erection of the penis. Due to blood vessel blockage by sickle cells, blood is trapped in the tissue of the penis. Priapism may be short in duration or it may be prolonged. Priapism can be triggered by low oxygen (hypoxemia), alcohol consumption, or sexual intercourse. Since priapism can be extremely painful and can result in damage to this tissue (causing impotence), rapid treatment is essential.

Kidney disease

The internal environment of the kidney is particularly prone to damage from sickle cells. Signs of kidney damage can include blood in the urine, incontinence, and enlarged **kidneys**. Adults with sickle cell disease often experience insufficient functioning of the kidneys, which can progress to kidney failure in a small percentage of adults with sickle cell disease.

Jaundice and gallstones

Jaundice is indicated by a yellow tone in the skin and eyes, and alone it is not a health concern. Jaundice may occur if bilirubin levels increase, which can occur with high levels of red blood cell destruction. Bilirubin is the final product of hemoglobin degradation, and is typically removed from the bloodstream by the **liver**. Therefore, jaundice can also be a sign of a poorly functioning liver, which may also be evidenced by an enlarged liver hepatomegaly. Increased bilirubin also leads to increased chance for gallstones in children with sickle cell disease. Treatment, which may include removal of the gall bladder, may be selected if the gallstones start causing symptoms.

Retinopathy

The blood vessels that supply oxygen to the retina, the tissue at the back of the eye, may be blocked by sickle cells, leading to a condition called retinopathy. This is one of the only complications that is actually more common in SC disease as compared to SS disease. Retinopathy can be identified through regular ophthalmology evaluations and effectively treated in order to avoid damage to vision.

Joint problems

Avascular necrosis of the hip and shoulder joints, in which bone damage occurs due to compromised blood flow due to sickling, can occur later in childhood. This

complication can affect an individual's physical abilities and result in substantial pain.

Diagnosis

In the United States, African Americans and Latino Americans have the highest risk of having the disease or trait. Sickle cell is also common among individuals of Mediterranean, Middle Eastern, and Eastern Indian descent. Individuals from these areas of ethnic groups should consider screening for sickle cell disease.

A **complete blood count (CBC)** will describe several aspects of an individual's blood cells. A person with sickle cell disease will have a lower than normal hemoglobin level, together with other characteristic red blood cell abnormalities. Hemoglobin electrophoresis is a test that can help identify the types and quantities of hemoglobin made by an individual. This test uses an electric field applied across a slab of gel-like material. Hemoglobins migrate through this gel at various rates and go to specific locations, depending on their size, shape, and electrical charge. Although sickle hemoglobin (Hb S) and regular adult hemoglobin (called Hb A) differ by only one amino acid, they can be clearly separated using hemoglobin electrophoresis. Isoelectric focusing and high-performance liquid chromatography (HPLC) use similar principles to separate hemoglobins and can be used instead of or in various combinations with hemoglobin electrophoresis to determine the types of hemoglobin present.

Another test, called the 'sickledex' can help confirm the presence of sickle hemoglobin, although this test cannot provide accurate or reliable diagnosis when used alone. When Hb S is present, but there is an absence or only a trace of Hb A, sickle cell anemia is a likely diagnosis. Additional beta globin DNA test that directly assays the beta globin gene can be performed to help confirm the diagnosis and establish the exact genetic type of sickle cell disease. CBC and hemoglobin electrophoresis are also typically used to diagnosis sickle cell trait and various other types of beta globin traits.

Diagnosis of sickle cell disease can occur under various circumstances. If an individual has symptoms that are suggestive of this diagnosis, the above-described screening tests can be performed followed by DNA testing, if indicated. Screening at birth using HPLC or a related technique offers the opportunity for early intervention. More than 40 states include sickle cell screening as part of the usual battery of blood tests done for newborns. This allows for early identification and treatment. Hemoglobin trait screening is recommended for any individual of a high-risk ethnic background who may be considering having children. When both members of a cou-

ple are found to have sickle cell trait, or other related hemoglobin traits, they can receive **genetic counseling** regarding the risk of sickle cell disease in their future children and various testing options.

Sickle cell disease can be identified before birth through the use of prenatal diagnosis. **Chorionic villus sampling** (CVS) can be offered as early as 10 weeks of pregnancy and involves removing a sample of the placenta made by the baby and testing the cells. CVS carries a risk of causing a **miscarriage** that is between 0.5 and 1%.

Amniocentesis is generally offered between 15 and 22 weeks of pregnancy, but can sometimes be offered earlier. Two to three tablespoons of the fluid surrounding a baby are removed. This fluid contains fetal cells that can be tested. Although both tests carry a risk of causing a miscarriage, the risk is not greater than 1%. Pregnant woman and couples may choose prenatal testing in order to prepare for the birth of a baby that may have sickle cell disease. Alternately, knowing the diagnosis during pregnancy allows for the option of pregnancy termination.

Preimplantation genetic diagnosis (PGD) is a relatively new technique that involves in-vitro fertilization followed by **genetic testing** of one cell from each developing embryo. Only the embryos unaffected by sickle cell disease are transferred back into the uterus. PGD is currently available on a research basis only and is relatively expensive.

Treatment

There are several practices that are intended to prevent some of the symptoms and complications of sickle cell disease. These include preventative **antibiotics**, good hydration, immunizations, and access to comprehensive care. Maintaining good health through adequate **nutrition**, avoiding stresses and infection, and getting proper rest is also important. Following these guidelines usually improves the health of individuals with sickle cell disease.

Penicillin

Infants are typically started on a course of penicillin that extends from infancy to age six. Use of this antibiotic is meant to ward off potentially fatal infections. Infections at any age are treated aggressively with antibiotics. Vaccines for common infections, such as *pneumococcal pneumonia*, are also recommended.

Pain management

Pain is one of the primary symptoms of sickle cell anemia, and controlling it is an important concern. The

methods necessary for pain control are based on individual factors. Some people can gain adequate pain control through over-the-counter oral painkillers (**analgesics**). Others individuals or painful events may require stronger methods, which can include administration of narcotics. Alternative therapies may be useful in avoiding or controlling pain, including **relaxation**, hydration, avoiding extremes of temperature, and the application of local warmth.

Blood transfusions

Blood transfusions are not usually given on a regular basis but are used to treat individuals with frequent and severe painful events, severe anemia, and other emergencies. In some cases blood transfusions are given as preventive measures, for example to treat spleen enlargement (splenomegaly) or prevent a second stroke (or a first stroke in an individual shown to be at high risk).

Regular blood transfusions have the potential to decrease formation of hemoglobin S, and reduce associated symptoms. However, there are limitations and risks associated with regular blood transfusions, including the risk of blood-borne infection and sensitization to **proteins** in the transfused blood that can make future transfusions very difficult. Most importantly, chronic blood transfusions can lead to **iron** overload. The body tends to store excess iron, such as that received through transfusions, in various organs. Over time, this iron storage can cause damage to various tissues and organs, such as the **heart** and endocrine organs.

Some of this damage can be prevented by the administration of a medication called desferrioxamine that helps the body to eliminate excess iron through the urine. Alternately, some individuals receive a new, non-standard treatment called erythrocytapheresis. This involves the automated removal of sickle cells and is used in conjunction with a reduced number of regular transfusions. This treatment also helps to reduce iron overload.

Hydroxyurea

Emphasis is being placed on developing drugs that treat sickle cell anemia directly. The most promising of these drugs in the beginning of the twenty-first century is hydroxyurea, a drug that was originally designed for anti-cancer treatment. Hydroxyurea has been shown to reduce the frequency of painful crises and acute chest syndrome in adults, and to lessen the need for blood transfusions. Hydroxyurea, and other related medications, seem to work by inducing a higher production of fetal hemoglobin. The major side effects of the drug include decreased production of platelets, red blood cells, and certain white

KEY TERMS

Amino acid—A type of molecule used as a building block for protein construction.

Anemia—A condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bilirubin—A yellow pigment that is the end result of hemoglobin breakdown. Bilirubin is cleared from the blood by action of liver enzymes and excreted from the body.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Bone marrow transplantation—A medical procedure in which normal bone marrow is transferred from a healthy donor to an ailing recipient. An illness such as sickle cell anemia that prevents production of normal blood cells may be treated with a bone marrow transplant.

Globin—One of the component protein molecules found in hemoglobin. Normal adult hemoglobin has a pair each of alpha-globin and beta-globin molecules.

Heme—The iron-containing molecule in hemoglobin that serves as the site for oxygen binding.

Hemoglobin—The red pigment found within red blood cells that enables them to transport oxygen throughout the body. Hemoglobin is a large molecule composed of five components: a heme molecule and two pairs of globin molecules.

Hemoglobin A—Normal adult hemoglobin contains a heme molecule, two alpha-globin molecules, and two beta-globin molecules.

Hemoglobin electrophoresis—A laboratory test that separates molecules based on their size, shape, or electrical charge.

Hemoglobin S—Hemoglobin that is produced in association with the sickle cell trait. The beta-globin molecules of hemoglobin S are defective.

Hydroxyurea—A drug that has been shown to induce production of fetal hemoglobin. Fetal hemoglobin has a pair of gamma-globin molecules in place of the typical beta-globins of adult hemo-

globin. Higher-than-normal levels of fetal hemoglobin can prevent sickling from occurring.

Impotence—The inability to have a penile erection, which can be due to tissue damage resulting from sickling within the penis (priapism).

Iron overload—A side effect of frequent transfusions in which the body accumulates abnormally high levels of iron. Iron deposits can form in organs, particularly the heart, and cause life-threatening damage.

Jaundice—A condition characterized by higher-than-normal levels of bilirubin in the bloodstream and an accompanying yellowing of the skin and eyes.

Mutation—A change in a gene's DNA. Whether a mutation is harmful is determined by the effect on the product for which the gene codes.

Magnetic resonance imaging—A type of imaging technique that allows the visualization of internal structures, such as the brain.

Narcotic—Strong, prescription medication that can be effective in treating sickle cell pain. Narcotics have the potential to be habit-forming if their use is not adequately supervised.

Nucleic acid—A type of chemical that is used as a component for building DNA. The nucleic acids found in DNA are adenine, thymine, guanine, and cytosine.

Ophthalmology—The medical specialty of vision and the eye.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Red blood cell—Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Screening—Process through which carriers of a trait may be identified within a population.

Sickle cell—A red blood cell that has assumed a elongated shape due to the presence of hemoglobin S.

blood cells. The effects of long-term hydroxyurea treatment are unknown.

Bone marrow transplantation

Bone marrow transplantation has been shown to cure sickle cell anemia in some cases. This treatment is reserved primarily for severely affected children with a healthy donor whose marrow proteins match those of the recipient, namely a brother or sister who has inherited the same tissue type. Indications for a bone marrow transplant are stroke, recurrent acute chest syndrome, and chronic unrelieved pain.

Bone marrow transplantations tend to be the most successful in children. Adults have a higher rate of transplant rejection and other complications. There is approximately a 10% fatality rate associated with bone marrow transplants performed for sickle cell disease. Survivors face potential long-term complications, such as chronic graft-versus-host disease (an immune-mediated attack by the donor marrow against the recipient's tissues), **infertility**, and development of some forms of **cancer**. A relatively recent advance in transplantation involves the use of donor stem cells obtained from cord blood, the blood from the placenta that is otherwise discarded following the birth of a new baby. Cord blood cells, as opposed to fully mature bone marrow cells, appear to be less likely to result in graft-versus-host disease in a recipient. This increases the safety and efficacy of the transplant procedure.

Surgery

Certain surgical interventions are utilized in the treatment of specific sickle cell-related complications. Removal of a dysfunctional **gallbladder** (cholecystectomy) or spleen (splenectomy) can often lead to improvements in health. Investigations are currently underway to establish the efficacy of hip coring surgery, in which a portion of affected bone is removed to treat avascular necrosis of the hip. The hope is that this may provide an effective treatment to alleviate some pain and restore function in an affected hip.

Psychosocial support

As in any lifelong, chronic disease, comprehensive care is important. Assistance in coping with the emotional, social, family-planning, economic, vocational, and other consequences of sickle cell disease can enable affected individuals to better access and benefit from their medical care providers.

Prognosis

Sickle cell disease is characteristically variable between and within affected individuals. Predicting the course of the disorder based solely on genes is not possible. Several factors aside from genetic inheritance determine the prognosis for affected individuals, including the frequency, severity, and nature of specific complications in any given individual. The availability and access of comprehensive medical care also plays an important role in preventing and treating serious, acute complications that cause the majority of sickle cell-related deaths. For those individuals who do not experience such acute events, life-expectancy is probably substantially greater than the average for all people with sickle cell disease. The impact of recent medical advances supports the hypothesis that current life-expectancies may be significantly greater than those estimated in the early 1990s. At that time, individuals with SS disease lived, on average, to their early- to mid-40s, and those with SC disease lived into the upper 50s. With early detection and comprehensive medical care, most people with sickle cell disease enjoy fairly good health throughout most of their lives. Most individuals can be expected to live well into adulthood, enjoying an improved quality of life including the ability to choose a variety of education, career, and family-planning options for themselves.

Health care team roles

Sickle cell disease is often initially identified as a result of a screening test. This may be ordered by a pediatrician, obstetrician or family physician. A phlebotomist or nurse often obtains a sample of blood. A laboratory technician processes the sample. A pathologist or hematologist analyzes the results of a test. A family doctor may return results to individuals who have been tested. A genetic counselor or other person with training in test interpretation and ethics must be available to assist tested persons to accurately assess their options in the future.

Prevention

Inheritance of sickle cell disease or trait cannot be prevented, but it may be predicted. Screening is recommended for individuals in high-risk populations.

L. Fleming Fallon, Jr., MD, DrPH

Sigmoidoscopy

Definition

Sigmoidoscopy is a diagnostic and screening procedure in which a rigid or flexible tube with a camera on the end (a sigmoidoscope) is inserted into the anus to examine the rectum and lower colon (bowel) for bowel disease, **cancer**, precancerous conditions, or causes of bleeding and **pain**.

Purpose

Sigmoidoscopy is used most often in screening for **colorectal cancer** or to determine the cause of rectal bleeding. It is also used in diagnosis of inflammatory bowel disease, microscopic and ulcerative colitis, and **Crohn's disease**.

Cancer of the rectum and colon is the second most common cancer in the United States. About 155,000 cases are diagnosed annually. About 55,000–60,000 Americans die each year of colorectal cancer.

A number of studies have suggested, and it is now recommended by cancer authorities that people over 50 be screened for colorectal cancer using endoscopy every three to five years. Individuals with inflammatory bowel disease, such as Crohn's disease or ulcerative colitis, who are at increased risk for colorectal cancer, may begin their screenings at a younger age, depending on when their disease was diagnosed. Many physicians screen such patients more often than every three to five years. Screening should also be done in patients who have a

family history of colon or rectal cancer or small growths in the colon (polyps).

Some physicians do this screening with a colonoscope, which allows them to see the entire colon. However, most physicians prefer sigmoidoscopy, which is less time consuming, less uncomfortable, and less costly.

Studies have shown that one quarter to one-third of all precancerous or small cancerous growths can be seen with a sigmoidoscope. About one-half are found with a 1 ft (30 cm) scope, and two-thirds to three-quarters can be seen using a 2 ft (60 cm) scope.

In some cases, the sigmoidoscope can be used therapeutically in conjunction with other equipment, such as electrosurgical devices, to remove polyps and other lesions found during the sigmoidoscopy.

Precautions

Sigmoidoscopy can usually be conducted in a physician's office or an outpatient clinic. However, some individuals should have the procedure done in a hospital day-surgery facility. Those with rectal bleeding may need full **colonoscopy** in a hospital setting. Patients whose **blood** does not clot well (possibly as a result of blood thinning medications) may need the procedure performed in a hospital setting as well.

Individuals with renal insufficiency or congestive **heart failure** need to be prepared in an alternative way, and must be carefully monitored during the procedure.

Sigmoidoscopy may be contraindicated in patients with severe active colitis or toxic megacolon (an extremely dilated colon). In general, patients on continuous ambulatory **peritoneal dialysis** are not candidates due to a high risk of developing intraperitoneal bleeding.

Description

Sigmoidoscopy may be performed using either a rigid or flexible sigmoidoscope, a thin tube with fiberoptics, electronics, a light source, and camera. The physician inserts the sigmoidoscope into the anus to examine the rectum (the first 1 ft/30 cm of the colon) and its interior walls. If a 2 ft/60 cm scope is used, the next portion of the colon can also be examined for any irregularities. The sigmoidoscope's camera is connected to a viewing monitor (television screen), so the rectum and colon are enlarged and viewed on a monitor. Images can then be recorded as still pictures for hard copy or the entire procedure can be videotaped.

If polyps, lesions, or other suspicious areas are found, the physician biopsies them for analysis. During the sigmoidoscopy, the physician may also use forceps,

KEY TERMS

Biopsy—The removal a small portion of tissue during sigmoidoscopy to perform laboratory tests to determine if the tissue is cancerous.

Colonoscopy—A diagnostic endoscopic procedure that uses a long flexible tube called a colonoscope to examine the inner lining of the entire colon; used for colorectal cancer screening and more thorough examination of the colon.

Colorectal cancer—Cancer of the large intestine, or colon, including the rectum (the last 16 in of the large intestine before the anus).

Congestive heart failure—Excess fluid accumulation in the lungs and surrounding tissues due to the weakness of the heart muscle and the inability to pump sufficiently.

Electrosurgical device—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures, often used in conjunction with laparoscopy.

Inflammatory bowel disease—Ulcerative colitis or Crohn's disease; chronic conditions characterized by periods of diarrhea, bloating, abdominal cramps, and pain, sometimes accompanied by weight loss and malnutrition because of the inability to absorb nutrients.

Pathologist—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

Polyp—A small growth, usually not cancerous, but often precancerous when it appears in the colon.

Renal insufficiency—The inability of the kidneys to process fluid fast enough to flush the body of impurities.

graspers, snares, or electrosurgical devices to remove polyps, lesions, or tumors.

The sigmoidoscopy procedure takes five to 20 minutes. Preparation begins one day before the procedure. There is some discomfort when the scope is inserted and throughout the procedure, similar to that experienced when a physician performs a rectal exam using a finger to test for occult blood in the stool (another major colorectal cancer screening test). The patient may also feel some minor cramping pain. There is rarely severe pain,

except for individuals with active inflammatory bowel disease.

Private insurance plans almost always cover the \$150 to \$200 cost of sigmoidoscopy for screening in healthy individuals over 50, or for diagnostic purposes. **Medicare** covers the cost for diagnostic exams, and may cover the costs for screening exams. **Medicaid** varies by state, but does not cover the procedure in most states. Some community health clinics offer the procedure at reduced cost, but this can only be done if a local gastroenterologist (a physician who specializes in treating **stomach** and intestinal disorders) is willing to donate his or her time.

Preparation

The purpose of preparation for sigmoidoscopy is to cleanse the lower bowel of stool so the physician can see the lining. Preparation begins 24 hours before the procedure, when the individual must begin a clear liquid diet. Preparation kits are available in drug stores. In normal preparation, about 20 hours before the exam, the patient begins taking a series of **laxatives**, which may be oral tablets or liquid. The individual must stop drinking four hours before the exam. An hour or two prior to the exam, the patient uses an enema or laxative suppository to finish cleansing the lower bowel.

Individuals need to be careful about medication before having sigmoidoscopy. They should not take aspirin, products containing aspirin, or ibuprofen products (Nuprin, Advil, or Motrin) for one week prior to the exam, because these medications can exacerbate bleeding during the procedure. They should not take any **iron** or **vitamins** with iron for one week prior to the exam, since iron can cause color changes in the bowel lining that interfere with the examination. They should take any routine prescription medication, but may need to stop certain medications; the physician should be consulted regarding routine prescriptions and their possible effect on sigmoidoscopy.

Aftercare

There is no specific aftercare necessary following sigmoidoscopy. If a biopsy was taken, a small amount of blood may appear in the next stool. Patients should be encouraged to pass gas following the procedure to relieve any bloating and cramping that may occur after the procedure. In addition, an **infection** may develop following sigmoidoscopy, and patients should be instructed to call their physician if a **fever** or pain in the abdomen develops over the few days after the procedure.

Complications

There is a slight risk of bleeding from the procedure. This risk is heightened in individuals whose blood does not clot well, either due to disease or medication, and in those with active inflammatory bowel disease. Rarely, trauma to the bowel or other organs can occur, resulting in an injury (perforation) that needs to be repaired or peritonitis, which must be treated with medication.

Results

A normal exam shows a smooth colon wall, with sufficient **blood vessels** for good blood flow.

For a cancer screening sigmoidoscopy, an abnormal result is one or more noncancerous or precancerous polyps, or clearly cancerous polyps. People with polyps have an increased risk of developing colorectal cancer in the future and may be required to undergo additional procedures, such as colonoscopy, or more frequent examinations.

Small polyps can be completely removed. Larger polyps may require the physician to remove a portion of the growth for laboratory biopsy. Depending on the laboratory results, the patient is then scheduled to have the polyp removed surgically, either as an “urgent” matter if it is cancerous or as an elective surgery within a few months if it is noncancerous.

In a diagnostic sigmoidoscopy, an abnormal result shows signs of active inflammatory bowel disease, either a thickening of the intestinal lining consistent with ulcerative colitis, or ulcerations or fissures consistent with Crohn’s disease.

Health care team roles

Sigmoidoscopy is performed by an experienced family physician or gastroenterologist. Nurses or physician assistants may be present during the procedure to assist the physician and monitor the patient. Biopsy specimens taken during the sigmoidoscopy are analyzed in the clinical laboratory by a pathologist. Sigmoidoscopes and procedural accessories must be sterilized or disinfected by clinical staff trained in proper scope reprocessing techniques.

Sinus endoscopy

Definition

Sinus endoscopy is a procedure used to examine, diagnose, and treat disorders of the nose, sinuses, or throat. During sinus endoscopy, an endoscope—a narrow, flexible tube fitted with a fiber-optic device such as a telescope or magnifying lens—is inserted into the nose, the interior of the nasal passages, sinuses, and throat.

Purpose

Sinus endoscopy is used diagnostically to evaluate structural defects, **infection** or damage to the sinuses, or structures in the nose and throat. It may be used to view polyps (growths) in the sinuses and to investigate causes of recurrent sinusitis (infection of the sinuses). During treatment, an **endoscope** may be used to view the affected area before, during, and after surgical procedures to correct anatomical malformations, sinus-drainage problems, or to remove polyps from the nose and throat.

Precautions

Insertion of the endoscope may cause a gag reflex and some discomfort, however, no special precautions are required to prepare for nasal endoscopy. Before the procedure begins, the nurse generally describes this and any other discomfort the patient may experience.

Description

This procedure is usually performed in a physician's office or other outpatient setting, such as a clinic or ambulatory surgical center. The endoscope is inserted into a nostril and threaded through the sinus passages to the throat. To visualize these areas more easily, and to record the areas being examined, the endoscope is fitted with a camera, monitor, or other viewing device.

Preparation

During the procedure, the patient is usually awake and seated upright in a chair. A local anesthetic spray or liquid may be applied to the throat to ease insertion of the endoscope and minimize discomfort.

Aftercare

Following sinus endoscopy procedures, most patients may immediately resume normal activities. If anesthetic was used, the patient may have to wait until the numbness wears off before eating or drinking.

Complications

The insertion and removal of the endoscope may trigger a gag reflex and can cause some discomfort. The procedure may also irritate the tissues of the nose and throat, causing a nosebleed or coughing.

Results

Under normal conditions, no polyps are found in the sinuses. There should also be no evidence of infection, swelling, injury, or an anatomical or structural defect that would prevent normal draining of the sinuses.

Polyps, growths, infections, or structural defects of the nasal passages are considered abnormal.

Health care team roles

Sinus endoscopy is usually performed by an otolaryngologist (a physician specializing in disorders of the ear, nose and throat). Before the procedure, some patients may undergo computed tomography (CT) scans or other imaging studies performed by radiological technologists.

KEY TERMS

Fiber-optic—Relating to the transmission of light through very fine, flexible glass or plastic fibers.

Polyp—A usually nonmalignant growth or tumor protruding from the mucous lining of an organ such as the nose, bladder, or intestine, often causing obstruction.

Patient education

Generally, the procedure is explained by the physician who will perform it. Since the procedure is generally performed in the physician's office or other outpatient setting, **patient education** also may be provided by nurses, nursing assistants, or certified medical assistants working in the medical office.

Skeletal muscles

Definition

Skeletal muscles have transverse striations and are under conscious or voluntary control by the **somatic nervous system**.

Description

Macroscopic

Skeletal muscles are often attached to bone, although this is not always the case. Tendons are a common means of attaching skeletal muscle to bone; they are

composed of collagen, a structurally strong yet flexible substance. A muscle's origin is the end that moves least on contraction; the other end is referred to as the insertion. There is a large range of muscle sizes, types, and functions. Most human muscles have muscle fibers arranged parallel to a tendon. A unipennate muscle, however, has all of its muscle fibers inserted at an angle into one side of a tendon.

Microscopic

Skeletal muscles are made up of bundles (called fascicles) of individual muscle fibers lined with connective tissue. Each muscle fiber is a giant multinucleated cell, formed by the fusion of myoblasts (muscle cell precursors) during development. Muscle fibers contain approximately one thousand myofibrils, tubular organelles that appear striated under a **microscope**; each myofibril is surrounded by a system of vesicles called the sarcoplasmic reticulum. The striations are due to alternating bands of light and dark regions called bands. The light regions are called I-bands, while the dark regions are called A-bands. A dividing line that runs through the A-band is called the Z-line, and the region between successive Z-lines is called the sarcomere.

The sarcomere is the functional unit of skeletal muscle and is associated with **muscle contraction**. It is composed primarily of two different contractile **proteins**: actin (or thin filaments) and myosin (or thick filaments). The filaments are arranged in an organized array so that their overlapping pattern produces the striations visible from under a microscope. The light I-bands are formed by actin filaments that are rooted at the Z-line, while the dark A-bands are composed of myosin filaments that overlap the actin filaments to varying degrees based on the extent of muscle contraction. The region in which there is no overlap (i.e., groups of actin filaments) in the center part of the A-band is called the H-band.

Function

Contraction

In a resting muscle, opposing actin filaments overlap myosin filaments only partially, resulting in the characteristic H-band. When a muscle contracts, however, the opposing actin filaments slide along the myosin filaments and are pushed together so that the H-bands (and I-bands) become narrower, while the A-bands remain the same length. The result is that the Z-lines come closer together without the actual length of the filaments changing. This mode of action is called the sliding filament mechanism.

The sliding filament mechanism is regulated by the binding of adenosine triphosphate (ATP) to myosin. ATP is a molecule present in all living cells that acts as an energy source. When ATP is not bound to myosin, projections along the myosin filaments called heads remain tightly bound to actin and therefore no sliding takes place (and subsequently, no muscle contraction). When ATP binds to myosin, however, a series of steps causes the myosin head to temporarily dissociate and change its conformation so that the actin and myosin filaments move relative to one another. This process, actively repeated in the many sarcomeres in a muscle fiber, results in muscle contraction.

Muscle contraction is also regulated by the **calcium** ion. A nerve impulse results in calcium being released from the sarcoplasmic reticulum. The calcium binds to various proteins that in turn cause conformational changes that expose the myosin-binding sites on the actin filaments so that contraction may occur.

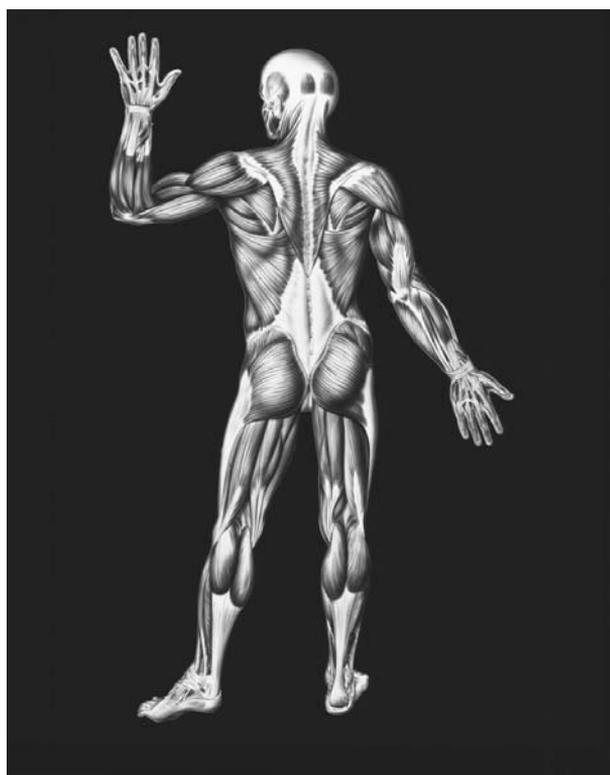

Lactic acid fermentation

Glucose is a major fuel for most organisms; when energy is needed, glucose can be quickly released from the body's stores and processed metabolically to produce ATP. This metabolic process occurs optimally under high-oxygen (aerobic) conditions. When oxygen cannot be replenished to the muscles as fast as it is being used (as in short bursts of extreme activity), glucose can be broken down anaerobically (under no- or low-oxygen conditions). Use of this pathway, however, leads to a buildup of the byproduct lactic acid in the muscles; this buildup causes muscle **pain** and cramps—uncontrollable shortening and hardening of muscle tissue—and limits the period of intense activity.

Role in human health

Neuromuscular disorders typically manifest themselves with one of four classes of symptoms (or any combination of the four):

- **Weakness:** Muscle weakness may be specific to a particular part of the body (i.e., neck, shoulder, arm, hand, leg, hip, etc.) or it may be generalized. Weakness may be caused by **brain** damage from a stroke or tumor, damage to the **spinal cord**, damage to a single nerve, or psychological problems.
- **Fatigue:** Individuals may suffer from chronic fatigue because of major depression, **multiple sclerosis**, stroke, neuromuscular transmission failure, or psychosomatic illness.
- **Pain:** Like muscle weakness, muscle pain may be specific (e.g., due to an muscle **abscess**) or general; it may

Skeletal muscles. (Photograph by John Bavosi. Science Photo Library. Photo Researchers, Inc. Reproduced by permission.)

also have a psychosomatic origin (i.e., associated with **anxiety** or depression).

- **Cramps:** Muscle pain caused by cramps is distinct from general muscle pain in that it often occurs in healthy individuals and causes intense pain.

Common diseases and disorders

- **Spasmodic torticollis:** This disease is characterized by painful spasms of the neck muscles that force the head to rotate and/or tilt. Its cause is usually unknown although occasionally conditions such as infections of the nervous system, tumors of the neck, or hyperthyroidism cause spasmodic torticollis.
- **Fibromyalgia:** Syndromes associated with fibromyalgia are characterized by localized or general pain or stiffness in muscles, tendons, and ligaments. There is no known cause for fibromyalgia but **stress**, inadequate sleep, injury, infections, and other conditions have been associated.
- **Muscular dystrophy:** The most common dystrophies (Duchenne's and Becker's) cause weakness in the muscles in or around the torso. In the case of Duchenne's muscular dystrophy (DMD), joint and muscle contrac-

KEY TERMS

Actin—A contractile protein that forms thin filaments in myofibrils; forms the I-band of the sarcomere.

Adenosine triphosphate (ATP)—A molecule present in all living organisms that acts as an energy source.

Fascicle—Bundles of muscle fibers surrounded by connective tissue.

Muscle fibers—Tubular multinucleated cells containing approximately one thousand contracting myofibrils.

Myofibrils—Tubular organelles found in muscle fibers that appear striated under a microscope; they are surrounded by a system of vesicles called the sarcoplasmic reticulum, important in the regulation of muscle contraction.

Myosin—A contractile protein that forms thick filaments in myofibrils; forms the A-band of the sarcomere with some overlap with actin filaments.

Sarcomere—The functional unit of muscle contraction; composed of striated bands of contractile proteins (actin and myosin).

tures develop in the form of cramps and amassment of fibrous tissue (including progressive destruction of muscle fibers).

- Tetanus: The bacillus *Clostridium tetani* produces a toxin called tetanospasmin that causes persistent spasms in the muscles of the jaw (hence the name “lockjaw”), the back, and/or the site of infection.
- Sports injuries: Muscle, ligament, and tendon injuries can be caused by inaccurate training advice, abnormalities in body structures, and overexertion. Common muscular injuries include ankle sprains, shin splints, hamstring injuries, and weightlifter’s back. Such injuries can often be prevented by warming up before **exercise**, cooling down after exercise, performing strengthening and stretching exercises, and wearing protective gear.

Skeletal system

Definition

The skeletal system is a living, dynamic, bony framework of the body, with networks of infiltrating **blood vessels**.

Description

Inside every person is a skeleton, a sturdy framework of about 206 bones that protects the body’s organs, supports the body, provides attachment points for muscles to enable body movement, functions as a storage site for **minerals** such as **calcium** and **phosphorus**, and produces **blood** cells. Living mature bone is about 60% calcium compounds and about 40% collagen. Hence, bone is strong, hard, and slightly elastic. Humans are born with over 300 bones but some bones, such as those in the **skull** and lower spine, fuse during growth, thereby reducing the number. Although mature bones consist largely of calcium—70% calcium salts and about 30% organic matrix, mostly collagen fibers—most bones in the skeleton of vertebrates, including humans, began as cartilage. Cartilage is a type of connective tissue, and contains collagen and elastin fibers. The hard outer part of bones are comprised mostly of a **proteins** such as collagen, in addition to a substance called hydroxyapatite. This substance is composed primarily of calcium and other minerals, and stores much of the body’s calcium; it is primarily responsible for the strength of bones. At the center of each bone is the marrow, which is softer and less dense than the rest of the bone. The marrow contains specialized cells that

produce blood cells that run through a bone, with nerves surrounding it.

Individual bones meet at areas called joints and are held in place by connective tissue. Most joints, such as the elbow, are called synovial joints, for the synovial membrane which envelops the joint and secretes a lubricating fluid. Cartilage lines the surface of many joints and helps reduce friction between bones. The connective tissues linking the skeleton together at the joints are tendons and ligaments. Ligaments and tendons are both made up of collagen, but serve different functions. Ligaments link bones together and help prevent dislocated joints. Tendons link bone to muscle.

Because the bones making up the human skeleton are inside the body, the skeleton is called an endoskeleton. Some animals, such as the crab, have an external skeleton called an exoskeleton.

Types of bone

Bones may be classified according to their various traits, such as shape, origin, and texture. Four types are recognized based on shape. These are long bones, short bones, flat bones, and irregular bones. Long bones have a long central shaft, called the diaphysis, and two knobby ends, called the epiphysis. In growing long bones, the diaphysis and epiphysis are separated by a thin sheet of cartilage. Examples of long bones include bones of the arms and legs, the metacarpals of the hand, metatarsals of the foot, and the clavicle. Short bones are about as long as wide. The patella, carpels of the wrist, and tarsals of the ankle are short bones. Flat bones take several shapes, but are characterized by being relatively thin and flat. Examples include the sternum, ribs, hip bones, scapula, and cranial bones. Irregular bones are the odd-shaped bones of the skull, such as the sphenoid, the sacrum, and the vertebrae. The common characteristic of irregular bones is not that they are similar to each other in appearance, but that they cannot be placed in any of the other bone categories.

Bones may also be classified based on their origin. All bone (as well as muscles and connective tissue) originates from an embryonic connective tissue called mesenchyme, which makes mesoderm, also an embryonic tissue. Some mesoderm forms the cartilaginous skeleton of the fetus, the precursor for the bony skeleton. However, some bones, such as the clavicle and some of the facial and cranial bones of the skull, develop directly from mesenchyme, thereby bypassing the cartilaginous stage. These types of bone are called membrane bone (or dermal bone). Bone which originates from cartilage is called endochondral bone.

Finally, bones are classified based on texture. Smooth, hard bone called compact bone forms the outer layer of bones. Inside the outer compact bone is cancellous bone, sometimes called the bone marrow. Cancellous bone appears open and spongy, but is actually very strong, like compact bone. Together, the two types of bone produce a light, but strong, skeleton.

Structure

The human skeletal system is divided into two main groups: the axial skeleton and the appendicular skeleton. The axial skeleton includes bones associated with the body's main axis including:

- the skull
- the spine or **vertebral column**
- the ribs

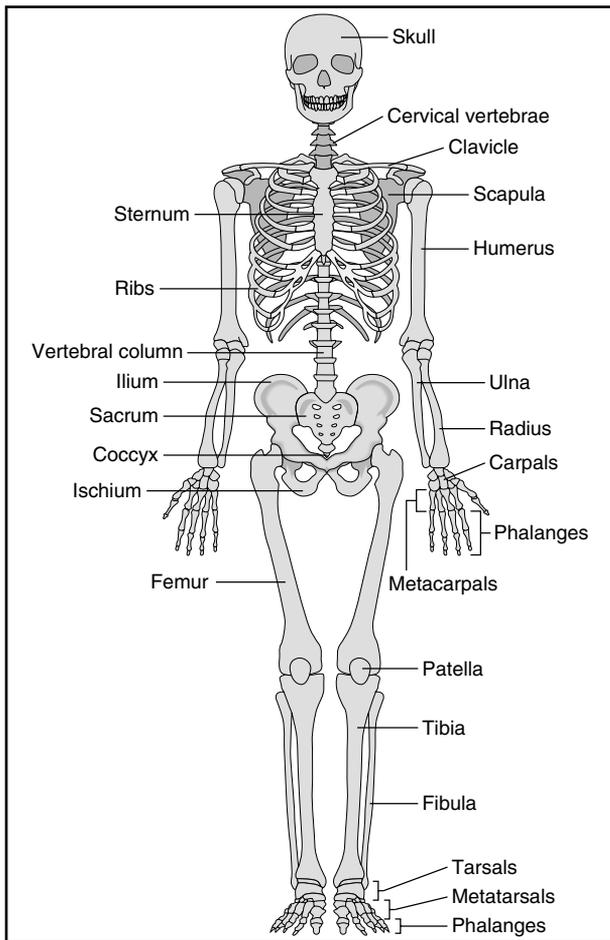

The appendicular skeleton consists of the bones that anchor the body's appendages to the axial skeleton including:

- the pectoral girdle (shoulder area)
- the pelvic girdle (hip area)
- the upper extremities (arms)
- the lower extremities (legs)

AXIAL SKELETON. There are 28 bones in the skull. Of these, eight bones comprise the cranium and provide protection for the **brain**. In adults, these bones are flat and interlocking at their joints, making the cranium immobile. Fibrous joints, or sutures occur where the bony plates of the cranium meet and interlock. Cartilage-filled spaces between the cranial bones of infants, known as soft spots or fontanelles, allow their skull bones to move slightly during birth. This makes birth easier and helps prevent skull **fractures**, but may leave the infant with an odd-shaped head temporarily while the skull regains its shape. Eventually, the fontanelles in an infant's head are replaced by bone, and fibrous joints develop. In addition to protecting the brain, skull bones also support and protect the sensory organs responsible for sight, **hearing**, **smell** and **taste**.

The eight bones of the cranium are:

- frontal
- parietal (2)
- temporal (2)
- ethmoid
- sphenoid
- occipital

Frontal view of the adult human skeleton. (Delmar Publishers, Inc. Reproduced by permission.)

The frontal bone forms the forehead and eyebrows. Behind the frontal bone are the two parietal bones. Parietal bones form the roof of the cranium and curve down to form the sides of the cranium. Also forming the sides of the cranium are the two temporal bones, located behind the eyes. Each temporal bone encloses the cochlea and labyrinth of the inner ear, and the ossicles, three tiny bones of the middle ear which are not part of the cranium. The ossicles are the malleus (hammer), incus (anvil), and stapes (stirrups). The temporal bones also attach to the lower jaw, and this is the only moveable joint in the skull. Between the temporal bones is the irregular shaped sphenoid bone, which provides protection for the **pituitary gland**. The small ethmoid bone forms part of the eye socket next to the nose. Olfactory nerves, or sense of smell nerves, pass through the ethmoid bone on their way to the brain. Forming the base and rear of the cranium is the occipital bone. The occipital bone has a hole, called the foramen magnum, through which the **spinal cord** passes and connects to the brain.

Fourteen bones shape the cheeks, eyes, nose, and mouth. These include:

- the nasal (2)
- zygomatic (2)
- maxillae (2)
- mandible

The upper, bony bridge of the nose is formed by the nasal bones and provides an attachment site for the cartilage making up the softer part of the nose. The zygomatic bones form the cheeks and part of the eye sockets. Two bones fuse to form the maxillae, the upper jaw of the mouth. These bones also form the hard palate of the mouth. The mandible forms the lower jaw of the mouth and is moveable, enabling chewing of food and speech. The mandible is the bone which connects to the temporal bones.

Located behind these facial bones are other bones which shape the interior portions of the eyes, nose, and mouth. These include:

- lacrimal (2)
- palatine (2)
- conchae (2)
- vomer bones

In addition to these 28 skull bones is the hyoid bone, located at the base of the tongue. Technically, the hyoid bone is not part of the skull but it is often included with the skull bones. It provides an attachment site for the tongue and some neck muscles.

Several of the facial and cranial bones contain sinuses, or cavities, that connect to the nasal cavity and drain into it. These are the frontal, ethmoid, sphenoid, and maxillae bones, all located near the nose. Painful sinus headaches result from the build up of pressure in these cavities. Membranes that line these cavities may secrete mucous or become infected, causing additional aggravation for humans.

The skull rests atop of the spine, which encases and protects the spinal cord. The spine, also called the vertebral column or backbone, consists of 33 stacked vertebrae, the lower ones fused. Vertebra are flat with two main features. The main oval shaped, bony mass of the vertebra is called the centrum. From the centrum arises a bony ring called the neural arch which forms the neural canal (also called a vertebral foramen), a hole for the spinal cord to pass through. Short, bony projections (neural spines) arise from the neural arch and provide attachment points for muscles. Some of these projections (called transverse processes) also provide attachment points for the ribs. There are also small openings in the

neural arch for the spinal nerves, which extend from the spinal cord throughout the body. Injury to the column of vertebrae may cause serious damage to the spinal cord and the spinal nerves, and could result in **paralysis** if the spinal cord or nerves are severed.

There are seven cervical, or neck, vertebrae. The first one, the atlas, supports the skull and allows the head to nod up and down. The atlas forms a condylar joint (a type of synovial joint) with the occipital bone of the skull. The second vertebra, the axis, allows the head to rotate from side to side. This rotating synovial joint is called a **pivot joint**. Together, these two vertebrae make possible a wide range of head motions.

Below the cervical vertebrae are the 12 thoracic, or upper back, vertebrae. The ribs are attached to these vertebrae. Thoracic vertebrae are followed by five lumbar, or lower back, vertebrae. Last is the sacrum, composed of five fused vertebrae, and the coccyx, or tail bone, composed of four fused bones.

The vertebral column helps to support the weight of the body and protects the spinal cord. Cartilaginous joints rather than synovial joints occur in the spine. Disks of cartilage lie between the bony vertebrae of the back and provide cushioning, like shock absorbers. The vertebrae of the spine are capable of only limited movement, such bending and some twisting.

A pair of ribs extends forward from each of the 12 thoracic vertebrae, for a total of 24 ribs. Occasionally, a person is born with an extra set of ribs. The joint between the ribs and vertebrae is a gliding (or plane) joint, a type of synovial joint, as ribs do move, expanding and contracting with breathing. Most of the ribs (the first seven pair) attach in the front of the body via cartilage to the long, flat breastbone, or sternum. These ribs are called true ribs. The next three pair of ribs are false ribs. False ribs attach to another rib in front instead of the sternum, and are connected by cartilage. The lower two pair of ribs which do not attach anteriorly are called floating ribs. Ribs give shape to the chest and support and protect the body's major organs, such as the **heart** and **lungs**. The rib cage also provides attachment points for connective tissue, to help hold organs in place. In adult humans, the sternum also produces red blood cells as well as providing an attachment site for ribs.

APPENDICULAR SKELETON. The appendicular skeleton joins with the axial skeleton at the shoulders and hips. Forming a loose attachment with the sternum is the pectoral girdle, or shoulder. Two bones, the clavicle (collar bone) and scapula (shoulder blade), form one shoulder. The scapula rest on top of the ribs in the back of the body. It connects to the clavicle, the bone which attaches the entire shoulder structure to the skeleton at the sternum.

The clavicle is a slender bone that is easily broken. Because the scapula is so loosely attached, it is easily dislocated from the clavicle, hence the dislocated shoulder injuries commonly suffered by persons playing sports. The major advantage to the loose attachment of the pectoral girdle is that it allows for a wide range of shoulder motions and greater overall freedom of movement.

Unlike the pectoral girdle, the pelvic girdle, or hips, is strong and dense. Each hip, left and right, consists of three fused bones, the ilium, ischium, and pubic. Collectively, these three bones are known as the innominate bone.

The innominates fuse with the sacrum to form the pelvic girdle. Specifically, the iliums shape the hips and the two ischial bones support the body when a person sits. The two pubic bones meet anteriorly at a cartilaginous joint. The pelvic girdle is bowl-shaped, with an opening at the bottom. In a pregnant woman, this bony opening is a passageway through which her baby must pass during birth. To facilitate the baby's passage, the body secretes a hormone called relaxin which loosens the joint between the pubic bones. In addition, the pelvic girdle of women is generally wider than that of men. This also helps to facilitate birth, but is a slight impediment for walking and running. Hence, men, with their narrower hips, are better adapted for such activities. The pelvic girdle protects the lower abdominal organs, such as the intestines, and helps supports the weight of the body above it.

The arms and legs, the upper and lower appendages of the body, are very similar in form. Each attaches to the girdle, pectoral or pelvic, via a **ball and socket joint**, a special type of synovial joint. In the shoulder, the socket, called the glenoid cavity, is shallow. The shallowness of the glenoid cavity allows for great freedom of movement. The hip socket, or acetabulum, is larger and deeper. This deep socket, combined with the rigid and massive structure of the hips, give the legs much less mobility and flexibility than the arms.

The humerus, or upper arm bone, is the long bone between the elbow and the shoulder. It connects the arm to the pectoral girdle. In the leg the femur, or thigh bone, is the long bone between the knee and hip which connects the leg to the pelvic girdle. The humerus and femur are sturdy bones, especially the femur, which is a weight bearing bone. Since the arms and legs are jointed, the humerus and femur are connected to other bones at the end opposite the ball and socket joint. In the elbow, this second joint is a type of synovial joint called a **hinge joint**. Two types of synovial joints occur in the knee region, a condylar joint (like the condylar joint in the first

vertebra) which connects the leg bones, and a plane, or **gliding joint**, between the patella (knee cap) and femur.

At the elbow the humerus attaches to a set of parallel bones, the ulna and radius, bones of the forearm. The radius is the bone below the thumb that rotates when the hand is turned over and back. The ulna and radius then attach to the carpal bones of the wrist. Eight small carpal bones make up the wrist and connect to the hand. The hand is made up of five long, slender metacarpal bones (the palms) and 14 phalanges of the hand (fingers and thumb). Some phalanges form joints with each other, giving the human hand great dexterity.

Similarly, in the leg, the femur forms a joint with the patella and with the fibula and tibia bones of the lower leg. The tibia, or shin bone, is larger than the fibula and forms the joint behind the patella with the femur. Like the femur, the tibia is also a weight bearing bone. At the ankle joint, the fibula and tibia connect to the tarsals of the upper foot. There are seven tarsals of the upper foot, forming the ankle and the heel. The tarsals in turn connect to five long, slender metatarsals of the lower foot. The metatarsals form the foot's arch and sole and connect to the phalanges of the feet (toes). The 14 foot phalanges are shorter and less agile than the hand phalanges. Several types of synovial joints occur in the hands and feet, including plane, ellipsoid and saddle. Plane joints occur between toe bones, allowing limited movement. Ellipsoid joints between the finger and palm bones give the fingers circular mobility, unlike the toes. The saddle joint at the base of the thumb helps make the hands the most important part of the body in terms of dexterity and manipulation. A saddle joint also occurs at the ankles.

Bone development and growth

Since most bone begins as cartilage, it must be converted to bone through a process called ossification. The key players in bone development are cartilage cells (chondrocytes), bone precursor cells (osteoprogenitor cells), bone deposition cells (osteoblasts), bone resorption cells (osteoclasts), and mature bone cells (osteocytes).

During ossification, blood vessels invade the cartilage and transport osteoprogenitor cells to a region called the center of ossification. At this site, the cartilage cells die, leaving behind small cavities. Osteoblast cells form from the progenitor cells and begin depositing bone tissue, spreading out from the center. Through this process, both the spongy textured cancellous bone and the smooth outer compact bone forms. Two types of bone marrow, red and yellow, occupy the spaces in cancellous bone. Red marrow produces red blood cells while yellow marrow stores fat in addition to producing blood cells.

Eventually, in compact bone, osteoblast cells become trapped in their bony cavities, called lacunae, and become osteocytes. Neighboring osteocytes form connections with each other and thus are able to transfer materials between cells. The osteocytes are part of a larger system called the Haversian system. These systems are like long tubes, squeezed tightly together in compact bone. Blood vessel, lymph vessels, and nerves run through the center of the tube, called the Haversian canal, and are surrounded by layers of bone, called lamellae, which house the osteocytes. Blood vessels are connected to each other by lateral canals called Volkmann's canals. Blood vessels are also found in spongy bone, without the Haversian system. A protective membrane called the periosteum surrounds all bones.

Bone development is a complex process, but it is only half the story. Bones must grow, and they do so via a process called remodeling. Remodeling involves resorption of existing bone inside the bone (enlarging the marrow cavities) and deposition of new bone on the exterior. The resorptive cells are the osteoclasts and osteoblast cells lay down the new bone material. As remodeling progresses in long bones, a new center of ossification develops, this one at the swollen ends of the bone, called the epiphysis. A thin layer of cartilage called the epiphyseal plate separates the epiphysis from the shaft and is the site of bone deposition. When growth is complete, this cartilage plate disappears, so that the only cartilage remaining is that which lines the joints, called hyaline cartilage. Remodeling does not end when growth ends. Osteocytes, responding to the body's need for calcium, resorb bone in adults to maintain a calcium balance.

Function

The skeletal system has several important functions:

- It provides shape and form to the body, while allowing for body movement.
- It supports and protects vital organs and muscles.
- It produces red blood cells for the body in the bone marrow. Each second, an average of 2.6 million red blood cells are to replace worn out blood cells and those destroyed by the **liver**.
- It stores minerals including calcium and phosphorus. When excess are present in the blood, the bones will store minerals. When the supply in the blood runs low, minerals will be withdrawn from the bones to replenish the blood supply.

Common diseases and disorders

Even though bones are very strong, they may be broken. Most fractures do heal. The healing process may be stymied if bones are not reset properly or if the injured person is the victim of malnutrition. Osteoprogenitor cells migrate to the site of the fracture and begin the process of making new bone (osteoblasts) and reabsorbing the injured bone (osteoclasts). With proper care, the fracture will fully heal, and in children, often without a trace.

The joint between the mandible and the temporal bones, called the temporomandibular joint, is the source of the painful condition known as temporomandibular joint dysfunction, or TMJ dysfunction. Sufferers of TMJ dysfunction experience a variety of symptoms including headaches, a sore jaw, and a snapping sensation when moving the jaw. There are several causes of the dysfunction. The cartilage disk between the bones may shift, or the connective tissue between the bones may be situated in a manner that causes misalignment of the jaw. Sometimes braces on the teeth can aggravate TMJ dysfunction. The condition may be corrected with **exercise**, or in severe cases, surgery. Another condition, cleft palate, is due to the failure of the maxillary bones in the jaw to completely fuse in the fetus.

Bones are affected by poor diet and are also subject to a number of diseases and disorders. Some examples include scurvy, rickets, **osteoporosis**, arthritis, and bone tumors. Scurvy results from the lack of **vitamin C**. In infants, scurvy causes poor bone development. It also causes membranes surrounding the bone to bleed, forming clots which are eventually ossified, and thin bones which break easy. In addition, adults are affected by bleeding gums and loss of teeth. Before modern times, sailors were often the victims of scurvy, due to extended periods of time at sea with limited food. They consequently tried to keep a good supply of citrus fruits, such as oranges and limes, on board because these fruits supply vitamin C. By the twenty-first century, scurvy had become extremely rare in Western societies.

Rickets is a children's disease resulting from a deficiency of **vitamin D**. This vitamin enables the body to absorb calcium and phosphorus; without it, bones become soft and weak and actually bend, or bow out, under the body's weight. Vitamin D is found in milk, eggs and liver, and may also be produced by exposing the skin to sunlight. Pregnant women can also suffer from a vitamin D deficiency, osteomalacia, resulting in soft bones. The elderly, especially women who had several children in succession, sometimes suffer from osteoporosis, a condition in which a significant amount of calcium from bones is dissolved into the blood to maintain the body's calcium balance. Weak, brittle bones dotted with

KEY TERMS

Bone—Composed primarily of a non-living matrix of calcium salts and a living matrix of collagen fibers, bone is the major component that makes up the human skeleton. Bone produces blood cells and functions as a storage site for elements such as calcium and phosphorus.

Calcium—A naturally occurring element which combines primarily with phosphate to form the nonliving matrix of bones.

Cartilage—A type of connective tissue that takes three forms: elastic cartilage, fibrocartilage, and hyaline cartilage. Hyaline cartilage forms the embryonic skeleton and lines the joints of bones.

Haversian system—Tubular systems in compact bone with a central Haversian canal which houses blood and lymph vessels surrounded by circular layers of calcium salts and collagen, called lamellae, in which reside osteocytes.

Marrow—A type of connective tissue which fills the spaces of most cancellous bone and which functions to produce blood cells and store fat.

Ossification—The process of replacing connective tissue such as cartilage and mesenchyme with bone.

Osteoblast—The bone cell which deposits calcium salts and collagen during bone growth, bone remodeling and bone repair.

Osteoclast—The bone cell responsible for reabsorbing bone tissue in bone remodeling and repair.

Osteocyte—Mature bone cell which functions mainly to regulate the levels of calcium and phosphate in the body.

Skeleton—Consists of bones and cartilage which are linked together by ligaments. The skeleton protects vital organs of the body and enables body movement.

Synovial joint—One of three types of joints in the skeleton and by far the most common. Synovial joints are lined with a membrane which secretes a lubricating fluid. Includes ball and socket, pivot, plane, hinge, saddle, condylar, and ellipsoid joints.

Vertebrates—Includes all animals with a vertebral column protecting the spinal cord such as humans, dogs, birds, lizards, and fish.

pits and pores are the result. Osteoporosis occurs most often in older people and in women after **menopause**. It affects nearly half of all those, men and women, over the age of 75. Women, however, are five times more likely than men to develop the disease. They have smaller, thinner bones than men to begin with, and they lose bone mass more rapidly after menopause (usually around age 50), when they stop producing a bone-protecting hormone called estrogen. In the five to seven years following menopause, women can lose about 20% of their bone mass. By age 65 or 70, though, men and women lose bone mass at the same rate. As an increasing number of men reach an older age, they are becoming more aware that osteoporosis is an important health issue for them as well.

Arthritis is another condition commonly afflicting the elderly. This is an often painful inflammation of the joints. Arthritis is not restricted to the elderly, and even young people can suffer from this condition. There are several types of arthritis, such as rheumatoid, rheumatic, and degenerative. Arthritis basically involves the inflammation and deterioration of cartilage and bone at the joint surface. In some cases, bony protuberances around the rim of the joint may develop. Most people will probably develop arthritis if they live to a significant older age. Degenerative arthritis is the type that commonly occurs with age. The knee, hip, shoulder, and elbow are the major targets of degenerative arthritis. A number of different types of tumors, some harmless and others more serious, may also affect bones.

Skin culture

Definition

A skin culture is a laboratory test used to isolate and identify the microorganism (bacterium, fungus, or virus) causing a skin **infection**, so the most effective antibiotic or other treatment for the infection can be determined.

Purpose

Skin infections are contagious and, if left untreated, can lead to serious complications. A skin culture helps the physician to diagnose and treat a skin infection.

Precautions

To avoid spreading pathogenic organisms to patients or other individuals, health care professionals should be cautious in the collection and handling of skin culture specimens.

Description

Skin infections may involve the superficial layer (epidermis) only or may involve the deeper dermis,

including the sweat glands, oil glands, lymphatics, and hair follicles within. Microorganisms can infect healthy skin, but more often they infect skin already damaged by an injury or an abrasion. The lesion produced by the infection is an early indication of which type of microorganism is causing the infection. For example, pustules are associated with impetigo (pyoderma) the most common bacterial skin infection. Pyoderma is most often caused by group A *Streptococcus*. Vesicular skin rashes are commonly caused by herpesviruses as in chickenpox. Scaly rashes are most commonly caused by dermatophytes, **fungi** that infect the keratinized skin (epidermis). Bacterial skin infections are the most common, and can result in ulcers, cellulitis, rashes, **boils**, abscesses, and other types of lesions.

The following types of microorganisms cause most skin infections and can be isolated by performing a skin culture:

- **Bacteria:** Aerobic gram positive cocci, *Streptococcus pyrogenes*, and *Staphylococcus aureus* are the most common isolates and are responsible for pyoderma. However many other bacteria cause skin infections less frequently. Usually, these are introduced through a wound in the skin caused by a bite, decubitus ulcer, burn, trauma, or puncture. Some notable genera are anaerobic bacteria such as *Bacteroides* and *Clostridium* from soils, gram negative rods such as *Aeromonas*, *Plesiomones*, and *Vibrio* from water. Organisms that live in the mouth of dogs and cats such as *Pasteurella multocida* can infect bite **wounds**.
- **Fungi** (molds and yeast): Three genera of fungi commonly cause ringworm of the skin, hair, and nails and are the most common fungi isolated from skin. These are *Trichophyton*, *Epidermophyton*, and *Microsporum*. *Candida* can colonize the epidermis as part of the normal flora but will infect burned skin and skin folds of newborns. Several other fungi may cause subcutaneous infection.
- **Viruses:** Rubella (German measles), rubeola, roseola, and herpes varicella zoster (chickenpox) are common causes of viral rashes in children. Herpes simplex 1 and cytomegalovirus may cause more complex infections in immunosuppressed adults. In addition, skin infections can be caused by enteroviruses, poxviruses and several others.
- Skin infections can also be caused by mycobacteria such as *Mycobacterium tuberculosis* and *M. leprae* the cause of leprosy, and skin lesions can be caused by some parasites when the larva enter the skin.

Based on the appearance of the lesion, the physician orders one or more types of skin cultures. Using **aseptic technique**, the physician, nurse, or other health care pro-

fessional collects a specimen. For open epidermal infections a sample of the lesion such as skin cells, pus, or fluid can be collected using a swab. For crusted or closed lesions, the surface of the vesicle or pustule should be removed with a scalpel blade in order to expose the infected skin before swabbing. Ringworm should be scraped using a scalpel blade to collect the keratinized skin. Deeper infections should be sampled by aspiration. Swabs for bacterial culture are placed in a sterile container (often containing transport medium such as Stuart or Cary-Blair) before being sent to the laboratory for culture. If anaerobic culture is requested the specimen is immediately placed in prerduced oxygen-free transport medium.

Bacterial skin cultures

A **Gram stain** is prepared by rolling the smear across the center of a glass slide or dropping a liquid specimen onto the center and allowing it to air dry. Gram-positive cells retain the crystal violet stain and appear dark purple, while gram-negative cells do not. Gram-negative bacteria are counterstained by the safranin and appear pink. In addition to classifying the bacteria seen, the Gram stain can identify yeast, hyphal elements, and organisms that require special culture media. For example, the presence of large gram-positive spore forming rods indicates the possible presence of *Clostridium spp.* and the need for anaerobic culture.

A routine bacterial skin culture involves inoculating (spreading a portion of the specimen on) several culture plates containing general-use enrichment media and selective media. Commonly used media include sheep blood agar plates, chocolate (heated blood) agar plates, MacConkey agar for isolation of gram-negative rods, and either phenylethyl alcohol (PEA) or colistin-naladixic acid (CNA) blood agar for isolation of gram positive cocci. Plates are incubated in air or 5–10% carbon dioxide and examined for growth daily for at least two days. Bacteria present in the specimen multiply and appear on the plates as visible colonies. These are Gram stained and subcultured (transferred) to other media in order to identify the organism. Complete identification usually requires one to two days following isolation of a pure culture. It is standard practice to perform an antibiotic sensitivity test on any bacterial pathogen isolated from a routine skin culture, except group A *Streptococcus*, which is susceptible to penicillin and related **antibiotics**. An antibiotic sensitivity test, also called an antibiotic susceptibility test, grows the bacteria in the presence of different antibiotics to determine which ones will effectively treat the infection by killing the bacteria.

Fungal skin cultures

Physicians request fungal skin cultures less frequently. A group of fungi called dermatophytes cause skin infections such as ringworm and athlete's foot. Yeast infections caused by *Candida* can thrive on moist skin, such as in diaper areas and in the folds of skin in the groin. Yeast infections can cause significant problems for newborns and patients with **AIDS** or depressed immune systems. Yeast infections are cultured on sheep blood agar and grow in one to two days. Dermatophytes are usually identified by a **KOH test**. In this test, a sample of skin scraped with a scalpel blade and transferred to a slide. After adding KOH, the slide is allowed to stand for five minutes in order to dissolve skin cells, hair, and debris. Lactophenol cotton blue stain can be added to make the fungi easier to see, or if a fluorescent **microscope** is available, calcofluor white stain may be added to the KOH preparation. This will cause the fungi to become fluorescent making them easier to identify. Dermatophytes are easily recognized under the microscope by their long branch-like tubular structures called hyphae. Fungi causing ringworm infections produce septate (segmented) hyphae. Some show the presence of spores formed directly from the hyphae (arthroconidia). Yeast infections of the skin can also be identified by the KOH test. Yeast cells appear round or oval, and budding forms may be seen.

A culture is requested only when specific identification of the fungus is necessary. For a routine **fungal culture**, the specimen is spread on a culture plate or tube containing nutrient media designed to grow fungi, incubated for up to four weeks, and observed for growth at regular intervals. Stains and biochemical tests are usually used to identify yeast and other fungi. Dermatophytes may be cultured on a medium called dermatophyte test medium (DTM). This is an agar slant containing phytone, dextrose, phenol red, cycloheximide, gentamicin, and chlortetracycline. The antibiotics inhibit the growth of normal skin flora. Skin scrapings, hair, or nail samples are added to the medium and allowed to grow at room temperature. Cultures are held for 14 days. Dermatophytes will turn the medium from yellow to red as they grow. Other fungi, called systemic fungi can enter the skin through puncture wounds, abrasions or cuts and cause subcutaneous infection. A common cause of systemic mycosis in the United States among gardeners and farmers is *Sporothrix schenckii*. Such fungi are cultured from skin aspirates on growth medium for fungi containing antibiotics to inhibit bacterial growth. Most commonly used are Sabouraud dextrose agar with antibiotics and mycosel agar with cycloheximide and chloramphenicol. Cultures are incubated at both 77°F and 96.8°F (25°C and 36°C). *Sporothrix schenckii* grows in about

four days but other fungi grow more slowly, and plates should be held for 30 days before reporting as negative.

Viral skin cultures

Viruses, such as herpes, can also cause skin infections. A specimen for viral culture is mixed with commercially prepared animal cells usually grown on a coverslip in a shell vial. Characteristic changes to the animal cells caused by the growing virus help to identify the virus. For rapid diagnosis, some laboratories use an electron microscope to identify viruses on the basis of morphology. For example, the herpes virus can be cultured from a vesicle (blister) which has been removed carefully with a scalpel blade. The base of the vesicle is swabbed with a sterile cotton applicator, and the virus taken to the laboratory in a tube of viral transport medium. Herpes can be cultured in several cell lines including human diploid fibroblasts (HDF), HEp2 cells (epithelial **cancer** cells from the larynx), primary monkey kidney cells (PMK), and rabbit kidney cells (RK). Cell cultures are inoculated and allowed to grow for one to three days at 96.8°F (36°C) in 5–10% carbon dioxide. Usually by the end of the first day of culture the cytopathic effect (CPE), formation of giant cells, can be seen by observing the cells under a microscope.

Preparation

Before ordering a skin culture, the physician will ask the patient for a complete medical history and perform a **physical examination** to determine possible causes of the skin infection and whether a skin culture is appropriate. For acute skin infections, immediate treatment is sometimes necessary.

All healthcare professionals who participate in collecting a skin culture specimen should be trained in aseptic technique. Before collecting the specimen, they should scrub their hands thoroughly with an antimicrobial soap and, in some cases, put on sterile gowns, masks, and gloves. Sterile instruments and containers should be assembled near the patient. If appropriate, a sterile drape can be placed around the site of the infection. After cleaning the infected area with alcohol and sterile saline, the physician, nurse, or other healthcare professional uses a sterile blade, swab, needle, syringe, or other instruments to collect a sample of skin cells, pus, or fluid from the lesion. It might be necessary to open the lesion before collecting the specimen.

Aftercare

Collection of the specimen could cause some slight bleeding at the infection site, which might require some

attention. Otherwise, no special aftercare is necessary for the patient following a skin culture.

The health care professionals who collect the specimen should ensure that any drapes, gowns, gloves, or instruments used for the collection are placed in the proper containers for disposal or sterilization. Then they should again scrub their hands thoroughly with an antimicrobial soap before leaving the area.

Complications

If aseptic technique is not used to collect the specimen, the patient or the healthcare professionals could develop postprocedure infections. The infection could also be transmitted to other individuals by contaminated hands or objects.

Results

Results for bacterial cultures are usually available in one to three days. Cultures for fungi and viruses may take longer—up to three or more weeks.

Many microorganisms that are found on a person's skin are normally considered to be harmless. When these microorganisms grow on a skin culture, they are reported as "normal flora." One of the most common of these microorganisms is *Staphylococcus epidermidis*. Other bacteria that live in the high salt environment of the skin include *Propionibacterium acnes*, *Corynebacterium xerosis*, and some yeasts.

Besides normal flora, any microorganism that grows on a skin culture is considered to be the cause of the infection if it is the only microorganism or the predominant microorganism; if it grows in large numbers; or if it is known to produce infection. *Staphylococcus aureus* and group A *Streptococcus* cause most bacterial skin infections. *Candida albicans* causes most yeast skin infections, and *Herpes simplex* is the most frequent cause of viral skin infections.

Health care team roles

The physician determines whether a skin culture is needed to diagnose a skin infection, and orders the test when appropriate. Then the physician, nurse, or other healthcare professional trained in aseptic technique collects the specimen and sends it to the laboratory. The clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) assumes responsibility for correct handling, culture, identification, and reporting of the results.

KEY TERMS

Antimicrobial—A substance or action that kills or inhibits the growth of microorganisms.

Aseptic technique—Practices performed before, during, and after a clinical procedure to prevent or reduce contamination and postprocedural infection.

Pathogen—An organism that causes disease.

Pyoderma—A pus-containing bacterial skin infection.

Selective media—Media designed to enhance the growth of one type of microorganism by inhibiting the growth of other types with antibiotics or other substances.

Sensitivity test—A laboratory test that shows which antibiotics will treat an infection by killing the bacteria.

Skull

Definition

The skull—or cranium—is the skeleton of the head. It includes the **brain** case and the bones of the face and jaw.

Description

The skull is the bony part of the head. It rests on the first vertebra of the spine, called the atlas. It belongs to the axial skeleton, meaning the skeleton associated with the **central nervous system**. That includes the skull, all the bones of the spine, the ribs, and the breastbone.

At birth, the skull of a baby is large when compared to the rest of the body. It is fairly compressible, with soft spots (fontanelles) that eventually harden around the age of eighteen months. In the adult, some bones of the skull are paired, meaning that there is a left and a right, while others are unpaired. They are connected by sutures, saw-like bony edges that serve as joints. Bones of the skull are usually classified as cranial bones, facial bones (splanchnocranium), or as bones that form the braincase (neurocranium). There are eight cranial bones and 14 facial bones. The facial bone assembly also includes air-filled spaces located all around the nose and called the paranasal sinuses.

Paired cranial bones

The paired cranial bones include parietal bones and the temporal bones.

The parietal bones are paired. Shaped like curved plates, they form the bulging sides and roof of the cranium. Fused in the middle along the sagittal suture, they meet the frontal bone along the coronal suture in the front of the skull. The point at which the two sutures meet is called the bregma. In the back of the skull, the parietals connect with the occipital bone along the lambdoid suture. The intersection of the lambdoid and sagittal sutures is called the lambda. The parietals meet the temporal bones in the lower portion of the skull along the squamosal and parieto-mastoid sutures. On the external surface near the center of the bone is the parietal eminence, or bulge. Slightly behind the bulge is found the parietal foramen (a foramen is an opening through bone that serves as a passageway for **blood vessels** and nerves). The parietals make contact with the following bones: occipital, frontal, temporal, sphenoid, and parietal.

The temporals form parts of the sides and base of the cranium. They are also paired left and right. Each temporal bone consists of two major sections, the squamous

portion, or flat section, and a very thick and rugged part, the petrosal portion. The petrosal portion contains the cavity of the middle ear and the three smallest bones of the body. The smallest bones are the bones of the ear: the malleus, the incus and the stapes. Located near the lower edge is a gap, the external auditory meatus, that leads inward to the ear. At the lower end of the petrosal portion is the slender styloid process. A process is a bony extension or projection on a bone and the styloid is of variable length, it serves as a muscle attachment for various thin muscles to the tongue and other structures in the throat. Another projection, the mastoid process, provides an attachment for some of the muscles of the neck. The temporals also house the internal structures of the ear and have depressions, called mandibular fossae, that assist in forming the shallow socket of the jawbone joint. A zygomatic process projects from the front of the temporal bone where it joins the zygomatic bone to help form the prominence of the cheek. The temporals make contact with the following bones: the zygomatics, parietals, mandible, occipital, and sphenoid.

Unpaired cranial bones

The unpaired cranial bones include the frontal bone, occipital bone, sphenoid bone, and ethmoid bone.

The frontal bone consists of two major sections, a vertical squamous portion that connects with the paired parietals along the coronal suture and forms the forehead, and two orbital plates, which form the left and right eye sockets (orbits). On its external surface, the squamous portion very often displays a left and right frontal eminence, or bulge. Additionally, the frontal bone has two supra-orbital ridges, which are bumps above each of the eye sockets. The frontal and nasal bones connect along the fronto-nasal suture. The frontal bone makes contact with the following bones: lacrimals, nasals, zygomatics, sphenoid, maxillae, parietals, and ethmoid.

The occipital bone forms the back of the skull and the base of the cranium. It consists of a large flattened section separated from a small thick portion by the foramen magnum—a large opening through which cranial nerves from the brain pass and enter the spine to become part of the **spinal cord**. On both sides of the foramen, there is a left and a right occipital condyle. A condyle is a rounded enlargement that has an articulating surface, or joint. The occipital condyles articulate with the first vertebra of the neck, the atlas (also known as the first cervical vertebra, or C1). The occipital makes contact with the following bones: parietals, temporals, sphenoid, and the atlas.

The sphenoid is a single bone that assists in connecting the cranial bones to the facial bones. It consists of

a hollow part, which contains the sphenoidal sinus, and three pairs of bony projections. The first projections are called the lesser wings and they contain the optic foramen, through which the optic (or second) cranial nerve passes before reaching the eye. The second pair are called the greater wings, they assist in forming the orbital plates for each of the eye sockets. The third pair are the pterygoid processes that run along the back section of the nasal passages toward the palate and provide muscle attachments for the jawbones. The sphenoid makes contact with the following bones: vomer, ethmoid, frontal, occipital, parietals, temporals, zygomatics, and palatines.

Like the sphenoid, the ethmoid is a single bone that helps to connect the cranial bones to the facial bones. It consists of various plates and paired projections. The upper projections are the crista galli that assist in dividing the left and right frontal lobes of the brain. Side projections from the crista galli are the left and right cribriform plates which provide a seat for the olfactory nerves. The nerves go through these plates into the nasal cavity below. Directly under the crista galli is the perpendicular plate which connects with the vomer bone and helps to separate the left and right nasal passages. The ethmoid makes contact with the following bones: sphenoid, frontal, maxillae, palatines, vomer, and lacrimals.

Paired facial bones

Paired facial bones include the lacrimals, nasals, zygomatics, maxillae, palatines, and inferior nasal conchae.

The lacrimal bones are the smallest and most fragile of the facial bones and they are paired left and right. They help form the back portion of each eye socket, and are rectangular in shape with two surfaces and four borders. The lacrimals contain a feature, called the lacrimal sulcus, which helps to form the lacrimal fossa. The lacrimal fossa is an opening for the lacrimal ducts that connects the corner of the eye to the nasal passage, and allows the tears from the eye to be channeled into the nose. The lacrimals make contact with the following bones: frontal, ethmoid, and maxillae.

Each nasal bone is a small rectangular bone. Together they form the bridge of the nose above the nasal cavity. They join with each other along the internasal suture and with the frontal bone above along the frontonasal suture. The point of intersection of both sutures is called the nasion. Nasal bones make contact with the following bones: frontal, maxilla, and other nasals.

The zygomatics are the cheek bones. They have three major features that connect them with surrounding bones. The first is the frontal process. The frontal process forms the wall of the eye socket and connects above with

the zygomatic process of the frontal bone. This section separates the eye orbit from the temporal fossa and has a projection called the marginal process. The third feature is the temporal process, and it connects with the zygomatic process of the temporal bone. Together these processes help to form the zygomatic arch which is the attachment for the masseter muscle, one of the major muscles used for chewing (mastication). The zygomatics make contact with the following bones: frontal, sphenoid, maxillae, and temporals.

The maxillae are also paired facial bones. They seat the upper teeth and form the upper jaw. In the upper part of the bone, the frontal process helps to form the nasal opening and ends by connecting with the frontal bone. A maxilla makes contact with the following bones: frontal, ethmoid, zygomatic, vomer, lacrimal, maxilla, nasal, palatine, mandible, and inferior nasal concha.

The palatines are paired left and right and connect with each other along the interpalatine suture. Both bones help form the back section of the hard palate as well as a portion of the nasal cavity. A palatine bone makes contact with the following bones: sphenoid, ethmoid, maxilla, vomer, and the other palatine bone.

The inferior nasal conchae are very thin and delicate paired bones that are elongated with curled-up ends. They are attached to the sides of the nasal cavity and connect to the maxilla and the bones that form the side wall of the nasal cavity. An inferior nasal concha makes contact with the following bones: ethmoid, lacrimal, maxilla, and palatines.

Unpaired facial bones

The unpaired facial bones include the vomer, mandible, and hyoid.

The vomer is a single flat bone. The upper part connects with the perpendicular plate of the ethmoid to form the nasal septum, the dividing wall that runs down the middle of the nose. The vomer makes contact with the following bones: sphenoid, ethmoid, palatines, and maxillae.

The largest facial bone is the mandible. It is the only bone of the skull that contains a movable joint. It is a strong, curved-shaped bone that encases the lower teeth in the alveolar process. It has rounded projections, called mandibular condyles on each end. The condyles link it to the temporal bone by hinges called the temporomandibular joints. The mandible makes contact with the following bones: temporals and maxillae.

The hyoid is a single small U-shaped bone that does not join with any other bone. It hangs from the styloid process of each temporal bone by means of ligaments.

KEY TERMS

Atlas—The atlas is not part of the skull. It is the first of the seven vertebrae of the neck and the one upon which the base of the skull rests. It is also the bone around which the skull rotates.

Axial skeleton—The skeleton associated with the central nervous system—the cranium, all the bones of the vertebral column, the ribs, and the sternum.

Brain—One of the two components of the central nervous system (CNS), the brain is the center of higher thought and emotion. It is responsible for the coordination and control of all body activities and for the perception and the interpretation of sense information.

Bregma—The point where the coronal and sagittal sutures of the skull meet.

Calvaria—The skull cap, roof of the skull, or cranium without the facial bones attached.

Condyle—A rounded enlargement that has an articulating surface.

Coronal suture—The suture between the two parietal bones and the frontal bone in the skull.

Cranial bones—The eight bones of the skull that form the braincase, which encloses the brain. They are the parietals, the temporals, the frontal, the occipital, the sphenoid, and the ethmoid bones.

Cranial nerve—In humans, there are 12 cranial nerves. They are connected to the brain stem and basically ‘run’ the head as well as help regulate the organs of the thoracic and abdominal cavities.

Cranium—The bones of the head.

Ethmoid bone—Skull bone located behind the nose.

External auditory meatus—The passage or canal in the skull for the tissues involved in hearing.

Facial bones—The 14 bones of the skull that form the face and jaw. The paired facial bones are the lacrimals, nasals, zygomatics, maxillae, palatines, and inferior nasal conchae. The unpaired facial bones are the vomer, mandible and hyoid.

Foramen—A hole in a bone, usually for the passage of blood vessels and/or nerves.

Foramen magnum—The large opening at the base of the skull that allows passage of the spinal cord.

Fossa—A pit, depression, or concavity, on a bone or formed from several bones.

Lambda—The point where the sagittal and lambdoid sutures of the skull meet.

Lambdoid suture—The suture between the two parietal bones and the occipital bone in the skull.

Mandible—The lower jaw bone.

Maxillae—The upper jaw bones, connected to the orbit, hard palate and nasal cavity.

Neurocranium—The braincase of the skull.

Process—A general term describing any marked projection or prominence on a bone.

Sagittal suture—The suture between the two parietal bones in the top of the skull.

Sinuses—Air-filled cavities of the skull. The ethmoid sinus is in the ethmoid bone, the maxillary sinus in the maxilla, the frontal sinus in the frontal bones and the sphenoid sinus in the sphenoid bone.

Skull—All of the bones of the head.

Sphenoid bone—An irregularly shaped bone located in front of the occipital bone in the base of the skull.

Spinal cord—The elongated part of the central nervous system (CNS) that lies in the vertebral canal of the spine from which the spinal nerves emerge.

Squamosal suture—The suture between a temporal bone and a parietal bone in the skull.

Squamous—Adjective meaning scaly, flat, and plate-like.

Splanchocranium—The facial bones of the skull.

Suture—The saw-like edge of a cranial bone that serves as joint between bones of the skull.

Vertebrae—The flat bones that make up the spine or vertebral column. The spine has 33 vertebrae.

Function

The skull encloses and protects the brain, provides a base for the attachments of the muscles of the head and

neck, and provides a structural element to form the first sections of the respiratory and digestive tracts. The bones of the skull are very hard, and protection of the brain is undoubtedly their most important function.

Common diseases and disorders

Disorders and conditions that affect the skull can be divided into two broad categories—craniofacial anomalies and trauma-related injuries. The most serious injury is a skull fracture, meaning a break or rupture in any of the skull bones. Craniofacial anomaly is a general term that includes malformations diagnosed at birth (congenital anomalies) and developmental anomalies that result from the abnormal growth of the skull and face after birth.

- **Basal skull fractures:** These are most commonly extensions of fractures of the roof of the skull. The usual locations are the temporal bone, the orbital surface of the frontal bone, and the occipital bone.
- **Jaw fractures:** These include mandibular fractures and maxillary fractures.
- **Facial fractures:** These can range from the fracture of one facial bone, for example a zygomatic fracture, to more severe trauma such as facial smash, which involves multiple fractures and extensive disruption of the bony architecture of the head.
- **Hemifacial microsomia:** Hemifacial Microsomia is a condition that affects the growth of the face on one or both sides. The severity of this disorder can vary from mild to severe. Although different facial structures can be affected, the most common areas include the ear, the oral cavity, and the mandible.
- **Goldenhar syndrome:** This syndrome is a variant of hemifacial microsomia. The symptoms of this disorder match those of hemifacial microsomia with the addition of epibulbar dermoids, which are benign tumors located just inside the opening of the eye orbit.
- **Treacher-Collins syndrome:** Also known as mandibulo-facial synostosis. The syndrome affects the size and shape of the ears, cheekbones, and upper and lower jaws.

Skull x rays

Definition

Skull x rays are performed to examine the nose, sinuses, and facial bones. These studies may also be referred to as sinus or maxillofacial x rays. X-ray studies produce films, also known as radiographs, by aiming x rays at bones and soft tissues of the body. X-ray beams are similar to light waves, except their shorter wavelength allows them to penetrate dense substances, producing images and shadows on film.

Purpose

Doctors may order skull x rays to aid in the diagnosis of a variety of diseases or injuries, such as:

Sinusitis

Sinus x rays may be ordered to confirm a diagnosis of sinusitis, or sinus **infection**.

Fractures

A skull x ray may detect bone **fractures**, resulting from injury or other disease. The skull x ray should clearly show the top of the skull, jaw bones (mandible), and facial bones. In larger facilities the computed tomography scan (CT) has begun to replace the skull x-ray as a screening tool, since a CT scan can offer more information about craniofacial injuries.

Tumors

Skull radiographs may indicate tumors in facial bones, tissues, or the sinuses. Tumors may be benign (not cancerous) or malignant (cancerous). If a tumor is suspected the patient will then be referred to another imaging modality (MRI or CT) for a more thorough examination.

Skull x rays may be used to help diagnose a number of injuries and conditions, including sinusitis, fractures, tumors, birth defects, and other diseases that result in changes in bone structure or other tissues and glands in the skull. (K. Beebe/Custom Medical Stock Photo. Reproduced by permission.)

Other

Birth defects (referred to as congenital anomalies) may be detected on a skull x ray by changes in bone structure. Abnormal tissues or glands resulting from various conditions or diseases may also be shown on a skull radiograph.

Precautions

As with any x-ray procedure, women who may be pregnant are advised against having a skull x ray if it is not absolutely necessary. However, a lead apron may be worn across the abdomen during the procedure to protect the fetus. Children are also more sensitive to x-ray exposure. Children of both sexes should wear a protective covering (a lead apron) in the genital/reproductive area. In general, skull x-ray exposure is minimal and x-ray equipment and procedures are monitored to ensure radiation safety.

Description

In many instances, particularly for sinus views, the patient will sit upright in a chair, perhaps with the head held stable by a foam sponge. Sitting upright helps demonstrate air-fluid levels within the sinuses. (Air-fluid levels indicate acute disease, such as acute sinusitis or hemorrhage.) A film cassette is located behind the patient. The x-ray tube is in front of the patient and may be moved to allow for different positions and views. A patient may also be asked to move his or her head at various angles and positions.

In some cases, the technologist will ask the patient to lie on a table and will place the head and neck at various angles. In routine skull x rays, as many as five different views may be taken to allow a clear picture of various bones and tissues. The radiologist may request additional views to help better demonstrate pathology. The length of the test will vary depending on the number of views taken, but in general, it should last about 10 minutes. The technologist will usually ask a patient to wait while the films are being developed to ensure that they are clear before going to the radiologist.

Preparation

There is no preparation for the patient prior to arriving at the radiology facility. Patients will be asked to remove jewelry, dentures, or other metal objects that may produce artifacts on the film. The referring doctor or x-ray technologist can answer any questions regarding the procedure. Any woman who is, or may be, pregnant should inform the technologist.

Aftercare

There is no aftercare required following skull or sinus x-ray procedures.

Complications

There are no common side effects from skull or sinus x ray. The patient may feel some discomfort in the positioning of the head and neck, but will have no complications. Any x-ray procedure carries minimal radiation risk, and children and pregnant women should be protected from radiation exposure to the abdominal or genital areas.

Results

Normal results should indicate sinuses, bones, tissues, and other observed areas are of normal size, shape, and thickness for the patient's age and medical history. Results, whether normal or abnormal, will be provided to the referring physician in a written report.

Abnormal results may include:

Sinusitis

Air in sinuses will show up on a radiograph as black, but fluid will be cloudy or white (opaque). This helps the radiologist to identify fluid in the sinuses. In chronic sinusitis, the radiologist may also note thickening or hardening of the bony wall of an infected sinus.

Fractures

Radiologists may recognize facial bone fractures as a line of defect.

Tumors

Tumors may be visible if the bony sinus wall or other bones are distorted or destroyed. Abnormal findings may result in follow-up imaging studies, such as **magnetic resonance imaging** (MRI) and computed tomography (CT).

Other

Skull x rays may also detect disorders that show up as changes in bone structure, such as Paget's disease of the bone or acromegaly (a disorder associated with excess growth hormone from the **pituitary gland**). Areas of calcification (a gathering of **calcium** deposits), depending on their appearance and distribution, may indicate a condition such as an infection of bone or bone marrow (osteomyelitis).

Health care team roles

Skull or sinus x rays may be performed in a doctor's office that has x-ray equipment. A radiologic technologist performs the procedure, and a physician interprets the results. The exam may also be performed in an outpatient radiology facility or a hospital radiology department.

Sleep and wakefulness

Definition

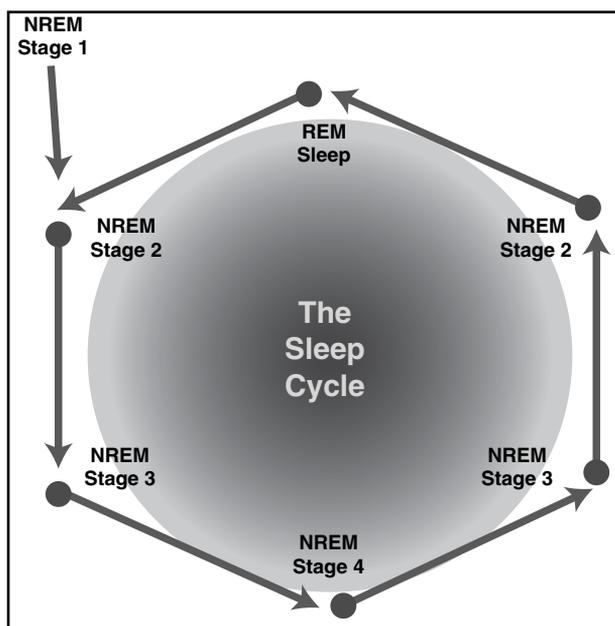

Sleep is a normal state of rest that is characterized by unconsciousness, reduced activity, and limited sensory responsiveness. Sleep differs from other states of reduced consciousness, such as drug intoxication or **coma**, because it is spontaneous, periodic, and readily reversible. Sleep is usually described by contrasting it with wakefulness, which is characterized by consciousness, sensory responsiveness, and purposeful activity.

Description

Sleep is one of the least understood aspects of human and animal behavior. It occurs in virtually every vertebrate species and seems to be necessary to healthy functioning, but science has been slow to discover how and why sleep occurs. The biological events that take place during sleep are subtle, and many seem to occur at a cellular level within the **brain**. These events are difficult to observe, and as a consequence our understanding of sleep has developed slowly.

Stages of sleep

Although the sleeping person seems inactive, the sleeping brain exhibits variations in activity throughout the sleep period. Recordings of brain activity, known as electroencephalograms (EEGs), show patterns that occur in a regular cycle lasting about 90 to 100 minutes. This cycle includes relatively brief periods of rapid-eye-

The sleep cycle. (Delmar Publishers, Inc. Reproduced by permission.)

movement (REM) sleep, characterized by back-and-forth movement of the eyes and changes in **autonomic nervous system** activity. REM is absent in the other phases of the sleep cycle, which are characterized as non-REM (NREM) sleep. Sleep can be divided into five distinct stages based on EEG and REM activity:

- Stage 1 NREM sleep: This lightest stage of sleep occurs as the person is just falling asleep. Stage 1 accounts for about 5% of a normal sleep period.
- Stage 2 NREM sleep: During this period the EEG exhibits characteristic patterns known as “sleep spindles” and K-complexes. This stage accounts for about 50% of a normal sleep period.
- Stage 3 NREM sleep: This stage is characterized by “slow wave” EEG activity, which is associated with deep sleep.
- Stage 4 NREM sleep This stage is very similar to Stage 3, the only difference being the amount of slow wave sleep that occurs. Together, Stages 3 and 4 account for about 20% of a normal sleep period.
- REM sleep. The EEG pattern of this stage is similar to that of Stage 1 NREM sleep. The sleeping person exhibits rapid eye movements and autonomic changes, as well as inactivity of the **skeletal muscles**. Most dreaming occurs during this stage of sleep. This stage accounts for about 20 to 25% of a normal sleep period.

The first 90-minute sleep cycle of the night begins with Stage 1 NREM sleep and progresses through Stages

2, 3, and 4, ending with a period of REM sleep. Subsequent cycles usually replace Stage 1 with the REM period. In a typical night of sleep, the earlier cycles tend to include more Stage 3 and 4 NREM sleep, with briefer REM periods. As the night progresses, the REM periods tend to get longer while the NREM periods get shorter.

Sleep and biological rhythms

Sleep is one of several biological processes that exhibit a pattern known as a circadian rhythm. A circadian rhythm recurs spontaneously on about a 24-hour cycle. Humans tend to sleep and wake up according to internal circadian rhythms, which seem to be part of our self-regulatory systems.

Circadian rhythms are regulated by a structure in the brain called the superchiasmatic nucleus, which is influenced by exposure to light. Damage to the superchiasmatic nucleus may result in loss of circadian rhythms, however, the individual still exhibits periodic tendencies to fall asleep. This is because a second, homeostatic process also regulates sleep. The individual seems to need sleep after periods of being awake, and the longer the period of wakefulness, the greater the likelihood that the person will fall asleep.

Sleep and the life cycle

The duration and patterning of sleep shows developmental changes throughout the life cycle. Newborns tend to sleep about 16 hours each day, with sleep occurring in relatively brief two to four-hour periods. As children grow, they sleep for longer periods at a time, with fewer sleep periods in a day, until they achieve the adult pattern of a single sleep period each day. The total amount of sleep also declines during childhood, until reaching the adult average of seven to nine hours per night.

In most adults, the amount of nightly sleep remains fairly stable until old age. Adults over 65 years of age tend to sleep less and report more frequent awakenings than younger adults. More than half of adults over 65 report some difficulty with sleep, although these sleep disturbances are often related to other problems, such as poor health or depression.

The patterns of REM and NREM sleep also show developmental changes. REM sleep tends to be much more prevalent in infants, with as much as 50% of their sleep time taken up by REM activity. This percentage declines throughout childhood and stabilizes at 20 to 25% in adolescence. In old age the percentage of sleep time devoted to REM declines to about 20%. Older adults also show a sharp decline in Stage 3 and Stage 4 NREM sleep.

Function

Experience suggests that sleep has some sort of restorative function. Humans feel refreshed and energized after a good night's sleep, and feel tired and ineffectual when they don't sleep well. But science has had difficulty going beyond this common-sense understanding of sleep. The physiological purpose of sleep continues to be something of a mystery.

The most common way to look for the purpose of sleep is to study people who have been deprived of sleep and measure the degree of impairment in their functioning. A large number of such studies have been done, with surprisingly slim results. Lack of sleep seems to have very little impact on functions such as motor coordination, sensory perception, or reflex activity, and most cognitive functions seem relatively unaffected as well. The biggest impact seems to be on short-term **memory** and sustained attention, both of which are impaired somewhat by sleep deprivation. This impairment may be due to the subjects' marked tendency to fall asleep for short periods as sleep deprivation is increased. By far, the most common outcome of sleep deprivation is increased sleepiness. As deprivation increases, the pressure to fall asleep intensifies to the point where it is almost impossible to keep subjects awake unless they are monitored constantly.

Role in human health

The quality and quantity of sleep are important indicators of overall health. Sleep is often affected by physical or emotional **stress**, and sleep disturbances are good indicators that something is amiss with a person. Although the majority of sleep complaints can be traced to psychosocial stress, sleep disturbance can be an important feature of many serious physical or psychological problems as well.

Sleep disturbance occurs in a wide variety of medical problems, including endocrine disturbances, gastrointestinal disorders, and **hypertension**. Chronic **pain** disorders such as arthritis and **fibromyalgia** also produce sleep disturbances, and sleep disruption is a common feature of a number of neurological disorders. Complaints about sleep are also very common with psychiatric illnesses, especially **anxiety** disorders and mood disorders, and they also occur in some forms of psychosis. Sleep disruption can be an important indicator of substance abuse. The most obvious case is the abuse of stimulants, such as **caffeine** or amphetamines, but alcohol abuse can also interfere with sleep, as can the abuse of sedatives.

Inadequate sleep is also a **public health** issue in its own right. A recent poll indicated that 63% of American

adults fail to get the recommended amount of sleep at night, and 69% report frequent sleep problems. Chronic lack of sleep causes daytime sleepiness, which increases the risk of accidents of all types, especially automobile accidents. One estimate suggests that driver sleepiness plays a role in 10% of serious automobile accidents. Lack of sleep also impairs work performance and may contribute to industrial accidents.

Common diseases and disorders

Sleep disorders can be classified as primary or secondary, depending on the presumed cause of the disorder. Primary sleep disorders are those that arise in the absence of other medical or psychiatric conditions, while secondary sleep disorders are likely caused by some other condition.

Some of the more common primary sleep disturbances include the following:

- **Primary insomnia:** This disorder is defined as difficulty getting to sleep or staying asleep that lasts for over one month. Primary insomnia is often triggered by psychological stress, but it may persist long after a stressful event occurs. It is often related to anxiety about sleep, as well as poor sleep hygiene.
- **Narcolepsy:** Narcolepsy is characterized by periodic attacks of uncontrollable sleepiness, sometimes triggered by strong emotions. Patients with narcolepsy often experience cataplexy, a sudden loss of muscle tone, which can result in falling and injuries. Other symptoms of narcolepsy include hallucinations and sleep **paralysis**. Narcolepsy occurs in around 0.04% of the general population.
- **Breathing-related sleep disorders:** This is a group of disorders that are all characterized by disturbed sleep due to periodic disruptions in breathing. The most common form is obstructive sleep apnea (OSA) syndrome, in which sleep is marked by periodic blockage of the upper airway. This disorder may affect 2 to 4% of the general population.
- **Nocturnal myoclonus and restless leg syndrome:** These are characterized by night-time discomfort and movement of the lower extremities. In nocturnal myoclonus, the person may be awakened by twitching or cramps in the legs. In restless leg syndrome, patients usually report a "crawly" feeling and the urge to move their legs. Both disorders interfere with sleep, and patients may complain of insomnia or daytime sleepiness.
- **Circadian rhythm sleep disorders:** In these disorders the timing of sleep is disturbed, so that the person's sleep schedule does not fit with external social demands. Shift work and long-distance travel can contribute to

KEY TERMS

Cataplexy—An abrupt and reversible loss of muscle tone. Cataplexy is one of the key symptoms of narcolepsy.

Circadian rhythm—A body rhythm that occurs in a 24-hour cycle. Sleep, body temperature, and some endocrine functions exhibit circadian rhythms.

Electroencephalogram (EEG)—A recording of electrical activity in the brain.

Insomnia—Difficulty falling asleep or staying asleep.

Narcolepsy—A sleep disorder characterized by sudden attacks of sleep. Key symptoms include cataplexy, hallucinations, and sleep paralysis.

Nocturnal myoclonus—A sleep disorder in which sleep is disturbed by twitching or cramps in the leg muscles. Nocturnal myoclonus is also known as periodic limb movements in sleep (PMLS).

Non-rapid eye movement (NREM) sleep—Stages of sleep during which rapid eye movements do not occur. The majority of sleep consists of the four stages of NREM sleep.

Rapid eye movement (REM) sleep—A stage of sleep during which the sleeper's eyes move back and forth rapidly. Most dreams occur during REM sleep.

Restless leg syndrome (RLS)—A sleep disorder in which the person is awakened by uncomfortable "crawly" feelings in the legs.

Sleep apnea—Temporary cessation of breathing during sleep.

Sleep hygiene—A set of behaviors associated with the timing and conditions of sleep. Good sleep hygiene involves setting a regular sleep schedule, avoiding bedtime stress, and restricting activities so that the bed becomes a place for sleeping.

Sleep paralysis—A sudden inability to move that occurs at the point of falling asleep or awakening.

these disorders, but they are also common in elderly people. Often these disorders are treated by light exposure and other efforts to "reset" the patient's internal clock.

- **Sleep terror disorder:** This is a disorder in which the patient wakes up physically aroused and screaming or

crying. Although these episodes resemble nightmares, they usually occur during NREM sleep rather than during the normal dreaming of REM sleep. The patient often cannot recall the episode the next morning. Sleepwalking disorder is a similar condition, involving complex movements and activities during sleep. It also occurs during NREM sleep. Both disorders are more common in children than adults.

Sleep disorders

Definition

Sleep disorders are a group of syndromes characterized by disturbance in a person's amount of sleep, quality or timing of sleep, or in behaviors or physiological conditions associated with sleep. There are about 70 different sleep disorders. To qualify for the diagnosis of

sleep disorder, the condition must be a persistent problem, cause an individual significant emotional distress, and interfere with social or occupational functioning. The text revision of the fourth edition (2000) of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)* specifically excludes temporary disruptions of sleeping patterns caused by travel or other short-term stresses.

Although sleep is a basic behavior in animals as well as humans, researchers still do not completely understand all of its functions in maintaining health. In the past 30 years, however, laboratory studies on human volunteers have yielded new information about the different types of sleep. Researchers have learned about the cyclical patterns of different types of sleep and their relationships to breathing, **heart** rate, **brain** waves, and other physical functions. These measurements are obtained by a technique called **polysomnography**.

There are five stages of human sleep. Four stages have non-rapid eye movement (NREM) sleep, with unique brain wave patterns and physical changes occurring. Dreaming occurs in the fifth stage, during rapid eye movement (REM) sleep.

- Stage 1 NREM sleep. This stage occurs while a person is falling asleep. It represents about 5% of a normal adult's sleep time.
- Stage 2 NREM sleep. In this stage, (the beginning of "true" sleep), the person's electroencephalogram (EEG) will show distinctive wave forms called sleep spindles and K complexes. About 50% of sleep time is stage 2 NREM sleep.
- Stages 3 and 4 NREM sleep. Also called delta or slow wave sleep, these are the deepest levels of human sleep and represent 10-20% of sleep time. They usually occur during the first 30-50% of the sleeping period.
- REM sleep. REM sleep accounts for 20-25% of total sleep time. It usually begins about 90 minutes after a person falls asleep, an important measure called REM latency. It alternates with NREM sleep about every hour and a half throughout the night. REM periods increase in length over the course of the night.

Sleep cycles vary with a person's age. Children and adolescents have longer periods of stage 3 and stage 4 NREM sleep than do middle aged or elderly adults. Because of this difference, a doctor will need to take a person's age into account when evaluating a sleep disorder. Total REM sleep also declines with age.

The average length of nighttime sleep varies among people. Most individuals sleep between seven and nine hours a night. This population average appears to be constant throughout the world. In temperate climates, how-

ever, people often notice that sleep time varies with the seasons. It is not unusual for people in North America and Europe to sleep about 40 minutes longer per night during the winter.

Description

The *DSM-IV-TR* classifies sleep disorders based on their causes. Primary sleep disorders are distinguished from those that are not caused by other mental disorders, prescription medications, substance abuse, or medical conditions. The two major categories of primary sleep disorders are the dyssomnias and the parasomnias.

Dyssomnias

Dyssomnias are primary sleep disorders in which a person suffers from changes in the amount, restfulness, and timing of sleep. The most important dyssomnia is primary insomnia, which is defined as difficulty in falling asleep or remaining asleep that lasts for at least one month. It is estimated that 35% of adults in the United States experience insomnia during any given year, but the number of these adults who are experiencing true primary insomnia is unknown. Primary insomnia can be caused by a traumatic event related to sleep or bedtime, and it is often associated with increased physical or psychological arousal at night. People who experience primary insomnia are often anxious about not being able to sleep. Individuals may then associate all sleep-related things (their bed, bedtime, etc.) with frustration, making the problem worse. They then become more stressed about not sleeping. Primary insomnia often begins in young adulthood or in middle age.

Hypersomnia is a condition marked by excessive sleepiness during normal waking hours. Affected persons either have lengthy episodes of daytime sleep or episodes of daytime sleep on a daily basis even though they are sleeping normally at night. In some cases, persons with primary hypersomnia have difficulty waking in the morning and may appear confused or angry. This condition is sometimes called sleep drunkenness and is more common in males. The number of people with primary hypersomnia is unknown, although 5-10% of people in sleep disorder clinics have the disorder. Primary hypersomnia usually affects young adults between the ages of 15 and 30.

Nocturnal myoclonus and restless legs syndrome (RLS) can cause either insomnia or hypersomnia in adults. Individuals with nocturnal myoclonus wake up because of cramps or twitches in the calves. These people feel sleepy the next day. Nocturnal myoclonus is sometimes called periodic limb movement disorder. RLS patients have a crawly or aching feeling in their calves that can be relieved by moving or rubbing the legs. RLS

often prevents people from falling asleep until the early hours of the morning, when the condition is less intense.

Kleine-Levin syndrome is a recurrent form of hypersomnia that affects a person three or four times a year. Doctors do not know the cause of this syndrome. It is marked by two to three days of sleeping 18–20 hours per day, hypersexual behavior, compulsive eating, and irritability. Men are three times more likely than women to have the syndrome. As of 2001, there is no cure for this disorder.

Narcolepsy is a dyssomnia characterized by recurrent “sleep attacks” that a person cannot fight. The sleep attacks are about 10–20 minutes long. A person feels refreshed by the sleep, but typically feels sleepy again several hours later. Narcolepsy has three major symptoms in addition to sleep attacks: cataplexy, hallucinations, and sleep **paralysis**. Cataplexy is the sudden loss of muscle tone and stability (“drop attacks”). Hallucinations may occur just before falling asleep (hypnagogic) or right after waking up (hypnopompic) and are associated with an episode of REM sleep. Sleep paralysis occurs during the transition from being asleep to waking up. About 40% of patients with narcolepsy have or have had another mental disorder. Although narcolepsy is often regarded as an adult disorder, it has been reported in children as young as three years old. Almost 18% of people with narcolepsy are 10 years old or younger. It is estimated that 0.02–0.16% of the general population suffers from narcolepsy. Men and women are equally affected.

Breathing-related sleep disorders are syndromes in which a person’s sleep is interrupted by problems with breathing. There are three types of breathing-related sleep disorders:

- **Obstructive sleep apnea syndrome.** This is the most common form of breathing-related sleep disorder, marked by episodes of blockage in the upper airway during sleep. It is found primarily in obese people. Persons with this disorder typically alternate between periods of snoring or gasping (when their airway is partly open) and periods of silence (when their airway is blocked). Very loud snoring is a clue to this disorder.
- **Central sleep apnea syndrome.** This disorder is primarily found in elderly people with heart or neurological conditions that affect their ability to breathe properly. It is not associated with airway blockage and may be related to brain disease.
- **Central alveolar hypoventilation syndrome.** This disorder is found most often in extremely obese people. Their airway is not blocked, but **blood** oxygen level is too low.

- **Mixed-type sleep apnea syndrome.** This disorder combines symptoms of both obstructive and central sleep apnea.

Circadian rhythm sleep disorders are dyssomnias resulting from a discrepancy between a person’s daily sleep and wake patterns and demands of social activities, shift work, or travel. The term circadian comes from a Latin word meaning daily. There are three circadian rhythm sleep disorders. Delayed sleep phase type is characterized by going to bed and arising later than most people. Jet lag type is caused by travel to a new time zone. Shift work type is caused by the schedule of a person’s job. People who are ordinarily early risers appear to be more vulnerable to jet lag and shift work-related circadian rhythm disorders than people who are “night owls.” There are some individuals who do not fit the pattern of these three disorders and appear to be the opposite of the delayed sleep phase type. These people have an advanced sleep phase pattern and cannot stay awake in the evening, but wake up on their own in the early morning.

PARASOMNIAS. Parasomnias are primary sleep disorders in which a person’s behavior is affected by specific sleep stages or transitions between sleeping and waking. They are sometimes described as disorders of physiological arousal during sleep.

Nightmare disorder is a parasomnia in which a person is repeatedly awakened from sleep by frightening dreams and is fully alert on awakening. The actual rate of occurrence of nightmare disorder is unknown. Approximately 10–50% of children between three and five years old experience nightmares. They occur during REM sleep, usually in the second half of the night. A child is usually able to remember the content of the nightmare and may be afraid to go back to sleep. More females than males have this disorder, but it is not known whether the gender difference reflects a difference in occurrence or a difference in reporting. Nightmare disorder is most likely to occur in children or adults under severe or traumatic **stress**.

Sleep terror disorder is a parasomnia in which a person awakens screaming or crying. The individual also has physical signs of arousal, like sweating, shaking, etc. It is sometimes referred to as pavor nocturnus. Unlike nightmares, sleep terrors typically occur in stage 3 or stage 4 NREM sleep during the first third of the night. A person may be confused or disoriented for several minutes and cannot recall the content of the dream. There is usually a return to sleep without being able to remember the episode the next morning. Sleep terror disorder is most common in children four to 12 years old and is outgrown in adolescence. It affects about 3% of children. Fewer than 1% of adults have the disorder. In adults, it

A patient suffering from acute sleep apnea is hooked up to monitors in preparation for a night's sleep at a Stanford University lab. (Photograph by Russell D. Curtis, Photo Researchers, Inc. Reproduced by permission.)

usually begins between the ages of 20 and 30. In children, more males than females have the disorder. In adults, men and women are equally affected.

Sleepwalking disorder, which is sometimes called somnambulism, occurs when a person is capable of complex movements during sleep, including walking. Like sleep terror disorder, sleepwalking occurs during stage 3 and stage 4 NREM sleep during the first part of the night. If individuals are awakened during a sleepwalking episode, they may be disoriented and have no **memory** of the behavior. In addition to walking around, persons with sleepwalking disorder have been reported to eat, use the bathroom, unlock doors, or talk to others. It is estimated that 10–30% of children have at least one episode of sleepwalking. However, only 1–5% meet the criteria for sleepwalking disorder. The disorder is most common in children eight to 12 years old. It is unusual for sleepwalking to occur for the first time in adults.

Unlike sleepwalking, REM sleep behavior disorder occurs later in the night and people can remember what they were dreaming. The physical activities of such persons are often violent.

Sleep disorders related to other conditions

In addition to the primary sleep disorders, the *DSM-IV-TR* specifies three categories of sleep disorders that are caused by or related to substance use or other physical or mental disorders.

Many mental disorders, especially depression or one of the **anxiety** disorders, can cause sleep disturbances. Psychiatric disorders are the most common cause of chronic insomnia.

Some people with chronic neurological conditions like **Parkinson's disease** or Huntington's disease may develop sleep disorders. Sleep disorders have also been associated with viral encephalitis, brain disease, and hypo- or hyperthyroidism.

The use of drugs, alcohol, and **caffeine** frequently produce disturbances in sleep patterns. Alcohol abuse is associated with insomnia. A person may initially feel sleepy after drinking, but wakes up or sleeps fitfully during the second half of the night. Alcohol can also increase the severity of breathing-related sleep disorders. With amphetamines or cocaine, a person typically suffers from insomnia during drug use and hypersomnia during drug

withdrawal. Opioids usually make short-term users sleepy. However, long-term users develop tolerance and may suffer from insomnia.

In addition to alcohol and drugs that are abused, a variety of prescription medications can affect sleep patterns. These medications include **antihistamines, corticosteroids, asthma** medicines, and drugs that affect the **central nervous system**.

Sleep disorders in children and adolescents

Pediatricians estimate that 20–30% of children have difficulties with sleep that are serious enough to disturb their families. Although sleepwalking and night terror disorder occur more frequently in children than in adults, children can also suffer from narcolepsy and sleep apnea syndrome.

Causes and symptoms

The causes of sleep disorders have already been discussed with respect to the *DSM-IV-TR* classification of these disorders.

The most important symptoms of sleep disorders are insomnia and sleepiness during waking hours. Insomnia is by far the more common of the two symptoms. It covers a number of different patterns of sleep disturbance. These patterns include inability to fall asleep at bedtime, repeated awakening during the night, and/or inability to go back to sleep once awakened.

Diagnosis

Diagnosis of sleep disorders usually requires a psychological history as well as a medical history. With the exception of sleep apnea syndromes, physical examinations are not usually revealing. A person's gender and age are useful starting points in assessing the problem. A doctor may also talk to other family members to obtain information about a person's symptoms. A family's observations are particularly important to evaluate sleepwalking, kicking in bed, snoring loudly, or other behaviors that an individual cannot remember.

Sleep logs

Many doctors ask people to keep a sleep diary or sleep log for a minimum of one to two weeks in order to evaluate the severity and characteristics of the sleep disturbance. An individual records medications taken as well as the length of time spent in bed, the quality of the sleep, and similar information. Some sleep logs are designed to indicate circadian sleep patterns as well as simple duration or restfulness of sleep.

Psychological testing

A physician may use **psychological tests** or inventories to evaluate insomnia because it is frequently associated with mood or affective disorders. The Minnesota Multiphasic Personality Inventory (MMPI), the Millon Clinical Multiaxial Inventory (MCMI), the Beck Depression Inventory, and the Zung Depression Scale are the tests most commonly used in evaluating this symptom.

Self-report tests

The Epworth Sleepiness Scale, a self-rating form recently developed in Australia, consists of eight questions used to assess daytime sleepiness. Scores range from 0–24, with scores higher than 16 indicating severe daytime sleepiness.

Laboratory studies

If a doctor is considering breathing-related sleep disorders, myoclonus, or narcolepsy as possible diagnoses, an affected person may be tested in a sleep laboratory or at home with portable instruments.

POLYSOMNOGRAPHY. Polysomnography can be used to help diagnose sleep disorders as well as conduct research into sleep. In some cases a person is tested in a special sleep laboratory. The advantage of this testing is the availability and expertise of trained technologists, but it is expensive. As of 2001, however, portable equipment is available for home recording of certain specific physiological functions.

MULTIPLE SLEEP LATENCY TEST. The multiple sleep latency test (MSLT) is frequently used to measure the severity of a person's daytime sleepiness. The test measures sleep latency (the speed with which an individual falls asleep) during a series of planned naps during the day. The test also measures the amount of REM sleep that occurs. Two or more episodes of REM sleep under these conditions indicates narcolepsy. This test can also be used to help diagnose primary hypersomnia.

REPEATED TEST OF SUSTAINED WAKEFULNESS. The repeated test of sustained wakefulness (RTSW) measures sleep latency by challenging a person's ability to stay awake. In the RTSW, a person is placed in a quiet room with dim lighting and is asked to stay awake. As with the MSLT, the testing pattern is repeated at intervals during the day.

Treatment

Treatment for a sleep disorder depends on what is causing the disorder. For example, if major depression is

the cause of insomnia, then treatment of the depression with antidepressants should resolve the insomnia.

Medications

Sedative or hypnotic medications are generally recommended only for insomnia related to a temporary stress (such as surgery or grief) because of the potential for addiction or **overdose**. Trazodone, a sedating antidepressant, is often used for chronic insomnia that does not respond to other treatments. Sleep medications may also cause problems for elderly persons because of possible interactions with their other prescription medications. Among the safer hypnotic agents are lorazepam, temazepam, and zolpidem. Chloral hydrate is often preferred for short-term treatment in elderly people because of its mildness. Short-term treatment is recommended because this drug may be habit forming.

Narcolepsy is treated with stimulants such as dextroamphetamine sulfate or methylphenidate. Nocturnal myoclonus has been successfully treated with clonazepam.

Children with sleep terror disorder or sleepwalking are usually treated with benzodiazepines because this type of medication suppresses stage 3 and stage 4 NREM sleep.

Psychotherapy

Psychotherapy is recommended for persons with sleep disorders associated with other mental disorders. In many cases an individual's scores on the Beck or Zung inventories will suggest the appropriate direction of treatment.

Sleep education

"Sleep hygiene" or sleep education for sleep disorders often includes instructing a person in methods to enhance sleep. People are advised to:

- Wait until they feel sleepy before going to bed.
- Avoid using the bedroom for work, reading, or watching television.
- Get up at the same time every morning no matter how much or how little they have slept.
- Avoid smoking and avoid drinking liquids with caffeine.
- Get some physical **exercise** on a daily basis, early in the day.
- Limit fluid intake after dinner; in particular, avoid alcohol because it frequently causes interrupted sleep.
- Learn to meditate or practice **relaxation** techniques.

- Avoid tossing and turning in bed; instead, people should get up and listen to relaxing music or read.

Lifestyle changes

People with sleep apnea or hypopnea are encouraged to stop smoking, avoid alcohol or drugs of abuse, and lose weight in order to improve the stability of the upper airway.

In some cases, individuals with sleep disorders related to jet lag or shift work may need to change employment or travel patterns. They may need to avoid rapid changes in shifts at work.

Children with nightmare disorder may benefit from limits on television or movies. Violent scenes or frightening science fiction stories appear to influence the frequency and intensity of children's nightmares.

Surgery

Although making a surgical opening into the windpipe (a tracheostomy) for sleep apnea or hypopnea in adults is a treatment of last resort, it is occasionally performed if a person's disorder is life threatening and cannot be treated by other methods. In children and adolescents, surgical removal of the tonsils and adenoids is a fairly common and successful treatment for sleep apnea. Most people with sleep apnea are treated with continuous positive airway pressure (CPAP). Sometimes an oral prosthesis is used for mild sleep apnea.

Alternative treatment

Some alternative approaches may be effective in treating insomnia caused by anxiety or emotional stress. **Meditation** practice, breathing exercises, and **yoga** can break the vicious cycle of sleeplessness, worry about inability to sleep, and further sleeplessness for some people. Yoga can help some people to relax muscular tension in a direct fashion. The breathing exercises and meditation can keep them from obsessing about sleep.

Homeopathic practitioners recommend that people with chronic insomnia see a professional homeopath. They do, however, prescribe specific remedies for at-home treatment of temporary insomnia: *Nux vomica* for alcohol or substance-related insomnia, *Ignatia* for insomnia caused by grief, *Arsenicum* for insomnia caused by fear or anxiety, and *Passiflora* for insomnia related to mental stress.

Melatonin has also been used as an alternative treatment for sleep disorders. Melatonin is produced in the body by the pineal gland at the base of the brain. This substance is thought to be related to the body's circadian rhythms.

KEY TERMS

Apnea—The temporary absence of breathing. Sleep apnea consists of repeated episodes of temporary suspension of breathing during sleep.

Cataplexy—Sudden loss of muscle tone (often causing a person to fall), usually triggered by intense emotion. It is regarded as a diagnostic sign of narcolepsy.

Circadian rhythm—Any body rhythm that recurs in 24-hour cycles. The sleep-wake cycle is an example of a circadian rhythm.

Dyssomnia—A primary sleep disorder in which the patient suffers from changes in the quantity, quality, or timing of sleep.

Electroencephalogram (EEG)—The record obtained by a device that measures electrical impulses in the brain.

Hypersomnia—An abnormal increase of 25% or more in time spent sleeping. Patients usually have excessive daytime sleepiness.

Hypnotic—A medication that makes a person sleep.

Hypopnea—Shallow or excessively slow breathing usually caused by partial closure of the upper airway during sleep, leading to disruption of sleep.

Insomnia—Difficulty in falling asleep or remaining asleep.

Jet lag—A temporary disruption of the body's sleep-wake rhythm following high-speed air travel across several time zones. Jet lag is most severe in people who have crossed eight or more time zones in 24 hours.

Kleine-Levin syndrome—A disorder that occurs primarily in young males, three or four times a year. The syndrome is marked by episodes of hypersomnia, hypersexual behavior, and excessive eating.

Narcolepsy—A life-long sleep disorder marked by four symptoms: sudden brief sleep attacks, cataplexy, temporary paralysis, and hallucinations. The hallucinations are associated with falling asleep or the transition from sleeping to waking.

Nocturnal myoclonus—A disorder in which the

patient is awakened repeatedly during the night by cramps or twitches in the calf muscles. Nocturnal myoclonus is sometimes called periodic limb movement disorder (PLMD).

Non-rapid eye movement (NREM) sleep—A type of sleep that differs from rapid eye movement (REM) sleep. The four stages of NREM sleep account for 75–80% of total sleeping time.

Parasomnia—A primary sleep disorder in which a person's physiology or behaviors are affected by sleep, the sleep stage, or the transition from sleeping to waking.

Pavor nocturnus—Another term for sleep terror disorder.

Polysomnography—Laboratory measurement of a person's basic physiological processes during sleep. Polysomnography usually measures eye movement, brain waves, and muscular tension.

Primary sleep disorder—A sleep disorder that cannot be attributed to a medical condition, another mental disorder, or prescription medications or other substances.

Rapid eye movement (REM) sleep—A phase of sleep during which a person's eyes move rapidly beneath the lids. It accounts for 20–25% of sleep time. Dreaming occurs during REM sleep.

REM latency—After a person falls asleep, the amount of time it takes for the first onset of REM sleep.

Restless legs syndrome (RLS)—A disorder in which a person experiences crawling, aching, or other disagreeable sensations in the calves that can be relieved by movement. RLS is a frequent cause of difficulty falling asleep at night.

Sedative—A medication given to calm agitated individuals; sometimes used as a synonym for hypnotic.

Sleep latency—The amount of time that it takes to fall asleep. Sleep latency is measured in minutes and is important in diagnosing depression.

Somnambulism—Another term for sleepwalking.

Practitioners of Chinese medicine usually treat insomnia as a symptom of excess yang energy. Cinnabar is recommended for chronic nightmares. Either magnetic

magnetite or “dragon bones” is recommended for insomnia associated with hysteria or fear. If the insomnia appears to be associated with excess yang energy arising

from the **liver**, a practitioner will suggest oyster shells. Acupuncture treatments can help bring about balance and facilitate sleep.

Dietary changes such as eliminating stimulant foods (coffee, cola, chocolate) and late-night meals or snacks can be effective in treating some sleep disorders. Nutritional supplementation with magnesium, as well as botanical medicines that calm the nervous system, can also be helpful. Among the botanical remedies that may be effective for sleep disorders are valerian (*Valeriana officinalis*), passionflower (*Passiflora incarnata*), and skullcap (*Scutellaria lateriflora*).

Prognosis

Prognosis depends on the specific disorder. Children usually outgrow sleep disorders. People with Kleine-Levin syndrome usually get better by age 40. Narcolepsy is a life-long disorder. The prognosis for sleep disorders related to other conditions depends on successful treatment of the substance abuse, medical condition, or other mental disorder. The prognosis for primary sleep disorders is affected by many things, including a person's age, gender, occupation, personality characteristics, family circumstances, neighborhood environment, and similar factors.

Health care team roles

Sleep experts are often trained in physiology, medicine or psychology. Such professionals often administer tests and make initial diagnoses. Physicians prescribe drugs for some forms of sleep disorders. Surgeons are occasionally called upon for surgical intervention. Nurses take part in any testing as well as providing pre-test **patient education**. Family members are often key members of a health care team when they provide information and help to make changes in the home. An affected person may become a member of the health care team when making dietary modifications, seeking alternative employment or deciding to undertake a course of therapy.

Prevention

Sleep disorders are difficult to prevent. Recognition of potential causes and avoidance of such situations or substances can prevent many forms of sleep disorders. Since many sleep disorders are relatively common and transitory, a good attitude about occasional problems with sleep is very helpful. This can prevent worrying.

Slightly movable joint

Definition

A slightly movable joint (amphiarthrosis) is an articulation between bones in which the motion is limited due to either fibrous tissue or cartilage.

Description

Joints are classified as either fibrous or cartilaginous. Only one type of fibrous joint is slightly movable. It is known as a syndesmosis. In a syndesmosis, bones are separated by a substantial space and united by fibrous connective tissue.

In another classification of joints, cartilaginous also has only one type that is considered slightly movable. It is known as a symphysis. In a symphysis, bony surfaces are united by fibrocartilage.

Function

The function of a syndesmosis and symphysis is to bind two bones together, thus holding portions of the **skeletal system** intact. Also, the limited motion available in either of these two types of joints allows certain movements to take place.

Role in human health

A syndesmosis connects two bones by connective tissue and is found throughout the human body. An example is the tibio-fibular syndesmosis, or the connective

tive tissue that binds the distal ends of the fibula and tibia. A syndesmosis allows the fibula and tibia to work in unison as part of the lower leg. The limited motion available at this joint allows the tibia and fibula to move about each other yet still remain as a unit. This available movement is extremely important in the actions of the foot and ankle complex. This example describes how a syndesmosis provides stability as well as slight mobility.

A symphysis is a cartilaginous joint in which the uniting entity is fibrocartilage. Similar to the syndesmosis, the symphysis is stable but there is limited motion. In the syndesmosis, the bones are separated by a large space, unlike the symphysis, in which the articular surfaces are closer together. An example of a symphysis in the human body is the attachment of one vertebral body to another by way of an intervertebral disk. The intervertebral disk is a fibrocartilage ring that unites individual vertebral bodies. The sum attachment of many vertebrae gives rise to the **vertebral column**. The importance of this symphysis is that minimal motion occurs between vertebrae, thus maintaining stability. The combination of small movements between each successive vertebral attachment is what allows the vertebral column to move as a unit, that is, to flex and extend.

Common diseases and disorders

In the human body, a syndesmosis provides a stable environment between two bones and also allows for limited but important motion. In the example previously cited, the disorder that can affect a syndesmosis is primarily orthopedic. The tibio-fibular syndesmosis plays an integral role in stabilizing and allowing motion of the lower leg, foot, and ankle. Clearly, injury to this structure such as tearing would impair the stability and mobility of the lower leg, foot, and ankle. Thus, an injury to a syndesmosis described in this example could lead to impaired function such as walking.

A symphysis binds two bones by fibrocartilage. As cited previously, a good example of a symphysis in the human body is the attachment of one vertebra to another by a fibrocartilaginous disk. One of the most common and obvious disorders that can affect this joint is injury to the fibrocartilaginous disk. Injury to this fibrocartilage can be due to trauma, tumor, or **osteoarthritis**. Depending on which fibrocartilaginous disk is injured in the spine, associated problems could be **pain**, weakness, numbness, or tingling in the limbs, trunk, or both. Problems associated with an injured disk could affect overall human function and limit movement.

The syndesmosis and symphysis play important roles in human health. Moreover, injury to these joints could lead to reduced function and possible disability.

KEY TERMS

Connective tissue—Tissue that has pliable fibers, which provide strength to the tissue and thus support to the structures it attaches to.

Fibrocartilage—Connective tissue made up of collagen fibers that unites two bones together as a joint.

Fibula—The outer or lateral bone of the lower leg.

Intervertebral disk—A fibrocartilaginous structure that attaches one vertebra to another. An intervertebral disk provides force attenuation in the spine and aids in the overall movement of the spine.

Tibia—The larger weight-bearing bone of the lower leg.

Smell

Definition

Smell is the ability of an organism to sense and identify a substance by detecting trace amounts of the sub-

stance that evaporate. Researchers have noted similarities in the sense of smell between widely differing species that reveal some of the details of how the chemical signal of an odor is detected and processed.

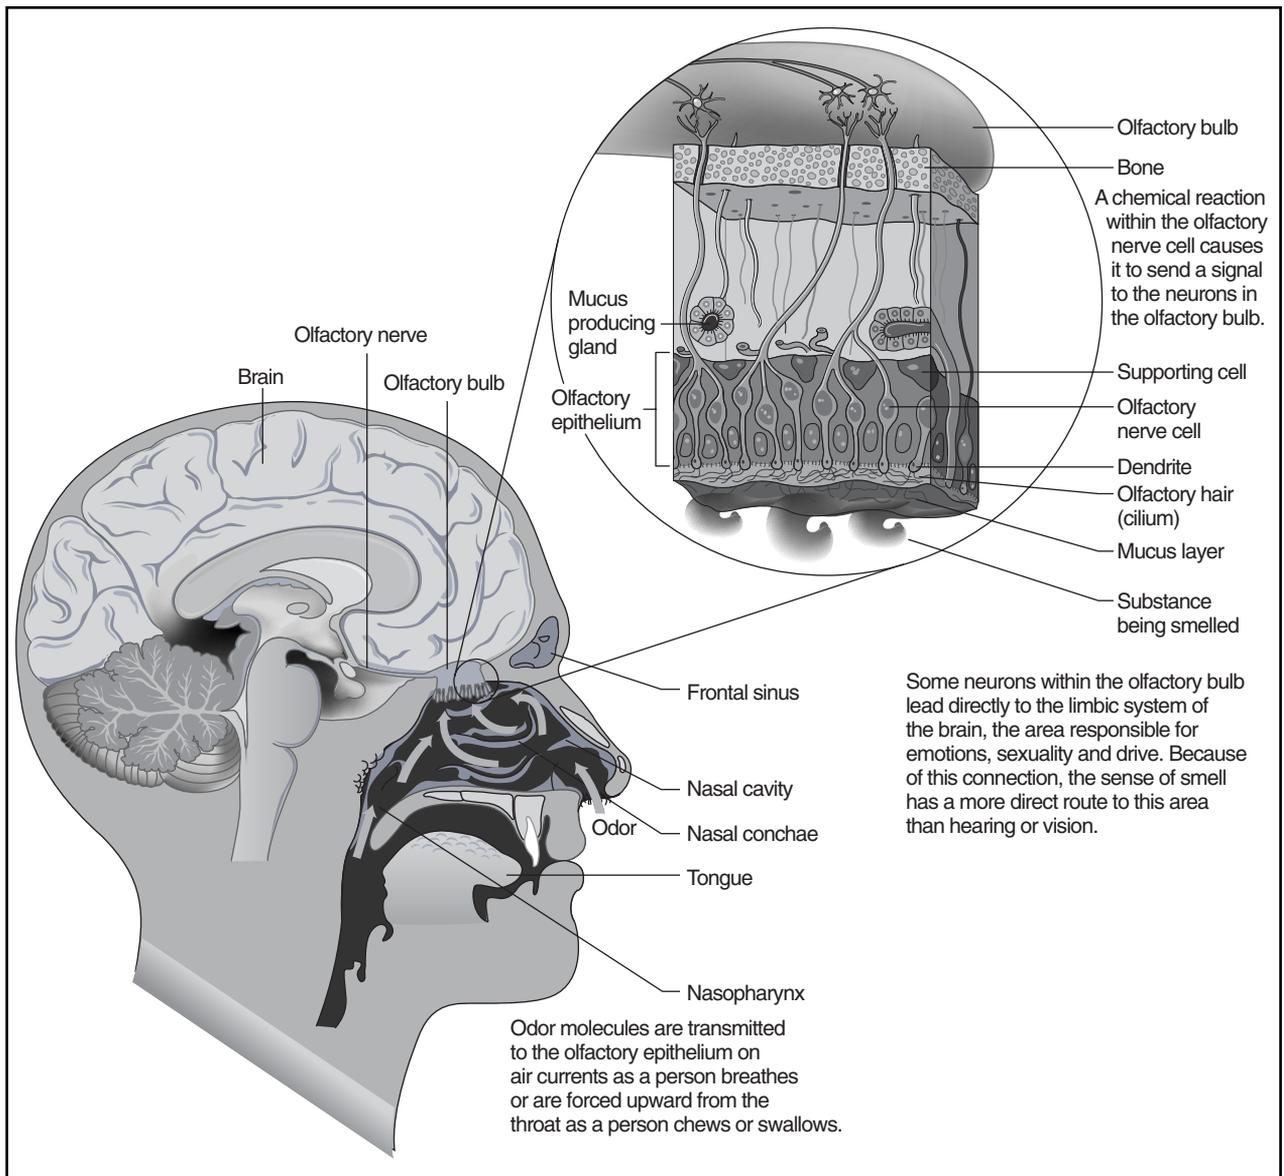

Description

The sense of smell has been a topic of debate from humankind's earliest days. The Greek philosopher Democritus of Abdera (460–360 B.C.), speculated that humans smell “atoms” of different size and shape that come from objects. His countryman Aristotle (384–322 B.C.), on the other hand, guessed that odors are detected when the “cold” sense of smell meets “hot” smoke or steam from the object being smelled. It was not until the late eighteenth century that most scientists and philosophers reached agreement that Democritus was basically right: the smell of an object is due to volatile, or easily evaporated, molecules that emanate from it.

In 1821, the French anatomist Hippolyte Cloquet (1787–1840) rightly noted the importance of smell for animal survival and reproduction; but his theorizing about the role of smell in human sex, as well as mental disorders, proved controversial. Many theories of the nineteenth century seem irrational or even malignant today. Many European scientists of that period fell into the trap of an essentially circular argument, that held that non-Europeans were more primitive, and therefore had a more developed sense of smell. The first half of the twentieth century saw progress in making the study of smell more rational. A Spanish neuroanatomist traced the architecture of the nerves leading from the nose to and through the **brain**. Other scientists carried out the first methodical investigations of how the nose detects scent molecules, the sensitivity of the human nose, and the differences between human and animal olfaction. But the most recent progress in studying the sense of smell and how it affects humans was made with the application of molecular science to the odor-sensitive cells of the nasal cavity.

The sense of smell is the most important sense for most organisms. A wide variety of species use their sense of smell to locate prey, navigate, recognize and perhaps communicate with kin, and mark territory. In a broad sense, the workings of smell in animals as different as mammals, reptiles, fish, and even insects are remarkably similar.

The sense of smell differs from most other senses in its directness; humans and other mammals actually smell microscopic bits of a substance that have evaporated and made their way to the olfactory epithelium, a section of the mucus membrane in the roof of the olfactory cavity. The olfactory epithelium contains the smell-sensitive ending of the olfactory nerve cells, also known as the

Sense of smell. (Illustration by Hans & Cassidy. Courtesy of Gale Group.)

olfactory epithelial cells. These cells detect odors through receptor **proteins** on the cell surface that bind to odor-carrying molecules. A specific odorant docks with an olfactory receptor protein in much the same way as a key fits in a lock; this in turn excites the nerve cell, causing it to send a signal to the brain. This is known as the stereospecific theory of smell.

Recently, molecular scientists have cloned the genes for the human olfactory receptor proteins. Although there are perhaps tens of thousands or more of odor-carrying molecules in the world, there are only hundreds, or at most about 1,000, kinds of specific receptors in any species of animal, including humans. Because of this,

scientists do not believe that each receptor recognizes a unique odorant; rather, similar odorants can all bind to the same receptor. It appears that a few loose-fitting odorant “keys” of broadly similar shape can turn the same receptor “lock.” Researchers do not yet know how many specific receptor proteins each olfactory nerve cell carries, but recent work suggests that the cells specialize just as the receptors do, and any one olfactory nerve cell has only one or a few receptors rather than many.

Function

It is the combined pattern of receptors that are tweaked by an odorant that allow the brain to identify it,

much as yellow and red light together are interpreted by the brain as orange. (In fact, just as people can be color-blind to red or green, some can be “odor-blind” to certain simple molecules because they lack the receptor for that molecule.) In addition, real objects produce multiple odor-carrying molecules, so that the brain must analyze a complex mixture of odorants to recognize a smell.

Just as the sense of smell is direct in detecting fragments of the objects, it is also direct in the way the signals transmitted to the brain. In most senses, such as **vision**, this task is accomplished in several steps: a receptor cell detects light and passes the signal to a nerve cell, which passes it on to another nerve cell in the **central nervous system**, which then relays it to the visual center of the brain. But in olfaction, all these jobs are performed by the olfactory nerve cell. In a very real sense, the olfactory epithelium is a direct outgrowth of the brain.

Role in human health

In humans, the olfactory nerve cell takes the scent message directly to the nerve cells of the olfactory bulb of the brain. There multiple signals from different olfactory cells with different odor sensitivities are organized and processed. The signal then goes to the brain’s olfactory cortex, where higher functions such as **memory** and emotion are coordinated with the sense of smell.

There is no doubt that many animals have a sense of smell far superior than humans. This is why, even today, humans use dogs to find lost persons, hidden drugs, and explosives although research on “artificial noses” than can detect scent even more reliably than dogs continues.

Because of their humble abilities of olfaction, humans are called microsmatic, rather than macrosmatic. Still, the human nose is capable of detecting over 10,000 different odors, some in the range of parts per trillion of air; and many researchers suspect that smell plays a greater role in human behavior and biology than has been previously thought. For instance, research has shown that human mothers can smell the difference between a vest worn by their baby and one worn by another baby only days after the child’s birth.

Yet some olfactory abilities of animals are probably beyond humans. Most vertebrates have many more olfactory nerve cells in a proportionately larger olfactory epithelium than humans, which probably gives them much more sensitivity to odors. The olfactory bulb in these animals takes up a much larger portion of the brain than it does in humans, giving the animal more ability to process and analyze olfactory information. In addition, most land vertebrates have a specialized scent organ in the roof of the mouth called vomeronasal organ. This

KEY TERMS

Anosmia—A disorder in which one is able to detect no odors.

Olfactory bulb—The primitive part of the brain that first processes olfactory information.

Olfactory cortex—The cerebral cortex that makes use of information from the olfactory bulb.

Olfactory epithelium—The patch of mucus membrane at the top of the nasal cavity that is sensitive to odor.

Olfactory nerve cell—The cell in the olfactory epithelium that detects odor and transmits the information to the olfactory bulb of the brain.

Pheromones—Scent molecules made by the body that attract a mate and help initiate mating behaviors.

Receptor protein—A protein in a cell that sticks to a specific odorant or other signal molecule.

Stereospecific theory—The theory that the nose recognizes odorants when they bind to receptor proteins that recognize the odorants’ molecular shape.

Volatile—Easily evaporated.

Vomeronasal—A pit on the roof of the mouth in most vertebrates that serves to detect odor molecules that are not as volatile as those detected by the nose.

organ, believed to be vestigial in humans, is a pit lined by a layer of cells with a similar structure to the olfactory epithelium, which feeds into its own processing part of the brain, called accessory olfactory bulb, an area of the brain that is absent in humans.

Researchers have learned a lot about how the olfactory nerve cells detect odorants. However, they have not yet learned how this information is coded by the olfactory cell. Scientists are only beginning to understand the role that smell plays in animal and human behavior. The vomeronasal sense of animals is still largely not understood and some researchers have even suggested that the human vomeronasal organ might retain some function, and that humans may have pheromones that play a role in sexual attraction and mating. However, this hypothesis is still very controversial.

Detailed study of the biology of the olfactory system may yield gains in other fields. For instance, olfactory

nerve cells are the only nerve cells that are derived from the central nervous system that can regenerate, possibly because the **stress** of their exposure to the outside world gives them a limited life span. Some researchers hope that studying regeneration in olfactory nerve cells or even transplanting them elsewhere in the body can lead to treatments for as yet irreversible damage to the spine and brain.

Common diseases and disorders

The most common complaint registered by patients is the loss of the sense of smell (anosmia). Smell disorders usually develop after an illness or an injury. Loss of the sense of smell is commonly caused by upper respiratory illnesses or a **head injury**. It can result from polyps in the nose or nasal cavity, sinus infections, hormonal fluctuations, or dental problems.

Social work in health care

Definition

Social work in health care helps people who are dealing with a medical problem to function within their situation. The social worker who specializes in health care works with clients and their families to provide services necessary to make their lives easier for the duration of the client's illness, and to help them deal with the consequences directly related to that illness.

Description

According to the code of ethics of the National Association of Social Workers (NASW), the profession of social work is dedicated to a set of core values. These values include social justice, service, dignity and worth of the person, importance of human relationships, integrity, and competence, and they form the foundation of social work. Social workers in the medical field provide a wide variety of services to clients who are going through a short-term medical crisis, suffering from chronic illnesses, facing a life-threatening disease, or in need of long-term care or rehabilitation.

The main concern of the social worker is to assist the client and the client's family in coping with their health care situation. Clients are faced with many problems when they have an accident, contract a sudden and debilitating illness, or are diagnosed with a chronic or life-threatening disease. Social workers help them assess these problems, identify their immediate and long term needs, and find resources to supply the needs.

Within the health care setting, the social worker has many responsibilities. The services provided by the social worker depend on the needs of the client. The worker acts as an advocate to secure the client's rights, directly counsels the client and the client's family, and refers the client to other social agencies, community resources, or facilities that can meet the client's immediate and long-term needs. The services provided by the social worker always depend upon the client's needs and the health care setting.

If the social worker is working in a hospital, these duties may include setting up home health care services after the client's discharge, arranging for meals to be delivered to the client's home, and setting appointments for follow-up care. The worker may also make arrangements for transportation to doctor's appointments and community social service agencies, and for long-term care within another facility.

Work settings

Duties of the social worker vary with the health care setting. Medical social workers may work in a hospital, hospice, assisted living center, nursing home, physical rehabilitation center, clinic, home health care agency, or drug rehabilitation or mental health center. Social workers may work in the health care facility or make home visits to work with their clients. They often work with other agencies and have to travel short distances for meetings with the agency members. Social workers confer with other agency workers or with health care team

members to assess client needs and to make plans for the client's care.

Hours of work vary for the social worker, depending upon the facility or agency within which he is employed. Usually the work hours are between 8 AM and 5 PM Monday through Friday, but the worker may be required to work hours as needed for emergencies. In larger urban areas or rural areas, the social worker may also be required to work during evening hours and on weekends to better serve the clients.

Education and training

Education, training, and licensing requirements may vary from state to state, but the NASW states that the minimum educational requirement for social workers is a baccalaureate degree in social work (BSW). However, people who hold a bachelor's degree in another discipline such as psychology, sociology, or urban studies may also qualify for entrance level jobs.

BSW programs prepare students for direct care of clients. Students who choose to major in social work must complete courses in social work practice, social work policies, human behavior and social environment, research methods, social work values and ethics, study of populations at risk, and the promotion of social justice. They must also complete 400 hours of supervised field work.

An advanced degree is the standard for many positions in social work including positions within the field of health care. A master's degree in social (MSW) allows the social worker to be certified for clinical and supervisory work.

Advanced education and training

A master's degree in social work qualifies the social worker to make clinical assessments, choose an area of specialization, manage large caseloads, and supervise social workers with lesser degrees. In addition to courses of specialization and assessment, the MSW candidate must complete 900 hours of supervised field work, or an internship.

Social workers may also acquire a Ph.D. or DSW in social work. This is required if they want to teach in an accredited program at a university or to work in a supervisory position as the head of a social service program.

The National Association of Social Workers requires social workers to complete 90 hours of continuing education classes every three years to continue their certification in the profession. Licensed professionals with

KEY TERMS

BSW—Baccalaureate degree in social work.

Long-term care—Placement of client in a facility that provides nursing and basic needs care when client is no longer able to provide that care at home.

MSW—Master's degree in social work.

NASW—National Association of Social Workers.

Needs assessment—Social worker conducts an interview with client and family, reviews charts, interviews other health workers to determine what specific services are required by client.

Urban studies—Course work in the sociology of urban areas.

advanced degrees may be required to complete more than 90 hours of continuing education classes.

Future outlook

Social work is a growing profession. The occupational outlook is optimistic. The national Bureau of Labor Statistics predicts that growth will continue at a rate exceeding that of other occupations until at least 2008. There are several reasons why the field of social work in health care continues to grow:

- the aging population of "baby boomers"
- advanced medical treatment
- longer life expectancy
- growth of home health care due to growing trend of early release of patients from hospitals
- replacement of workers seeking career change
- stress and burnout among social workers causing them to leave profession
- increase in population of people living with AIDS

Somatoform disorders

Definition

Somatoform disorders is the umbrella term developed by the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* in 1980 to describe a group of conditions characterized by the presence of physical symptoms without evidence of a physiologic cause. *DSM-IV* divides these conditions into six separate psychiatric disorders.

- somatization disorder
- undifferentiated somatoform disorder
- conversion disorder
- **pain** disorder
- hypochondriasis
- body dysmorphic disorder

Description

It is helpful to understand that the present classification of these disorders reflects recent historical changes in the practice of medicine and psychiatry. When psychiatry first became a separate branch of medicine at the end of the nineteenth century, the term hysteria was commonly used to describe mental disorders characterized by altered states of consciousness (for example, sleepwalking or trance states) or physical symptoms (for example, a “paralyzed” arm or leg with no neurologic cause) that could not be fully explained by a medical disease. The term dissociation was used for the psychological mechanism that allows the mind to split off uncomfortable feelings, memories, or ideas so that they are lost to conscious recall. Sigmund Freud and other pioneering psychoanalysts thought that the hysterical patient’s symptoms resulted from dissociated thoughts or memories reemerging through bodily functions or trance states. Prior to the fourth edition of *DSM* in 1980, all mental disorders that were considered to be forms of hysteria were grouped together on the basis of this theory about their cause.

Since 1980, however, the somatoform disorders and the so-called dissociative disorders have been placed in separate categories on the basis of their chief symptoms. In general, the somatoform disorders are characterized by disturbances in the patient’s physical sensations or ability to move the limbs or walk, while the dissociative disorders are marked by disturbances in the patient’s sense of identity or **memory**.

Somatization disorder

Somatization disorder was formerly called Briquet’s syndrome, after the French physician who first recognized it. Z. J. Lipowski defined somatization in the *American Journal of Psychiatry* as “the tendency to experience and communicate somatic distress and symptoms not accounted for by pathologic findings, to attribute them to physical illness and to seek medical help for them.”

Somatization disorder typically begins before the age of 30. It is estimated that worldwide, between 0.2% and 2% of the population will develop this disorder in their lifetime. In the United States, it is nearly twice as common in women, but in other cultures, it is believed to be more widespread in men. Some psychiatrists think that the high female-to-male ratio in this disorder in North America reflects the cultural pressures on women and the social expectation that women are generally physically weak or sickly. It is also likely to run in families. As many as 20% of the mothers, sisters, or daughters of somatization disorder patients have the same illness. Their male first-degree relatives are more apt to have anti-social personality disorder or addiction problems. When asked to self-assess health, somatization disorder patients usually rate their well-being as worse than people suffering from actual long-term illness do. Physical complaints normally develop or increase during times of **stress**, and though these people look for help frequently, it is highly unusual for them to find relief.

Undifferentiated somatoform disorder

Undifferentiated somatoform disorder is generally less specific than somatization disorder, and requires only the presence of one symptom to be consistently present. But patients suffering from undifferentiated somatoform disorder often complain of fatigue, loss of appetite, or difficulty swallowing. Symptoms commonly develop when the person is under stress or is depressed, and to meet *DSM-IV* criteria, must have no physical basis and remain for more than six months.

Conversion disorder

In conversion disorders, people typically report a loss or change in the function of some part of their body that does not correlate with what medical science knows today of anatomy or physiology. Symptoms are often neurological in nature, such as seizures that are not seen on EEG, or an inability to move an arm or leg, or walk. The disorder gets its name from the notion that the patient is converting a psychological conflict or problem into an inability to move specific parts of the body or to use the senses normally. An example of a conversion reaction would be a patient who loses his or her voice in a situation in which he or she is afraid to speak. The symptom simultaneously contains the **anxiety** and serves to get the patient out of the threatening situation. The resolution of the emotion that underlies the physical symptom is called the patient's primary gain, and the change in the patient's social, occupational, or family situation that results from the symptom is called a secondary gain. Doctors sometimes use these terms when they discuss the aftereffects of conversion disorder or of other somatoform disorders on the patient's emotional adjustment and lifestyle.

Unlike somatization disorder, the symptoms of conversion disorder typically occur in adolescence or early adulthood, when the person is under extreme stress. It does not appear to run in families. It is estimated that as many as one in four people admitted to a general hospital have experienced conversion symptoms, but that the disorder is more likely to occur among less educated or sophisticated people. Females are at least twice as likely to develop conversion disorder symptoms, and men are more likely to develop such symptoms in occupational settings or military service.

Pain disorder

Pain disorder is marked by the experience of severe pain in the absence of physical cause for the pain, or markedly unwarranted complaint of pain from an actual illness. *DSM-IV* requirements include duration of a minimum of six months, a curtailment of normal activities such as work or school, and relationship problems. Prescription drug dependency often accompanies somatoform pain disorder, but drug-seeking does not cause it. Somatoform pain disorder is not deliberately put on. This category of somatoform disorder covers a range of patients with a variety of ailments, including chronic headaches, back problems, arthritis, muscle aches and cramps, or pelvic pain. In some cases the patient's pain appears to be largely due to psychological factors, but in other cases the pain is derived from a medical condition as well.

Pain disorder is frequently accompanied by what are termed the Five D's. These are:

- depressed mood
- disturbed sleep pattern
- dysfunction in social situations
- decreased activity level
- decreased physical activity

Because pain is such an individual experience, the incidence of somatoform pain disorder is unclear. It is known that between 10–15% of all of the population that suffer from back pain eventually become work-disabled. What percent of these people suffer from somatoform pain disorder is unclear.

Hypochondriasis

Hypochondriasis is a somatoform disorder marked by excessive fear of or preoccupation with having a serious illness that persists in spite of medical testing and reassurance. It was formerly called hypochondriacal neurosis.

Although hypochondriasis is usually considered a disorder of young adults, it is now increasingly recognized in children and adolescents. It may also develop in elderly people without previous histories of health-related fears. The disorder accounts for about 5% of psychiatric patients, and is equally common in men and women. Patients typically are abnormally attentive to normal bodily functions such as heartbeat or perspiring. *DSM-IV* criteria include the presence of unrealistic fears or beliefs for at least six months. During any six month period, between 4% and 6% of the population suffers from hypochondria. Episodes can last anywhere from months to years, and it is a persistent, relapsing condition. Chronic stress is believed to play a large role in its occurrence.

Body dysmorphic disorder

Body dysmorphic disorder is a new category in *DSM-IV*. It is defined as a preoccupation with an imagined or exaggerated defect in appearance. Most cases involve features on the patient's face or head, but other body parts—especially those associated with sexual attractiveness, such as the breasts or genitals—may also be the focus of concern. Patients with this disorder are often found in plastic surgery clinics. They frequently have histories of seeking or obtaining plastic surgery or other procedures to repair or treat supposed defects, but it seldom if ever provides them with long-term relief.

Though the average age of body dysmorphic disorder patients is thirty, it is regarded as a chronic condition that usually begins in the patient's late teens and fluctu-

ates over the course of time. It was initially considered to be a relatively unusual disorder, but it is now estimated that two percent of those seeking plastic surgery may be dysmorphic disorder patients. It appears to affect men and women with equal frequency. Some may even meet the criteria for a delusional disorder of the somatic type.

Somatoform disorders in children and adolescents

In children and adolescents, the most common somatoform disorder is conversion disorder, though body dysmorphic disorders are being reported more frequently. Conversion reactions in this age group usually reflect stress in the family or problems with school, rather than long-term psychiatric disturbances. Some psychiatrists speculate that adolescents with conversion disorders frequently have overprotective or over-involved parents with a subconscious need to see their child as sick. In many cases the son or daughter's symptoms become the center of family attention. The rise in incidence of body dysmorphic disorder in adolescents is thought to reflect the increased influence of media preoccupation with physical perfection.

Causes and symptoms

In somatoform disorders, the patient's reported symptoms are considered to be the unconscious manifestation of very real emotional suffering. In classic psychoanalytic theories, unconscious conflicts are the result of painful early-life events that are re-awakened in adult life by similar stressors. Because the person is unable to express the re-awakened emotion because of fear or guilt, their emotions are repressed and changed into physical symptoms.

Because *DSM-IV* groups the somatoform disorders into their present category on the basis of symptom patterns, their causes as presently understood include several different factors.

Family stress

Family stress is believed to be one of the most common causes of somatoform disorders in children and adolescents. Conversion disorders in this age group may also be connected with physical or sexual abuse within the family of origin.

Parental modeling

Somatization disorder and hypochondriasis may result in part from the patient's unconscious reflection or imitation of parental behaviors. This "copycat" behavior is particularly likely if the patient's parent derived considerable secondary gain from his or her symptoms.

Cultural influences

Cultural influences appear to affect the gender ratios and body locations of somatoform disorders, as well as their frequency in a specific population. Some cultures (for example, Greek and Puerto Rican) report higher rates of somatization disorder among men than is the case for the United States. In addition, researchers found lower levels of somatization disorder among people with higher levels of education. People in Asia and Africa are more likely to report certain types of physical sensations (for example, burning hands or feet, or the feeling of ants crawling under the skin) than are Westerners.

Biological factors

Genetic or biological factors may also play a role. For example, people who suffer from somatization disorder may also differ in how they perceive and process pain.

Diagnosis

Accurate diagnosis of somatoform disorders is important to prevent unnecessary surgery, laboratory tests, or other treatments or procedures. But it is equally important for physicians and all healthcare staff to carefully evaluate the person to assure that an actual physical cause for the somatoform-appearing symptom is not being missed. Diagnosis of somatoform disorders requires a thorough physical workup. Pain disorder patients have, on occasion, later been discovered to actually have **cancer**, and a detailed examination is especially necessary when conversion disorder is a possible diagnosis, because some neurological conditions, including **multiple sclerosis** and myasthenia gravis, have been misdiagnosed as conversion disorder. Some patients who receive a diagnosis of somatoform disorder ultimately go on to develop neurologic disorders.

In addition to ruling out medical causes for the patient's symptoms, a doctor who is evaluating a patient for a somatization disorder will consider the possibility of other psychiatric diagnoses or of overlapping psychiatric disorders. Somatoform disorders often coexist with **personality disorders** because of the chicken-and-egg relationship between physical illness and certain types of character structure or personality traits. At one time, the influence of Freud's theory of hysteria led doctors to assume that the patient's hidden emotional needs cause the illness. But in many instances, the patient's personality may have changed over time due to the stresses of adjusting to a chronic disease. This gradual transformation is particularly likely in patients with pain disorder. Patients with somatization disorder often develop panic

attacks or agoraphobia together with their physical symptoms. In addition to anxiety or personality disorders, the doctor will usually consider major depression as a possible diagnosis when evaluating a patient with symptoms of a somatoform disorder. Pain disorders may be associated with depression, and body dysmorphic disorder may be associated with obsessive-compulsive disorder.

Treatment

Psychiatric therapies

Patients with somatoform disorders are not considered good candidates for psychoanalysis or other forms of insight-oriented **psychotherapy**. They can benefit, however, from supportive approaches aimed at symptom reduction and stabilization of the patient's personality. Some patients with pain disorder benefit from group therapy or support groups, particularly if their social network has been limited by their pain symptoms. Cognitive-behavioral therapy is also used sometimes to treat pain disorder.

Family therapy is usually recommended for children or adolescents with somatoform disorders, particularly if the parents seem to be using the child as a focus to divert attention from other difficulties. Working with families of chronic pain patients also helps avoid reinforcing dependency within the family setting.

Medications

Patients with somatoform disorders are sometimes given anti-anxiety drugs or **antidepressant drugs** if they have been diagnosed with a coexisting mood or anxiety disorder. In general, though, it is considered better practice to avoid prescribing medications for these patients since they run the risk of becoming psychologically dependent on them.

Hypnosis is a time-honored technique used since Freud's time as part of a general psychotherapeutic approach to conversion disorder. It may allow patients to recover memories or thoughts connected with the onset of the physical symptoms.

Alternative treatment

Patients with somatization or pain disorders may be helped by a variety of alternative therapies including acupuncture, **hydrotherapy**, therapeutic massage, **yoga**, **meditation**, botanical medicine, and homeopathic treatment. These are often available through both pain and stress reduction clinics that many general hospitals now have.

Prognosis

Somatization disorder is considered to be a chronic disturbance that tends to persist throughout the patient's life, but a recent three year follow-up study reported in *Caring For The Mind: The Comprehensive Guide to Mental Health* showed that a consistent approach using education and reassurance resulted in noticeable improvement.

The prognosis for conversion disorder is considered to be good. Ninety percent of patients recover within a month, and only one in five will ever have a recurrence.

People suffering from hypochondriasis have a more optimistic outlook if treatment is initiated early, before they have gotten themselves into a cycle of medical tests and procedures. There has been very little research regarding the effectiveness of treatment in body dysmorphic disorder.

Health care team roles

In many cases a somatoform disorder diagnosis is made in a general medical clinic by a primary care practitioner, rather than by a psychiatrist. Children and adolescents with somatoform disorders are most likely to be diagnosed by their primary care physician, or pediatrician.

Primary care practitioner (PCP)

A PCP is typically a licensed medical doctor. Because somatoform disorders are associated with physical symptoms, patients are much more apt to be seen by primary care physicians. Their lengthy medical histories make a long-term relationship with a trusted PCP a safeguard against unnecessary treatments as well as being a comfort to the patient. Many PCPs prefer to schedule brief appointments on a regular basis with the patient and keep referrals to specialists to a minimum. This practice also allows them to monitor the patient for any new physical symptoms or diseases. However, some PCPs work with a psychiatric consultant.

Psychiatrist

Psychiatrists are licensed medical doctors that have undergone a three year psychiatric residency. They are often the providers of both education and support for patients with somatoform disorders.

Registered nurse (RN), psychiatric nurse, or licensed practical nurse (LPN)

Both RNs and LPNs must complete a prescribed course in nursing and pass a state examination. RNs typ-

KEY TERMS

Briquet's syndrome—Another name for somatization disorder.

Conversion disorder—A somatoform disorder characterized by the transformation of a psychological feeling or impulse into a physical symptom. Conversion disorder was previously called hysterical neurosis, conversion type.

CT scan—Computerized Tomography Scanning. A diagnostic technique in which the combined use of a computer and x rays passed through the body at different angles produces clear, cross-sectional images.

Dissociation—A psychological mechanism in which the mind splits off certain aspects of a traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity.

Hysteria—The earliest term for a psychoneurotic disturbance marked by emotional outbursts and/or disturbances of movement and sense perception. Some forms of hysteria are now classified as somatoform disorders and others are grouped with the dissociative disorders.

Hysterical neurosis—An older term for conversion disorder or dissociative disorder.

MRI—Magnetic Resonance Imaging. A diagnostic technique that provides very clear cross-sectional images of organs and structures in the human body without x rays or other radiation.

Primary gain—The immediate relief from guilt, anxiety, or other unpleasant feelings that a patient derives from a symptom.

Repression—A unconscious psychological mechanism in which painful or unacceptable ideas, memories, or feelings are removed from conscious awareness or recall.

Secondary gain—The social, occupational, or interpersonal advantages that a patient derives from symptoms. A patient's being relieved of his or her share of household chores by other family members would be an example of secondary gain.

Somatoform disorder—A category of psychiatric disorder characterized by physical complaints that appear to be medical in origin but that cannot be explained in terms of a physical disease, the results of substance abuse, or by another mental disorder.

Stressor—Any interference that disturbs a person's healthy mental and physical well-being.

ically have a degree in nursing, and psychiatric nurses have additional training specific to psychiatry. Both RNs and LPNs are often the people who deal the most with patients with somatoform disorders in general hospitals, clinics and on psychiatric units. An open mind and non-judgmental attitude toward the patient and careful, detailed observation of symptoms can be highly useful. The provision of education about the nature of these illnesses will typically come from both physicians and nurses.

Clinical laboratory scientist

Clinical laboratory scientists have specialized training and must pass a state examination. They draw **blood** samples or test urine or other specimens that are ordered by the physician to help in making a correct diagnosis.

Radiologic technologist

Radiologic technologists have specialized training and must pass a state examination. They take x rays or

other imaging such as MRIs or **CT scans** that are ordered by the physician to help in making a correct diagnosis.

Social workers

Social workers are usually either certified (CSW) or licensed clinical social workers (LCSW). A two-year graduate program degree and specialized training including supervised clinical work in working with the mentally ill, and state licensure are typical requirements. Social workers often conduct supportive groups or programs that help people vent feelings or work on ways to better be able to cope.

Specialized therapists

Stress reduction therapists are a good example of this category. They are not necessarily licensed in all states, but typically have a degree in one of the human service fields such as social work, psychology or nursing. They are often certified in a specific stress reduction program such as the now-nationwide one that was developed

at University of Massachusetts Medical Center by Dr. Jon Kabat-Zinn. Most of these stress reduction programs incorporate standard supportive group therapy techniques with alternative medicine areas such as yoga and meditation.

Prevention

Generalizations regarding prevention of somatoform disorders are difficult because these syndromes affect different age groups, vary in their symptom patterns and persistence, and result from different problems of adjustment to the surrounding culture. In theory, allowing expression of emotional pain in children, rather than regarding it as a weakness, might reduce the secondary gain of physical symptoms that draw the care or attention of parents.

Sore throat

Definition

Sore throat is an upper respiratory **infection** that may be caused by inflammation of the pharynx, larynx,

or tonsils. Thus, it is a symptom of many conditions, but most often is associated with **common cold** or **influenza**. Sore throat may be caused by either a virus or **bacteria** in addition to certain environmental conditions. Most sore throats heal without complications, but they should not be ignored because some develop into serious illnesses.

Description

Almost everyone gets a sore throat at one time or another. Sore throat and cold are more prevalent among children in daycare centers or schools and seem to be related to their lack of resistance as compared to the adolescents and adults. It is interesting to note that women in the age of 20–30 are affected by more cold attacks than men, which may be attributed to their contact with children. Sore throats are most common during the winter months when upper respiratory infections (colds) are more frequent. The National Center for Health Statistics has estimated that common cold symptoms (which include sore throat) amounted to 62 million cases, in 1996, that needed medical attention.

Sore throats can be either acute or chronic. Acute sore throats are more common. They last from three to seven days. A chronic sore throat lasts much longer and is a symptom of an unresolved underlying condition or disease, such as a sinus infection.

Causes and symptoms

Sore throats have many different causes, and may or may not be accompanied by cold symptoms, **fever**, or swollen lymph glands. Proper treatment depends on understanding the cause of the sore throat.

Viral sore throat

Viruses cause 90-95% of all sore throats. Cold and flu viruses are the main culprits although about 200 different viruses are known to cause the symptoms of sore throat. Rhinoviruses cause 30-35% of all adult colds in fall, spring, and summer. Coronaviruses cause the infections in winter and spring. These viruses cause an inflammation in the throat and occasionally the tonsils (tonsillitis). The causative agents of viral tonsillitis are Epstein-Barr virus, influenza virus, enterovirus, or adenoviruses. Cold symptoms almost always accompany a viral sore throat. These can include a runny nose, cough, congestion, hoarseness, conjunctivitis, and fever. The level of throat **pain** varies from uncomfortable to excruciating, when it is painful for the patient to eat, breathe, swallow, or speak.

Another group of viruses that cause sore throat are the adenoviruses. These may also cause infections of the **lungs** and ears. In addition to a sore throat, symptoms that accompany an adenovirus infection include cough, runny nose, white bumps on the tonsils and throat, mild **diarrhea**, vomiting, and a rash. The sore throat lasts about one week.

A third type of virus that can cause severe sore throat is the coxsackie virus. It can cause a disease called herpangina. Although anyone can get herpangina, it is most common in children up to age ten and is more prevalent in the summer or early autumn. Herpangina is sometimes called summer sore throat.

Three to six days after being exposed to the virus, an infected person develops a sudden sore throat that is accompanied by a substantial fever usually between 102-104°F (38.9-40°C). Tiny grayish-white blisters form on the throat that turn into ulcerative lesions. Throat pain is often severe, interfering with swallowing. Children may become dehydrated if they are reluctant to eat or drink because of the pain. In addition, people with herpangina may vomit, have abdominal pain, and generally feel ill and miserable.

One other common cause of a viral sore throat is mononucleosis. An estimated 90% of mononucleosis cases are caused by the Epstein-Barr virus (EBV), while the remaining cases may be attributed to the cytomegalovirus. EBV is known to infect B lymphocytes (a subset of white **blood** cells). The infection spreads to the **lymphatic system, respiratory system, liver, spleen, throat** and salivary glands. Symptoms appear 30-50 days after exposure.

Mononucleosis, sometimes called the “kissing disease,” is extremely common. It is estimated that by the age of 35-40, 80-95% of Americans will have had mononucleosis. Often, symptoms are mild, especially in young children, and are diagnosed as a cold. Since symptoms are more severe in adolescents and adults, more cases are diagnosed as mononucleosis in this age group. One of the main symptoms of mononucleosis is severe sore throat.

Although a runny nose and cough are much more likely to accompany a sore throat caused by a virus than one caused by a bacteria, there is no absolute way to tell what is causing the sore throat without a laboratory test. Viral sore throats are contagious and are passed directly from person to person by coughing and sneezing.

Bacterial sore throat

About 5-10% of sore throats are caused by bacteria. The most common bacterial sore throat results from an infection by group A *Streptococcus*. This type of infec-

tion is commonly called **strep throat**. Anyone can get strep throat. This organism may also cause laryngitis, which is predominantly marked by hoarseness of voice, sore throat, dry and persistent cough, and fever. Yet another ailment caused by *Streptococcus* is pharyngitis, which is inflammation of pharynx leading to fever, tenderness in the neck glands, sore throat, abdominal pain, headache, cough, hoarseness, and skin rash. Other bacteria that are known to cause pharyngitis are groups C and G *Streptococcus*, *Yersinia enterocolitica*, and rarely *Corynebacterium diphtheriae*. Untreated streptococcal pharyngitis may lead to peritonsillar **abscess** that is accompanied by severe sore throat and hoarseness of voice. In these cases, immediate intervention by otolaryngologists is required to aspirate the abscess.

Pharyngeal gonorrhea, a sexually transmitted bacterial disease, causes severe sore throat. Gonorrhea in the throat is transmitted by having oral sex with an infected person.

Noninfectious sore throat

Not all sore throats are caused by infection. Postnasal drip can irritate the throat and make it sore. It can be caused by hay fever and other **allergies** that are irritating to the sinuses. Environmental and other conditions, such as heavy smoking or breathing secondhand smoke, heavy alcohol consumption, breathing polluted air or chemical fumes, or swallowing substances that burn or scratch the throat can also cause pharyngitis. Dry air, like that in airplanes or from forced hot air furnaces, can make the throat sore. People who breathe through their mouths at night because of nasal congestion often get sore throats that improve as the day progresses. Sore throat caused by environmental conditions is not contagious.

Diagnosis

It is easy for people to tell if they have a sore throat, but difficult to know what has caused it without laboratory tests. Most sore throats are minor and heal without any complications. A small number of bacterial sore throats do develop into serious diseases. Because of this, it is advisable to see a doctor if a sore throat lasts more than a few days or is accompanied by fever, nausea, or abdominal pain.

Diagnosis of a sore throat begins with a **physical examination** of the throat and chest. The examiner will also look for signs of other illness, such as a sinus infection or bronchitis. Since both bacterial and viral sore throat are contagious and pass easily from person to person, the health care provider will seek information about whether the patient has been around other people with

flu, sore throat, colds, or strep throat. If it appears that the patient may have strep throat, laboratory Tests will be performed.

If mononucleosis is suspected, the doctor may do a mono spot test to look for antibodies indicating the presence of the Epstein-Barr virus. The test is inexpensive, takes only a few minutes, and can be done in a physician's office. An inexpensive blood test can also determine increased lymphocytes and the presence of specific antibodies to the mononucleosis virus.

Treatment

Effective treatment varies depending on the cause of the sore throat. As frustrating as it may be to the patient, viral sore throat is best left to run its course without drug treatment. **Antibiotics** are ineffective against viruses. They do not shorten the length of the illness, nor do they lessen the symptoms.

Sore throat caused by a streptococci or another bacteria must be treated with antibiotics. Penicillin is the preferred medication. Oral penicillin must be taken for ten days. Patients need to take the entire course of antibiotic prescribed, even after symptoms of the sore throat improve. Incomplete treatment may lead to the relapse of the symptoms. Occasionally a single **intramuscular injection** of long-acting penicillin G is administered instead of ten days of oral treatment. In cases of penicillin allergy, cephalexin, cefuroxime, or cefprozil are the preferred alternative antibiotics that are recommended. These medications generally cost under fifteen dollars.

Mononucleosis, being a viral infection, is self-limiting with no means of therapeutic control. Rest, a healthy diet, plenty of fluids, avoiding strenuous exercises and competitive sports are recommended. The acute phase of infection is treated with acetaminophen (Datril, Tylenol, Panadol) or ibuprofen (Advil, Nuprin, Motrin, Medipren). Nearly 90% of mononucleosis infections are mild. The infected person does not normally get the disease again.

In the case of chronic sore throat, it is necessary to treat the underlying disease to heal the sore throat. If sore throat is caused by environmental factors, the aggravating stimulus should be eliminated from the sufferer's environment.

Home care for sore throat

Regardless of the cause of a sore throat, there are some **home care** steps that can be taken to ease discomfort. These include:

- Taking acetaminophen or ibuprofen for pain. Aspirin should not be given to children because of its associa-

tion with increased risk for Reye's syndrome, a serious disease.

- Gargling with warm double strength tea or warm salt water made by adding one teaspoon of salt to eight ounces of water.
- Drinking plenty of fluids, but avoiding acid juices like orange juice, which can irritate the throat. Sucking on popsicles is a good way to get fluids into children.
- Eating soft, nutritious foods like noodle soup and avoiding spicy foods.
- Refraining from smoking.
- Resting until the fever is gone, then resuming strenuous activities gradually.
- Often minimizing the dryness by using room humidifier may improve the symptoms of sore throat, especially in pediatric population.
- Antiseptic lozenges and sprays may aggravate the sore throat rather than improve it.

Alternative treatment

Alternative treatment focuses on easing the symptoms of sore throat using herbs and botanical medicines.

- Aromatherapists recommend inhaling the fragrances of essential oils of lavender (*Lavandula officinalis*), thyme (*Thymus vulgaris*), eucalyptus (*Eucalyptus globulus*), sage (*Salvia officinalis*), and sandalwood.
- Ayurvedic practitioners suggest gargling with a mixture of water, salt, and turmeric (*Curcuma longa*) powder or astringents such as alum, sumac, sage, and bayberry (*Myrica* spp.).
- Herbalists recommend taking osha root (*Ligusticum porteri*) internally for infection or drinking ginger (*Zingiber officinale*), slippery elm (*Ulmus fulva*), sage or marshmallow tea for pain. Also fresh juice of *Echinacea* along with the root of goldenseal may have a soothing effect on the throat. The tannins found in blueberries, blackberries and red raspberries have also been shown to be effective for sore throats
- Homeopaths may treat sore throats with superdilute solutions of *Lachesis*, *Belladonna*, *Phytolacca*, or yellow jasmine (*Gelsemium*).
- Nutritional recommendations include **zinc** lozenges every two hours along with **vitamin C** with bioflavonoids, **vitamin A**, and beta-carotene supplements.

KEY TERMS

Antigen—A foreign protein to which the body reacts by making antibodies.

Conjunctivitis—An inflammation of the membrane surrounding the eye; also known as pink-eye.

Lymphocyte—A type of white blood cell. Lymphocytes play an important role in fighting disease.

Pharynx—The pharynx is the part of the throat that lies between the mouth and the larynx or voice box.

Tonsils—Fleshy tissues located on either side of the back of the throat.

Toxin—A poison. In the case of scarlet fever, the toxin is secreted as a byproduct of the growth of the streptococcus bacteria and causes a rash.

Prognosis

Sore throat caused by a viral infection generally clears up on its own within one week with no complications. The exception is mononucleosis. Ninety percent of cases of mononucleosis clear up without medical intervention or complications, so long as **dehydration** does not occur. In young children the symptoms may last only a week, but in adolescents the symptoms last longer. Adults over age 30 have the most severe and long lasting symptoms. Adults may take up to six months to recover. In all age groups fatigue and weakness may continue for up to six weeks after other symptoms disappear.

In rare cases of mononucleosis, breathing may be obstructed because of swollen tonsils, adenoids, and lymph glands. If this happens, the patient should immediately seek emergency medical care.

Patients with bacterial sore throat begin feeling better about 24 hours after starting antibiotics. If left untreated strep throat may lead to scarlet fever, rheumatic fever resulting in rheumatic **heart** disease or glomerulonephritis. Scarlet fever is a combination of sore throat with rash of sand paper consistency that may appear in the lower abdomen and gradually spread to the trunk. Rheumatic fever is marked by inflammation and pain in the joints. In severe cases, inflammation of the heart valves can lead to **heart failure**. Glomerulonephritis is inflammation of glomeruli that serve as filters in the kidney. The damaged filters result in red urine due to the release of red blood cells. The treatment for this disorder is aimed at control-

ling the symptoms. Taking antibiotics within the first week of a strep infection will prevent these complications. People with strep throat remain contagious until after they have been taking antibiotics for 24 hours.

Health care team roles

Sore throat may not always need medical intervention, but persistent sore throats and accompanying symptoms should not be ignored. A general physician helps in determining whether the sore throat is a result of a viral or bacterial infection. A thorough physical examination followed by laboratory tests in cases of a doubtful bacterial infection is performed. If a bacterial sore throat is diagnosed by the physician, antibiotics are prescribed. Health care professionals, including the pharmacists, play a key role in cautioning the patient regarding the potential allergic reactions associated with the intake of antibiotics. Some of these reactions may be serious and need immediate medical intervention.

There may be lingering symptoms or changes in the symptoms after visiting the doctor. Some of the concerns will be:

- persistent fever
- continuing and severe sore throat
- discomfort in opening the mouth wide
- dizziness

In such cases, a doctor's advice is highly recommended. In addition, health care professionals will provide the best resources for **nutrition**, suggestions for pain relievers and effective home remedies for viral sore throats.

Prevention

There is no way to prevent a sore throat; however, the risk of getting one or passing one on to another person can be minimized by:

- Washing hands well and frequently.
- Avoiding close contact with someone who has a sore throat.
- Not sharing food and eating utensils with anyone.
- Cleaning the environmental surfaces with a disinfectant.
- Not smoking.
- Avoiding polluted air.
- Using a room humidifier at home during the winter months when the dryness is maximum.

- Avoiding exposures to sudden and frequent changes in temperatures (in winter, being exposed to severe cold outside and heated room within the home).

Speech disorders

Definition

A speech disorder is a communication disorder characterized by an impaired ability to produce speech sounds or normal voice, or to speak fluently.

Description

Speech disorders belong to a broad category of disorders called communication disorders that also include language and **hearing** disorders. Communication disorders affect one person out of every ten in the United States. Speech disorders refer to difficulties producing speech sounds or problems with voice quality. They may be characterized by an interruption in the flow or rhythm of speech such as **stuttering**, or by problems with the way sounds are formed, also called articulation or phonological disorders, or they may involve voice problems such as pitch, intensity, or quality. Often, there is a combination of several different problems.

Speech disorders can either be present at birth or acquired as a result of stroke, **head injury**, or illness. The production of intelligible speech is the result of very complex interactions originating in the **brain**. When the brain sends a series of speech signals to the speech muscles, the muscles need to produce the series of sounds that will convey the intended message. Major speech disorders that can impair this process include:

- **Articulation disorders:** Articulation is the production of speech sounds, and persons affected by articulation disorders experience difficulty in being understood because they produce incorrect speech sounds. As a result, their speech is not intelligible. They may substitute one sound for another or may distort the sound with the result that it sounds incorrect, even though still recognizable, or omit one or more sounds in a word.
- **Phonological disorders:** Phonology is the science of speech sounds and sound patterns and of the language rules that dictate how sounds may be combined to produce language. Persons affected by phonological disorders do not use the conventional rules for their native language but substitute their own variants. This affects classes of sounds, as opposed to single sounds. Sounds are characterized by where in the mouth they are produced, how they are produced, and by how the larynx (voice box) is used. Any unusual deviation in these features is called a phonological process. Fronting and backing are examples of phonological processes, characterized by the production of sounds at the front or at the back of the mouth when they should be produced the other way around. For example, the word "go," produced at the back of the mouth, might be used instead of "doe," which is produced in the front.
- **Stuttering:** Normal speech is fluent, in that it is spoken effortlessly and without hesitation. A break in fluent speech is called a dysfluency. Although some degree of dysfluency occurs in normal speech from time to time, stuttering has more dysfluencies than is considered average. Normally developing preschool children often demonstrate dysfluencies that are effortless and last for brief periods of time. However, changes in the types of dysfluency behavior and the frequency of occurrence may signal the development of a problem. Normal dysfluencies consist of word or sentence repetitions, fillers ("um," "ah"), or interjections. Stuttering behavior includes sound or syllable repetition, prolongations (the unnatural stretching out of sounds), and blocks, which refers to an inability to produce the sound, as if it gets stuck and cannot come out. Stuttering dysfluencies are also often accompanied by tension and anxiety.
- **Voice disorders:** There are two types of voice disorders: organic voice and functional voice disorders.

Organic voice disorders are associated with disease and require medical intervention. Functional voice disorders are the result of abuse or misuse of the larynx. Sounds are produced when the vocal cords of the throat come close together and vibrate with air coming from the **lungs**. These vibrations produce a series of pulses that then cause the air to resonate and produce voice sounds. People have unique voice characteristics and it is therefore difficult to define a normal voice. Generally speaking, a normal voice is pleasant sounding and has appropriate pitch and loudness for the age and gender of the speaker. A voice disorder is therefore present when the voice is not pleasant sounding, or when it is too loud or too soft or too high-pitched or low-pitched for the speaker's gender.

- **Apraxia:** This is a speech disorder in which voluntary muscle movement is impaired without muscle weakness. There are two main types of apraxias: buccofacial apraxia and verbal apraxia. Buccofacial apraxia impairs the ability to move the muscles of the mouth for non-speech purposes such as coughing, swallowing, and wiggling of the tongue. Verbal apraxia impairs the proper sequencing of speech sounds. Apraxias can either be acquired or developmental and have different degrees of severity, ranging from the inability to initiate speech to mild difficulties with the pronunciation of multi-syllabic words.
- **Dysarthria:** This is a speech disorder that affects the muscles involved in the production of speech. As a result, speech is slow, weak, inaccurate, and hesitant. The production of clear speech requires that several muscle systems work together. First, the lungs must provide the air required to activate speech. Then, the larynx must allow the air to vibrate. The soft palate that separates the oral and nasal cavities must also direct the air to one or both cavities to produce the different sounds. Finally, the lips, tongue, teeth, and jaw then must all move in a concerted way to shape the sounds into the various vowels, consonants, and syllables that make up the sounds of language. Dysarthria results from a weakness in any one of these elements or in the absence of proper coordination between them. If, for example, the lungs are weak, then speech will be too quiet or produced one word at a time. Childhood dysarthria can be present at birth or acquired as a result of disease or accident, as is the case for adult dysarthria.

Causes and symptoms

The causes of articulation and phonological disorders are unclear, although it has been observed that they tend to develop in children before age four and run in

families. The symptoms vary, depending on whether other disorders are present, but typically involve difficulty in making specific speech sounds. Articulation is considered a disorder when it is unintelligible or draws negative attention to the speaker. For example, the word "super" is pronounced as "thuper."

The causes of stuttering are not very well understood. There is some evidence that stuttering has a genetic cause since it has been observed to run in some families. According to the National Stuttering Association (NSA), current research suggests a connection between stuttering and the brain's ability to coordinate speech. The major symptom of stuttering, found in preschoolers but not adults, is persistent dysfluency of language that exceeds 10%.

The main causes of organic voice disorders include neuromuscular disorder, **cancer**, vocal cord **paralysis**, endocrine changes, various benign tumors such as inflammatory growths (granulomas), or consisting of a mass of **blood vessels** (hemangiomas) or occurring on mucous membranes (papillomas). Functional voice disorders are caused by abuse or misuse of the larynx. Misuse of the voice includes talking for excessively long periods of time or yelling. Abuse occurs as a result of excessive throat clearing, laughing, crying, coughing, or smoking. Both abuse and misuse of the voice can damage the vocal cords, or may result in nodules, polyps, contact ulcers, or **edema**.

Acquired apraxias occur as a result of brain damage and can often be linked to specific lesion sites on the brain. They can result from stroke, head injury, brain tumors, toxins, or infections. In the case of developmental apraxia of speech (DAS), it is usually present at birth. There are no specific lesion sites in the brain associated with DAS, and no direct cause has been identified. However, since young children only use a few words, it has been proposed that delays in language expression can impair a child's ability to gain control over the speech muscles.

Childhood dysarthria can be present at birth or acquired with diseases such as **cerebral palsy**, Duchenne **muscular dystrophy**, or myotonic dystrophy. Adult dysarthria may be caused by stroke, degenerative diseases such as Parkinson's or Huntington's disease, amyotrophic lateral sclerosis, **multiple sclerosis**, myasthenia gravis, **meningitis**, brain tumors, toxins, drug or alcohol abuse, or lead **poisoning**.

Diagnosis

Speech disorders are usually identified using a combination of hearing tests and physical exams. Physicians

then recommend specialized evaluation by speech-language pathologists, who can best establish an accurate diagnosis.

A stuttering diagnosis is established on the basis of the type, frequency, and duration of speech dysfluency. The number of dysfluencies occurring in 100 words is counted to determine the dysfluency percentage. One half a stuttered word per minute is the usual criterion. Determining the type of stuttering behavior, either overt or covert, is the most important factor in diagnosing stuttering.

Organic and functional voice disorders are diagnosed with the assistance of an ear, nose, and throat specialist, a otolaryngologist, who can identify the organic cause of the voice disorder, if present. Several tests can be used to screen for possible tumors in the throat or laryngeal box area. Only in the absence of an organic cause will the voice disorder be diagnosed as functional, indicating that it is due to abuse or misuse of the voice.

A diagnosis of apraxia is not easy to establish but is usually indicated when children do not develop speech normally and are unable to produce consonant sounds.

Treatment

Speech pathologists have designed approaches for treating speech disorders with the type of treatment depending upon the type of impairment. A wide variety of treatment techniques are available for treating affected children, adolescents, and adults. A thorough assessment is normally conducted with the aim of determining the most effective and acceptable treatment approach for each disorder on an individual basis. A common treatment for many patients involves increasing sensory motor awareness of selected aspects of speech and systematically shaping the target speech behaviors.

Treatment for articulation/phonological disorders is usually based on increasing the affected person's awareness about how speech sounds make the meaning of words different. As a result, therapy often involves pronunciation exercises designed to teach how to produce sounds and words more clearly to increase understanding of the differences between the various speech sounds and words.

Treatment plans for stuttering depend on the severity of the dysfluency and may include seeing a speech-language pathologist. Most treatment plans include breathing techniques, **relaxation** strategies to help relax speech-associated muscles, posture control, and other exercises designed to help develop fluency.

Speech-language pathologists use many different approaches to treat voice problems. Functional voice dis-

orders can often be successfully treated by voice therapy. Voice therapy involves identifying voice abuses and misuses and designing a course of treatment aimed at eliminating them. Voice disorders may require surgery if cancer is present.

Treatment of apraxia depends on the extent of the impairment. For individuals diagnosed with moderate to severe apraxia, therapy may be for them to start saying individual sounds and contrasting them, thinking about how the lips and tongue should be placed. Other specialized drills use the natural rhythm of speech to increase understanding. Individuals affected with mild apraxia are taught strategies to help them produce the words that give them difficulty. Several treatment programs have been developed for developmental apraxias. Some feature the use of touching cues, others modify traditional articulation therapies.

Treatment of dysarthria usually aims at maximizing the function of all speech systems with the use of compensatory strategies. Patients may be advised to take frequent pauses for breath, or to exaggerate articulation, or to pause before important words to emphasize them. If there is muscle weakness, oro-facial exercises may also be prescribed to strengthen the muscles of the face and mouth that are used for speech.

Prognosis

The prognosis depends on the cause of the disorder; many speech disorders can be improved with speech therapy. In the case of childhood speech disorders, prognosis also significantly improves with early diagnosis and intervention. Children who do not receive speech therapy and do not outgrow their speech difficulties will continue to have the disorder as adults.

Health care team roles

The treatment of speech disorders belongs to the field of speech-language pathology. Speech-language pathologists assist individuals who have speech disorders and collaborate with families, teachers, and physicians to design an appropriate course of treatment, which depends on the specific nature of the disorder. They also provide individual therapy to affected persons, consult with teachers about effective classroom strategies to help children with speech disorders, and work closely with families to develop effective therapies.

Prevention

Prevention of speech disorders is centered on identifying at-risk infants. The following conditions are con-

KEY TERMS

Apraxia—Motor disorder in which voluntary movement is impaired without muscle weakness.

Articulation disorder—Also called phonological disorder; type of speech disorder characterized by the way sounds are formed.

Communication disorder—Disorder characterized by an impaired ability to communicate, including language, speech, and hearing disorders.

Dysarthria—Speech disorder due to a weakness or lack of coordination of the speech muscles.

Dysfluency—Any break or interruption in speech.

Language disorder—Communication disorder characterized by an impaired ability to understand and/or use words in their proper context, whether verbal or nonverbal.

Phonological process—Any unusual change in the place, manner, or larynx characteristics of a produced sound.

Phonology—The science of speech sounds and sound patterns.

Speech disorder—Communication disorder characterized by an impaired ability to produce speech sounds or by problems with voice quality.

Speech-language pathology—This field, formerly known as speech therapy, is concerned with disorders of speech and language.

Stuttering—Speech disorder characterized by speech that has more dysfluencies than is considered average.

Vocal cords—Either of the two pairs of folds of mucous membrane located in the throat and projecting into the cavity of the larynx.

sidered to represent high-risk factors, and children exposed to them should be tested early and regularly:

- diagnosed medical conditions such as chronic ear infections
- biological factors such as fetal alcohol syndrome
- genetic defects such as Down syndrome
- neurological defects such as cerebral palsy
- family history such as family incidence of literacy difficulties

Stuttering can be prevented by parents avoiding undue corrections of dysfluency in their children. As young children begin to speak, some dysfluency is normal because they have a limited vocabulary and have difficulty expressing themselves. This results in dysfluent speech, and if parents place excessive attention on the dysfluency, a pattern of stuttering may develop. Speech therapy with children at risk for stuttering may prevent the development of a stuttering speech disorder.

Speech reading

Definition

Speech reading, also called lipreading, is ‘reading’ the visual clues of a spoken message, meaning the movements of the lips, the tongue, the lower jaw, the eyes, the eyebrows, and the facial expression and gestures of the speaker, in an effort to process all of the available visible, situational, and auditory cues.

Purpose

Speech reading is intended for people affected by a **hearing loss** or who are close to someone affected by a **hearing loss**. Speech readers mostly use their eyes to supplement the verbal information received through their ears. It is a technique available to any person having lost hearing during adult life, whether the loss is mild or severe, and its purpose is to support or replace hearing.

Description

Speech produces not only sounds but visible movements of the lips, tongue, and jaw of the speaker as well. These movements are called articulators of speech. Because of the physical constraints imposed by the muscles involved in the articulation of speech sounds, the same speech sounds are produced with a consistent pattern of physical movements and these movements are then associated with specific sounds. Speech reading is based on this principle, that many of the sounds produced during speech may be “seen” by paying attention to the articulators of speech.

Preparation

Speech reading is taught by special educators. In typical classes, the speech educator and the students usually sit in a horseshoe seating arrangement so as to ensure that everyone present can see whoever is speaking. Teachers use a variety of exercises, focused on presenting material without using voice so as to develop the visual perception of the speech articulators in the participants, who can learn how to recognize sounds that are visible, sounds that are less visible, and sounds that can not be seen. Sounds that look like each other are differentiated, and explanations are provided as to why some words can get mixed up during speech reading. The exercises help students use what they can see, as well as the partial sounds that they can hear.

There is no special preparation required for speech reading, except the motivation to learn. However, the following recommendations are found helpful:

- **Position.** Speech readers are asked to position themselves with their back to the light so as to see the speaker’s face clearly.
- **Relaxation.** A relaxed atmosphere favors speech reading.
- **Recollection of speech sounds.** Speech readers are encouraged to watch the speaker’s face closely and to try to recall how their voice sounded.
- **Speech movement.** They are also encouraged to pay attention to the movements made by the lips, tongue and jaw as the person speaks, so as to learn how to differentiate the articulators, some being more recognizable than others.
- **Facial expression.** The facial expression of speakers is very important in speech reading, as it conveys a lot of information about the topic and the speaker’s mood and feelings.
- **Gestures.** Gestures such as nodding and pointing also provide a lot of clues about what the speaker is saying.

Results

Speech reading recognizes that speech comprehension is an integrated process by which a listener, whether hearing-impaired or not, uses all possible information to understand a spoken message. In speech reading, the focus is on the overall meaning of the message as opposed to its specific spoken details. The result is that **vision** can then supplement the information obtained through the ears, by including all aspects of non-verbal communication as well, such as facial expressions and body language.

Health care team roles

Speech reading is taught by speech pathologists specialized in hearing disorders.

Speech pathology

Definition

The field of speech pathology, formerly known as speech therapy, is concerned with disorders of speech and language. A speech-language pathologist is a professional trained to diagnose and treat language and **speech disorders**.

Description

Speech pathology addresses the pathology of speech and language, meaning the “diseases” of speech and language and their functional effects on the affected person. Speech and language delays and disorders cover a wide range, from simple word substitutions in sentences to the inability to understand or use language for functional communication. The causes of speech and **language disorders** are wide and varied, including **hearing loss**, neurological disorders, traumatic **brain** injury, mental retardation, drug abuse, physical disabilities, and emotional abuse. Frequently, the cause is also unknown. In 1997-98, more than one million students were enrolled in spe-

cial education programs designed by speech-language pathologists as a result of speech or language disorders.

Work settings

Speech-language pathologists work in a wide variety of settings ranging from private practice to the public sector and with agencies treating specific disabilities. Some examples are:

- kindergartens
- primary schools
- high schools
- nursing homes
- hospitals
- universities
- rehabilitation centers
- mental health centers
- community health centers
- private practice

In any of these work settings, a speech-language pathologists’s typical workload may include:

- advising a mother on feeding a baby with a cleft palate
- helping a high school student who stutters
- helping a stroke victim to regain communication skills
- providing special training for teachers, doctors, or parents
- advising parents on the prevention of language disorders
- helping children and adults to learn to read
- treating people with brain injuries to regain language
- assisting people to develop control of vocal and respiratory systems for correct voice production

Due to the wide implications of speech and language disorders, speech-language pathologists usually work in close collaboration with other professionals such as medical specialists, educators, engineers, scientists, and other allied health professionals and technicians.

For example, in the vocational school context, speech-language pathologists collaborate with teachers and counselors in establishing communication goals related to the work experiences of students and propose strategies that are designed for the important transition from school to employment.

A speech therapist works with a young boy with dyspraxia, a difficulty in expressing language. (Photograph by Hattie Young. Science Source/Photo Researchers. Reproduced by permission.)

Education and training

Speech-language pathologists first complete a bachelor's degree which covers all aspects of communication development and disorders, followed by a master's degree. Many universities integrate both degrees into one sequence of training with the bachelor's degree providing the required background in theoretical and clinical areas and the master's program providing professional training for speech-language pathology careers.

A typical master's program in Speech-Language Pathology will usually include courses such as: Research Methods in Communication Disorders, Neuromotor Disorders of Speech Production, Disorders of Phonology, Neurologic Communication Disorders in Adults, Disorders of Speech Fluency, Language Intervention: from birth to age 21, **Voice Disorders**, Language

Assessment from Childhood to Adulthood, and Augmentative and Alternative Communication (AAC).

Employment in speech-language pathology requires both a master's degree in a program of study accredited by the American Speech-Language-Hearing Association (ASHA) and a credential or license. These requirements vary from state to state. Completion of the master's program provides the training required for students to qualify for a state license as a speech-language pathologist and the state credential for working as a speech-language pathologist in the public school system. The ASHA issues the Certificate of Clinical Competence (CCC) in speech-language pathology.

In the United States, ASHA is the professional, scientific, and certification association for speech-language pathologists, audiologists, and speech, language, and hearing scientists. The Association holds that academic studies are not sufficient to prepare an individual to func-

KEY TERMS

Aphasia—Acquired language disorder caused by damage to the areas of the brain responsible for language function.

ASHA—The American Speech-Language-Hearing Association. In the United States, the association that regulates and provides credentials for speech-language pathologists, audiologists, and speech, language, and hearing scientists.

Communication disorder—Disorder characterized by an impaired ability to communicate. Communication disorders include language, speech, and hearing disorders. They are associated with a wide variety of physical and psychological causes.

Language disorder—Communication disorder characterized by an impaired ability to understand and/or use words in their proper context, whether verbal or nonverbal. The disorder can be either developmental or acquired.

Phonology—The science of speech sounds and sound patterns.

Speech disorder—Communication disorder characterized by an impaired ability to produce speech sounds or by problems with voice quality.

Speech pathology—The field of speech pathology, formerly known as speech therapy, is concerned with disorders of speech and language. A speech pathologist is a professional trained to diagnose and treat language and speech disorders.

tion as a fully competent professional able to provide high quality care in speech-language pathology. All applicants for the CCC are accordingly required to successfully complete a clinical fellowship as well as the national examination in speech-language pathology. The clinical fellowship is intended to enable individuals to obtain supervised professional clinical experience in order to qualify for the CCC. Professional experience includes direct patient contact, consultations, record keeping, and all other duties associated with clinical work. All nonpublic school work settings require ASHA-CCC and/or state license or certification. Each state's guidelines may require ASHA certification as well as state license in addition to educational certification for employment in public schools for speech-language pathology.

Advanced education and training

The ASHA sponsors continuing education programs for speech-language pathologists. The courses of advanced study are conducted by leaders in the field of speech pathology and designed to keep speech-language pathologists abreast of new research findings, clinical techniques, and treatment models. Recognized experts also lead discussions on important ethical and regulatory issues that affect speech pathology. Alternatively, speech-language pathologists may elect to pursue doctorate work at a university and further specialize in those areas of basic research that contribute directly or indirectly to the identification, treatment, and prevention of speech and language disorders. For example, they may conduct advanced research on how people communicate. Others may design and develop equipment or techniques for diagnosing and treating speech problems.

Future outlook

The outlook for the field of speech pathology is very promising due mainly to the extraordinary advances in computer technology. Computers are being used for a wide variety of speech-language pathology applications. For example, computer programs are available for articulation and voice therapy that provide visual displays of speech: voicing, loudness, pitch, and articulation. Speech capture programs are being developed to assist the evaluation of speech/language patterns and for use in the treatment of disorders. Speech-language pathologists can use such programs, adjusting settings to provide visual reinforcement of the patient's attempts to correctly produce the target sound. Increasingly, programs and software are becoming available for testing and monitoring all major speech elements such as articulation, pitch, rhythm, duration, volume, and stress. This improved and greater use of computer technology has enabled speech-language pathologists to better serve those with speech-language disorders. There are improved augmentative devices for those with neuromuscular diseases and head injuries. For those with difficulty comprehending spoken language, the technology exists and is being used to modify the human speech signal and improve listening and comprehending skills which are fundamental for learning to read and write. For both children and adults, computer-based treatment programs exist for home use, making treatment more efficient.

Major areas of speech-language pathology software development include:

- Word-retrieval programs. These programs are mainly used to treat people affected by **aphasia**, a language disorder caused by damage to the areas of the brain

responsible for language function. Speech-language pathologists use them to treat aphasia at the word or sentence level.

- **Speech production software.** This type of software is being developed for teaching purposes, for example to teach the proper sounds of vowels, and also for voice analysis purposes in the clinical setting.
- **Reading comprehension programs.** These are programs that can teach word relationships interactively and monitor the level of functional reading.
- **Cognitive exercises software.** This type of software is used to test logic and deduction patterns, the ability to follow directions, and the understanding of traffic signs or of word associations.

Speech-language pathology is a very dynamic field. According to the U.S. Department of Labor, employment of speech-language pathologists is expected to grow at a much faster rate than the average for all occupations up to year 2008.

Sphygmomanometer

Definition

A sphygmomanometer is a device for monitoring **blood pressure**.

Purpose

The sphygmomanometer is designed to monitor the **blood** pressure by measuring the force of the blood in the **heart** where the pressure is greatest, during the contraction of the ventricles as blood is pumped from the heart to the rest of the body (systolic pressure), and during the period when the heart is relaxed between beats and pressure is lowest (diastolic pressure).

The device is used to establish a baseline at a health-care encounter and on admission to the hospital. Checking blood pressure is also performed to monitor the effectiveness of medication and other methods to control **hypertension**, and as a diagnostic aid to detect various diseases and abnormalities.

Description

The sphygmomanometer consists of a hand bulb pump, a unit that displays the blood pressure reading, and an inflatable cuff that is wrapped around the patient's upper arm. Care should be taken to ensure the cuff is the correct size to give an accurate reading. Children and adults with smaller or larger than average-sized arms require special sized cuffs appropriate for their needs. A **stethoscope** is also used in conjunction with the sphygmomanometer to hear the blood pressure sounds. Some devices have the stethoscope already built in.

The sphygmomanometer can be used in a variety of settings:

- home

The gauge on an aneroid sphygmomanometer shows the blood pressure reading as the inflatable cuff deflates.
(Custom Medical Stock Photo. Reproduced by permission.)

- hospital
- primary care, clinic, or clinician's office
- ambulance
- dental office

There are three types of equipment for monitoring blood pressure.

The mercury-based unit has a manually inflatable cuff attached by tubing to the unit that is calibrated in millimeters of mercury. During **blood pressure measurement**, the unit must be kept upright on a flat surface and the gauge read at eye level. Breakage of the unit may cause dangerous mercury contamination and would require specialist removal for disposal.

The aneroid unit is mercury free and consists of a cuff that can be applied with one hand for self-testing, a stethoscope that is built in or attached, and a valve that inflates and deflates automatically with the data displayed on an easy-to-read gauge that will function in any position. The unit is sensitive and if dropped, may require recalibration.

The automatic unit is also mercury free and is battery operated. It has a cuff that can be applied with one hand for self-testing, and a valve that inflates and deflates automatically. (Units with manual inflation are also available.) The reading is displayed digitally and a stethoscope is not required, therefore, the unit is useful for someone who is **hearing** impaired. A wrist monitor is also available for home testing. Some more expensive models also remember and print out recordings. The automatic units may be more portable than the bulkier mercury devices.

Blood pressure can be measured with any of the units, although mercury units are becoming less common due to the hazards of mercury.

Operation

The flow, resistance, quality, and quantity of blood circulating through the heart and the condition of the arterial walls are all factors that influence the blood pressure. If blood flow in the arteries is restricted, the reading will be higher.

Blood pressure should be routinely checked every one to two years. It can be checked at any time but is best performed when the patient has been resting for at least five minutes, so that exertion prior to the test will not unduly influence the outcome of the reading.

To record blood pressure, the patient should be seated with his left arm bent slightly, and the arm bare or with the sleeve loosely rolled up. With an aneroid or automatic unit, the cuff is placed level with the heart and wrapped around the upper arm, one inch above the elbow. Following the manufacturer's guidelines, the cuff is inflated and then deflated and the nurse records the reading.

If the blood pressure is monitored manually, a cuff is placed level with the heart and wrapped firmly but not tightly around the arm one inch above the elbow over the brachial artery, with creases in the cuff smoothed out. With a stethoscope over the brachial artery in front of the elbow with one hand and listening through the earpiece, the cuff is inflated well above normal levels (to about 200mm Hg), or until no sound is heard. The cuff is then inflated a further 10mm Hg above the last sound heard. The valve in the pump is slowly opened no faster than 5mm Hg per second to deflate the pressure in the cuff to the point where a tapping sound is heard over the brachial artery. This point is noted as the systolic pressure. The sounds continue as the pressure in the cuff is released and the artery is no longer occluded. At this point, the noises are no longer heard and this is noted as the diastolic pressure.

With children, the tapping noise changes to a soft muffled sound. That point is noted as the diastolic pressure, since sounds continue to be heard as the cuff deflates to zero.

Blood pressure results are recorded with the systolic pressure first, then the diastolic pressure (e.g. 120/70).

Maintenance

Devices should be checked and calibrated annually by a qualified technician to ensure accurate readings.

Health care team roles

The appropriate sized cuff should be used to give an accurate reading. Repeated measurements may be required if hypertension is suspected. One elevated reading does not mean that hypertension is present. The blood

KEY TERMS

Aneroid monitor—A monitor that works without fluids, i.e. without mercury.

Blood pressure—The tension of the blood in the arteries measured in millimeters of mercury by a sphygmomanometer or by an electronic device.

Diastolic—Minimum arterial blood pressure during ventricular rest.

Systolic—Maximum arterial blood pressure during ventricular contraction.

pressure measurement is recorded and compared with normal ranges for the patient's age and medical condition and a decision made on whether any further medical intervention is required.

Training

The method of recording blood pressure should be consistent, especially the diastolic pressure, as a different reading will be obtained if it is measured when the sounds change or when they disappear. All healthcare professionals should be aware of the normal values for blood pressure measurement based on age and medical history.

Spinal cord

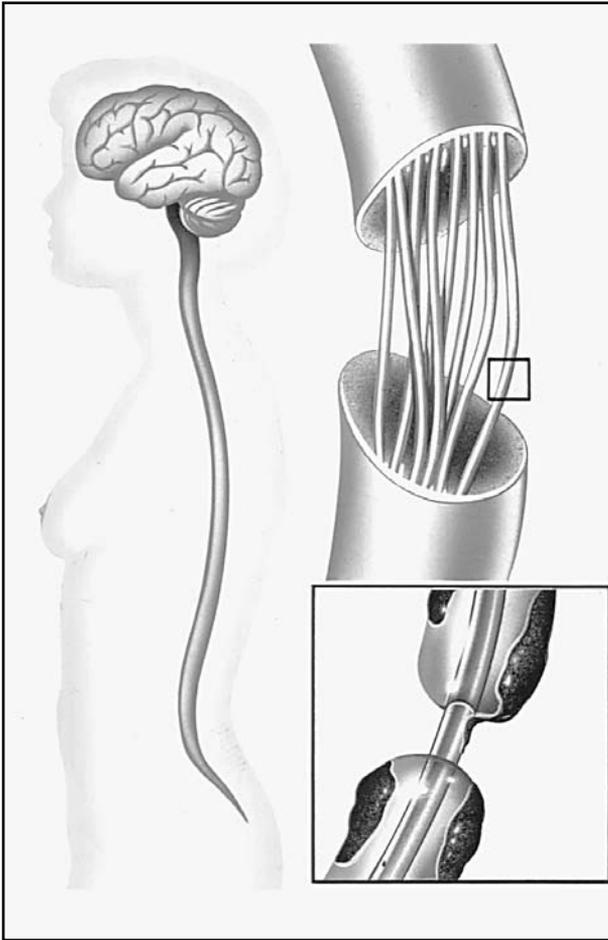

Definition

The spinal cord is the elongated bundle of nervous tissue that carries nerve impulses between the **brain** and the rest of the body. It lies in the vertebral canal of the **vertebral column**.

Description

The spinal cord lies within the vertebral canal, which is the hollow part of the vertebral column, or spine, that consists of 33 bones called vertebrae. The canal is formed by the stacked vertebrae which all contain a central vertebral foramen, or hole. The spinal cord extends from the lowest part of the brain, called the brainstem, through a hole located at the base of the **skull**, the foramen magnum, and continues down the vertebral canal to the twenty-first vertebra of the spine.

Like the brain, the spinal cord is protected by three layers of membranes, called meninges. The inner meninge that makes direct contact with the spinal cord is called the pia mater. It is separated from the second layer by a space called the subarachnoid space. This space is filled with cerebrospinal fluid (CSF), the colorless fluid that bathes the entire brain and spinal cord. The second layer is the thin and spider web-like arachnoid mater and it is separated from the outermost layer by a space called the subdural space. The outermost layer is the dura mater, a protective sheath made of tough fiber. Between the dura mater and the bone of the vertebral canal is a space, called the epidural space, which contains a small amount of fatty tissue and **blood vessels**. The spinal dura mater

The brain and spinal cord comprise the central nervous system. At the right is a magnified view of the spinal cord showing the individual nerves. The inset shows an individual axon covered with a myelin sheath. (Photo Researchers, Inc. Reproduced by permission.)

prolongs the dura mater that lines the skull cavity and extends to the sacrum, the second to last bone of the vertebral column. It also covers each of the spinal nerves as they leave the vertebral canal. Both the arachnoid and pia mater also prolong the arachnoid and pia surrounding the brain, but unlike the arachnoid, which continuously follows the dura mater, the pia ends where the spinal cord ends. A stringy extension of the pia mater, called the filum terminale joins the end of the spinal cord to the end of the dura mater. Additionally, the pia mater contains thin projections called denticulate ligaments, that connect the spinal cord to the dura mater.

Function

The major function of the spinal cord is to carry nerve impulses between the brain and the rest of the body. Together, the brain and the spinal cord constitute

the **central nervous system (CNS)**. The other nerves of the nervous system, that is the motor and sensory nerves, constitute the peripheral nervous system (PNS).

The spinal cord consists of a core of grey nervous tissue surrounded by a thicker section of white tissue. The grey matter looks like a butterfly with outspread wings and the upper and lower sections of these wings are called the posterior and anterior horns. The tissues of the spinal cord are full of nerve cells, also called neurons. **Neurons** with large cell bodies that are located in the anterior horns give rise to motor nerve fibers that connect to spinal nerves which pass out of the cord to skeletal muscle. The grey matter of the spinal cord also contains other neurons that connect together to form nerve pathways and the white matter contains nerves that are wrapped in myelin sheaths and form nerve tracts. The tracts that conduct sensory impulses from the body to the brain are called ascending tracts and those that conduct motor impulses from the brain to muscles and glands are called descending tracts.

Thirty-one pairs of spinal nerves emerge from the spinal cord. They are all mixed nerves, meaning that they provide a two-way communication system for sensory and motor information exchange between the spinal cord and the rest of the body. Spinal nerves are numbered according to the vertebral column level from which they stem. There are eight pairs of cervical nerves, C1 to C8, twelve pairs of thoracic nerves, T1 to T12, five pairs of lumbar nerves, L1 to L5, five pairs of sacral nerves, S1 to S5, and one pair of coccygeal nerves.

Role in human health

The spinal cord is an extremely important component of the CNS because it provides the crucial link between the brain and the spinal nerves that connect to the individual muscles and organs of the body. The role of the spinal cord in human health however, is not only to carry this sensory and motor information. It also carries a great deal of other crucial information as well, having to do with involuntary and automatic body functions. For example, the regulation of the chemical contents of the **blood** and body fluids is carried out by an automatic feedback control system that involves the spinal cord and its attached network of peripheral nerves. The regulation the **heart, stomach,** and intestines are other examples. These are all vital body functions of which we are unaware of and that all proceed with the involvement of the spinal cord nervous tissues.

KEY TERMS

Arachnoid mater—One of three meninges covering the central nervous system (CNS) the others are the dura and pia maters. The dura mater encloses the arachnoid which in turn covers the pia mater.

Brain stem—Lowest part of the brain that connects with the spinal cord. It is a complicated neural center with several neuronal pathways between the cerebrum, spinal cord, cerebellum, and motor and sensory functions of the head and neck. It consists of the medulla oblongata, the part responsible for cardiac and respiratory control, the midbrain, which is involved in basic, involuntary body functions, and the pons, where some cranial nerves originate.

Central nervous system (CNS)—One of two major divisions of the nervous system. The CNS consists of the brain, the cranial nerves and the spinal cord.

Cerebrospinal fluid (CSF)—A clear colorless fluid that circulates in the brain and in the subarachnoid spaces surrounding the brain and spinal cord. The CSF lies between the spinal cord and the arachnoid mater thereby suspending the spinal cord in fluid.

Cervical vertebrae—Vertebrae of the neck.

Epidural space—This space lies between the dura mater and the walls of the vertebral canal, it contains loose connective tissue, blood vessels and some fatty tissue.

Foramen—A hole in a bone usually for the passage of blood vessels and/or nerves.

Foramen magnum—Large opening at the base of the skull that allows passage of the spinal cord.

Intervertebral disk—Disk-shaped pads of fibrous cartilage interposed between the vertebrae of the vertebral column that provide cushioning and join the vertebrae together.

Meninges—The membranes that surround and protect the brain and spinal cord. There are three layers: the dura mater (outermost), arachnoid membrane (middle) and the pia mater (innermost).

Nervous system—The entire system of nerve tissue in the body. It includes the brain, the brainstem, the

spinal cord, the nerves and the ganglia and is divided into the peripheral nervous system (PNS) and the central nervous system (CNS).

Paraplegia—Paraplegia is permanent paralysis of the trunk and lower limbs. It is caused by injury or disease affecting the spinal cord below the chest or waist.

Peripheral nerves—The nerves outside of the brain and spinal cord, including the autonomic, cranial, and spinal nerves. These nerves contain cells other than neurons and connective tissue as well as axons.

Peripheral nervous system (PNS)—One of the two major divisions of the nervous system. The PNS consists of the somatic nervous system (SNS), that controls voluntary activities and of the autonomic nervous system (ANS), that controls regulatory activities. The ANS is further divided into sympathetic and parasympathetic systems.

Quadraplegia—Quadraplegia is permanent paralysis of the trunk, lower and upper limbs. It is caused by injury or disease affecting the spinal cord at the neck level.

Sacrum—The triangular-shaped bone found between the fifth lumbar vertebra and the coccyx. It consists of five fused vertebrae and it articulates on each side with the bones of the pelvis (ilium), forming the sacroiliac joints.

Sensory nerve—A nerve that receives input from sensory cells, such as the skin or muscle receptors.

Skull—All of the bones of the head.

Spinal cord—Elongated part of the central nervous system (CNS) that lies in the vertebral canal of the spine and from which the spinal nerves emerge.

Vertebra—Flat bones that make up the vertebral column. The spine has 33 vertebrae.

Vertebral canal—Hollow part of the vertebral column formed by the vertebral foramina of the stacked vertebrae. It encloses the spinal cord.

Vertebral foramen—The opening formed in vertebrae that allows passage of the spinal cord.

Common diseases and disorders

Spinal cord injuries are usually the result of trauma to the vertebral column. When dislocations and frac-

tures of the spine occur, the vertebrae may press on the spinal cord, thus compressing the nerves. Pressure applied to the spinal cord may result in muscle weakness or **paralysis**. It could also cause abnormal sensations,

such as **pain**, tingling, or burning. In severe cases, the cord might even be torn or severed, and the function of the spinal cord risks being seriously impaired if not altogether destroyed. A damaged spinal cord results in loss of sensation and/or motor function below the level of the injury. Thus, injuries to the cord at the chest or waist level may result in paraplegia, which is paralysis of the legs and/or part of the trunk. Damage to the cord in the neck region may result in paralysis of all four limbs and the trunk, a condition called quadriplegia, and it can be fatal. Other disorders of the spinal cord include:

- Epidural abscesses. Infections that occur in the epidural space around the dura mater. These create pockets of infected fluid that affect the spinal nerve roots and generate enough pressure to impair neurological function.
- Foraminal stenosis. Normally, nerve roots have enough room to easily slip through the foramina of the spine. However, with age and disease, they may become clogged and blocked, thus trapping and compressing the nerves.
- Pinched nerve. The two nerves most commonly pinched in the spinal cord are L5 and S1. The L5 nerve supplies the nerves to the muscles that raise the foot and big toe, and a pinched L5 may lead to weakness in these muscles. Likewise, a pinched S1 may lead to weakness with the large muscle in the back of the calf.
- Sciatica. The compression of the spinal roots of the sciatic nerve. It is characterized by pain in the low back region that radiates down the back of the thigh, the leg and into the foot. It results from diseased sciatic nerve roots or can be caused by a tumor, or intervertebral disc displacement resulting from injury or inflammation.
- Spinal stenosis. A narrowing of spaces in the spine that results in pressure on the spinal cord and nerve roots. This disorder usually involves the narrowing of one or more of three areas of the spine: the vertebral canal, the canals at the base or roots of nerves branching out from the spinal cord, and the vertebral foramina. It is usually a degenerative disorder caused by old age, but may also be an inherited disease.

Spinal cord injury

Definition

Spinal cord injury is damage to the spinal cord that causes loss of sensation and motor control.

Description

Approximately 11,000 new spinal cord injuries (SCIs) occur each year in the United States. About 200,000 people are currently affected. Spinal cord injuries can happen to anyone at any time of life. The typical patient, however, is a man between the ages of 19 and 26, injured in a motor vehicle accident (about 35% of all SCIs), a fall (20%), an act of violence (15%), most often related to firearms use, or a sporting accident (14%). According to the Centers for Disease Control, violence-related SCIs have been steadily increasing since 1980, and in 2001, violence is associated with 30% of all SCI cases.

Most SCI patients are white, but the nonwhite fraction of SCI patients is larger than the nonwhite fraction of the general population. In fact, the SCI rate among blacks, who are at higher risk for SCI than whites, has been rising in recent years. Alcohol or other drug abuse plays an important role in a large percentage of all spinal cord injuries. Six percent of people who receive injuries to the lumbar spine die within a year, and 40% of people

who sustain the more frequent higher, or rostral injuries, also die within a year.

Short-term costs for hospitalization, equipment, and home modifications are approximately \$140,000 for an SCI patient capable of independent living. Lifetime costs may exceed one million dollars. Costs may be three to four times higher for the SCI patient who needs long-term institutional care. Overall costs to the American economy in direct payments and lost productivity are more than \$10 billion per year.

Causes and symptoms

Causes

The spinal cord descends from the **brain** down the back through the spinal canal that lies within the bony spinal column. The spinal cord is composed of **neurons** and axons (nerve cells). The neurons carry sensory data from the areas outside the spinal cord (periphery) to the brain, and convey motor commands from brain to periphery. Peripheral neurons are bundled together to comprise the 31 pairs of peripheral nerve roots. The peripheral nerve roots enter and exit the spinal cord by passing through the spaces between the stacked vertebrae (the neural foramen). Each pair of nerves is named for the vertebra from which it exits. These are known as:

- C1-8. These nerves enter from the seven cervical or neck vertebrae.
- T1-12. These nerves enter from the thoracic or chest vertebrae.
- L1-5. These nerves enter from the lumbar vertebrae of the lower back.
- S1-5. These nerves enter through the sacral, or pelvic vertebrae.
- Coccygeal. These nerves enter through the coccyx, or tailbone.

Peripheral nerves carry motor commands to the muscles and internal organs, and transmit sensations from these areas and from the body's surface. (Sensory data from the head, including sight, sound, **smell**, and **taste**, do not pass through the spinal cord and are not affected by most SCIs. These nerves, called the cranial nerves, pass through the brain stem.) Damage to the spinal cord interrupts these signals. The interruption damages motor functions that enable the muscles to move, sensory functions (e.g., feeling heat and cold, and autonomic functions (e.g., urination, sexual function, sweating, and **blood pressure**)).

Spinal cord injuries most often occur where the spine is most flexible, in the regions of C5–C7 of the neck, and T10–L2 at the base of the rib cage.

Several physically distinct types of damage are recognized. Sudden and violent jolts to nearby tissues can jar the cord. This jarring causes a transient neurological deficit, known as temporary spinal **concussion**. Concussion symptoms usually disappear completely within several hours of injury. A spinal contusion, or bruise, is bleeding within the spinal column. The pressure from the excess fluid may kill spinal cord neurons. Spinal compression is caused by an object, such as a tumor, pressing on the cord. Lacerations, or tears, cause direct damage to cord neurons. Lacerations may be caused by bone fragments or missiles, such as bullets. Spinal transection describes the complete severing of the cord. Most spinal cord injuries involve two or more of these types of damage.

Symptoms

PARALYSIS AND LOSS OF SENSATION. The extent to which movement and sensation are damaged depends on the level of the spinal cord injury. Nerves leaving the spinal cord at different levels control sensation and movement in different parts of the body. The distribution is roughly as follows:

- C1–C4: head and neck
- C3–C5: diaphragm (chest and breathing)
- C5–T1: shoulders, arms and hands
- T2–T12: chest and abdomen (excluding internal organs)
- L1–L4: abdomen (excluding internal organs), buttocks, genitals, and upper legs
- L4–S1: legs
- S2–S4: genitals and muscles of the perineum

Damage below T1, which lies at the top of the rib cage, causes **paralysis** and loss of sensation in the legs and trunk below the injury. Injury at this level usually does no damage to the arms and hands. Paralysis of the legs is called paraplegia. Damage above T1 involves the arms as well as the legs. Paralysis of all four limbs is called quadriplegia.

Cervical, or neck injuries, not only cause quadriplegia, but also may cause difficulty in breathing. Damage in the lower part of the neck may leave enough diaphragm control to allow unassisted breathing. Patients with damage at C3 or above, just below the base of the **skull**, require mechanical assistance from a ventilator or a diaphragmatic nerve stimulation to breathe.

Symptoms also depend on the extent of the SCI. A completely severed cord causes paralysis and loss of sensation below the wound. If the cord is only partially severed, some function will remain below the injury.

Damage limited to the front portion of the cord causes paralysis and loss of sensations of **pain** and temperature. Other sensation may be preserved. Damage to the center of the cord may spare the legs, but paralyze the arms. Damage to the right or left half causes loss of position sense, paralysis on the side of the injury, and loss of pain and temperature sensation on the opposite side.

AUTONOMIC DYSREFLEXIA. Body organs that self-regulate, such as the **heart**, gastrointestinal tract, and glands, are controlled by autonomic nerves. Autonomic nerves emerge from three different places: above the spinal column, in the lower back from vertebrae T1-L4, and from the lowest regions of the sacrum at the base of the spine. In general, these three groups of autonomic nerves operate in balance. Spinal cord injury can disrupt this balance, a condition called autonomic dysreflexia or autonomic hyperreflexia. Patients with injuries at T6 or above are at greatest risk.

SPASTICITY AND CONTRACTURE. A paralyzed limb is incapable of active movement, but the muscle still has tone, a constant low level of contraction. Normal muscle tone requires communication between the muscle and the brain. Spinal cord injury prevents the brain from telling the muscle to relax. The result is prolonged **muscle contraction** or spasticity. Since the muscles that extend and those that bend a joint are not usually equal in strength, the involved joint is bent, often severely. This constant pressure causes deformity. As the muscle remains in the shortened position over several weeks or months, the tendons remodel and cause permanent muscle shortening or contracture. When muscles have permanently shortened, the inner surfaces of joints, such as armpits or palms, cannot be cleaned and the skin breaks down in that area.

HETEROTOPIC OSSIFICATION. Heterotopic ossification is an abnormal deposit of bone in muscles and tendons that may occur after injury. It is most common in the hips and knees. Initially heterotopic ossification causes localized swelling, warmth, redness, and stiffness of the muscle. It usually begins one to four months after the injury and is rare after one year.

In autonomic dysreflexia, irritation of the skin, bowel, or bladder causes a highly exaggerated response from autonomic nerves. This response is caused by the uncontrolled release of norepinephrine, a hormone similar to adrenaline. Uncontrolled release of norepinephrine causes a rapid rise in **blood** pressure and a slowing of the heart rate. These symptoms are accompanied by throbbing headache, nausea, **anxiety**, sweating, and goose bumps below the level of the injury. The elevated blood pressure can rapidly cause loss of consciousness, seizures, cerebral hemorrhage, and death. Autonomic dysreflexia is most often caused by an over-full bladder

or bladder **infection**, impaction or hard, impassable fecal mass in the bowel, or skin irritation from tight clothing, sunburn, or other irritant. Inability to sense these irritants before the autonomic reaction begins is a major cause of dysreflexia.

LOSS OF BLADDER AND BOWEL CONTROL. Bladder and bowel control require both motor nerves and the **autonomic nervous system** (ANS). Both of these systems may be damaged by SCI. When the ANS triggers an urge to urinate or defecate, continence is maintained by contracting the anal or urethral sphincter, respectively. The sphincter is a ring of muscle that contracts to close off a passage or opening in the body. When the neural connections to these muscles are severed, conscious control is lost. In addition, loss of feeling may prevent sensations of fullness from reaching the brain. To compensate, the patient may help empty the bowel or bladder by using physical maneuvers that stimulate autonomic contractions before they would otherwise begin. The patient may not, however, be able to relax the sphincters. If the sphincters cannot be relaxed, the patient will retain urine or feces.

Retention of urine may cause muscular changes in the bladder and urethral sphincter that make the problem worse. Urinary tract infection is common. Retention of feces can cause impaction. Symptoms of impaction include loss of appetite and nausea. Untreated impaction may cause perforation of the **large intestine** and sepsis (rapid overwhelming infection).

Complications

DEEP VENOUS THROMBOSIS. Blood does not flow normally through a paralyzed limb that is inactive for long periods. The blood pools in the deep veins and forms clots, a condition known as deep vein thrombosis. A clot, or thrombus, can break free and lodge in smaller arteries in the brain (causing a stroke), or in the **lungs** (causing pulmonary embolism).

DECUBITUS ULCERS (PRESSURE ULCERS). Inability to move may also lead to decubitus ulcers (pressure ulcers or bedsores). Decubitus ulcers form where skin remains in contact with a bed or chair for a long time. The most common sites of pressure ulcers are the buttocks, hips, and heels. Decubitus ulcers can cause sepsis (infection) and may seriously jeopardize recovery.

Diagnosis

The location and extent of SCI is determined by obtaining a history, performing a **physical examination**, and ordering appropriate imaging studies. Imaging studies usually include a combination of computed tomogra-

phy (CT) scans, **magnetic resonance imaging** (MRI) scans, and traditional x rays. Computed tomography or MRI scans may be enhanced with an injected contrast dye. These diagnostic imaging studies are explained to patients by nurses and radiologic technicians. The studies are usually performed by these technicians, and are read, or interpreted, by a radiologist and/or a neuroradiologist.

Treatment

Acute care of SCI

Onlookers should not move a person who may have sustained SCI. Emergency medical personnel are best equipped to transport the injured patient. Treatment of SCI begins with immobilization. This strategy prevents partial injuries of the cord from severing it completely. Since the early 1980s, the use of splints to completely immobilize suspected SCI at the scene of the injury has helped reduce the severity of spinal cord injuries. Intravenous methylprednisolone, a steroidal anti-inflammatory drug, is given during the first 24 hours to reduce inflammation and limit tissue destruction.

Restoration of function and mobility

Rehabilitation after SCI seeks to prevent complications, promote recovery, and make the most of remaining function. Rehabilitation is a complex and long-term process; it requires a team of professionals, including a neurologist, physiatrist (or rehabilitation specialist), physical therapist, and occupational therapist. Other specialists who may be needed include a respiratory therapist, vocational rehabilitation counselor, social worker, speech-language pathologist, nutritionist, special education teacher, recreation therapist, and clinical psychologist. Support groups provide a critical source of information, advice, and support for SCI patients and their families.

While the possibility of using functional electrical stimulation (FES) for ambulation (outside of the laboratory) remains distant, the use of FES to deal with other aspects of SCI (such as loss of grasp capabilities in quadriplegia) is actually more advanced and more likely to be in common use in the foreseeable future.

Instruction in activities of daily living

Physical therapy focuses on mobility to maintain range of motion of affected limbs and reduce contracture and deformity. Additionally, it helps to compensate for lost skills by using those muscles that are still functional, and helps to increase any residual strength and control in affected muscles. Adaptive equipment such as braces,

canes, or wheelchairs can be suggested by a physical therapist.

The goal of **occupational therapy** is to restore the ability to perform the activities of daily living, such as eating and grooming, with tools and new techniques. Modifications of the home and workplace to accommodate and address the individual impairment are also addressed by the occupational therapist.

Treatment of sexual dysfunction

Men who have sustained SCI may be unable to achieve an erection or ejaculate. Sperm formation may be abnormal and fertility may be compromised. Fertility and the ability to achieve orgasm are less impaired for women. Women may still be able to become pregnant and deliver vaginally.

Prevention of complications

DECUBITUS ULCERS (PRESSURE ULCERS). Turning the patient in bed at least every two hours prevents the formation of decubitus ulcers. The patient should be turned more frequently when redness begins to develop in sensitive areas. Special mattresses and chair cushions can distribute weight more evenly to reduce pressure. Skin should be carefully attended to by nurses and other caregivers in order to maintain skin integrity and prevent ulcers from developing. Electrical stimulation is sometimes used to promote muscle movement to prevent decubitus ulcers.

SPASTICITY AND CONTRACTURE. Range of motion (ROM) exercises help to prevent contracture. Chemicals can be used to prevent contractures from becoming fixed when ROM **exercise** is inadequate. Phenol or alcohol can be injected into the nerve, or botulinum toxin can be injected directly into the muscle. Botulinum toxin is associated with fewer complications, but it is more expensive than phenol and alcohol. Contractures can be released by cutting the shortened tendon or transferring it surgically to a different site on the bone, where deformity will be lessened by its pull. Such tendon transfers may also be used to increase strength in partially functional extremities.

DEEP VENOUS THROMBOSIS. Deep venous thrombosis may be prevented by using passive ROM exercises, sequential compression stockings, intermittent pneumatic compression devices, and kinetic (movement) therapies. Heparin and aspirin may also be administered to prevent deep venous thrombosis.

HETEROTOPIC OSSIFICATION. Etidronate disodium (Didronel), a drug that regulates the body's use of **calcium**, is used to prevent heterotopic ossification.

KEY TERMS

Autonomic nervous system—The part of the nervous system that controls involuntary functions such as sweating and blood pressure.

Botulinum toxin—Any of a group of potent bacterial toxins or poisons produced by different strains of the bacterium *Clostridium botulinum*.

Computed tomography (CT)—An imaging technique in which cross-sectional x rays of the body are compiled to create a three-dimensional image of the body's internal structures.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Motor—Of or pertaining to motion, the body apparatus involved in movement, or the brain functions that direct purposeful activity.

Motor nerve—Motor or efferent nerve cells carry impulses from the brain to muscle or organ tissue.

Peripheral nervous system—The part of the nervous system that is outside the brain and spinal cord. Sensory, motor, and autonomic nerves are included.

Postural drainage—The use of positioning to drain secretions from the bronchial tubes and lungs into the trachea or windpipe.

Range of motion (ROM)—The range of motion of a joint from full extension to full flexion (bending) measured in degrees like a circle.

Sensory nerves—Sensory or afferent nerves carry impulses of sensation from the periphery or outward parts of the body to the brain. Sensations include feelings, impressions, and awareness of the state of the body.

Voluntary—An action or thought undertaken or controlled by a person's free will or choice.

Treatment begins three weeks after the injury and continues for 12 weeks. Surgical removal of ossified tissue is possible.

AUTONOMIC DYSREFLEXIA. Bowel and bladder care and attention to potential irritants prevent autonomic dysreflexia. It is treated by prompt removal of the irritant. Drugs to lower blood pressure are used when necessary. Patients and friends and families of the patient should

be educated about the symptoms and treatment of dysreflexia, because immediate intervention is usually necessary.

LOSS OF BLADDER AND BOWEL CONTROL. Normal bowel function is promoted through adequate fluid intake and a diet rich in fiber. Evacuation is stimulated by deliberately increasing the abdominal pressure, either voluntarily or by using an abdominal binder.

Bladder care involves continual or intermittent catheterization. The full bladder may be detected by feeling its bulge against the abdominal wall. Urinary tract infection is a significant complication of catheterization and requires frequent monitoring.

SEXUAL DYSFUNCTION. Counseling can help patients to adjust to changes in sexual function after SCI. Erection may be enhanced through the same means used to treat erectile dysfunction in the general population.

Prognosis

The prognosis for SCI depends on the site and extent of injury. Injuries of the neck above C4 with significant involvement of the diaphragm hold the gravest prognosis. Respiratory infection is one of the leading causes of death in long-term SCI. Overall, 85% of SCI patients who survive the first 24 hours are alive ten years after their injuries. Recovery of function is impossible to predict. Partial recovery is more likely after an incomplete wound than after the spinal cord has been completely severed.

Health care team roles

Initial medical management, including immobilization and transport of SCI patients, is usually provided by emergency medical personnel. Upon arrival, the physicians and nurses in the hospital emergency department assess the nature and extent of the injury. Imaging studies are performed by radiologic technicians and interpreted by radiologists and neuroradiologists. Consultation with a neurosurgeon determines whether surgical intervention will be beneficial in treating the injury.

Following emergency treatment, assessment and completion of the diagnostic work-up, critical care vigilant monitoring of SCI patients is provided by the nurses. The aim of monitoring is to identify the decreased cardiac output that may result from sympathetic nerve blockade; excessive autonomic nerve responses (i.e., distended bladder or bowel); problems associated with breathing, and the risk of aspiration.

Nurses, social workers, physical and occupational therapists, pastoral counselors, and other medical and mental health professionals may be called upon to help patients and families manage their emotional responses to the injury. Feelings of anxiety, anger, denial may be experienced by hopeless patients and families.

Patient education

Patient education is an essential part of the rehabilitation process. Every member of the treatment team is involved in patient education. Patients and families are taught by nurses to recognize symptoms requiring immediate medical attention, and to provide selected care (e.g., a bowel program to prevent impaction). They may be instructed by physical and occupational therapists to use adaptive devices and equipment. Education may help to reduce feelings of powerlessness and hopelessness, and can assist in the creation of realistic expectations about recovery.

Many SCI patients also benefit from participation in peer support groups. They are enabled by the groups to meet others with comparable conditions, thereby reducing feelings of isolation, and allowing them to share experience-tested coping strategies.

Prevention

Risk of spinal cord injury can be reduced through prevention of the accidents that lead to it. Chances of injury from automobile accidents, the major cause of SCIs, can be significantly reduced by driving at safe speeds, avoiding alcohol while driving, not talking on mobile phones while driving, and using seat belts.

Paralysis and loss of sensation

Some limited mobility and sensation may be recovered, but the extent and speed of recovery cannot be predicted with any accuracy. Experimental electrical stimulation has been demonstrated to allow some control of muscle contraction in paraplegia. This experimental technique offers the possibility of unaided walking. Further development of current control systems will be needed before useful movement is possible outside the laboratory.

A pulmonologist, or respiratory therapist, can promote airway hygiene through instruction in assisted coughing techniques and postural drainage. **Ventilators**, facial or nasal masks, and tracheostomy equipment, where necessary, can also be prescribed by the respiratory professional. He or she can provide instruction in their use, as well.

Spinal orthoses

Definition

Spinal orthoses, also known as braces, are devices worn on the body to treat conditions such as **scoliosis**, back **pain**, and injury.

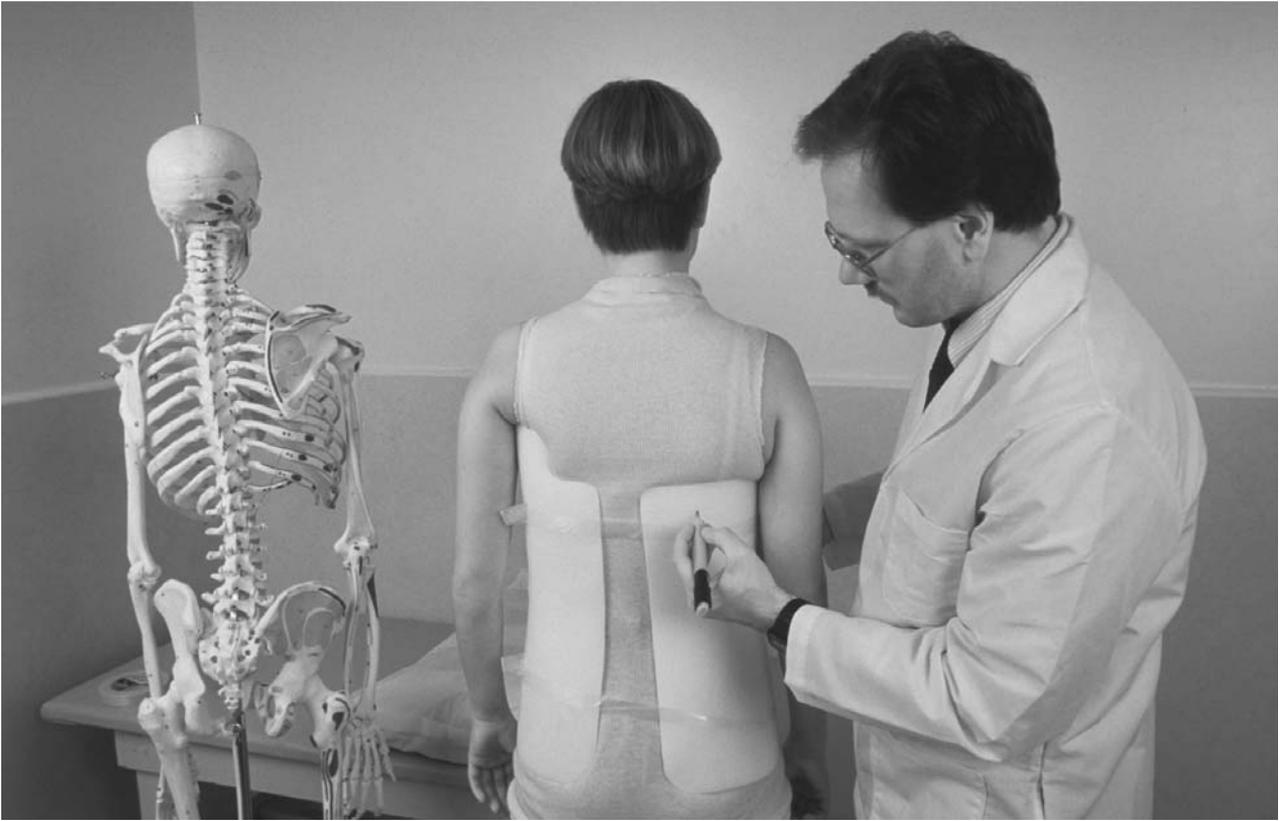

Purpose

Most spinal orthoses are designed to adjust skeletal alignment, limit torso movement, and compress the **stomach**.

Scoliosis

Spinal orthoses are used to treat longterm spinal conditions such as scoliosis. The brace is worn to stop the progression of scoliosis, which is the lateral (side-to-side) curvature of the spine. This condition progresses as a person grows and is primarily seen in children and adolescents. In general, scoliosis can not be reversed. Therefore, the goal of treatment is stop the progression of scoliosis.

Orthopedists usually diagnosis this condition based on an x ray showing curves of 10 degrees or more. Treatment is usually indicated when curves measure 25 degrees or more. Scoliosis progresses more slowly as

A patient with scoliosis is fitted with a brace. (Photograph by Aaron Haupt. Science Source/Photo Researchers. Reproduced by permission.)

patients reach skeletal maturity, so use of spinal orthosis is prescribed for patients with at least 18 months of growing left. In older patients, scoliosis is treated with surgery.

Back pain

Spinal orthoses are worn to relieve back pain and to provide back support after an injury or to treat conditions such as degenerative disc disorder. Other uses of spinal orthoses include protecting the back after surgery and the stabilization and support of a weak back.

Description

For more than two thousands years, doctors have tried to treat scoliosis by having patients wear devices to keep their spines rigid. Equipment used throughout the centuries included bandages bolstered by splints, leather appliances, and plaster casts. During the Middle Ages, the craftsmen who made armor for knights also produced bulky metal corsets to stop the progression of scoliosis.

Today, braces made of materials ranging from cotton to plastic are used to treat conditions related to the back and spine. Spinal orthoses vary in size from the cloth belts worn

for back support to the rigid full-torso Milwaukee brace used to stop the progression of scoliosis. Braces used to treat scoliosis are prescribed by an orthopedist. The orthosis may be custom-made or fitted from a prefabricated brace.

Corsets and belts

Cloth corsets and belts are generally made of cotton, nylon, or rayon. These flexible orthoses are used to relieve back pain and to restrict movement.

Rigid and semi-rigid spinal orthoses

The braces worn to treat scoliosis or during rehabilitation from spinal surgery are generally classified as rigid or semi-rigid orthoses. The rigid orthosis immobilizes the spine and prevents spinal motion. It is designed to apply force in every direction, distributing pressure over a broad area. A semi-rigid brace combines the support of a rigid brace with the flexibility of a cloth orthosis.

Orthoses for scoliosis

Orthoses prescribed for the treatment of scoliosis generally fall into three categories, with model variations in each group.

THE MILWAUKEE BRACE. The Milwaukee brace is a full-torso orthosis developed during the late 1940s. Named for the location of the doctors who developed it, the orthosis consists of pressure pads held in place by three vertical metal bars. The bars extend from a neck ring, a type of collar worn around the neck. The bars are secured at the neck ring and anchored to a plastic pelvic girdle. The rear vertical bar extends down the back. There are two shorter bars in front.

The neck ring centers the head and straightens the spine. The pads apply pressure to the spinal curve to keep it from worsening. Patients wear the brace under clothing, and it is worn for much of the day. While it effectively stops the progression of scoliosis, wearing the brace with the visible neck ring can be embarrassing for patients.

LOW-PROFILE BRACES. During the 1970s, doctors in Boston developed a brace that extends from under the arms to the hips. Variations of this brace are known as thoracolumbar-sacral orthoses (TLSOs), the Boston brace, the low-profile brace, and the underarm brace. The orthosis consists of a plastic corset with pressure pads attached to the inside. The original braces opened from the back. Current models open in the front or back. However, the back-opening orthosis generally keeps the pelvis in place. This reduces the flattening of the lower back that can occur when scoliosis is treated with an orthosis.

Patients wear the underarm brace for much of the day. This orthosis is regarded as low-profile because it is not visible when worn under clothes.

THE CHARLESTON NIGHTTIME BENDING BRACE. This orthosis developed in 1979 forces the spine to one side. It is held in place away from the direction of the spinal curve. The bending brace is curved and is designed to be worn only at night when the patient sleeps. Most patients have no trouble sleeping in this brace once they have adjusted to wearing it. In addition, many young patients appreciate the option of wearing the brace only at home and going to school without wearing a brace.

Operation

The overall length of time for wearing a spinal orthosis depends on the patient's age and condition. If the brace stops the progression of scoliosis, the patient wears an orthosis until reaching skeletal maturity (around age 15 or 16). The orthopedist or other health professional will determine the amount of wearing time when a brace is used to treat other conditions. While daily wearing times will also vary by the patients, there are set times for

how long orthoses should be worn during treatment for scoliosis.

Scoliosis treatment

Orthopedists are divided about how long some spinal orthoses should be worn each day to treat scoliosis. While some doctors believe that the brace must be worn fulltime, others maintain that part-time bracing can be effective. In some cases, this recommendation is based on the patient's condition and age. In other cases, the health care team realizes that young patients embarrassed by the awkward Milwaukee brace may stop wearing it. In these situations, doctors believe that a shorter wearing time or a split schedule could be more effective.

For fulltime bracing to stop the progression of scoliosis, the daily wearing time is:

- 22-23 hours for the Milwaukee brace. The patient can remove the orthosis when bathing. Some doctors allow the patient to remove the brace when exercising; others say that it can be worn while doing some exercises.
- 20 hours for the Boston brace. Daily wearing time of 16 hours may be effective. However, reduced time could increase the risk of curve progression.
- During the eight to nine hours of sleep for the Charleston bending brace.

Precautions

Patients should be told that it takes time to adjust to wearing an orthosis. A light shirt or other article of clothing should be worn under the brace because the appliance should not touch the skin. The health care team should realize that patient compliance is a crucial part of treatment, especially during treatment of scoliosis. Younger patients should be counseled about the importance of their treatment. They should be consulted about the type of orthosis chosen and advised about how to make adjustments to wardrobe so that they feel they fit in.

Furthermore, the patient should be advised to **exercise** regularly. Exercise helps to preserve spinal motion and keeping adjacent muscles strong.

Maintenance

For scoliosis braces, adjusting the tension on chest straps may be necessary. In addition, the spinal orthosis will need to be adjusted as the patient grows. Generally, a brace needs to be replaced after 15 months.

KEY TERMS

Disc—A circle of cartilage located between vertebrae in the spine.

Torso—The trunk of the human body, the area exclusive of the head and limbs.

Vertebrae—The back bones that form the spinal column. The bones are connected by discs and facet joints.

Health care team roles

Patients are seen by an orthopedist, a physician specializing in the treatment of musculoskeletal disorders. This specialty is concerned with deformities, diseases and injuries of the arms, legs, spine, and associated structures. The physician examines the patient, interprets x-rays, and establishes a treatment plan.

If a brace is needed, the patient is sent to an orthotist, an allied health professional who measures, designs, and fits orthopedic equipment like spinal orthoses. Orthotists may supervise several staff members. In some workplaces, the orthotics assistant assists the orthotist and may fabricate, repair, and maintain braces. However, orthoses may be made by the orthotics technician, an allied health worker who takes direction from the orthotist and the orthotics assistant. The technician also repairs and maintains braces. In some settings, the technician may have no contact with patients. Physical therapists will help the patient set up an exercise or rehabilitation program. In addition, a nurse may help plan treatment.

When a patient begins treatment for scoliosis, the orthopedist generally sees the patient several times annually. These appointments are scheduled every four to six months to allow the health care team to assess the patient's growth. The orthotist and orthotic technician may need to adjust a brace or fit a new orthosis. Once the patient is skeletally mature and bracing treatment ends, the patient usually returns a year later for a follow-up assessment that includes an x ray. The patient may be asked to return in five years. Patients are urged to return if a problem develops or they become pregnant.

Training

Members of the health care team receive training in the use of spinal orthoses while studying for their respective professions. For the orthopedist, this training is part

of medical school. For the orthopedic nurse, this training comes during nursing school.

Orthotists earn a four-year bachelor of science degree and finish with specialized orthotic training. They also serve a clinical residency. Orthotics technicians complete programs that last from six months to one year. In addition, people working in these allied health professions can receive certification through the American Academy of Orthotics and **Prosthetics**. Board certification is based on factors including education, employment, continuing education courses, and membership in the academy.

The name of the academy reflects the relationship between the fields of orthotics and prosthetics. While orthotics usually focuses on temporary treatment with a brace, prosthetics involves permanent replacement of a body part with an artificial appliance. However, some patients will require both prosthetics and orthotics, so schools offer degrees and certificates in both disciplines.

Spinal traction

Definition

Spinal traction is the process of applying force through body weight, weights, and/or pulleys to draw apart the vertebrae of the spine.

Purpose

Spinal traction may be indicated when a patient complains of cervical, low back, or radiating **pain** that is likely caused by a vertebral disc protrusion or degenerative changes. It is used to accomplish one or more of the following purposes: distract (pull apart) vertebral bodies, distract and glide the facet joints, widen the intervertebral foramen (openings to the spinal canal formed by the vertebrae), or stretch spinal musculature. Release of discal pressure and widening of intervertebral space can reduce discal pain and pain caused by impingement of nerves exiting the **spinal cord**.

Precautions

In general, traction should not be applied when there is a disease process that reduces the body's tolerance to force. Traction is contraindicated when there is a tumor, **infection**, vascular disorder, ligamentous instability, **osteoporosis**, or claustrophobia.

Description

Types of spinal traction include: sustained, intermittent mechanical, manual, positional, auto-traction, and gravity traction. Sustained traction is applied with heavy weights or a mechanical device that apply the force to maintain a constant traction for a time period of one to 30 minutes. Intermittent mechanical traction is more widely used in the United States; it involves the use of a split table and a mechanical device to apply and withdraw force every few seconds. In manual traction, the physical therapist may use the weight of his or her body in applying a traction force to the spine. Manual traction is often used to assess a patient's response to traction, or when adjustment of the position or amount of force may be needed. Positional traction allows the patient to be positioned to maximize the effect of traction on the suspected causative structure, or to allow the patient to remain in a preferred posture until pain is relieved. Self-traction allows the patient to position him or herself to provide traction with the assistance of gravity. Gravity lumbar traction is administered in one of two ways. Either the rib cage is grasped in a vest, allowing the weight of the legs to provide a traction force; or the ankles or pelvis are grasped, allowing the upper body to exert the traction force.

In order for traction to be effective, the force must be great enough to cause separation at the target spinal segment(s). A wide range of forces, from 30–300% of body weight, has been shown to be effective in studies of lumbar traction; however, a traction force of such large magnitude as 300% may cause damage to the vertebral structures. Thirty percent of body weight has been shown to be effective in reduction of symptoms. For cervical traction, research has shown that 20–45 lb (7.4–16.8 kg) is an effective range for producing separation.

With mechanical lumbar traction, traction harnesses are placed around the patient's pelvis and thorax. The patient then lies on a split table on his or her back, **stomach**, or side, depending upon the position thought to be optimal for the specific symptoms being treated. The split table allows for minimizing of friction forces. The straps of the harness are hooked to the motorized traction unit that is programmed for the traction force, overall time, and hold/rest periods desired.

For cervical traction, it has been found that patients are able to relax better and forces of gravity interfere less in the supine versus sitting position. To straighten out the normal lordosis and provide a more longitudinal pull, the neck often is flexed to approximately 20–30°, unless treating the joints of the first and second cervical vertebrae. Several types of head halters and devices are available to connect to the traction source.

Preparation

Before traction is applied, a full evaluation should be done to determine the possible causes of the patient's symptoms and uncover potential contraindications to traction. Physical therapists often use manual traction as part of the evaluation to assess the effects it has on symptoms. It is important that the patient is able to relax when traction is applied, so that muscle guarding does not take place. Modalities such as heat may be used to help with **relaxation**.

Aftercare

Traction usually is one part of a patient's plan of care. The physical therapist may teach a patient exercises, body mechanics, self-traction, and **pain management** techniques that should be performed at home between treatment times and after the course of **physical therapy** is finished.

Complications

It is important that the patient reports any adverse reactions or increase in pain after each treatment. Adverse reactions can be more easily avoided by keeping

the initial treatment times short (less than 10 minutes) with low force to allow the patient to become accustomed to the procedure.

Results

The desired outcome of traction is the reduction of neurological signs and pain in the neck, back and/or extremities, allowing for return to functional activities. Although clinicians often find favorable results with the use of traction, research with randomized, controlled trials showing statistically significant positive results is still sparse. This may be due in part to lack of good research design and the many factors involved in back pain.

Health care team roles

The physician usually refers the patient to physical therapy for conservative treatment of neck or back pain. The physical therapist examines the patient and makes decisions regarding the appropriate plan of care, which may include traction. The physical therapist determines the specifications for traction and sets up the patient on the apparatus for the first few times, being sure to monitor the patient intermittently. The physical therapist assistant may set up the patient for future treatments, with guidance from the physical therapist regarding duration and force specifications.

Spirometry tests

Definition

Spirometry is the measurement of airflow into and out of the **lungs**. The patient is given instructions on how to perform the breathing maneuvers. To perform the procedure the nose is pinched off, and the patient breathes as instructed through a mouthpiece attached to the spirometer. The three breathing maneuvers are practiced before recording the procedure, and the highest of three trials is used for evaluation of breathing. The instrument measures air flow by electronic or mechanical displacement principles and uses a microprocessor and recorder to calculate and plot air flow.

The test produces a recording of the patient's ventilation under conditions involving both normal and maximal effort. The recording, called a spirogram, shows the volume of air moved and the rate at which it is moved into and out of the lungs. There are several lung capacities that are measured by spirometry. Accurate measurement of these are dependent upon the patient performing the appropriate maneuver properly. The most common are described below:

- **Vital capacity (VC):** This is the amount of air in liters that is moved out of the lung during normal breathing. The patient is instructed to breathe in and out normally to full expiration for this maneuver. Vital capacity is normally about 80% of the total lung capacity. Because of the elastic nature of the lungs and surrounding thorax, a small volume of air will remain in the lungs after full exhalation. This volume is called the residual volume (RV).
- **Forced vital capacity (FVC):** After breathing out normally to full expiration the patient is instructed to breath in with a maximal effort and then exhale as forcefully and rapidly as possible. The FVC is the volume of air that is expelled into the spirometer following a maximum inhalation effort.
- **Forced expiratory volume (FEV):** At the start of the FVC maneuver, the spirometer measures volume of air that is delivered through the mouthpiece at timed intervals of 0.5, 1.0, 2.0, and 3.0 seconds. The sum of these measurements normally constitutes about 97% of the FVC measurement. The most commonly used FEV measurement is FEV-1, which is the volume of air exhaled into the mouthpiece in one second. The FEV-1 should be at least 70% of the FVC.
- **Forced expiratory flow 25-75% (FEF 25-75):** This is a calculation of the average flow rate over the center portion of the forced expiratory volume recording. It is determined from the time in seconds at which 25% and

75% of the vital capacity is reached. The volume of air exhaled in liters per second between these two times is the FEF 25-75. This value reflects the status of the medium and small sized airways.

- **Maximal voluntary ventilation (MVV):** A maneuver in which the patient breathes as deeply and as fast as possible for 15 seconds. The average airflow (liters per second) indicates the strength and endurance of the respiratory muscles.

Normal values for FVC, FEV, FEF, and MVV are dependent on the patient's age, gender and size (height).

Purpose

Spirometry is the most commonly performed **pulmonary function test (PFT)**. The test can be performed at the bedside, in a physician's office, or pulmonary laboratory. It is often the first test performed when a problem with lung function is suspected. Spirometry may also be suggested by an abnormal x ray, arterial **blood gas analysis**, or other diagnostic pulmonary test result. In March 2000, the National Lung Health Education Program recommended that regular spirometry tests be performed on persons over 45 years old who have a history of smoking. Spirometry tests are also recommended for persons having a family history of lung disease, chronic respiratory ailments, and persons of advanced age. Spirometry measures ventilation, the movement of air into and out of the lungs. The spirogram will identify two different types of abnormal ventilation patterns, obstructive and restrictive. Common causes of an obstructive pattern are **cystic fibrosis, asthma**, broniectasis, bronchitis, and **emphysema**. These conditions may be collectively referred to using the acronym CABBE. Chronic bronchitis, emphysema, and asthma result in dyspnea and ventilation deficiency, a condition known as chronic obstructive pulmonary disease (COPD). As of 2001, COPD is the fourth leading cause of death among Americans. Common causes of a restrictive pattern are **pneumonia, heart** disease, **pregnancy**, lung fibrosis, pneumothorax (collapsed lung), and pleural effusion (compression caused by chest fluid).

Obstructive and restrictive patterns can be identified on spirographs. Volume (liters) is plotted on the y-axis versus time (seconds) on the x-axis. A restrictive pattern is characterized by a normal shape showing reduced volumes for all parameters. The reduction in volumes indicates the severity of the disease. An obstructive pattern produces a spirogram with an abnormal shape. Inspiration volume is reduced. The volume of air expelled is normal, but the air flowrate is slower causing an elongated tail to the FVC.

A flow-volume loop spirogram is another way of displaying spirometry measurements. This requires a FVC maneuver followed by a forced inspiratory volume (FIV). Flow rate in liters per second is plotted on the y-axis and volume (liters) is plotted on the x-axis. The expiration phase is shown on top and the inspiration phase on the bottom. The flow-volume loop spirogram is helpful in diagnosing upper airway obstruction and can differentiate some types of restrictive patterns.

Some conditions produce specific signs on the spirogram. Irregular inspirations with rapid frequency are caused by hyperventilation associated with **stress**. Diffuse fibrosis of the lung causes rapid breathing of reduced volume that produces a repetitive pattern known as the penmanship sign. Serial reduction in the FVC peaks indicates trapped air inside the lung. A notch and reduced volume in the early segments of the FVC is consistent with airway collapse. A rise at the end of the expiration is associated with airway resistance.

Spirometry is used to assess lung function over time and is often used to evaluate the efficacy of bronchodilator inhalers such as albuterol. It is important that the patient not use a bronchodilator prior to the evaluation. Spirometry is performed before and after inhaling the bronchodilator. In general, a 12% or greater improvement in both FVC and FEV-1 and/or an increase in FVC by 0.2 liters is considered a significant improvement in an adult patient.

Precautions

The physician ordering the test should be aware of any medications and medical conditions which may affect the validity of the test. The patient's smoking habits and history should be documented thoroughly. The subject must be able to understand and respond to instructions for the breathing maneuvers. Therefore, the test may not be appropriate for very young, unresponsive, or physically impaired persons. Spirometry is contraindicated in patients whose condition will be aggravated by forced breathing. Hemoptysis, pneumothorax, recent heart attack, unstable angina, aneurysm (cranial, thoracic, or abdominal), thrombotic condition, recent thoracic or abdominal surgery, nausea or vomiting are conditions that may contraindicate spirometry. The test should be terminated, if the patient shows signs of significant head, chest, or abdominal **pain** while the test is in progress.

Spirometry is dependent upon the patient's full compliance with breathing instructions especially his or her willingness to extend a maximal effort at forceful breathing. Therefore, the patient's emotional state needs to be considered when performing the procedure.

KEY TERMS

Bronchodilator—A drug, usually self-administered by inhalation, that dilates the airways.

Forced expiratory volume (FEV)—The volume of air exhaled from the beginning of expiration to a set time (usually 0.5, 1, 2, and 3 seconds).

Forced vital capacity (FVC)—The volume of air that can be exhaled forcefully after a maximal inspiration.

Vital capacity (VC)—The volume of air that can be exhaled following a full inspiration.

Preparation

The patient's age, sex, and race are recorded, and height and weight are measured before starting the procedure. The patient should not have eaten heavily within three hours of the test. He or she should be instructed to wear clothing that is loose fitting over the chest and abdominal area. The respiratory therapist or other testing personnel should explain and demonstrate the breathing maneuvers to the patient. The patient should practice breathing into the mouthpiece until he or she is able to duplicate the maneuvers successfully on two consecutive tries.

Aftercare

No special care is usually required following spirometry. The occasional patient may become light-headed or dizzy. Such patients should be asked to rest or lie down, and they should not be discharged until after the symptoms subside. In rare cases, the patient may experience pneumothorax, intracranial **hypertension**, vertigo, chest pain, or uncontrolled coughing. In such cases, additional care directed by a physician may be required.

Results

The results of spirometry tests are compared to predicted values based on the patient's age, gender, and height. For example, a young adult in good health is expected to have the following FEV values:

- FEV-0.5 50-60% of FVC
- FEV-1 75-85% of FVC
- FEV-2 95% of FVC
- FEV-3 97% of FVC

In general, any value falling between 80% and 100% of the predicted value is considered normal. Values between 60% and 79% indicate mild lung dysfunction. Values between 40% and 59% indicate moderate lung dysfunction, and values below 40% indicate severe dysfunction.

Health care team roles

Spirometry tests are ordered by a physician, and results are evaluated by a pulmonologist, a physician with special training in pulmonary function. Spirometry testing is performed most often by a registered respiratory therapist (RRT), certified respiratory technician (CRTT), certified pulmonary function technologist (CPFT), or registered pulmonary function technologist (RPFT).

Sports injuries

Definition

A sports injury is any bodily damage sustained during participation in competitive or non-competitive ath-

letic activity. Sports injuries can affect bones or soft tissue (i.e., muscles, ligaments, tendons).

Description

Sports injuries are identified as either acute or chronic. Acute sports injuries are characterized by the sudden appearance of symptoms, usually associated with a single traumatic incident. Signs and symptoms of acute sports injuries include **pain**, swelling, and deformity in the affected area, and in the case of joint injuries, limited ability to move the joint. Common acute sports injuries include **sprains and strains**, contusions (i.e., serious bruises), joint dislocations, bone **fractures**, and concussions.

Chronic sports injuries, also called overuse injuries, are identified with more gradual onset and are caused by repetitive light trauma to soft tissue or bone. Typically, pain and swelling worsen during athletic activity but decrease after the activity is stopped. Overuse injuries include tendonitis, **bursitis**, shin splints, and stress fractures.

The United States Consumer Product Safety Commission (CPSC) estimates that, in 1998, there were over one million sports injuries among persons 35–54 years old. Moreover, the number of sports injuries in this age group increased by one-third between 1991 and 1998. The CPSC believes that the rise in injuries is because of increased sports participation among baby boomers.

The CPSC National Electronic Injury Surveillance System also reports that over 3.5 million sports injuries in children younger than age 15 are treated at hospitals and clinics annually. Children are particularly vulnerable to sports injuries because their bones, muscles, and connective tissue have not fully matured, and because they have not yet developed mature neuromuscular coordination.

Causes and symptoms

Acute sports injuries are caused by excessive force applied to bone or soft tissue during sports activity. These injuries are commonly associated with **falls** and high-speed collisions. Specific signs and symptoms depend on the nature of the impact and the body region affected.

Acute sports injuries

SOFT TISSUE INJURIES. Soft tissue injuries occur typically in the knee, shoulder, and ankle. In the knee, tears of the anterior cruciate ligament (ACL) and of the meniscus (i.e., cartilage in the knee) are common. A twisted knee, a sudden directional change, or a misaligned landing from a jump can cause these knee injuries. With the

ACL tear, a “pop” in the knee is frequently felt at the time of the injury. This popping sensation is accompanied by pain and weakness in the knee. A tear of the meniscal cartilage is identified by pain over the area of the meniscus area underneath the edge of the patella, or kneecap), and the pain intensifies if a finger is gently pushed on the edge of the kneecap. The athlete is also often unable to fully extend the knee. With both ACL and meniscus tears, there is swelling several hours after the injury occurs.

In the shoulder, strains of the rotator cuff tendons and dislocation of the shoulder are frequently seen. Tendon strains are associated with overly vigorous throwing movements, and are characterized by the patient complaining of pain if the arm is rotated against resistance. Shoulder dislocations are identified by deformity in the shoulder joint, and pain and lack of mobility in the joint area.

Ankle sprains are the most common injury in sports that require running and jumping. Ankle sprains occur when ligaments in the ankle have been stretched or torn. There is typically swelling and tenderness, and in more serious cases, the athlete is unable to put much weight on the foot of the injured ankle.

SKELETAL INJURIES. Fractures are breaks in the bone due to collisions or falls, and commonly appear in the leg and arm. Symptoms include pain, swelling, and bruising at the site of the fracture. There is also weakness in the limb and an inability to bear weight on the limb. With open fractures, bone fragments protrude through the skin.

BRAIN INJURIES. Brain injuries cause more deaths than any other type of sports injuries. A common brain injury is the **concussion**, an injury caused by the impact of the brain against the interior surface of the **skull**. Concussions often follow a blow to the head or a very rapid acceleration of the head. Loss of consciousness is an important symptom in brain injuries. Other signs and symptoms of concussion include headache, vomiting, delayed motor or verbal responses, partial loss of **vision**, **memory** loss, lack of coordination, or erratic and inappropriate behavior.

Chronic sports injuries

Chronic or overuse injuries are caused by repetitive stress to soft tissue or bone and typically result from a sudden increase in the duration or intensity of athletic activity. In some cases, chronic injuries can be a precipitating factor in acute injuries such as strains and sprains.

SOFT TISSUE INJURIES. Tendonitis, or inflammation of the tendon, is one of the most common overuse injuries and often affects the joints at the elbow, knee, shoulder, and foot. In the elbow joint, tendonitis is known

This man has ruptured his biceps from weight lifting. (NMSB/Custom Medical Stock Photo. Reproduced by permission.)

as golfer's elbow or tennis elbow, and is often caused by poor technique. Shoulder tendonitis is caused by repetitive overhead motions and is common in swimming and in sports requiring throwing motions. In the foot, inflammation of the Achilles tendon (i.e., in the heel area) is caused by biomechanical misalignments, inadequate stretching, sudden increases in training, and athletic play on hard or banked surfaces. Symptoms of tendonitis include pain, redness, swelling, and warmth of the affected area. These symptoms diminish when athletic activity is stopped. Bursitis, an inflammation of the connective tissue of joints, is also common in the knee.

SKELETAL INJURIES. Stress fractures are tiny breaks in the bone caused by repetitive forces. Stress fractures frequently affect the leg, foot, and ankle after training has been suddenly intensified or the sport has been played on hard surfaces. Other risk factors of stress fractures are **osteoporosis** and eating disorders, which tend to weaken bone. Symptoms of stress fractures include pain when weight is placed on the leg or foot, with pain increasing after athletic activity. There may be swelling and point tenderness (i.e., pain when a small region of the affected area is lightly pushed).

Diagnosis

Acute injuries are usually self-evident, as they are associated with a specific traumatic event. After the trauma, the physician performs a **physical examination** of the athlete to identify the specific injury. In the case of suspected joint or skeletal injuries, a radiological technician will take x rays, and the radiologist will confirm or rule out a dislocation, bone fracture, or soft tissue injury.

With overuse injuries, the physician conducts a physical examination and uses signs, symptoms, and training history to diagnose the injury. If a stress fracture is suspected, a bone scan or **magnetic resonance imaging** (MRI) of the area may be performed.

Treatment

For sports injuries, Protection-Rest-Ice-Compression-Elevation (PRICE) is the standard of treatment. PRICE specifies the elements of first-line treatment. Depending on the type of injury, protection may mean immobilizing the affected area with a brace, tape, or wrap, or simply avoiding activities that aggravate the injury. Rest means refraining from activities that prevent recovery from injury; in many cases, cross-training is considered rest

because it exercises areas that do not affect the injury. Ice should be used to relieve pain and swelling. Compression, with tape or elastic wraps, is used to limit swelling and stabilize the area. Elevation, where the injured body part is placed above the level of the **heart**, is also used to prevent swelling.

Some clinicians use the extended PRICE-MM (i.e., Medication and Modalities) regimen, which includes therapeutic use of medication and modalities (i.e., rehabilitation). Nonsteroidal anti-inflammatory medicines such as ibuprofen (e.g., Advil, Motrin) and naproxen (e.g., Naprosyn) have traditionally been used for **pain management** with sports injuries. Injections of **corticosteroids** are sometimes used to control inflammation and pain, but since these injections reduce the strength and flexibility of soft tissue, corticosteroids are used sparingly, primarily for specific overuse syndromes.

The goal of modalities, as in modes of rehabilitation therapies, is to return the athlete to the sport as quickly and as safely as possible. Rehabilitation can begin as soon as the physician permits, typically after internal bleeding has stopped. Modalities include cold and heat therapies, therapeutic ultrasound, range of motion exercises, and resistance exercises.

In serious cases of acute and overuse injuries, PRICE-MM may not be sufficient, and surgery may be required to repair injuries.

Prognosis

For most sports injuries, the PRICE-MM regimen should be sufficient to restore the athlete to the previous level of performance. The prognosis is good as long as the rehabilitation has successfully restored the strength and flexibility of the injured area, and the athlete takes care to prevent recurrence of the injury, suspending activity and undertaking appropriate therapy if pain recurs. With some serious injuries, the athlete will not be able to return to the sport or return to the previous level of activity in that sport.

Health care team roles

In school and youth sports, the nurse is often the first health care provider to evaluate acute injuries and is often responsible for some **first aid of wounds** and injuries until a physician can attend to the athlete. In school settings, since the nurse is in more frequent contact with children, he or she can advise on general measures to prevent injuries such as warm-up and stretching. In clinical settings, the nurse takes a detailed medical and training history that can help the physician diagnose the injury.

The athletic trainer is often on call for emergency care of acute sports injuries and performs first aid on the injured athlete. He or she specializes in sports activities and can give more specific advice for overall conditioning, training, and treatment of the athlete. The athletic trainer also serves as a liaison between the athlete and coaches, parents, and physicians.

Prior to student participation in athletic activity, the the preparticipation physical examination is performed by the physician to assess the patient's fitness for the sport. If the athlete is injured, a diagnosis of the injury is made by the physician and a prescription for appropriate treatment is given. Medical and radiological tests are conducted by technologists. The results assist in determination of the physician's diagnosis. For rehabilitation, the patient may be referred to a physical therapist. For serious injuries requiring surgery, the patient may be referred to an orthopedic surgeon.

Prevention

Many acute and overuse sports injuries are caused by increases in training intensity that put too much physical stress on the athlete's body. This often happens for in amateur athletes who do not sustain regular training regimens and overdo their workouts when they do train. These injuries can be prevented with a variety of training and educational regimens.

For youths and adults, the physical exam can be used to identify weaknesses that may predispose the athlete to injury, and that should be developed prior to engaging in athletic activity. Pre-season conditioning programs that slowly increase intensity level are useful in developing the athlete's level of fitness in preparation for the sports season. Flexibility training, strength training, and cross training have also been shown to prevent injuries by improving the body's resilience.

Finally, education can be effective in preventing certain common sports injuries. The athlete can be shown how to wear protective gear correctly, how to perform the correct throwing, swinging, blocking, or tackling motion to prevent injury, and how to adjust body biomechanics in the event of an unpreventable fall. Although not all sports injuries can be prevented, the damage from many injuries can be minimized with appropriate training.

Sports nutrition

Definition

Sports **nutrition** consists of the nutritional guidelines involving primarily carbohydrate, protein and fluid intake that are used to improve athletic performance.

Purpose

Optimal nutrition improves physical activity, athletic performance and recovery from **exercise**, whether one exercises recreationally or trains as a competition athlete. Consuming adequate food and fluid during, before, and after exercise does several things: maintains **blood** glucose, maximizes performance, and improves recovery time.

Precautions

Athletes who do not consume enough food to make the energy their bodies need risk nutrient deficiencies, loss of muscle mass and increase risk of injury and illness. In particular, female athletes who undereat put themselves at risk for low bone mass and amenorrhea. Athletes who desire weight loss should seek professional help to assure a slow weight loss before competition begins.

Description

Athletes do not need a diet substantially different from the U.S. Recommended Dietary Guidelines. However, the intake and timing of **carbohydrates**, protein, and fluids all affect athletic performance. The following guidelines are advised.

Meeting energy needs is the first priority for athletes, with caloric requirements influenced by many factors such as age, sex, lean body mass, and frequency and intensity of the exercise. Great variation among individuals exists in the energy needed to maintain weight and body composition. Men and women aged 19-50 years who are slightly to moderately active were established by the 1989 Recommended Daily Allowances as 2,200 and 2,900 kcal per day, respectively. However, the male endurance athlete may need as high as 5,000 kcal per day.

The body prefers carbohydrates as an energy source, using blood glucose during the first minutes of exercise. Then the stored carbohydrate form called glycogen becomes depleted to some extent, with a slow walk using up less glycogen than a one-hour jog. In endurance exercise, the energy source shifts to circulating blood glucose provided from the breakdown of **fats**. A diet consisting of 55%-60% carbohydrate is sufficient for most athletes, with daily recommendations ranging from 6-10 gm/kg body weight, depending on the type of sport, energy expended, sex and environmental conditions.

A practice called carbohydrate loading, which first depletes glycogen stores and then restores them with a 70% carbohydrate intake, is sometimes used in athletes performing exhausting events lasting at least 90 minutes. However, it entails weeks worth of preparation to adjust exercise and diet.

Protein and fat both contribute to the energy pool but in much less amounts. Protein needs of athletes receive a lot of attention but a balanced diet usually meets requirements. Endurance athletes and strength-training athletes do need more protein, 1.2 gm up to 1.6 gm/kg for strength training, versus the usual 0.8 to 1 gm/kg. Few athletes are protein-deficient, because the extra calories eaten due to exercise needs provide adequate protein. Research on individual amino acids supplementation is inconsistent and their use is not advocated.

As for fat, diets containing 20-25% energy from fat are recommended to ensure adequate carbohydrate intake. Because of negative effects on some people's blood **lipids**, fat intake should not be decreased below 15% of calories.

Vitamin and mineral supplementation is not required if a variety of foods are eaten. **Calcium**, **iron** and **zinc** can be low in the diets of athletes, particularly females. Of these, iron depletion is the most common, and occurs most often in female athletes, long-distance runners and vegetarians.

Fluid intake is probably the most neglected aspect of an athlete's diet. Muscle activity during exercise produces heat, which the body gets rid of through sweat. It is very important that water be replaced to prevent **dehydration**.

Fluid losses can exceed 2 qts (1.8 L) per hour, especially in humid environments or in sports where padding blocks effective sweating. Performance becomes impaired in dehydration. The amount of fluid needed depends on how much sweat is lost during exercise.

The use of ergogenic aids, products that claim to increase performance or work output, is controversial. Athletes should carefully evaluate products before use.

During exercise

During exercise, the following guidelines should replace fluid losses and maintain carbohydrate levels. These are especially important for endurance events lasting longer than an hour or in extreme environment.

- Drink small amounts (6-12 oz) of plain, cool water every 15-20 minutes during workouts, as tolerated, particularly if it is hot or humid or during longer exercise.
- For exercise lasting over one hour or in high humidity, a sports drink like Gatorade or PowerAde, which contain 6% carbohydrate (15–20 gm or 8 oz), can maintain blood glucose levels, preserve glycogen stores, and improve performance. Beverages such as undiluted fruit juice contain greater than 8% carbohydrate and may cause intestinal upset.

Preparation

Before exercise

The following is recommended one to two hours before exercise:

- Exercisers should eat a carbohydrate snack, such as yogurt, cereal, or a bagel one or more hours before exercise if it has been several hours since a meal. Grains, fruits and dairy products all contain high amounts of carbohydrates and help keep a steady blood sugar. People who experience **stomach** upset or drops in blood sugar called hypoglycemia should avoid carbohydrates immediately before exercise.
- Drink about two cups (14-22 oz) of fluid before exercise.

Aftercare

After exercise

The following tips help after exercise:

- The athlete should drink adequate fluids to replace sweat losses. The best measurement of fluid loss is weighing before and after exercise. Drinking 16–24 oz of fluid (non-caffeinated, non-alcoholic) for every

KEY TERMS

Carbohydrates—Sugars or starches composed of long sugar chains, which serve as a main energy source.

Endurance athlete—An athlete who trains continuously, for long durations and over an extended period of time.

Glycogen—The main storage form of carbohydrate, which occurs primarily in the muscle and liver

pound (0.45 kg) of body weight lost during exercise is recommended. If the previous meal included sodium, there is no need for an electrolyte drink after a session of moderate duration.

- Eat a high carbohydrate snack or drink some juice, when muscles are geared up to replace expended glycogen. Especially after strenuous competition or training, a snack that also contains some protein will help build and repair muscle tissue.

Complications

Vegetarian athletes may be at risk for inadequate energy, protein, and micronutrients intakes, particularly if they eliminate dairy from their diet. Consultation with a registered dietitian is recommended.

While incorrect carbohydrate or fluid intake usually leads to reduced performance, too much dehydration can be deadly. A loss of 5% of body weight due to sweating can result in heat stroke, a severe condition characterized by high **fever**, collapse, cessation of sweating, and sometimes **coma**. Hypohydration occurs when athletes dehydrate themselves before competing, such as for a weight category. Hyponatremia (low blood sodium concentrations) can develop from prolonged heavy sweating and failure to replace sodium, or when excess water is retained in the body.

Results

Research over the past 20 years shows good nutrition affects exercise performance. Optimal sport nutrition increases glycogen stores prior to exercise, supplies carbohydrate during prolonged exercise, and assures adequate hydration before, during and after exercise.

Health care team roles

- The training of exercise physiologists includes sports nutrition. Also, athletes can seek consultations with a licensed nutrition specialist or registered dietitian trained in sport nutrition.
- Nursing and other allied health professionals should ask patients about their exercise and nutrition habits, particularly when patients present with unexplained weight loss, bone **fractures** or nutrient deficiencies.

Sports participation in children

Definition

Sports participation in children involves the issue of children playing or competing in sports and the related concerns regarding **nutrition**, growth, injury and psychosocial factors.

Description

As more and more children participate in recreational or competitive sports activities, the issue of sports participation has increasingly become a topic of discussion. It is estimated that 25% of girls and 50% of boys aged

eight to 16 participate in sports in the United States. Even more participate in sports in the United Kingdom. These numbers have increased the discussion and research on the effects of early athletic training on children's growing bodies. Specific areas of concern include the cardiovascular and musculoskeletal systems, nutrition, sexual maturation, psychosocial implications, and injury prevention and treatment.

Viewpoints

Studies have shown that, in general, childhood activity is on the decline and childhood **obesity** is on the rise. Requirements for physical education in schools have become less stringent. One survey sponsored by the Centers for Disease Control reports that 50% of high school students are not enrolled in physical education, and more than 80% of high school students do not participate in 20 minutes of physical activity three times per week. There is clearly a need for the encouragement of physical activity in children and adolescents. At the other end of the spectrum, however, injuries and other ramifications of intense athletic participation cannot be ignored.

One of the major concerns related to sports participation is the incidence of injury. Thirty to 40 percent of all pediatric accidents occur during athletics, with 10% of all childhood head injuries being related to sports participation. An estimated three million children and adolescents visit emergency rooms each year for sports-related injuries, while another five million require a visit to their physicians. Some parents and professionals view these statistics as viable reasons to keep children away from organized sports participation, however, a large number of injuries occur during unsupervised activities as well, such as diving and skiing. In any case, excessive stress to the body can cause tissue injuries; particularly concerning being those to the epiphyseal plates, as they can result in growth disturbances.

Research studies have identified several factors contributing to **sports injuries**, including but not limited to inadequate equipment, intensity of competition, and poor playing technique. Preventative measures can address many of these contributors in order to help reduce risk, but some researchers opine that increased surveillance is still required to determine which preventative measures would be most effective. Surveillance would include determination of the most prevalent types of injuries, who is affected and why they occur.

Another area of concern related to early sports participation is nutrition. Proper nutrition is important for all youth, and vital for young athletes. Opponents of early sports participation may point out that children who

engage in activities requiring slim figures, such as ballet or gymnastics, may place their growth at risk through inadequate nutrition and even pathologic eating behaviors. One study of rhythmic gymnasts noted that while gymnasts did not have adequate caloric intake for their energy expenditure, the composition of their diets reflected better nutritional practices than those of non-athletes.

Other areas of concern include: cardiac implications, sexual maturation, and psychosocial aspects of sports participation. The research on cardiac function with intense **exercise** has not demonstrated adverse effects, although opponents may point to research indicating that myocardial function can be depressed after intense exercise. In relation to sexual maturation, athletic girls tend to have a later onset of menstruation than do those not participating in sports. In addition, amenorrhea, or cessation of menstrual period, is common with intense training. Opponents of childhood athletics also point to psychosocial problems caused by **anxiety** and stress of competition. Research studies have shown that these problems do occur in a small minority of youth athletes due to burnout, inability to participate in other activities, and parental demands. Proponents of sports participation recommend that psychosocial problems can be limited with participation in a variety of sports as opposed to early specialization.

Professional implications

Allied health professionals, including nurses, physical therapists, exercise physiologists and athletic trainers, play important roles in client education, injury prevention and treatment. These professionals may assist clients and their families by:

- Providing general information regarding benefits and risks to youth athletics so that clients and families can make informed decisions regarding level of participation.
- Encouraging children to participate in activities consistent with their abilities and interests, while discouraging early specialization, parental pressure and emphasis only on winning.
- Providing education regarding proper coaching, early identification of signs related to overuse injuries, and importance of rest.
- Monitoring body composition, height, weight, cardiac function, nutrition, and stress level regularly.
- Emphasizing the importance of general fitness versus training only sports-specific skills, and the importance of warm-up, cool-down and flexibility.

Sports participation impacts children physically, socially, and emotionally. Children can be impacted positively or negatively, so parents should watch for problems in any of these areas. (Photograph by Richard Cummins. Corbis. Reproduced by permission.)

- Identifying individual risk factors to injury (e.g., malalignment, muscle-tendon imbalance, disease, improper footwear) and provide education regarding these factors.
- Recommending and providing pre-participation physical examinations that include: medical history; screening of body systems; orthopedic evaluation; flexibility, strength, speed, agility, power, endurance, balance, and coordination assessment; and clearance for sports participation by a physician.

Sprains and strains

Definition

A sprain is an injury to ligaments and/or the joint capsule that occurs in response to large stresses. A strain is disruption of the contractile elements in muscle and/or tendon. An easy way to remember the difference between sprain and strain is that strain is spelled with a "t," which can infer the associated word tendon.

Description

Sprains

Sprains are categorized into three levels of severity. In a mild sprain, or first degree sprain, few ligamentous fibers have been torn, and the ligament is not significantly weakened. There may have been some slight bleeding. In a moderate sprain, also known as a second degree sprain, there is more disruption of the ligamentous fibers (40%–50% of the fibers are torn) and ligamentous weakness is present. Moderate bleeding occurs. In a severe sprain, also named a third degree sprain, there is complete disruption of the ligamentous fibers or joint capsule and there is no strength of the ligamentous tissue. Marked swelling, secondary to bleeding, is present. Many athletes have suffered a complete tear, or third degree sprain, of the anterior cruciate ligament (ACL) of their knee.

Strains

Strains are also referred to as first degree, second degree or third degree strains. In a first degree strain there is usually mild damage to the muscle or tendon with only a few fibers torn. There is minimal bleeding. A second degree strain presents with moderate weakness as the contractile components are torn. There is more bleeding

and swelling. In a third degree strain there is complete rupture of the muscle or tendon. A third degree strain is considered a complete tear, accompanied by bleeding, swelling, and loss of function of the associated muscle. An example of a third degree strain would be a rupture of the biceps tendon.

Causes and symptoms

Both sprains and strains are due to increased demand or large stresses placed on the involved structures, i.e., ligament, muscle, or tendon.

Sprains

In a first degree or mild sprain, there is minor weakness, minimal disability, and no muscle spasms of the surrounding musculature. In a second degree sprain, the individual may complain of moderate disability and report instability. For example, in a second degree sprain of the lateral ankle, the individual may report, "the ankle feels like giving way." In a third degree sprain the individual will complain of **pain** secondary to swelling. Furthermore, the individual will report having major impairment in function, i.e., weight bearing activities.

Strains

An individual with a mild strain may complain of mild irritation of the affected area with no appreciable change in function. A secondary strain will cause the individual to complain about swelling, some minimal stiffening, moderate disability, and moderate pain. In a severe strain, the individual will report a marked loss of function, swelling of the affected area, muscle spasms secondary to guarding, and significant weakness. Interestingly, because of the complete rupture in severe strains, there will be little or no pain on stretching or with movement. Any pain present is probably due to the severe swelling secondary to bleeding.

Diagnosis

Sprains

Functional testing and clinical observation are often sufficient to establish a diagnosis of sprain. In addition to the above symptoms, a variety of tests can be performed in an effort to evaluate the integrity and stability of the joint. For example, a clinician might test an injured knee by applying medial and lateral stress to the knee.

Four ligaments are important for the stability of the knee joint: the lateral collateral ligament, the medial collateral ligament, the anterior cruciate ligament and the posterior cruciate ligament. The collateral ligaments are

largely responsible for the stability of the knee joint in response to lateral and medial stress. Lateral force (also known as a valgus stress) pressures the medial ligament and medial force (also known as varus) pressures the lateral ligament. If a patient has sprained either ligament, the joint should be abnormally mobile—the more mobile, the more severe the sprain. Other tests to determine the status of the cruciate ligaments, such as the Lachman test and the posterior drawer test, may also be performed. Some of the more common knee injuries associated with football are tears of the medial collateral ligament (MCL) and/or the anterior cruciate ligament (ACL). Sometimes the forces that caused the injury are so severe that the MCL, ACL, and medial meniscus (cartilage) are all disrupted. This is termed an “unhappy triad.”

Depending on factors like the severity of the sprain, the nature of the injury, and the severity of the sprain, x rays may also be indicated. X rays do not indicate the severity of the sprain, merely whether a fracture has occurred or not. Ultrasonography and **magnetic resonance imaging** (MRI) may be used to determine the severity of a sprain. MRI has the additional benefit of offering multiple types of information. For example, in cases of suspected neck sprain, MRI can show whether the injury is truly a sprain, a strain, or originates from abnormalities in the cervical (intervertebral) disks.

Strains

MRI is also an important tool in the evaluation of strain. Although not indicated in the majority of cases, MRI provides the most accurate diagnostic information of the imaging techniques currently available (as of 2001). Other imaging techniques include ultrasound and computerized axial tomography (CAT scan), but their use is limited. In most cases, however, diagnosis is obtained from clinical observation and functional testing.

When evaluating a first degree strain, findings will show a mild loss of strength during resistance testing, a decreased range of motion, and minimal muscle guarding. In a second degree strain, the strength test will indicate moderate weakness, decreased range of motion, and moderate pain when stretching the tendon or muscle. In a third degree strain, findings will be more pronounced with significant swelling and major weakness compared to the uninvolved side. There will be marked loss of function and significant disability.

One common example of a strain is a hamstring strain, known more commonly as a pulled hamstring. In baseball, when a batter has just hit the ball in the infield, she or he will need to run quickly to first base. On approaching the first base bag, the batter may reach out and extend with the leg to touch the base. A common

injury at the point of extension is a tear of one of the following muscles (more commonly known as the hamstrings): biceps femoris, semimembranosus, or semitendinosus (tearing of all three is rare). When the hamstrings are over-extended, such as when the baseball player over extends the leg, a muscle or tendon tear may occur.

Treatment

Sprains

In a mild sprain the goal in treatment is to decrease any swelling that is present and prevent loss of motion secondary to stiffness. Ice, elevation, and compression should be used before and after treatment sessions. **Therapeutic exercise** should include range of motion, stretching, and strengthening of the surrounding musculature. In a moderate sprain, treatment is more conservative and the clinician must minimize the risk of further injury. Modalities should be continued to decrease swelling and pain. The RICE (rest, ice, compression, and elevation) principle should continue throughout treatment. A general rehabilitation pathway of strengthening, range of motion, and flexibility all need to continue and progress as tolerated. In a severe sprain, there are usually two options: surgical and non-surgical. In the surgical option, the ligament is re-attached by the physician. The non-surgical approach relies on bracing to minimize motion and allow for healing. The rehabilitation plan is complex in either of these approaches, but the goal is to initially minimize motion followed by slow progression into range of motion and strengthening.

Strains

Treatment of first and second degree strains is similar to treatment of sprains. It consists of utilizing the RICE principle and protecting the affected area from overstretching or overuse. Rehabilitation should focus on range of motion, decreasing swelling and pain, and gradual introduction of a strengthening program. Severe strains may require surgical repair, and protocols of rehabilitation are different for each affected area. Initial treatment could be immobilization followed by guarded range of motion, flexibility, and strengthening therapies.

Prognosis

Sprains

In a mild sprain, the individual can usually engage in normal activities within three to six weeks. In a moderate sprain, normal activities can usually resume in approximately eight to 12 weeks—ligamentous tissue requires approximately eight to 10 weeks to heal. By the third or

KEY TERMS

Immobilization—To keep a limb or joint free from movement and to maintain position. Movement is stopped by either bracing or casting.

Irritation—Minimal disruption of a structure that may cause bleeding. An irritation can present with minimal swelling and a feeling of discomfort to the individual. Usually, function is not impaired secondary to an irritation. An irritation can progress to a more severe impairment if healing is not allowed to appropriately take place.

Modalities—A term used to describe treatment modes that are applied to the individual. In rehabilitation, a few examples of a modality could be heat, ice, ultrasound, electrical stimulation, and traction.

Range of motion—The amount of motion that a joint has. There is active range of motion and passive range of motion. Active range of motion is the range the joint can traverse under voluntary contraction. The individual moves the limb using their muscle power. Passive range of motion is the range that the joint moves though while either a machine or individual moves the limb. In passive range of motion the limb is usually moved for the individual with no muscle contraction.

Therapeutic exercise—A general term to describe a multitude of exercises, stretching and general rehabilitation. Can include range of motion, resistive exercises such as weight training, postural correction exercises, and exercises that incorporate coordination and balance training.

fourth week, however, the individual with a moderate sprain will usually have a normal range of motion and be free of pain. Therefore, the key to recovery from a moderate strain is to prevent the patient from returning to normal activity before the ligament heals.

The prognosis for a complete rupture (severe sprain) varies. Success depends on the management of the injury, and the subsequent level of desired activity. A return to normal activity may require from six months to one year.

Strains

The prognosis for treating first or second degree strains is good. The major problem is stressing the affected area too soon. Overstressing the affected area too early in recovery may cause the strain to become chronic. A

chronic strain could lead to further complications such as muscle spasm and possible myositis.

Health care team roles

It is appropriate that physicians, nurses, therapists, and other allied health partners be familiar with the prevention and care of sprains and strains. Moreover, nurses and allied health partners should be involved in **patient education** that focuses on minimizing the risk of over-use injuries.

Prevention

The best prevention for sprains and strains is to have optimal muscular strength, muscular flexibility, and endurance. Appropriate warm-up exercises before an activity may further minimize the potential for injury. Sprains may also be prevented by the use of a brace.

Sprains are caused by excessive stress to a ligament or capsule. Optimal strength, flexibility and endurance help the muscles to accept and distribute forces that might otherwise be placed on the joint. If muscles are weak and not flexible, increased demand placed on the area will need to be absorbed by the ligaments or joint capsule. Increased demand on these structures will put them at greater risk for failure, i.e. tearing. Braces may absorb some of this extra demand. For example, persons wishing to avoid ankle injury may choose to tape their ankle or wear a lacing brace before engaging in activities with injury potential. Persons with prior ankle injuries may utilize an air stirrup.

Surfaces may also play a role in sprains and strains. A controversial example is the comparison of football injuries on natural grass and artificial turf. One study found an increased rate of anterior cruciate ligament sprains in football players playing on artificial turf compared to sprains on natural grass. A less controversial example might be the comparison of a manicured lawn to a field of wild prairie grass. The prairie grass might hide many dips in the field that would be apparent in a manicured lawn. Such a field would provide a greater likelihood of injury due to the unpredictability and unevenness of the surface (there is a greater chance for unexpected excessive forces on a joint).

Sputum analysis

Definition

Sputum is a substance comprised of mucous, foreign matter, and saliva that is found in the **lungs** or bronchial tree. A sputum analysis is a group of tests performed in a laboratory on a sputum specimen obtained from a sick patient. A portion of the sputum specimen is stained and put on a slide for examination of cells and organisms. Another portion of the specimen is put on an agar plate to see if infectious organisms grow and can be identified. Some of the sputum may be placed in special solutions to test for specific diseases.

Sputum

Term	Description	Associated with
Fetid	Foul-smelling, typical of anaerobic infection	Bronchiectasis, lung abscess, or cystic fibrosis
Frothy	White or pink-tinged, foamy, thin sputum	Pulmonary edema
Hemoptysis	Expectoration of blood or bloody sputum; amount may range from blood-streaked to massive hemorrhage	A variety of pathologies
Mucoid	White or clear, not generally associated with bronchopulmonary infection	Chronic cough (acute or chronic bronchitis, cystic fibrosis)
Purulent	Pus, yellow or greenish sputum, often copious and thick	Acute and chronic infection
Rusty	Descriptive of the color of sputum (also called prune juice)	Pneumococcal pneumonia

SOURCE: Rothstein, J.M., S.H. Roy, and S.L. Wolf. *The Rehabilitation Specialist's Handbook*. 2nd ed. Philadelphia: F.A. Davis Co., 1998.

Purpose

The purpose of a sputum analysis is to help identify microorganisms that are causing respiratory disease or **infection**. The most common reason for obtaining a sputum specimen is to test for infectious **tuberculosis**. A sputum analysis, however, is also used to identify disease-producing organisms that may be causing **pneumonia**, bronchitis, lung **abscess**, or other respiratory disease. A sputum analysis may be used to identify conditions such as: aspiration pneumonia, histoplasmosis, cryptococcosis, blastomycosis, mycoplasma pneumonia, plague, mycobacterial infection, and pneumocystic pneumonia.

Precautions

A sputum specimen should not be collected immediately following a meal because the sputum or the process of collecting the sputum may cause gagging and vomiting.

Good hand washing and the use of gloves are necessary when collecting a sputum specimen. A disposable gown and filter-mask should be worn if reactivated infectious tuberculosis is suspected.

About 1 teaspoon (3-5 cc) of sputum should be collected to have a sufficient quantity for proper testing. The specimen cup should not be left at the bedside for the client to randomly spit into. Specimens must be fresh and taken immediately to the laboratory for effective analysis.

KEY TERMS

Agar—A gelatinous culture media used in laboratories to grow microorganisms such as bacteria.

Bronchoscopy—The examination of the inside of a client's airway and bronchus by a physician using a flexible scope connected to a light source and video camera.

Sputum—A substance coughed up from the airway, bronchi or lungs comprised of saliva, foreign matter, and mucous.

The specimen must be coughed up from the lungs or bronchial tree. It can be mixed with saliva, but a specimen that is only saliva is not adequate for proper testing.

An infant or young child cannot cough up sputum on command. Sputum specimens must be obtained with a nasal-pharyngeal aspirator connected to a mucous trap or by bronchial washings performed during a **bronchoscopy**. If using a nasal-pharyngeal aspirator, the tubing must have a one way valve on the testers side of the tubing to prevent the inhalation of infected droplets from the patient or a trap that connects directly to a suction apparatus.

The use of **antibiotics**, anti-inflammatory drugs, or steroids may affect the test results. If the patient is receiving any of these medications, the physician should be notified, and it should be notified on the laboratory slip.

Description

The patient should take three slow deep breaths and cough forcefully with the exhalation of the third breath. Sputum that is coughed up should be spit directly into the sterile specimen cup. The process is repeated until the required amount of sputum is collected. The cap is then placed on the specimen cup.

If the patient has difficulty raising sputum, the physician should be notified. Some patients may require postural drainage and cupping to loosen and drain secretions. Others may require an aerosol treatment with saline or medications to open the air sacs and allow drainage of the sputum before it can be collected. In certain cases the physician may elect to perform a bronchoscopy to collect the sputum for analysis. A bronchoscopy is performed in a special setting where the client can be sedated and monitored during the procedure.

A nasal-pharyngeal mucous trap is used to collect sputum from an infant or young child that cannot under-

stand instructions. A small tube is inserted through the nasal passage and into the pharynx. This process usually stimulates the infant to cough. As the child coughs up sputum, it is pulled through the tubing and into a mucous trap. The mucous trap is placed in a plastic biohazard specimen bag that is sealed, labeled, and sent to the lab for analysis. If a specimen from an infant can not be collected, the physician should be notified. The sputum may need to be collected through a bronchoscope by the physician.

Special testing may require variance in the sputum collection procedure. For example, sputum for viral studies may require that the client gargles and expectorates with a nutrient broth. The medical setting's lab manual should be consulted for instructions to collect sputum for special testing.

Preparation

The procedure is explained to the patient. Fluid intake should be encouraged the night before the test. The specimen should be obtained in the morning before meals. The patient should abstain from smoking, eating, or chewing gum before the specimen collection. If the patient has dentures, they should be removed. The patient rinses his mouth with plain water before the test to clear debris from the mouth. The patient is seated in an upright position. A capped sterile specimen cup is placed near the patient. Good handwashing and the use of gloves is necessary for this procedure. Other protective gear is used as instructed (i.e., for known tuberculosis client with potentially reactivated tuberculosis). The laboratory manual of the medical setting should be consulted for specific specimen directions.

Aftercare

The patient should be allowed to relax and breathe quietly. The specimen cup is labeled with the patient's name, doctor, time, date, and type of specimen. The specimen cup is placed in a biohazard labeled plastic sealed bag. The specimen does not need to be refrigerated but should be transported to the lab immediately for testing. Good handwashing is necessary after the procedure. Used tissues and gloves should be placed in a contaminated trash bag that can be sealed and discarded.

Complications

There are no complications to obtaining a non-invasive sputum specimen. Complications of obtaining a specimen by nasal tracheal aspiration or bronchoscopy are rare but may include trauma to the throat or tracheal tissue and/or secondary infection.

Results

A sputum analysis, when used in conjunction with other tests such as chest x rays or **blood** cultures, is an important diagnostic tool. It is an effective method for identifying unknown organisms that are causing respiratory infections or disease. Identification of the organism allows proper selection of antibiotic or other drug therapy to treat specific respiratory disease and provide a positive outcome for the client. Improper collection or handling of a sputum specimen may invalidate the test results.

Health care team roles

A sputum specimen is usually collected by a licensed nurse or respiratory therapist in the medical setting. Other medical personnel, however, such as medical office technicians or other non-professional staff can be taught the correct method for obtaining a sputum specimen. A patient or patient's family can be trained to collect a sputum specimen in the home. The specimen should be taken promptly to a lab for analysis. A laboratory technician will prepare the specimen for analysis, and a pathologist will ultimately be responsible for analyzing the sputum specimen.

Sputum culture

Definition

A sputum culture is a microbiology test performed to isolate and identify microorganisms causing an **infection** of the lower respiratory tract.

Purpose

Infections of the **lungs** and bronchial tubes are caused by several pathogenic microorganisms, including **bacteria, fungi, viruses**, and parasites which are responsible for a variety of diseases including pulmonary **tuberculosis**, bacterial **pneumonia**, viral and mycoplasma (atypical) pneumonia, chronic bronchitis and bronchiectasis. A chest x-ray provides visual evidence suggestive of a respiratory infection; a culture identifies the microorganism causing the infection.

Precautions

For best results, the specimen should be obtained prior to initiating any therapy. The health care worker should wear a mask to avoid inhalation of airborne pathogens that may be introduced into the air during the collection process. The specimen should be taken to the laboratory within 30 minutes of collection.

Description

Sputum collection

Based on the clinical condition of the patient, the physician determines what group of microorganism is likely to be causing the infection, and then orders one or more bacterial, viral, or fungal cultures. For all culture types, the sputum must be collected into a sterile container and care must be taken to minimize specimen contamination by the normal flora of the mouth and throat. Once in the laboratory, each culture type is handled differently.

Sputum must be expectorated from the bronchi by deep forceful coughing. The recovery of sputum is best in the early morning. The patient should rinse his or her mouth by gargling with water prior to coughing. Taking deep breaths and lowering the head helps bring up the sputum. Sputum must not be held in the mouth but immediately spat into a sterile container. For tuberculosis, the physician may request sputum samples from the patient on three consecutive mornings. In some cases the patient will be unable to produce the sputum, and an aerosol of saline will be needed to loosen the congestion. In such cases the sputum can be aspirated using a suction device.

In some cases sputum will be collected during a **bronchoscopy** or endotracheal procedure. These specimens, like coughed-up sputum, will be contaminated with normal flora from the mouth or throat and are not suitable for anaerobic culture. When anaerobic infection is suspected, the physician will collect the sample by transtracheal aspiration. These specimens and those collected by **thoracentesis** (removal of pleural fluid via chest wall puncture) are not contaminated by upper respiratory flora and are suitable for both aerobic and anaerobic culture.

Gram stain

The **Gram stain** is always performed when sputum is submitted for culture. Additional stains such as the acid-fast stain for tuberculosis are performed only upon request. The Gram stain is used to determine the acceptability of the specimen for culture, and aids the technologist in selecting special growth media that might be needed. Almost all bacteria are described by their Gram stain characteristics: color (purple or pink), shape (cocci or bacilli), and size; arrangement, presence, or absence of spores.

The Gram stain is performed by the following method:

- A portion of the sputum is smeared onto a glass **microscope** slide, air dried, and heat-fixed.
- The slide is flooded with crystal violet stain, which is allowed to set for 30-60 seconds.
- The crystal violet is rinsed off with a gentle stream of water.
- The slide is flooded with Gram's iodine, which is allowed to set for 60 seconds.
- The iodine is removed with a gentle stream of water.
- The slide is decolorized by rinsing with 95% ethanol, drop by drop, until the alcohol rinses clear.
- The slide is flooded with safranin, which is allowed to set for 30 seconds.
- The safranin is rinsed off with a stream of water.
- The excess water is removed by blotting with bibulous paper.
- The slide is allowed to air dry.
- The slide is observed under the microscope using both low power and oil immersion lenses.

Gram-positive cells retain the crystal violet stain and appear dark purple, while gram-negative cells do not. Gram-negative bacteria are counterstained by the safranin and appear pink. Gram staining also helps determine the integrity of the sputum specimen. The presence of many epithelial cells and few white **blood** cells indicates a con-

taminated sample, one not adequate for culture. The presence of many white blood cells and bacteria in the specimen signifies an acceptable sample for culture, and provides a preliminary indication of infection.

Bacterial culture

Streptococcus pneumoniae is the most common pathogen causing bacterial pneumonia, but almost any organism can be implicated. Other bacterial isolates include *Staphylococcus aureus*, *Haemophilus influenzae*, *E. coli*, *Enterobacter spp.*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Mycobacterium tuberculosis*.

Using a sterile swab, a portion of the sputum sample is transferred to each plate and then streaked for isolation using a sterilized inoculating loop. Cultures should be performed using sheep blood agar, chocolate (heated blood) agar, and MacConkey agar. All plates are incubated in 5-10% carbon dioxide at 36°C for 24 hours. Plates are examined for growth and colonies are Gram stained and subcultured (transferred) to appropriate media for biochemical identification. Plates showing normal flora are incubated for an additional day. If *L. pneumophila* is suspected, the sputum should be plated on BCYE-alpha agar (buffered charcoal-yeast extract with alpha-ketoglutarate). Plates are cultured in air or 2.5% carbon dioxide for three to five days at 36°C. Small convex gray colonies are stained with fluorescent-labeled antibody specific for *L. pneumophila*. If atypical pneumonia is suspected, the sputum is plated on a medium that supports the growth of *Mycoplasma pneumoniae* such as SP4. The plates are incubated in air at 36°C. Colonies grow slowly and are almost microscopic. They are identified by cutting a block of agar, and staining it with Dienes stain. *M. pneumoniae* demonstrate their typical fried egg appearance. Alternatively, the colonies can be identified using a fluorescent-labeled antibody specific for *M. pneumoniae*. Plates showing no growth are held up to four weeks before reporting as negative. Because of the long culture time, *Mycoplasma pneumoniae* is not usually cultured. Infections with this organism are diagnosed by enzyme immunoassay for IgM antibodies produced against the organism. A high concentration of these antibodies indicates acute infection.

The results of the initial Gram stain are available the same day, or in less than an hour if requested by the physician. A preliminary report on the status of the culture is usually available after one day. This report notes the presence or absence of bacterial growth, the Gram stain of any organism isolated, and presumptive identification (if possible). The final report, usually available in

one to three days, includes organism identification, an estimate of the quantity of the bacteria, and the results of the antibiotic sensitivity testing.

Fungal culture

Fungal cultures of sputum are used primarily to identify the presence or *Histoplasma capsulatum*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and *Paracoccidioides brasiliensis*. However, opportunistic yeast or fungi such as *Candida spp.*, *Aspergillus spp.*, and *Fusarium spp.* can cause pneumonia in immunocompromised patients. Definitive diagnosis depends upon the presence of clinical signs of pulmonary infection, a positive chest x-ray, and laboratory identification of the organism. In addition, histological results of open **lung biopsy** may reveal the organisms by microscopic examination of stained tissue. For the laboratory identification, the sputum is first examined microscopically via a direct smear using one or more of the following methods:

- 10% KOH preparation
- India ink preparation
- calcofluor white stain
- Gram stain
- Kinyoun's acid fast stain
- lactophenol cotton/aniline blue wet mount

In many cases, direct smears are sufficient to establish a preliminary diagnosis based upon the appearance of the yeast seen or the characteristic spores and hyphae produced by the fungus. If a **fungal culture** is ordered or suspected from direct smear, a portion of the sputum is transferred to an appropriate growth medium such as Sabauroad-dextrose agar or brain-heart infusion-blood agar. When infection with a dimorphic fungus is suspected (i.e., infection by *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*), the cultures are incubated at both 25°C and at 36°C in order to demonstrate conversion of the mold form at 25°C to the yeast form at 36°C. Rapidly growing fungi such as *Coccidioides immitis* may appear in three to four days, while slow growing fungi such as *Histoplasma capsulatum* may require several weeks. For this reason cultures are held for four weeks before signing out as negative. Identification is made on the basis of growth rate, appearance and color of colonies, and microscopic appearance demonstrating characteristic hyphae and/or spores. Microscopic evaluation is performed by transferring a loop or drop of the fungal culture onto a glass slide, adding one to two drops of lactophenol cotton blue stain, placing a coverglass over the material, and examining under the microscope.

In some cases, a culture filtrate is prepared and tested using antibodies to the exoantigens produced by the dimorphic fungi. This is done by the double immunodiffusion technique that permits direct comparison of precipitation reactions for the cultures and known fungal antigens controls.

Viral culture

Viruses that are a common cause of respiratory tract infection include adenoviruses, rhinoviruses, **influenza**, parainfluenza, enteroviruses, respiratory syncytial virus, retroviruses, herpes simplex, and cytomegalovirus. Because viruses need host DNA to replicate, they will not grow on artificial media. Therefore, viral cultures are inoculated onto cell cultures. These may be **cancer** cells grown in monolayers in the laboratory or cells taken from animal tissues and used to prepare a monolayer. Cell types commonly used for viral isolation are human diploid fibroblasts (HDF), HEp2 cells (epithelial cancer cells from the larynx), A549 cells (human **lung cancer** cells); primary monkey kidney cells (PMK), and rabbit kidney cells (RK). Cell cultures are inoculated and allowed to grow for one to three days at 36°C in 5-10% carbon dioxide. Within one to three days a characteristic cytopathic effect (CPE) can be seen by observing the cells under a microscope.

Mycobacterial culture

Mycobacterium tuberculosis is a respiratory infection commonly transmitted via the air to the lungs, where it thrives, causing **fever**, cough, and blood spitting. Pneumonia can also be caused by *M. bovis*, *M. avium* complex, and *M. kansasii*.

Most mycobacteria that cause pneumonia such as *Mycobacterium tuberculosis* grow very slowly requiring from two to six weeks for culture. *Mycobacterium tuberculosis* stains very poorly with Gram stain; therefore, acid-fast (light microscopy) and fluorescent staining methods are used to identify mycobacteria by direct microscopic examination of sputum. A smear can provide a presumptive diagnosis of mycobacterial disease; confirm that cultures growing on media are acid-fast; and demonstrate a patient's response to antibiotic therapy from post-treatment sputum cultures.

There are three staining methods commonly employed to test for mycobacteria. Two acid-fast stains, Ziehl-Neelsen and Kinyoun use light microscopy; the third method uses auramine or a combination of auramine and rhodamine and requires a fluorescent microscope. The advantage of fluorescent staining resides in the ability to examine much larger areas of the smear in a shorter period of time. Fluorescent staining is

more sensitive and detects approximately 18% more cases. Its disadvantage is that the stain also detects organisms that are non-viable. While a positive finding provides a basis for initiating antibiotic treatment, the sensitivity of the direct smear is highly variable. Therefore, when **acid-fast culture** is requested, all sputum samples (meeting the laboratory's criteria for sputum) are cultured, even when the direct smear exam shows no evidence of acid-fast bacteria.

Sputum for culture of mycobacteria must be decontaminated. This is commonly done by adding a mucolytic agent such as N-acetyl-L-cysteine and a clearing agent, sodium hydroxide, to an equal amount of the sputum. The suspension is mixed and allowed to stand for 15 minutes, then phosphate buffered saline is added and the sample is centrifuged. The supernatant is decanted and the remaining sample is resuspended with bovine albumin and used for culture.

An acid-fast culture can detect as few as 10 to 100 CFU/mL of sputum. Culture media may be enriched with egg, albumin, or a mixture of salts, **vitamins**, cofactors, fatty acids, glucose, and other nutrients. Media also contain malachite green or **antibiotics** to retard the growth of other bacteria and yeast. The sputum should be inoculated on at least one solid medium such as American Thoracic Society or Lowenstein-Jensen and one liquid medium such as Middlebrook 7H9. Cultures are set up at several different temperatures and examined daily for several weeks to characterize the rate of growth. Colonies are subcultured and transferred to appropriate media for biochemical identification. This process can take several more weeks and therefore, other identification methods are often performed concurrently. These include analysis of cell wall fatty acids by either gas or high-performance liquid chromatography (HPLC) and DNA probe testing. High-performance liquid chromatography can rapidly identify the species of mycobacteria from cultures, but according to the CDC, laboratories that use HPLC report that the method requires a highly experienced technologist and usually takes a long time (about six months) for initial incorporation into their laboratories. DNA probe testing can be done on as little as a single colony and demonstrates a far more rapid turnaround time than biochemical testing. Probes are available for many species but not all mycobacterium, and may be falsely negative (i.e., a low hybridization rate) if contaminating organisms are present. For these reasons, this method is used in conjunction with biochemical testing.

Other microorganisms that cause various types of lower respiratory tract infections also require special culture or staining procedures to grow and identify. For example, *Pneumocystis carinii* in bronchial lavage, sputum, or lung biopsy samples is detected by observing the

organisms with special stains such as methenamine silver stain or a fluorescent monoclonal antibody stain. *Pneumocystis carinii* causes pneumonia in people with weakened immune systems, such as people with **AIDS**, and does not grow in culture. The diagnosis is based on the results of these stains, the patient's symptoms, and medical history.

Antibiotic susceptibility testing

With the exception of *Streptococcus pneumoniae* or other strep which are sensitive to penicillin and related antibiotics, antibiotic susceptibility testing is performed on all isolates. Susceptibility testing is performed for most other organisms by the microtube broth dilution or Kirby Bauer method. The selection of antibiotics for testing depends upon the organism isolated (i.e., gram-negative, gram-positive, aerobe, anaerobe, mycobacteria, or yeast).

The Kirby-Bauer antibiotic susceptibility test method is commonly used for gram-positive and gram-negative aerobic bacteria. Antibiotic disks are placed on a plate containing a clear medium such as Mueller-Hinton agar that has been swabbed uniformly with a standardized broth suspension of a pure culture of the bacteria to be tested. The plate is then incubated at 36°C for 18-24 hours. The zone of no growth (zone of inhibition) around each disk is measured, and compared to predetermined cutoffs for each antibiotic concentration used. If the zone size equals or exceeds the cutoff, the organism is susceptible. If not, the organism is resistant. The results are reported as sensitive (organism inhibited by antibiotic), intermediate (inconclusive effect of antibiotic on organism), or resistant (organism not inhibited by the antibiotic).

Preparation

The specimen for culture should be collected before antibiotics are begun as the antibiotics may prevent microorganisms present in the sputum from growing in culture. The best time to collect a sputum sample is early in the morning, before the patient has had anything to eat or drink. The patient should first rinse his or her mouth with water to decrease mouth bacteria and dilute saliva.

If coughing up sputum is difficult, a nurse or respiratory therapist can have the patient breathe in sterile saline produced by a nebulizer. This nebulized saline coats the respiratory tract, loosening the sputum, and making it easier to cough up.

It is also useful to obtain information concerning travel to foreign countries, exposure to animals, and diagnosed or suspected immunosuppressive disease.

Aftercare

There are no specific requirements for care after obtaining the specimen. However, if the patient is found to have tuberculosis, several measures will be taken to prevent the spread of this airborne disease.

Complications

There are no complications associated with this test.

Results

Sputum from a healthy person will have no growth on culture. However, a mixture of microorganisms, typically found in a person's mouth and throat often contaminates the culture. In such cases the report will indicate the presence of normal flora contamination.

The preliminary report will note the presence of bacteria and white blood cells on the Gram stain and describe the appearance of the bacteria and the number of cells seen. Preliminary culture results will identify the Gram stain or presumptive identification of any organisms recovered.

Health care team roles

Sputum culture is requested by a physician. A nurse or respiratory therapist will provide instructions to the patient for collecting a sputum sample. Bronchoscopy, transtracheal aspiration, bronchial lavage or brushing, and thoracentesis are performed by a physician. Clinical laboratory scientists/medical technologists who specialize in microbiology will perform the culture and antibiotic sensitivity tests.

Sputum specimen collection

Definition

Sputum specimen collection is a procedure designed to collect expectorated secretions from a patient's respiratory tract.

Purpose

Sputum is collected to be used as a laboratory specimen for the isolation of organisms that might be causing abnormalities of the respiratory tract.

Precautions

This procedure should not be performed if the patient is unable to take several deep breaths or cough deeply from the **lungs**.

KEY TERMS

Expectorate—To cough up excessive secretions from the respiratory tract.

Haemoptysis—The presence of blood in the sputum.

Hypertonic saline—Saline that has a higher osmotic pressure than normal saline.

Inhalation—A medicinal substance for inhaling.

Mucoid—Resembling the thick liquid secreted by the mucous glands.

Mucopurulent sputum—Sputum containing mucus and pus.

Pulmonary embolism—A clot in the lungs.

Description

When secretions from the respiratory tract are expectorated, the secretions are called sputum. A **sputum culture** is a sample of expectorated sputum.

Induced sputum is a procedure to assist patients who have difficulty expectorating sputum. The patient inhales nebulized saline to loosen the sputum. To collect an induced sputum sample, the patient's mouth should be rinsed thoroughly with water to reduce the amount of oral **bacteria** that are normally present from contaminating the sputum. The patient then inhales 20–30 ml of hypertonic saline from an ultrasonic nebuliser. The sputum is loosened and collected in a sterile sputum container.

The patient should be supervised during the collection of the sputum to ensure the expectorated product has come from the lungs rather than saliva from the oral cavity. The sample is best taken first thing in the morning when the production of sputum is greatest.

To collect an expectorated sputum sample, the patient should gargle and rinse out the mouth with water to reduce the amount of oral bacteria that are normally present from contaminating the sputum. The patient must take a deep breath and cough into a sterile sputum container.

For a suspected common bacteria, one sputum sample may be required. If the suspected **infection** is more complex, a sputum sample may be required on three to five successive mornings.

Preparation

If there is any difficulty in expectorating, the physician may suggest the use of an inhalation, an expectorant, or physiotherapy to aid in producing sputum for collection. The sputum should be transferred to the laboratory within two hours for analysis.

Results

Sputum is mucoidal in appearance, resembling the thick liquid secreted by the mucous glands. It can be clear, white, or greenish in color, even **blood** stained. Blood in the sputum is called haemoptysis and may be a pink froth, mucus with a streak of blood, or an obvious clot, red in color representing fresh blood or brownish representing old blood. Haemoptysis may indicate that there has been some trauma to the respiratory tract, or that there is an infection present such as **tuberculosis** or even carcinoma. If it is determined that the blood is not from a simple cut to the mouth or a nosebleed, it is considered a serious condition and should be treated immediately. The sputum may also be frothy, indicating that the patient's pulmonary **blood pressure** is raised. Mucopurulent sputum contains mucus and pus and indicates an infection, such as an **abscess**, is present.

There may be an unpleasant odor associated with sputum.

Health care team roles

The procedure must be fully explained to the patient. The nurse should note if the patient has any difficulty with expectoration, and report it to the physician.

Staphylococcal infections

Definition

Staphylococcal (staph) infections are communicable diseases caused by various species of staphylococcal **bacteria** and are generally characterized by the formation of abscesses. They are the leading cause of nosocomial infections (infections originating in hospitals) in the United States.

Description

Classified since the early twentieth century as among the deadliest of all disease-causing organisms, staph exists on the skin or inside the nostrils of 20% to 30% of healthy people. It is sometimes found in breast tissue and the mouth, as well as the genital, urinary, and upper respiratory tracts.

Although staph bacteria are usually harmless, when injury or a break in the skin enables the organisms to invade the body, consequences can range from minor discomfort to death. **Infection** is most likely to occur in:

- newborns
- women who are breastfeeding
- individuals whose immune systems have been compromised by radiation treatment, **chemotherapy**, or medication
- intravenous drug users
- patients with surgical incisions, skin disorders, and serious illness such as **cancer**, diabetes, and lung disease

Types of infections

Staph infections produce pus-filled abscesses located just beneath the surface of the skin or deep within the body. Risk of infection is greatest among the very young and the very old.

A localized staph infection is confined to a ring of dead and dying white **blood** cells and bacteria. The skin above it feels warm to the touch. Most of these abscesses eventually burst, and pus that leaks onto the skin can cause new infections.

A small fraction of localized staph infections enter the bloodstream and spread through the body. In children, these systemic (affecting the whole body) or disseminated infections frequently affect the ends of the long bones of the arms or legs, causing a bone infection called osteomyelitis. When adults develop disseminated staph

infections, bacteria are most apt to infect the **brain**, **heart**, **kidneys**, **liver**, **lungs**, or spleen.

There are three staphylococcal species that commonly cause infections: *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Staphylococcus saprophyticus*.

Staphylococcus aureus

Named for the golden color of the bacteria grown under laboratory conditions, *S. aureus* is a hardy organism that can survive in extreme temperatures or other inhospitable circumstances. About 70% to 90% of the population carry this strain of staph in the nostrils at some time. Staph aureus is present (colonizes) on the skin of 5% to 20% of healthy people. As many as 40% carry it elsewhere, such as in the throat, vagina, or rectum, for periods of time varying from hours to years without developing symptoms or becoming ill. These individuals may be called asymptomatic carriers.

S. aureus flourishes in hospitals, where it colonizes in health care personnel and postoperative patients along with those who have acute dermatitis, insulin-dependent diabetes, dialysis-dependent kidney disease; or patients who receive frequent allergy-desensitization injections. Staph bacteria can also contaminate bedclothes, catheters, and other objects.

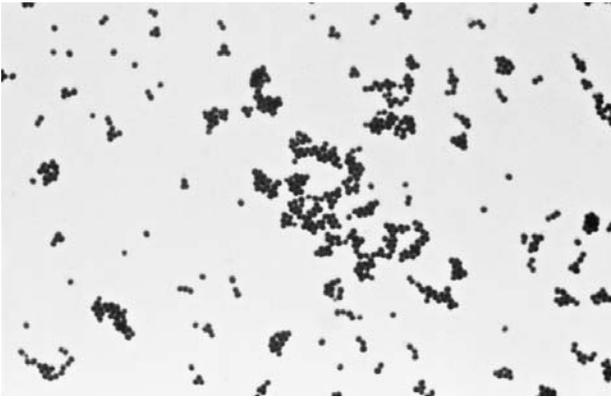

S. aureus causes a variety of infections. Folliculitis, a condition characterized by **boils** and inflammation of the skin surrounding a hair shaft, is the most common. Toxic shock and scalded skin syndromes are among the most serious.

TOXIC SHOCK. Toxic shock syndrome is a life-threatening infection characterized by sudden onset of symptoms: severe headache, **sore throat**, **fever** as high as 105°F, and a sunburn-like rash that spreads from the face to the rest of the body. Symptoms also may include **dehydration** and watery **diarrhea**.

Shock (inadequate blood flow to peripheral parts of the body) and loss of consciousness occur within the first 48 hours. Between the third and seventh day of illness, skin peels from the palms of the hands, soles of the feet, and other parts of the body. Kidney, liver, and muscle damage often occur.

SCALDED SKIN SYNDROME. Rare in adults and most common in newborns and children under the age of five, scalded skin syndrome originates with a localized skin infection. A mild fever and/or an increase in the number of infection-fighting white blood cells may occur.

A bright red rash spreads from the face to other parts of the body and eventually forms scales. Large, soft blisters develop at the site of infection and elsewhere. When

Gram stain of *Staphylococcus*. (Delmar Publishers, Inc. Reproduced by permission.)

they burst, they expose inflamed skin that looks as if it had been burned.

MISCELLANEOUS INFECTIONS. *S. aureus* can also cause:

- septic arthritis
- bacteremia (bacteria in the bloodstream)
- carbuncles (pockets of infection and pus under the skin)
- cellulitis (tissue inflammation that spreads below the skin, causing **pain** and swelling)
- **endocarditis** (inflammation of the valves and walls of the heart)
- meningitis (inflammation of tissue that encloses and protects the **spinal cord** and brain)
- osteomyelitis (inflammation of bone and bone marrow)
- pneumonia

Staphylococcus epidermidis

Capable of clinging to tubing such as that used for intravenous feeding, prosthetic devices, and other non-living surfaces, *S. epidermidis* is the organism that most often contaminates devices that provide direct access to the bloodstream.

The most common cause of bacteremia in hospital patients, this strain of staph is most likely to infect cancer patients, whose immune systems have been compromised, and high-risk newborns receiving intravenous supplements. *S. epidermidis* also accounts for two of every five cases of prosthetic valve endocarditis. Prosthetic valve endocarditis is endocarditis of an artificial heart valve. Although contamination usually occurs during surgery, symptoms of infection may not become evident until a year after the operation. More than half of the patients who develop prosthetic valve endocarditis die.

Staphylococcus saprophyticus

Existing within and around the urethra of about 5% of healthy males and females, *S. saprophyticus* is the second most common cause of unobstructed urinary tract infections in sexually active young women. This strain of staph is responsible for 10% to 20% of infections affecting healthy outpatients.

Causes and symptoms

Staph bacteria can spread through the air, but infection is almost always the result of direct contact with open sores or body fluids contaminated by these organisms. Staph bacteria often enter the body through inflamed hair follicles or oil glands. They also penetrate skin damaged by **burns**, cuts and scrapes, infection, insect bites, or **wounds**.

Multiplying beneath the skin, bacteria infect and destroy tissue in the area where they entered the body. Staphylococcal bacteremia (staph infection of the blood) develops when bacteria from a local infection infiltrate the lymph glands and bloodstream. These infections, which can usually be traced to contaminated catheters or intravenous devices, usually cause persistent high fever and may cause shock. They also can cause death within a short time.

Warning signs

Common symptoms of staph infection include:

- pain or swelling around a cut, or an area of skin that has been scraped
- boils or other skin abscesses
- blistering, peeling, or scaling of the skin; most common in infants and young children
- enlarged lymph nodes in the neck, armpits, or groin

Patients should be advised to contact a physician or seek medical attention whenever:

- Lymph nodes in the neck, armpits, or groin become swollen or tender.
- An area of skin that has been cut or scraped becomes painful or swollen, feels hot, or produces pus; may mean the infection has spread to the bloodstream.
- A boil or carbuncle appears on any part of the face or spine. Staph infections affecting these areas can spread to the brain or spinal cord.
- A boil becomes very sore. Usually a sign that infection has spread, this condition may be accompanied by fever, chills, and red streaks radiating from the site of the original infection.

- Boils develop repeatedly. This type of recurrent infection could be a symptom of diabetes.

Diagnosis

Blood tests that show unusually high concentrations of white blood cells may suggest staph infection, but diagnosis is based on laboratory analysis of material removed from pus-filled sores and on analysis of normally uninfected body fluids, such as blood and urine. Physicians may order x rays to locate internal abscesses and evaluate the severity of infection. Needle biopsy (removing tissue with a needle, then examining it under a **microscope**) may be used to assess bone involvement.

Treatment

Superficial staph infections can generally be cured by keeping the area clean, using antibacterial soaps that leave a germ-killing film on the skin, and applying warm, moist compresses to the affected area for 20 to 30 minutes three or four times a day.

Severe or recurrent infections may require a course of treatment with cephalexin or other oral anti-staphylococcal **antibiotics** lasting seven to 10 days. The location of the infection and the identity of the causal bacteria determines which of several effective medications should be prescribed.

In case of a more serious infection, antibiotics may be administered intravenously for as long as six weeks. Intravenous antibiotics are also used to treat staph infections around the eyes or on other parts of the face.

Surgery may be required to drain or remove abscesses that form on internal organs or on shunts or other devices implanted inside the body.

Alternative therapies for staph infection are intended to strengthen the **immune system** and prevent recurrences. Among the therapies believed to be helpful for the person with a staph infection are **yoga** (to stimulate the immune system and promote **relaxation**), acupuncture (to draw heat away from the infection), and selected herbal remedies. Patients should be counseled to use alternative therapies as complementary medicine in conjunction with conventional antibiotic treatment or other prescribed treatment.

Prognosis

Most healthy people who develop staph infections recover fully within a short time. Others develop repeated infections. Some patients become seriously ill, requiring long-term therapy or emergency medical care. A small percentage die from severe infection.

A close-up of woman's finger and nail cuticle infected with *Staphylococcus aureus*. (Custom Medical Stock Photo. Reproduced by permission.)

Health care team roles

Physicians supervise the treatment of staph infections in a hospital setting. Generally, laboratory technicians perform blood work and radiology technicians perform x rays when indicated. Nurses provide bedside management and patient-family education.

Prevention

Health care providers have a critical role in the prevention of nosocomial infections. Health care providers and patients should always wash their hands thoroughly with warm water and soap after treating a staph infection or touching an open wound or the pus it produces. Pus that oozes onto the skin from the site of an infection should be removed immediately. The affected area should then be cleansed with antiseptic or with antibacterial soap.

Because some strains of staph bacteria are known to contaminate artificial limbs, prosthetic devices implanted within the body, and tubes used to administer medication or drain fluids, catheters and other devices should be removed on a regular basis, if possible, and examined for microscopic signs of staph. Symptoms may not become evident until many months after contamination has occurred, so this practice should be followed even with patients who show no sign of infection. Nurses also teach importance of hand washing to staff, patients, and families.

To prevent infection from spreading from one part of the body to another, patients should be advised to shower rather than bathe during the healing process. Since staph infection is easily transmitted from one member of a household to others, towels, washcloths, and bed linens used by someone with a staph infection should not be used by anyone else. They should be changed daily until

KEY TERMS

Abscess—A cavity containing pus surrounded by inflamed tissue.

Endocarditis—Inflammation of the lining of the heart, and/or the heart valves, caused by infection.

Nosocomial infections—Infections acquired by a patient while in the hospital.

symptoms disappear and laundered separately in hot water with bleach. The judicious use of antibiotics in the treatment setting also helps prevent infections from becoming worse by lessening the likelihood that bacterial strains resistant to antibiotics will arise.

Children should frequently be reminded not to share:

- brushes, combs, or hair accessories
- caps
- clothing
- sleeping bags
- sports equipment
- other personal items

Sterilization techniques

Definition

Sterilization techniques include all the means used to completely eliminate or destroy living microorganisms on any object, including tools used to test or treat patients.

Purpose

The term microorganism, or microbe, refers to any single-celled living organism, including **bacteria**, **viruses**, and **fungi**. (Though viruses are not true single-celled organisms, medical science still usually classifies them as microorganisms.) Microbes can be transferred by direct contact or indirectly through a vehicle (like a surgical tool) or via the air the patient breathes. If favorable conditions for growth exist in the new host, microbes reproduce and establish colonies. Many of these microscopic organisms are normal inhabitants of the human body (called microflora). For example, varieties of the bacterium *Staphylococcus* are normal inhabitants of the skin and nasal passages, and many different species of bacteria live in the small and **large intestine**, aiding in the process of digestion.

However, many types of microorganisms are pathogenic (considered foreign to the host body) and, upon entering the body, cause **infection** when they either damage cells directly or release toxins that will eventually cause damage. The prevention of disease-causing microbes in a patient-care environment is generally accomplished through aseptic or sterile techniques. The goal is to create as germ-free an environment as possible, primarily through sterilization and the maintenance of sterile/nonsterile barriers.

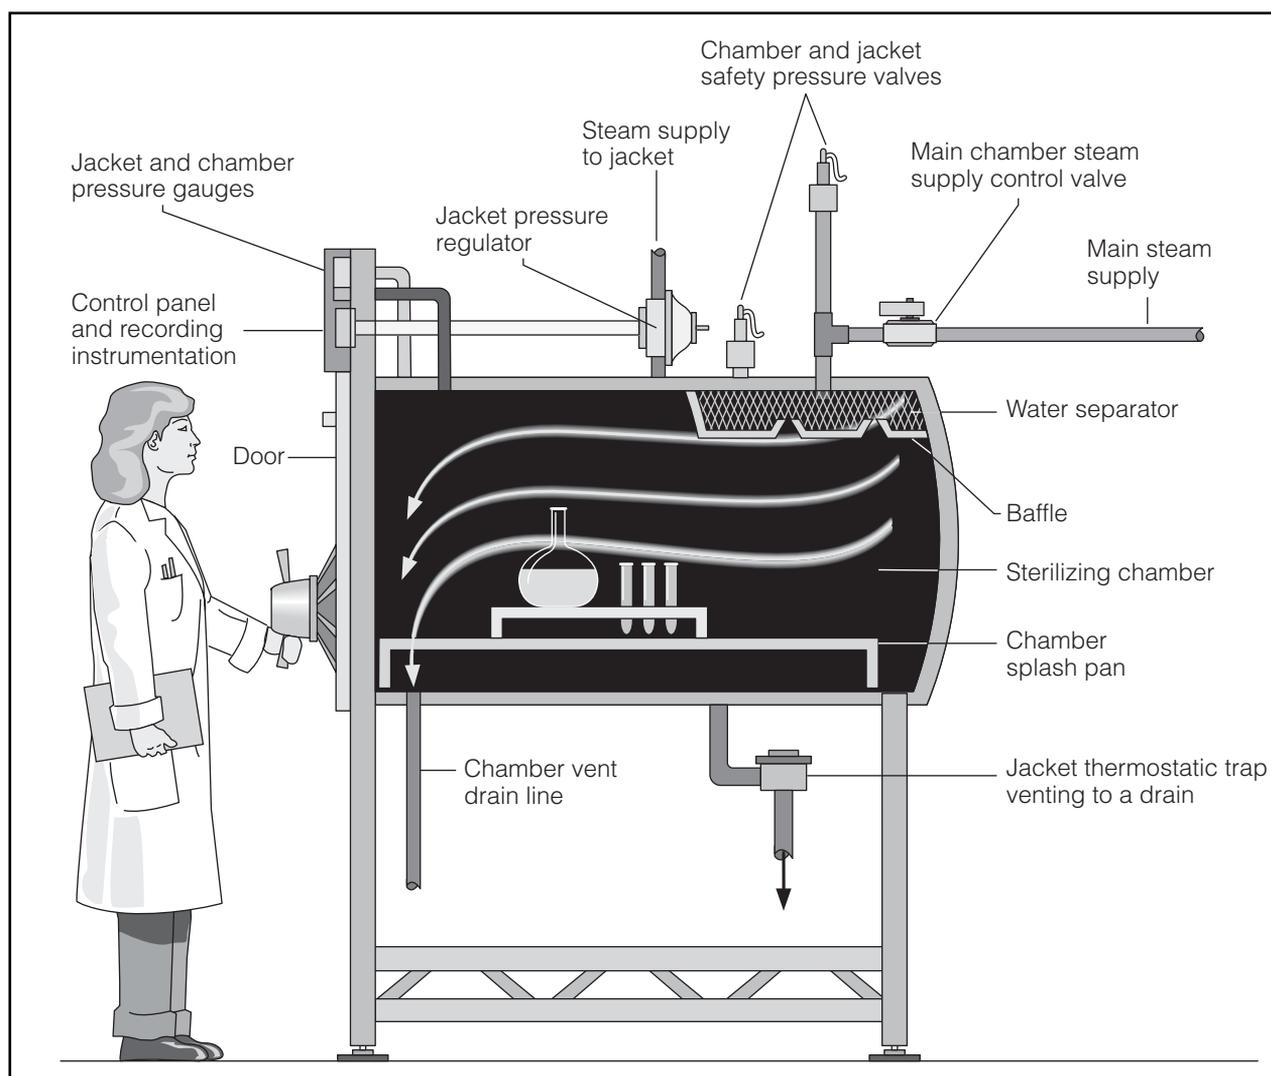

Precautions

Like foods sold in the grocery store, sterile medical and surgical solutions and some other equipment have expiration dates indicating when the product is no longer considered sterile. Although many hospitals consider sterile, prepackaged disposable materials to be sterile indefinitely if the packaging is undamaged, sterile goods must be examined carefully to ensure that there are no breaks in the integrity of the packaging or that the package has not gotten wet. Microbes are able to enter sterile goods through either breaks in the wrapping (the sterile barrier) or moisture. If the wrapper is no longer intact, or has been wet, sterile goods must be repackaged and resterilized.

Description

Patients having invasive medical or surgical procedures are at risk for infection primarily from four sources:

- Infection is transferred from other people, including patients and health care providers. Such infection is called direct transmission, which usually occurs as a result of direct contact with skin or bodily fluids, including saliva, coughing, and spitting.

A technician operates a steam pressure sterilizer. (Hans & Cassidy. Courtesy of Gale Group.)

- Infection results from equipment or other objects that come in contact with the patient. This is called vehicle-borne infection because the microbe is transported from another place on some object or vehicle and introduced through a break in the skin or mucosal membranes. Primary examples are **food poisoning** caused by contaminated food items or infection caused by the use of non-sterile equipment in an invasive procedure like **bronchoscopy** or phlebotomy.
- Infection arises from the patient's own body, such as the possible contamination of a surgical site during intestinal resection if the patient's own fecal material contaminates the abdominal cavity contents.
- The air transports microbes. An example of air-borne infection is **tuberculosis**, in which bacteria are trans-

mitted on air currents to others through coughing or spitting.

Managing as germ-free an environment as possible is necessary for surgical procedures and even minor medical treatments normally done in a doctor's office, such as suturing a laceration. Patients with conditions or under treatments that cause the **immune system** to be compromised are sometimes treated in an artificially created environment called reverse isolation. Leukemia patients, especially those on aggressive **chemotherapy** who receive bone marrow transplants and people with **immunodeficiency** disorders (which can lead to little or no natural defense against infection), are all potential candidates for reverse isolation procedures. Patients with **AIDS** (acquired immune deficiency syndrome) may be treated in an environment of isolation, both direct and reverse isolation for their protection, as well as the pro-

tection of caregivers. An extreme example of reverse isolation is the use of a sterilized plastic tent with filtered air circulation called an isolator. (**Premature infants** may be placed in special sterile plastic bassinets called an isolette.)

Aseptic technique

It has been known since the days of Florence Nightingale that clean surroundings are definitely less conducive to the growth of microorganisms than unclean ones. The creation of sterile environments always includes scrupulous cleanliness. The use of disinfectants in washing furniture, walls and floors, as well as in soaking medical equipment or other patient-care items is another important measure. Disinfectants are harsh chemical compounds described as bactericidal (capable of killing bacteria), or bacteriostatic (capable of stopping the growth or reproduction of bacteria). Some of these disinfectants may also be antiviral agents or antifungal. Disinfectants are usually too toxic to tissue to be used directly on the body. **Antiseptics** are chemical compounds that are also either bactericidal or bacteriostatic. But these are usually more diluted solutions and can safely be used in direct contact with human tissues. Common antiseptics include iodine, hydrogen peroxide, and thimerosal.

The importance of hand washing before and after the care of any patient cannot be over-stressed. It remains the simplest and most effective means of preventing infection. The Center for Disease Control (CDC) estimates that American hospitals produce two million hospital-borne infections (known as nosocomial infections) each year, and approximately one-quarter of these are postoperative surgical incision infections. Postoperative infections result from breaks in sterile technique during surgery or breaks in **aseptic technique** during **wound care**. Further, CDC studies have shown that the average compliance with hand washing by health care providers from 1981 to 1999 has never risen above 50%. Proper procedure is for health care personnel to scrub their hands prior to and immediately after performing any procedure on a patient, regardless of whether latex gloves were worn or not. Gloves, as a barrier, can be breached via holes the size of pinpoints.

For both surgery and reverse isolation, staff are usually required to wear presterilized gloves, hair nets, masks, and gowns, with clean shoe coverings. Insertion of a urinary catheter, changing a surgical drain, cleaning a **tracheotomy** tube or doing a sterile dressing are all instances when health care providers wear gloves. They also create what is termed a sterile field or area that has been prepared with antiseptics or covered with impene-

trable sterile drapes to reduce the likelihood of organism transfer.

Before surgical procedures, the operative site skin area is cleansed with an antiseptic solution, and sterile drapes are applied to the periphery. In the case of bowel surgery, **laxatives** and **enemas** are given prior to the surgery to remove as much fecal material as possible, thus limiting the amount of contamination from feces. When the bowel is clamped shut, all instruments, drapes, and sponges that may have come in contact with the patient are removed and replaced with sterile equipment before proceeding any further. In both surgical suites and in reverse isolation patients' rooms, air is passed through a special ventilation system that filters out microorganisms.

Five means are commonly used to sterilize objects in the patient's environment. These include:

- Moist heat is used via steaming or autoclaving (steaming under high pressure). Much like a pressure cooker used to can food at home and destroy bacteria, an autoclave circulates steam at temperatures of 260°F (120°C) at sustained pressure of 20 pounds per square inch for designated periods of time. All equipment used in carrying out medical or surgical procedures such as instruments, tubings (including catheters), bandages, and linens used for drapes are sterilized, usually in an autoclave.
- Ionizing and non-ionizing radiation is sometimes used. Ultraviolet light is a type of non-ionizing radiation used for items sensitive to heat.
- The passage of liquids through a filter sufficiently fine so as to trap microbes.
- Gas sterilization, usually using ethylene oxide, interferes with the **metabolism** and therefore the development of microorganisms and inhibits the growth of spores. It is effective in the sterilization of heat-sensitive items and penetrates deeply, but it has to be used with care since it is poisonous.
- Strong disinfectants are used primarily for instruments, such as thermometers and scopes that could not survive autoclaving. Medical equipment soaked in disinfectants to destroy microbes should be rinsed off prior to use due to the toxicity of many of the compounds used for disinfecting. Certain gasses such as ethylene oxide used for sterilization are extremely toxic to human beings and should be used with care.

Preparation

In general, preparations include standard sterilization techniques for the patient, health care staff, and environment. Surgery patients requiring reverse isolation pro-

cedures should be told about the actions of microorganisms, including the ways they gain entry into the human body, the diseases that can be caused, and how sterilization techniques work to prevent infection. Hair is no longer routinely removed from the site of the surgical incision prior to surgery as the skin is a natural barrier to infection and shaving it often produces small skin breaks.

Aftercare

Aftercare following use of sterilized or surgically clean equipment would include monitoring patients for the signs and symptoms of infection, which usually occur within 48 to 71 hours. Signs and symptoms of infection include:

- fever
- inflammation, or redness and swelling at the site of infection, often accompanied by **edema** and erythema
- purulent or pus-like drainage from wounds
- abnormally elevated white **blood** count
- pain at the site of infection

Complications

There should be no complications from using proper sterilization and aseptic techniques. An allergy to any of the various antiseptics used to sterilize skin prior to surgery may produce dermatitis or irritation. If disinfectant used to clean instruments are not properly rinsed before use, an inflammatory response similar to a first-degree burn may result on surfaces contacted by the solution.

Results

Proper sterilization techniques result in the prevention of infection. Sterilization techniques must be monitored and continually improved upon.

Health care team roles

All health care personnel are responsible for the primary means of preventing infection, which is hand washing. In the early days of nursing, sterilization of equipment and cleanliness of the patient's environment was the nurse's principal responsibility. The nurse still bears responsibility or accountability in these areas even though they may be implemented by others.

- Sterilization technicians work in either the operating room area of a hospital or in the hospital's central supply. They receive special orientation and training in sterile techniques at the health care facility where they are employed. They are responsible for carrying out

KEY TERMS

Bacteria—A group of single-celled organisms that can only be seen under a microscope and sometimes cause disease in other living things.

Fungi—Parasitic single-celled life forms that range from yeasts and mildews to mushrooms. Several minute or microscopic forms cause disease in other living things.

Ionizing radiation—Radiation that causes atoms or groups of atoms to carry a positive or negative electrical charge. Vital processes of life depend upon ions moving across cell membranes.

Non-ionizing—Radiation that does not cause atoms or groups of atoms to carry a positive or negative electrical charge. Vital processes of life depend upon ions moving across cell membranes.

Virus—A submicroscopic infective agent regarded as an extremely simple microorganism or extremely complex molecule capable of growth and multiplication only in living cells.

sterilization procedures and for monitoring sterile equipment conditions and expiration dates. Sometimes nurses or operating room technicians are responsible for providing sterile equipment.

- Some registered nurses (RNs) are certified in **infection control** and are required to keep statistical data on the incidence and types of infections in a health care facility. These RNs typically serve on infection control committees, along with physicians and clinical pharmacists.
- Clinical laboratory scientists have specialized training and must pass a state examination. They draw blood samples and culture wound drainage specimens, which are ordered by the physician to monitor patients for infection and for routine assessment of nosocomial infection sources throughout a facility.

Stethoscope

Definition

The stethoscope is an instrument used to listen to sounds produced by the body. It is used to listen to the **lungs, heart**, and intestinal tract.

Purpose

A stethoscope is used to detect and study heart, lung, **stomach**, and other sounds in humans and animals. Using the stethoscope, the listener can hear abnormal respiratory, cardiac, pleural arterial, venous, uterine, fetal, and intestinal sounds.

Description

Stethoscopes vary in their design and material. Most are made of rubber tubing, shaped in a "Y," allowing sound to enter the device at one end, travel up the tubes and through to the ear pieces. Many stethoscopes have a two-sided sound-detecting device, which listeners flip, depending on whether they need to hear high or low frequencies. However, some of the newer models have one pressure-sensitive head. The various types of stethoscopes include: binaural stethoscopes, designed for use with both ears; single, designed for use with one ear; differential, with which listeners can compare sounds at two different body sites; and electronic, which electronically

amplifies tones. Some stethoscopes are designed specifically for hearing the fetal heartbeat or esophagus.

Operation

Some stethoscopes must be placed directly on the skin, while others can work effectively through clothing. For the stethoscopes with a two-part sound detecting device at the end, listeners press the rim against the skin, using the bowl-shaped side, to hear low-pitched sounds. The other flat side, called the diaphragm, detects high-pitched sounds.

Maintenance

In order to avoid the spread of **infection**, stethoscopes should be cleaned after each use—especially when placed directly on the patient's skin.

Health care team roles

Everyone on the health care team uses a stethoscope, as the provider may need to listen to sounds produced by the heart, lungs, stomach, or another body organ often.

Training

Stethoscope users must learn to assess what they hear. When listening to the heart, one must listen to the left side of the chest, where the heart is located. Specifically, it is between the fourth and sixth ribs, almost directly below the breast. The stethoscope must be moved around; the health care provider should listen for different sounds emanating from different locations. The bell of the instrument—generally used to listen to sounds of low pitch, and then its diaphragm—should be used to listen to different areas of the heart. The sounds will be different. "Lub-dub" is the sounds produced by the normal heart. Every time this sound is detected, it means that the heart is contracting one time. The noises represent the heart valves clicking to close. When one hears "lub," the atrioventricular valves are closing, and "dub" means the the pulmonic and aortic valves. Other heart sounds, such as the quiet "whoosh," heard after "lub-dub," reflect the existence of a "murmur." These are heard when the **blood** moves through the heart, and mean that there is "turbulence" in the blood flow. If a valve remains closed, rather than opening completely, one might hear a murmur. These are not at all uncommon; in fact, many people have them and are unaffected.

The lungs and airways require different listening skills than those used to detect heart sounds. The stethoscope must be placed over the chest, and the patient must

breathe in and out deeply, and slowly. Using the bell, the different sounds should be noted in various areas of the chest. Then, the diaphragm should be used in the same way. There will be no wheezes or crackles in normal lung sounds. When performing “percussion,” on the chest, the health care practitioner should be listening for sounds made by sounds the patient makes. One would lightly “thump” around the stethoscope, against the chest, with one finger. Lungs that sound hollow are normal; they have no air in them. Lungs that have a more solid sound appear dead. On percussion, this “dead” sound may be solidification of the lung. In this case, one might make an initial diagnosis of **pneumonia**.

When crackles or wheezes are detected, the practitioner is hearing lung sounds that are abnormal. When the chest wall is being rubbed by the lung, “friction rubs” are detected. When there is fluid in the lungs, crackles will be hard. This is often heard when the patient has pneumonia, or pulmonary **edema**. A high-pitched whistling sound (a wheeze) is often heard when there is pneumonia, or when an airway disease (like bronchitis) is present. Lastly, an infection between the lung and the chest might produce the friction rubs—squeaky noises that infections like pleuritis (an infection between the lung and chest wall) produce.

To listen to the abdomen, the stethoscope should be held over its upper left side. One can hear “gurgling” just under the ribs. The intestines, in the lower part of the abdomen, can also be heard. The noises they make are “borborygmus”—and they are normal. The abdomen is also a site where percussion can be heard. If one thumps all around the bell of the stethoscope, the individual will hear a solid sound, as if the organ is “dead.” When the sound is hollow, it means that the intestinal tract has gas in it.

Despite these somewhat basic instructions, it takes experience and skill to determine what tests might be needed once examination with the stethoscope has been completed. Examination with this instrument is particularly noninvasive, but useful. It can assist the physician and health care team in localizing the problem about which the patient is complaining.

Stomach

Definition

The stomach is a muscular J-shaped organ of the digestive tract. It temporarily stores and mixes food; it also secretes gastric juice into the lumen (the hollow inside the stomach) and a hormone called gastrin into the **blood**.

Description

The stomach is located in the upper left quadrant of the abdomen, just beneath the diaphragm. It is positioned between the esophagus (the passage between the mouth and stomach) and the **small intestine**. There is a sphincter (circular muscle) between the esophagus and the stomach, which allows food to pass into the stomach and prevents chyme (the semi-fluid mass into which food is converted by gastric enzymes) from flowing backwards into the esophagus. The pyloric valve is situated between the stomach and the small intestine, which allows chyme to pass into the small intestine and back into the stomach.

The stomach is divided into three general areas. The upper portion of the stomach near the esophagus is called

the fundus; the middle section of the stomach is called the body; and the bottom portion of the stomach where the pyloric sphincter is located is called the antrum. When the stomach is completely distended (expanded), it measures about 10 in (26 cm) by about 4 in (10 cm). It can hold about one quart of semiliquid chyme.

The wall of the stomach is made up of four layers: the mucous, submucous, muscular, and peritoneal layers. The mucous and submucous layers are made up of ridges called rugae. Within the ridges are gastric glands made up of mucous cells, parietal cells, chief cells, and G-cells. Each of these cells secretes a chemical that aids in the process of digestion.

The muscular layer is actually composed of three different layers of smooth muscle, each with fibers running in a different direction: horizontal, vertical, and diagonal. The muscles are responsible for mixing the chyme and moving it through the stomach to the small intestine.

The peritoneal layer is the outer layer of stomach tissue. It is part of the peritoneum that lines the inside of the abdomen, covering most of the organs. It does not play a role in digestion.

The stomach has a large supply of **blood vessels** for the absorption of nutrients from digested food. Branches of the vagus nerve supply both sensory and nervous fibers to the stomach.

Function

Food storage

The stomach's primary role is to act as a temporary receptacle for food. While the food is in the stomach, it is mixed with gastric juices that are secreted by cells in the mucosal layer.

There are three general phases regulating gastric juice secretion. The first, or cephalic, phase occurs before food is actually eaten. The thought, **smell** and sight of food cause the **brain** to send signals to the stomach to increase its gastric secretions. The second phase is the gastric phase, which occurs when food enters the stomach. The food causes the stomach to stretch, which in turn sends nervous impulses to the brain. The brain sends return impulses back to the stomach to begin secreting gastrin. Gastrin then stimulates the release of other gastric juices. The third phase is called the intestinal phase, which occurs when food enters the small intestine. This phase results in a decrease in the movement of chyme into the small intestine, ensuring that the small intestine does not receive too much chyme at one time.

The stomach secretes 2–3 quarts (liters) of gastric juices every day. There are several types of specialized cells in the stomach that secrete gastric juices. Like the **pancreas**, the stomach has both exocrine and endocrine glandular functions. Exocrine secretory glands contain three types of secretory cells: chief cells, parietal cells and mucous cells. Endocrine cells called G-cells are scattered throughout the mucosa.

Exocrine secretions

Exocrine glands are located in the fundus and body of the stomach. The chief cells in these exocrine glands secrete pepsinogen, the inactive precursor of pepsin. Pepsin is an enzyme that is responsible for the initial breakdown of protein molecules into smaller polypeptides. If pepsin did not have an inactive form, it would destroy the chief cells as they produced it. Pepsin can be activated in the stomach, because the stomach lining is protected from its action.

The exocrine glands of the fundus and body of the stomach also contain parietal cells. These parietal cells secrete hydrochloric acid (HCl), which makes the stomach strongly acidic, with a pH of about 2 or 3. This is an optimal pH for the action of pepsin. Hydrochloric acid is responsible for transforming the inactive pepsinogen into active pepsin. The hydrochloric acid in the chyme also stimulates the production of pancreatic and biliary secretions that further stimulate digestion. The acidic environment kills most **bacteria** that enter the digestive tract through the mouth. Parietal cells also release a chemical called the intrinsic factor, which is necessary for the absorption of **vitamin B₁₂**.

Mucous cells release an alkaline mucous fluid into the gastric wall, protecting it against the damaging action of stomach acid. The fluid neutralizes the hydrochloric acid and also acts as a lubricant, protecting the inner lining of the stomach.

Endocrine secretions

The G-cells are the only endocrine cells located in the stomach and are located mainly in the antrum of the stomach where there are few acid producing cells. G-cells release the hormone gastrin into the bloodstream. Gastrin acts on the parietal cells, stimulating them to release hydrochloric acid.

Muscular activity

The stomach must undergo muscular contractions in order to mix food and gastric juices together. These waves of involuntary muscular contractions are called peristalsis. When food is present, peristaltic contractions

pass through the stomach muscles about two or three times every minute and continue at a constant rhythm. Pressure will begin to develop in the lower part of the stomach. When there is sufficient pressure, a small amount of the stomach's contents moves through the pyloric sphincter and into the duodenum (the first section of the small intestine). It takes about two to six hours for the entire contents of the stomach to empty, depending on the composition of the person's diet. Low-fat meals leave the stomach more quickly than high-fat meals. Psychological states also affect the rate of stomach emptying; depression and fear may cause the stomach to empty slowly, while anger and aggression may cause the stomach to empty quickly.

After the chyme has entered the duodenum and the pyloric sphincter has closed, some of the food returns to the stomach through retropulsion. Retropulsion is a process in which the stomach contents are squirted back into the stomach at a rate of about three times per minute. Retropulsion mixes the food with gastric juices and breaks larger clumps of food into smaller pieces.

Role in human health

The stomach prepares food for digestion in the small intestine. If the stomach is not functioning properly, there are many problems that can arise with regard to digestion. Further, the contents of the stomach are so acidic and caustic to other organs of the body that they can cause problems if they leak out of the stomach, as may happen with perforating ulcers of the duodenum or penetrating **wounds** of the abdomen.

Common diseases and disorders

Gastritis

Gastritis is a common health problem. It is an inflammation of the gastric mucosal layer caused by a range of factors, including bacterial infections, medications (particularly NSAIDs), acute **stress**, and spicy foods or alcohol. Gastritis can result in a lowered functioning of chief cells and parietal cells. Less pepsin is provided to the stomach, resulting in incomplete breakdown of **proteins**. There is also less stomach acid secretion, allowing overgrowth of microbial populations and a decrease in the absorption of vitamin B₁₂. Gastritis can occur at any age, but chronic gastritis is frequently seen in the elderly.

Gastroenteritis

Gastroenteritis is another common disorder of the digestive tract, characterized by inflammation of the stomach and the intestines. It is the most common cause

of mortality in underdeveloped nations, and in the United States it ranks second to the **common cold** as a cause of lost work time. Gastroenteritis is caused by specific bacteria (*Staphylococcus aureus*, *Escherichia coli*, etc.), amoebae or other parasites. The symptoms of gastroenteritis include **diarrhea**, nausea, vomiting, and abdominal cramping. Patients can become dehydrated and malnourished if this disorder continues over an extended period of time.

Peptic ulcer disease

Peptic ulcers can occur in the stomach, although they are more likely to develop in the small intestine. Small lesions develop in the mucosal membrane, causing bleeding. Other symptoms include heartburn and indigestion. Researchers think that a bacterium (*Helicobacter pylori*) or heavy consumption of aspirin can cause this type of ulcer. Although peptic ulcer disease can occur in children, it usually affects people 20–50 years of age.

Gastroesophageal reflux

Gastroesophageal reflux (GER) or gastroesophageal reflux disease (GERD) is caused by a malfunctioning sphincter between the esophagus and the stomach, resulting in a release of chyme back into the esophagus. The esophagus cannot tolerate the acidic nature of the chyme. Consequently, the acid causes a burning sensation called "heartburn." Generally, taking **antacids** after meals or medications to reduce acid secretion can relieve GERD. Severe cases may require surgery.

Cancer of the stomach

Cancer of the stomach affects about 24,000 people in the United States each year. It occurs most often in adults over 55; it is more common in men than in women, and more common in African Americans than in Caucasians. Stomach cancer may develop in any part of the stomach and metastasize (spread) to other parts of the digestive tract or to such distant organs as the ovaries or **lungs**. The early symptoms of stomach cancer are often vague and nonspecific, which means that they can be caused by a range of other health problems. A definite diagnosis of stomach cancer requires a series of laboratory tests and a biopsy of a tissue sample obtained by an instrument called a gastroscope.

The most common treatment for stomach cancer is surgical removal of part or all of the stomach. This procedure is called a gastrectomy. Patients with stomach cancer may also be treated with **chemotherapy**, radiation therapy, or immunotherapy.

KEY TERMS

Antrum—The lower portion of the stomach near the pyloric sphincter.

Chyme—The mass of semiliquid, partially digested food found in the stomach.

Fundus—The upper portion of the stomach near the esophagus.

Gastrin—A hormone that stimulates the secretion of gastric juice.

Gastritis—Inflammation of the stomach.

Gastroenteritis—Inflammation of the stomach and the intestines.

Lumen—The hollow inside a tubular organ such as the digestive tract.

Pepsin—An enzyme produced in the stomach that breaks down proteins in the presence of hydrochloric acid.

Peristalsis—Muscular contractions that move food through the digestive tract.

Retropulsion—A process in which muscular contractions push food that has entered the duodenum backward into the stomach. Retropulsion helps to mix the chyme with gastric juices, and to break large lumps of food into smaller pieces.

Rugae—Ridges or folds in the mucosal and submucosal layers of tissue in the wall of the stomach.

Sphincter—A circular band of muscle that encircles an orifice of the body or one of its hollow organs, such as the digestive tract.

Stomatitis

Definition

Stomatitis is an inflammation of the mucous membranes of the mouth. It may involve the cheeks, gums, tongue, lips, and roof or floor of the mouth. The inflammation may be caused by conditions within the mouth itself, such as poor **oral hygiene** and poorly fitted dentures, or from mouth **burns** caused by hot foods or drinks. It also may be caused by factors affecting the entire body, such as medications, allergic reactions, or infections.

Description

Stomatitis is an inflammation of the lining of any of the soft-tissue structures of the mouth. It is usually a painful condition, associated with redness, swelling, and occasionally bleeding from the affected area. Stomatitis affects all age groups, from infants to the elderly.

Causes and symptoms

A number of factors can cause stomatitis. Poorly fitted oral appliances, cheek biting, or jagged teeth can persistently irritate the oral structures. Chronic mouth

breathing may cause dryness of the mouth tissues, which in turn can lead to irritation. Drinking beverages that are too hot can burn the mouth, causing irritation and **pain**. Some diseases, such as infections (bacterial, viral, and fungal), gonorrhea, measles, leukemia, pellagra, oral erythema multiforme and **AIDS** may present with oral symptoms. **Chemotherapy** and radiation therapy can cause stomatitis by destroying the healthy cells of the oral cavity. Other causes include deficiencies in the **B vitamins** or **vitamin C**, and **iron deficiency anemia**. Stomatitis may also follow overuse of alcohol, tobacco, and spicy foods, as well as exposure to certain toothpastes and mouthwashes. Exposure to heavy metals, such as mercury, lead, or bismuth may also cause stomatitis.

Aphthous stomatitis, also known as “canker sores,” is a specific type of stomatitis that presents with shallow, painful ulcers that are usually located on the lips, cheeks, gums, or roof or floor of the mouth. These ulcers can range from pinpoint size up to 1 inch (2.5 cm) or more in diameter. Though the specific causes of canker sores are unknown, nutritional deficiencies are suspected.

The symptoms of stomatitis may include:

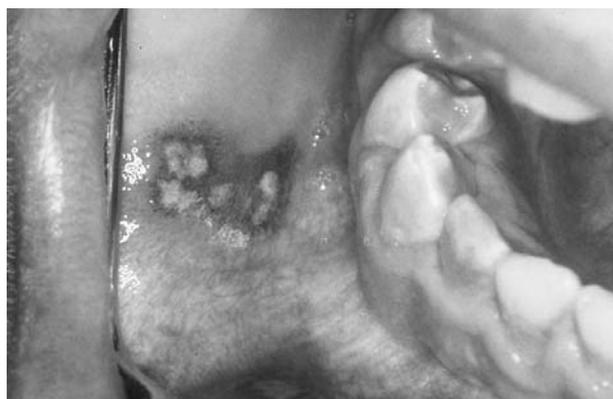

- reddened mucous membranes in the mouth
- painful areas in the mouth
- increased sensitivity to spicy foods
- presence of ulcers in the oral cavity
- dry or swollen tongue
- difficulty swallowing

Diagnosis

The patient will often present with complaints of painful lesions in the oral cavity. The physician or nurse performs a thorough assessment of the mouth, noting any signs of stomatitis. Regular oral examinations are especially important for the patient undergoing **cancer** treatment. A patient’s history may disclose a dietary deficiency, a systemic disease, or contact with materials causing an allergic reaction. **Blood** tests may be done to determine if any **infection** is present. Cultures of the mouth may be sent to the laboratory for microscopic evaluation, again to determine if an infectious agent is causing the stomatitis.

Treatment

The treatment of stomatitis is based on the problem causing it. Local cleansing and good oral hygiene is essential. Sharp-edged foods such as peanuts, tacos, and potato chips should be avoided. A soft-bristled toothbrush should be used, and the teeth and gums should be

This patient is afflicted with stomatitis, a common inflammatory disease of the mouth. (Photograph by Edward H. Gill. Custom Medical Stock Photo. Reproduced by permission.)

brushed very carefully. A dentist can correct local factors, including ill-fitting dental appliances. Infectious causes can usually be treated with **antibiotics** or other medications. Systemic causes, such as AIDS, leukemia, and anemia are treated by the appropriate medical specialist. Minor mouth burns from hot beverages or hot foods will usually resolve on their own in a week or so. Chronic problems with aphthous stomatitis are treated by first correcting any nutritional deficiencies. If those measures are ineffective, medication can be prescribed that is applied to each aphthous ulcer with a cotton-tipped applicator. This therapy is only successful with a limited number of patients. Mouth pain can be alleviated through the use of prescribed topical or oral **analgesics**.

Other treatments include measures to maintain oral hygiene and increase comfort as the stomatitis heals. These measures include:

- Avoiding spicy or acidic foods, or very hot foods.
- Avoiding tobacco products and alcohol.
- Rinsing the oral cavity after meals and before bedtime with a mild saltwater or baking soda and water solution to help keep the mouth clean and free of debris.

Some limited studies have suggested that a few alternative therapies may be effective in preventing and treating stomatitis. These include the use of glutamine, an amino acid; **vitamin E** supplementation; and chamomile mouthwashes. The patient with stomatitis should be instructed to consult their health care professional prior to using any alternative treatments.

Prognosis

The prognosis for the resolution of stomatitis is based on the cause of the problem. Many local factors

KEY TERMS

Aphthous stomatitis—A specific type of stomatitis presenting with shallow, painful ulcers. Also known as canker sores.

can be modified, treated, or avoided. Infectious causes of stomatitis can normally be managed with medications. Uncomplicated cases of stomatitis caused by cancer treatment will usually resolve within two to four weeks.

Health care team roles

The physician and nurse are responsible for thoroughly assessing the oral cavity for signs and symptoms of stomatitis. An awareness of the causes and associated conditions is important when treating the patient. The nurse should instruct the patient on the appropriate treatment and preventative measures, and about any medications used to treat the stomatitis.

Prevention

Stomatitis caused by local irritants can be prevented by good oral hygiene, regular dental checkups, and good dietary habits. Problems with stomatitis caused by systemic diseases can be minimized by practicing good oral hygiene measures, and by closely following the medical therapy prescribed. Cancer patients undergoing treatment can decrease the severity of stomatitis by maintaining good nutritional intake, good oral hygiene, and by having frequent assessments of the oral cavity by their health care professional.

Stone analysis

Definition

Kidney stones are solid accumulations of material that form through precipitation in the tubal system of the kidney. Kidney stones cause problems when they block the flow of urine through or out of the kidney. When the stones move along the ureter, they cause severe **pain**.

Gallbladder stones are also solid accumulations of material that form through precipitation in the **liver** and then move into the gall bladder. They cause problems when they block the flow of bile out of the liver or out of the gall bladder. They can cause attacks of gall bladder disease (cholecystitis), hepatitis or **pancreatitis**. They can also cause severe pain.

Purpose

The purpose of analyzing kidney and gallbladder stones is to determine the source of the stones. Different materials can form stones. Once the source of the stones is known, steps can be taken to prevent subsequent formation.

Precautions

An adequately stocked laboratory is needed for accurate analysis of stones. The most difficult aspect of stone analysis is obtaining the stones.

Passing a kidney stone is exquisitely painful. Once passed, persons with stones must strain their urine to recover any stones. Retrieving a kidney stone is painful for the person experiencing the stone. It also requires skill on the part of an operator to retrieve the stone.

A gallbladder stone must also be obtained before chemical analysis can be performed. Gallbladder stones can become lodged at several locations and cause considerable pain and discomfort. Retrieving a stone usually requires surgery. Commonly, the gallbladder is removed in the process of collecting a stone.

Description

Kidney stones

Urine is formed by the **kidneys**. The kidney is made up of microscopic units called nephrons. Each nephron contains a capillary tuft (glomerulus) and a tubule. **Blood** flows into the kidneys, and engorges the capillary tufts. Water and small solutes pass through the vessel walls forming a filtrate of the plasma which enters the underlying space (Bowman’s capsule). The walls of the capsule

form a tubule that traverses the kidney. The cells of the tubule modify the filtrate along its length ultimately forming the urine which passes out of the body. Sometimes, a problem causes the dissolved solutes to become supersaturated resulting in the formation of crystals. When tiny crystals associate together they form a larger solid mass called a kidney stone or calculus. A kidney stone is also called a nephrolith or urolith (nephro-refers to the kidney, uro- refers to urine, and -lith means stone). Kidney stones have multifactorial causes, but some predisposing conditions are:

- **Diet:** Excessive **calcium** in water and foods rich in oxalate or purines can lead to excessive excretion of calcium, oxalate and uric acid in urine.
- **Dehydration:** Water deprivation or loss from other sources causes stasis in the tubules and concentrates the solutes there.
- **Deficiency of inhibitors:** Some dietary substances such as ascorbic acid and citric acid promote loss of organic calcium salts that are soluble. Absence of these can lead to excessive amounts of oxalate and phosphate.
- **Drugs:** Some drugs such as tetracycline are poorly soluble and may precipitate forming stones or become part of the stone matrix.
- **Metabolic disorders:** Hyperparathyroidism causes excessive calcium excretion by the kidneys. Cystine stones form because of a defect in the renal tubular reabsorption of dibasic amino acids, a condition known as cystinuria.
- **Genetics:** Some people produce and excrete greater quantities of certain metabolites such as uric acid.
- **pH:** Most solutes are only soluble within a finite pH range. For example, phosphates and carbonates are insoluble at an alkaline pH. Uric acid and calcium oxalate are insoluble at an acidic pH. People who produce chronic acid urine are more prone to develop uric acid and calcium oxalate crystals.

Many people never find out that they have stones in their kidneys. These stones are small enough to allow the kidney to continue functioning normally, never causing any pain. These are called “silent stones.” Kidney stones cause problems when they interfere with the normal flow of urine. They can block (obstruct) the flow down the tube (the ureter) that carries urine from the kidney to the bladder. The kidney does not normally experience any back pressure. When pressure builds from backed-up urine, the kidney may swell (hydronephrosis). If the kidney is subjected to this pressure for some time, it may cause damage to the delicate kidney structures. In the most severe case, this back pressure causes the pressure in Bowman’s space to equal the **blood pressure** in the

glomerular capillaries and filtration stops. The person stops producing urine, and waste products accumulate in the blood leading to renal failure. When the kidney stone is lodged further down the ureter, the backed-up urine may also cause the ureter to swell (hydronephrosis). Because the ureters are muscular tubes, the presence of a stone will make these muscular tubes spasm, causing severe pain.

About 10% of all people will have a kidney stone in their lifetimes. Kidney stones are most common among:

- Caucasians
- males
- people over the age of 30
- people who previously have had kidney stones
- relatives of persons with kidney stones

Gallbladder stones

Approximately 80% of gallbladder stones are primarily cholesterol (over 70% cholesterol by weight). They also contain bile pigments, bile acids, fatty acids, and calcium salts. The remainder of gall stones are primarily made of bilirubin. The primary constituents are calcium bilirubinate, calcium phosphate, and calcium carbonate. A gallbladder stone is also called a cholelith (chole-refers to the gallbladder and -lith means stone). Cholesterol-rich gallbladder stones typically develop when the following three conditions exist:

- supersaturation of gallbladder, due mainly to increased biliary cholesterol secretion
- abnormally rapid precipitation of micro-crystals of cholesterol due to an excess of promoters and/or a shortage of inhibitors of crystallization
- stasis within the gallbladder due to the combination of impaired motility, primarily reduced emptying in response to food and/or crystal trapping by an abnormally thick mucus glycoprotein on the gallbladder lining

Many people do not realize that they have stones in their gallbladders. These stones are small enough to allow the liver, gallbladder, and **pancreas** to continue functioning normally, never causing any pain. Gallbladder stones cause problems when they interfere with the normal flow of bile. They can obstruct the flow down the common bile duct that carries bile from the gallbladder to the **small intestine**. Gall stones may obstruct the pancreatic duct, the tube that connects the pancreas with the common bile duct. This can cause inflammation of the pancreas (pancreatitis). The pancreas and gall bladder do not normally experience any back pressure. When pressure builds from backed-up bile (gall bladder) or pancreatic secretions (pancreas), swelling

will occur. If the pancreas is subjected to this pressure for some time, it may cause damage to the internal structures of the organ. When the gallbladder is subjected to pressure, it simply enlarges and exerts pressure on the liver. When a gallbladder stone is lodged at the end of the common bile duct (in the Sphincter of Oddi where it opens into the small intestine), the backed-up bile may also cause all of the structures (liver, gallbladder, pancreas and ducts) to swell. Because the ducts have muscle tissue in their walls, the presence of a stone will make them spasm, causing pain.

About 12% of men and 25% of all women will develop gallstones in their lifetimes. Gallbladder stones are most common among:

- Caucasians
- females
- women who have had children
- people over the age of 40
- people who previously have had gallbladder stones
- people who are overweight

Composition of stones

Kidney stones can be composed of a variety of substances. About three-fourths of kidney stones contain calcium. The most prevalent kidney stone is made up of calcium oxalate usually in combination with other calcium salts. In addition to the chemical name, stones are often described by their mineralogical properties. For example, calcium oxalate exists in two forms, the monohydrate which is called whewellite and the dihydrate which is called weddellite. The most common types of kidney stones include:

- calcium oxalate (whewellite and weddellite)
- magnesium ammonium phosphate (struvite)
- tricalcium phosphate (whitlockite); calcium phosphate (apatite); and calcium hydrogen phosphate dihydrate (brushite)
- uric acid stones

Gallbladder stones are usually composed of cholesterol. They also contain some:

- bile pigments
- bile acid
- calcium salts

People who have kidney stones usually do not have symptoms until the stones pass into the ureter. Prior to this, some individuals may notice blood in their urine. Once the stone is in the ureter, however, most people will experience bouts of very severe pain. The pain is crampy

and spasmodic, and is referred to as “colic.” The pain usually begins in the flank region, the area between the lower ribs and the pelvis. As the stone moves closer to the bladder, a person will often feel the pain radiating along the inner thigh. In women, the pain may be felt in the vulva. In men, the pain may be felt in the testicles. Nausea, vomiting, extremely frequent and painful urination, and obvious blood in the urine are common. **Fever** and chills usually mean that the ureter has become obstructed, allowing **bacteria** to become trapped in the kidney causing a kidney **infection** (pyelonephritis).

People who have gallbladder stones usually do not have symptoms until the stones pass into the common bile duct. Once the stone is in the common bile duct, however, most people will experience bouts of pain, especially after eating fatty meals. The pain is also referred to as colicky. The pain usually begins in the upper right quadrant of the abdomen, the area just beneath the right ribs. As the stone moves closer to the Sphincter of Oddi, a person will often feel the pain radiating throughout the entire abdomen. If it obstructs the pancreatic duct, it may be felt in the posterior portion of the abdomen as flank pain. Nausea, vomiting, light (clay) colored stools and flatulence are common. Fever and chills usually mean that the Sphincter of Oddi has become obstructed, forcing pancreatic fluid and liver discharges to be trapped in their respective organs, often causing inflammation of the liver (hepatitis), gallbladder (cholecystitis) and pancreas (pancreatitis).

Preparation

Kidney stones that are less than 5 mm in diameter are usually passed. The physician or nurse must instruct the patient in the proper technique to recover the stone once it is passed. Special laboratory equipment is required for stone analysis. Most clinical laboratories do not perform this service. Consequently the stone must be packaged and mailed to a reference laboratory that performs stone analysis.

Laboratory analysis

For the most part, the analysis is qualitative in nature. Testing involves macroscopic evaluation of the stone. This includes determination of its weight, size, shape, hardness, and color. Kidney stones are usually analyzed by x ray diffraction. The stone is pulverized into a fine powder and the powder is spread over a glass fiber mat and exposed to x rays. The crystals scatter the x rays and the various patterns produced are analyzed to determine the chemical composition. The composition of non-crystalline stones cannot be determined by this method and are usually analyzed by infrared spectroscopy. These

crystals are usually composed of drugs or their metabolites that precipitated in the tubules. In special cases the stone may be analyzed by chemical analysis and by microscopic analysis. For example, cystine stones can be readily detected by grinding a small piece of the stone into a powder. The powder is boiled in a small amount of deionized water and a solution of sodium cyanide is added. The cyanide reduces the cystine to cystiene. After standing for five minutes, several drops of sodium nitroprusside are added. The solution will turn red if cystiene is present. Gall stones are composed of either cholesterol or bilirubin. These can be analyzed by infrared analysis, x ray diffraction or chemical analysis (detection of cholesterol and bilirubin after organic extracton).

Many stones can be seen using a basic x ray, but some cannot. A more sensitive imaging procedure is to use a series of x rays taken after injecting iodine dye into a vein. This procedure is called an intravenous pyelogram (IVP). The dye allows the **urinary system** to be visualized. In the case of an obstruction, the dye will be stopped by the stone or will only be able to get past the stone at a slow trickle.

A cholangiogram is used to visualize the location of a gallbladder stone that is causing an obstruction. A tube is passed though the mouth, throat and **stomach**. It enters the small intestine and is inserted into the Sphincter of Oddi. Dye is injected, allowing the interior of the common bile duct and connected structures to be visualized. As with a kidney stone, the dye is stopped by an obstruction, allowing a radiographer to pinpoint the position of a stone. A CT or MRI scan may also be used to locate a gallbladder stone.

Persons are prepared prior to obtaining a stone for analysis. Preparation for surgery (gallstones) involves anesthesia. Preparation for collecting passed kidney stones involves straining urine through a special sieve. Preparation for surgical collection of a kidney stone involves sedation and passing a catheter through a person's urethra and bladder before entering the ureter.

Aftercare

After stones have been analyzed, the goal becomes preventing subsequent formation by eliminating the cause of the stone.

Prevention

Prevention of kidney stones depends on the type of stone and the presence of an underlying disease. In almost all cases, increasing fluid intake so that a person consistently drinks several quarts of water a day is an important preventive measure. Persons with calcium

stones may benefit from taking a medication called a diuretic, which has the effect of decreasing the amount of calcium passed in the urine. Eating less meat, fish, and chicken may be helpful for individuals with calcium oxalate stones. Other items in the diet that may encourage calcium oxalate stone formation include beer, black pepper, berries, broccoli, chocolate, spinach, and tea. Uric acid stones may require treatment with a medication called allopurinol. Struvite stones will require removal and an affected person should receive an antibiotic. Adjustment of pH is an important preventative measure. For example, if the stone contains calcium phosphate or calcium carbonate or a mixture of these, an acidifier is used to keep the urine pH below seven because these stones form in alkaline urine. When a disease is identified as the cause of stone formation, treatment specific to that disease may lessen the likelihood of repeated stones.

Preventing gallbladder stones is usually accomplished by dietary modification. Fat intake must be diminished. This will also prevent intestinal colic as the gallbladder is usually removed. Drugs that inhibit the formation of cholesterol by the liver may be used. **Niacin**, cholestyramine, cholestipol, lovastatin, simvastatin, pravastatin, fluvastatin and gemfibrozil have all been approved for use in the United States as of 2001. Some experts recommend daily supplements of methionine. The drug ursodiol (Actigall) has also been approved for treatment of gallbladder stones.

Complications

Complications of actual stone analysis include laboratory error. These are very rare.

Complications for people with stones include recurrence. They also may include adverse drug reactions. These, too, are uncommon.

Results

A person with a kidney stone will say that the most important aspect of treatment is adequate pain relief. Because the pain of passing a kidney stone is so severe, narcotic pain medications (such as meperidine or morphine) are often required. It is believed that stones may pass more quickly if a person is encouraged to drink large amounts of water (2-3 quarts, or 2-3 L per day). If an individual is vomiting or unable to drink because of the pain, it may be necessary to provide fluids through a vein. If symptoms and urine tests indicate the presence of infection, **antibiotics** will be required.

A person with a gallbladder stone also finds that the most important aspect of treatment is adequate pain relief. Because the pain of gallbladder disease attacks are

so uncomfortable, pain medications (such as ibuprofen or acetaminophen with codeine) are often required. If symptoms and tests indicate the presence of infection, antibiotics will be required.

Treatment

Although most kidney stones will pass on their own, some will not. Surgical removal of a stone may become necessary when a stone appears too large to pass. Surgery may also be required if the stone is causing serious obstructions, pain that cannot be treated, heavy bleeding, or infection. Several alternatives exist for removing stones. One method involves passing a tube into the bladder and up into the ureter. A tiny basket is then passed through the tube, and an attempt is made to snare the stone and pull it out. Open surgery to remove an obstructing kidney stone was relatively common in the past, but current methods allow the stone to be crushed with shock waves (called **lithotripsy**). These shock waves may be aimed at the stone from outside of the body by passing the necessary equipment through the bladder and into the ureter. The shock waves may be aimed at the stone from inside the body by placing the instrument through a tiny incision located near the stone. The stone fragments may then pass on their own or may be removed through the incision. All of these methods reduce an individual's recovery time considerably when compared to the traditional open operation.

An individual with a gallbladder stone will usually have the gallbladder removed. The most common procedure for this task is a laparoscopic cholecystectomy. Three small incisions are made in the abdomen. Into one, a thin tube with a light and camera lens is passed. Into the second and third, thin tubes through which instruments are inserted, is passed. A surgeon visualizes the interior of the abdomen on a television screen using the camera in the first tube and removes the gall bladder using the instruments inserted through the second and third tubes. Using this approach, post-surgical complications have been reduced and the time required for recovery has been significantly reduced (when compared to traditional open surgical techniques).

Health care team roles

A physician makes an initial diagnosis of kidney or gall stones. A radiologist confirms the diagnosis using x rays or ultrasonography. A surgeon is needed to operatively remove a kidney or gall stone. Lithotripsy is performed by a technician under the supervision of a physician. Occasionally, open surgery is required and is performed by a surgeon. Nurses assist in lithotripsy and surgery. A laboratory specialist performs a chemical analysis of the stone to determine its composition and

origin. Pharmacists may dispense pain medications and antibiotics as required.

Stool culture

Definition

A stool culture is a laboratory test used to isolate and identify pathogens in the feces of patients suspected of

having digestive tract infections. A sample of the patient's feces is placed on several different types of nutrient media and observed for growth. Any suspicious organisms that grow on the media are identified using microscopic and biochemical tests.

Purpose

Physicians normally order stool cultures on patients with symptoms of gastrointestinal **infection**, most commonly **diarrhea**. The purpose of this test is to isolate **bacteria** or other organisms that might be causing the symptoms so they can be identified. Identification of the causative organism is essential in determining how to treat the patient. For example, administering an antibiotic merely on the basis of the patient's symptoms could, in some cases, make the condition worse.

Precautions

A stool culture is performed only if an infection of the digestive tract is suspected. The test has no harmful effects.

Description

A routine stool culture (also called a fecal culture) is for the isolation of *Campylobacter*, enterotoxigenic *E. coli* (O57:H7), *Shigella*, and *Salmonella*. Less frequently isolated bacterial causes of diarrhea are *Vibrio spp.*, *Yersinia enterocolitica*, and *Aeromonas spp.* Requests for stool cultures for the isolation of other intestinal pathogens should include special instructions. The most common example is *Clostridium difficile*, which causes pseudomembranous colitis.

Stool cultures may be performed on rectal swabs containing feces or submitted stool samples. Swabs are placed in a tube containing Stuart or other transport medium and then delivered to the laboratory. Cultures for *C. difficile* are usually collected by swabbing the rectum (whereas watery stool is needed for immunoassay of *C. difficile toxin*). The swab must be placed immediately into prerduced (oxygen free) transport medium because this organism is a strict anaerobe. To submit a stool specimen for routine culture, the patient or caregiver collects a stool sample in a special container, taking care not to contaminate the specimen with water, urine, or other materials. Some containers include a transport solution to stabilize the specimen. Although some requests are for stool cultures on two or more consecutive days, a single specimen is considered to be sufficient. It is important to return the specimen to the doctor's office or the laboratory in the time specified by the physician or nurse. Laboratories normally do not accept stool specimens that

are contaminated or that arrive after the specified time period.

A routine bacterial stool culture involves placing a sample of the stool on several kinds of enriched and selective media containing nutrients that support the growth of certain types of organisms. Routine culture should include a sheep blood agar plate, MacConkey agar plate, MacConkey agar with sorbitol, Hektoen or XLD (xylose lysine desoxycholate) plate, Campy plate, and GN (gram-negative) broth. Blood agar supports the growth of most bacteria including *Staphylococcus aureus*, *Listeria monocytogenes*, and yeast, which are infrequently implicated in **food poisoning** or gastrointestinal infections, but do not grow on the other media. Most intestinal pathogens are gram-negative bacilli. MacConkey agar is selective for these organisms and differentiates those that can ferment lactose from those that cannot. MacConkey sorbitol substitutes sorbitol for lactose. This allows differentiation of nonpathogenic *E. coli* that ferment sorbitol well from the O57:H7 strain, which does not. Hektoen or XLD enhance the growth of *Salmonella* and *Shigella* by suppressing the growth of gram-positive organisms and gram-negative normal flora. They also differentiate lactose and sucrose fermenters such as *E. coli* from *Salmonella* and *Shigella*, which are not. Several drops of the GN broth can be transferred to Hektoen or XLD agar after a four-hour incubation at 36°C. This procedure can yield isolated colonies of a pathogen the next day that can be used to perform biochemical identification, serotyping, and antibiotic susceptibility tests. Campy agar contains 10% sheep blood, sodium bisulfite, and three **antibiotics**. The sodium bisulfite reduces some of the oxygen in the medium which enhances recovery of *Campylobacter*. The antibiotics prevent other gram-negative bacilli and yeast from growing. All inoculated media except the Campy plate are incubated in air or 5-10% carbon dioxide at 36°C and are examined for growth at 24 hours and again the next day. Campy plates must be incubated at 42°C. Plates are examined at 24 hours and each day for the next two days. Cultures for *Clostridium difficile* require CCFA agar and thioglycolate broth. These are incubated in an oxygen free environment at 36°C for two days. CCFA is cycloserine-cefoxitin fructose agar and it inhibits the growth of other enteric anaerobes found as normal flora in stool. *C. difficile* produces large yellow colonies on CCFA agar that will fluoresce yellow-green.

Gram stains are not performed routinely, but may be requested for the semiquantitation of white blood cells. If any suspicious bacterial colonies grow, they are presumptively identified on the basis of colonial growth, physical characteristics, microscopic features, and biochemical tests. The colonies are subcultured (transferred)

to an appropriate medium to obtain a pure culture. This is used to make a suspension of the organism that is inoculated onto biochemical media. Commercially prepared systems for rapid identification are used. These contain multiple pads or wells of media used to test for key defining biochemical characteristics. After overnight incubation, reactions are read by an automated computerized instrument that aids in species identification. Pure cultures are also used to perform antibiotic sensitivity testing. This is typically done by the microtube broth dilution method. This test determines the minimum inhibitory concentration (MIC) of each antibiotic required to prevent growth of the organism. Results are used to determine those antibiotics to which the organism is susceptible.

The length of time needed to perform a stool culture depends on the laboratory instrumentation and the culture methods used. A routine stool culture usually takes 72 hours or longer to complete.

Preparation

Before ordering a stool culture, the physician, or other health care professional, will ask the patient for a complete medical history and perform a **physical examination** to determine possible causes of the gastrointestinal problem. Information about the patient's diet, any medications taken, and recent travel may provide clues to the identity of possible infectious organisms.

A stool culture normally doesn't require any special preparation. Patients do not need to change their diets before collecting a specimen. Intake of some substances can contaminate the stool specimen and should not be taken the day before collection. These substances include castor oil, bismuth, and laxative preparations containing psyllium hydrophilic mucilloid.

Aftercare

No aftercare is necessary following a stool culture.

Complications

No complications are associated with this test.

Results

Some bacteria that are normal inhabitants of the digestive tract are known as the enteric bacteria. *Escherichia coli*, *Klebsiella*, *Enterobacter*, and *Pseudomonas* are members of this group. The enteric bacteria usually do not cause infection in the digestive tract, and are reported as normal flora in a stool culture. Because the presence of normal flora helps to protect

against pathogens, the absence of normal flora in a stool culture is also reported. When only normal flora are found the results are reported as "no enteric pathogens found." When normal flora are absent from the stool, a heavy growth of an organism not usually pathogenic may be recovered. Such organisms should be reported in this case.

The following bacteria are not normal inhabitants of the digestive tract, and are known to cause gastrointestinal infection:

- *Campylobacter*
- *Shigella*
- *Salmonella*
- *Yersinia*
- enterotoxigenic *E. coli*
- *Vibrio*
- *Aeromonas*

Although non-toxigenic strains of *E. coli* are normal flora of the intestines, *E. coli* O157:H7 is an intestinal pathogen. It produces a toxin (poison or harmful chemical) that causes severe inflammation and bleeding of the colon. Infection with this enterotoxigenic strain of *E. coli* is usually associated with eating contaminated meat, juice, or fruits.

Clostridium difficile, like enterotoxigenic *E. coli*, can produce a toxin that causes severe diarrhea. However, this bacterium does not become harmful unless the normal intestinal bacteria are suppressed. Patients taking certain antibiotics may be susceptible to infection with *Clostridium difficile*. In some cases, the stool culture is used to detect the toxin produced by this bacterium. Other bacteria that produce toxins are *Staphylococcus aureus* and *Bacillus cereus*.

If bacteria are not the cause of an intestinal infection, a fungal or viral culture might be necessary. Patients with **AIDS**, or other **immune system** diseases, sometimes have gastrointestinal infections caused by fungal organisms such as *Candida*, or by viral organisms including *Cytomegalovirus* (CMV). *Candida* can also become an opportunistic intestinal pathogen when antibiotics or radiation have destroyed the normal stool flora.

Several intestinal parasites, such as *Giardia lamblia*, also cause gastrointestinal infection and diarrhea. Parasites are not cultured, but are identified microscopically with a stool ova and parasites test.

Health care team roles

The physician orders the stool culture, evaluates the results, and determines the most appropriate treatment.

KEY TERMS

Bismuth—A substance used in medicines to treat diarrhea, nausea, and indigestion.

Enteric—Pertaining to the intestine.

Enterotoxigenic—Refers to an organism that produces toxins in the gastrointestinal tract that cause such things as vomiting, diarrhea, and other symptoms of food poisoning.

Feces—Material excreted by the intestines.

Gastrointestinal—Referring to the digestive tract; the stomach and the intestines.

Normal flora—Refers to normal bacteria found in a healthy person.

Pathogen—An organism that causes disease.

Psyllium hydrophilic mucilloid—A plant material contained in some laxatives.

Toxin—A poison; usually refers to protein poisons produced by bacteria, animals, and some plants.

Most laboratories provide instructions for the collection of a stool specimen. The physician, nurse, or other health care professional should instruct or assist the patient in collecting the specimen correctly and without contamination. Once the specimen is ready, the patient or health care professional should ensure that the specimen arrives at the laboratory within the time specified. The clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) performs the stool culture and sensitivity tests.

Stool ova & parasites test

Definition

The stool ova & parasites (O & P) test involves examination of a stool (feces) sample for the presence of intestinal parasites. The distinct types of parasites differ with regard to their structures, life stages, and transmission forms. A parasite may be a worm that has a mature form, an immature form (larvae), and eggs (ova). A parasite may be a protozoa with an adult form that lives in the intestines (trophozoite) and a round, encapsulated transmissible form (cyst). Stool analyses examine all parasitic forms that may be present in the sample.

Purpose

The ova and parasites test is performed to identify intestinal parasites and their eggs or cysts in patients with symptoms of gastrointestinal **infection**. Patients may have no symptoms, or may experience **diarrhea**, **blood** in the stools, and other gastrointestinal distress. Stool O & P testing is usually ordered along with tests for the bacterium *Clostridium difficile* as well as a **stool culture** since overlapping symptoms may result from bacterial or parasitic infections. Identification of a particular parasite indicates the cause of the patient's disease and determines the medication needed to treat it.

Precautions

Health care providers should always use proper **infection control** procedures when handling stool samples since they are potentially infectious material.

Description

The stool O & P test is also called the stool ova and parasites test or the ova and parasites collection.

Examination of the stool for ova and parasites is done to diagnose parasitic infection of the intestines. Parasites can go through several different life stages depending on the unique characteristics of each type of parasite. For example, the parasite *Entamoeba histolytica* causes amoebiasis, a parasitic intestinal infection that can cause diarrhea and cramps. This disease is common in developing countries with poor sanitation or in the United States in institutions with poor hygiene practices. The stool of an infected person contains cysts of the parasite. These cysts have a protective covering and can survive outside the body in feces. If food or water is contaminated with such feces, another person can consume the cysts. Mature cysts that are ingested then turn into trophozoites that feed inside the **large intestine**. Some trophozoites then begin to encyst and create protective walls around their small, round center. These cysts are then expelled from the body in feces that can infect food or water, and the transmission process to another person is repeated. Stool O & P tests require the health care professional to identify parasites in a variety of structural forms.

The most common intestinal parasites in North America that cause infections are:

- roundworms: *Ascaris lumbricoides*
- hookworms: *Necator americanus*
- pinworms: *Enterobius vermicularis*
- whipworm: *Trichuris trichiura*
- tapeworms: *Diphyllobothrium latum*, *Taenia saginata*, and *Taenia solium*
- protozoa: *Entamoeba histolytica* (an amoeba), and *Giardia lamblia* (a flagellate)

Numerous other parasites are found in other parts of the world. These may be contracted by travelers to other countries. Patients with acquired immune deficiency syndrome (AIDS) or other **immune system** disorders are commonly infected with the parasites in the Microsporidia phylum, *Cryptosporidium*, and *Isospora belli*.

A stool O & P test may be performed in the physician's office or at an external laboratory. There are several commercial kits with instructions that patients can use at home to collect stool samples. These kits are comprised of sterile containers containing special chemical fixatives. The feces should be collected directly into the container and the patient should be careful not to contaminate the sample with urine, water, or other materials. Three specimens are collected, usually two or three days apart. However, as many as six specimens may be needed within 14 days to identify some organisms (like *E. histolytica*). A specimen held at room temperature should be examined within three hours. If testing is delayed, the

sample may be refrigerated for two to three days or preserved. If a preservative is used, it must preserve all forms of the parasite (including eggs, or cysts and trophozoites, etc.) without interfering with the testing required for the stool sample. A commonly used preservative is the combination merthiolate-iodine-formalin (MIF).

In the laboratory, the stool sample is examined for a variety of parasitic forms. Some parasites are large enough to be seen without a **microscope**. For others, microscope slides are prepared with either fresh unstained stool or stool dyed with special stains. These preparations are viewed with a microscope to detect the presence of parasites or their eggs.

The recovery of ova or parasite forms depends upon the consistency of the stool sample, which suggests the parasitic stage is likely to be present. For example, if the stool specimen is soft or loose, it may be more likely to contain trophozoites. If the stool specimen is formed, then it may be more likely to contain cysts.

A stool examination usually requires three procedures: a direct wet mount, a concentration test, and a permanent smear. A direct wet mount requires preparing a slide with an appropriate fecal sample and then viewing the slide under a microscope for evidence of parasites. In a concentration by sedimentation test, chemicals (most often ethyl acetate and formalin) are used to separate the parasites from other fecal material (oils, **fats**, etc.). When a test tube containing the sample and these chemicals is centrifuged, the sedimentation on the bottom of the tube contains the parasite forms while the fats and other substances are closer to the top of the tube. The sediment is then appropriately processed and examined for parasite forms. A permanent smear is made by preparing a slide with a fecal sample and adding Gomori trichrome stain. When viewed with a microscope, the background appears blue-green while parasite forms stain blue-green and red. This test is required to identify trophozoites and is the most sensitive of the three tests.

Sometimes another method of examination must be used, as is the case for *Cryptosporidium*. Modified acid-fast staining must be used for this organism. When this stain is used, forms of the organism (oocysts) turn red.

Obtaining a specimen to identify pinworm (*E. vermicularis*) infection requires a different technique. Adult parasites lay eggs outside of the intestines on the skin folds of the anus. Eggs are usually not present in stool. Clear adhesive tape or a sticky swab or paddle is applied to the anus. Eggs then stick to the tape, swab, or paddle and can be examined microscopically. When adhesive tape is used, this technique is often called the "scotch tape method" of collection.

KEY TERMS

Amoeba—A type of protozoa (one-celled animal) that can move or change its shape by extending projections of its cytoplasm.

Bismuth—A substance used in medicines to treat diarrhea, nausea, and indigestion.

Cryptosporidium—A type of parasitic protozoa.

Centrifuged—Spun via a centrifuge. A centrifuge is a specialized machine used to spin a test tube at a very fast rotation in order to separate the particles inside the tube into different layers according to their density.

Feces—Material excreted by the intestines.

Flagellate—A microorganism that uses flagella (hair-like projections) to move.

Gastrointestinal—The digestive tract; the stomach and intestines.

Isospora belli—A type of parasitic protozoa.

Microsporidia—A phylum of small parasitic protozoans.

Parasite—An organism that lives on or inside another living organism (host), causing damage to the host.

Protozoa—One-celled eukaryotic organisms belonging to the kingdom Protista.

Immunological testing of stool is a faster diagnostic tool and does not require knowledge of the structures and life stages of parasites. Fresh or fresh-frozen stool is diluted, filtered, and added to a commercial device containing antibodies that will react if several specific parasite antigens are present in the stool sample. If the antigen of the parasite is present, a purple color is produced. However, this type of testing can only be conducted with unpreserved stool and can only assist in identifying a few common parasites.

Insurance coverage for stool ova and parasites may vary among different insurance plans. This test usually is covered if ordered by a physician approved by the patient's insurance plan, and if it is done at an approved laboratory. However, since insurance plans vary greatly, patients should contact their insurance company with regard to specifics.

Preparation

The physician, or other healthcare provider, will ask the patient for a complete medical history, and perform a

physical examination to determine possible causes of the gastrointestinal symptoms. Information about the patient's diet, any medications taken, and recent travel may provide clues to the identity of possible infectious parasites.

Patients should avoid taking any medications or treatments containing mineral oil, castor oil, or bismuth, magnesium or other antidiarrheal medicines, or **antibiotics** for up to 10 days before collecting the specimen.

Aftercare

The patient should avoid taking preparations that interfere with specimens for the duration of time the specimen collection is required.

Complications

There are no complications associated with a patient providing a stool sample for stool O & P testing.

Results

Normally, parasites and eggs are not found in stools. Some parasites are not pathogenic (for example, *Endolimax nana* and *Iodamoeba butschlii*), which means they do not cause disease. If these are found, no treatment is necessary. The presence of any pathogenic parasite indicates an intestinal parasitic infection. Depending on the parasite identified, other tests may be required to determine if the parasite has invaded other parts of the body. Some parasites travel from the intestines to other parts of the body and may already have caused damage to other tissues by the time a diagnosis is made. For example, the roundworm *Ascaris* penetrates the intestinal wall and can cause inflammation in the abdomen. It can also migrate to the **lungs** and cause **pneumonia**. This kind of injury can occur weeks before the roundworm eggs appear in the stool.

Other types of damage caused by intestinal parasites include anemia due to hemorrhage caused by hookworms, and anemia caused by depletion of **vitamin B₁₂** due to infection with the tapeworm *Diphyllobothrium latum*.

When a parasite is identified, the patient can be treated with the appropriate medications to eliminate the parasite.

Health care team roles

Training

A physician orders a stool O & P test. Stool samples may be collected by a physician, nurse, physician assis-

tant, or other trained health care professionals. Laboratory professionals (usually called clinical laboratory scientists or medical technologists) who perform microscopic tests for stool ova and parasites have received specialized training in preparing, handling, and examining the samples. These professionals have been trained to look for specific characteristics of parasite forms that will lead to accurate diagnosis and treatment for the patient.

Patient education

Health care providers should teach the patient how to use the collection kit, how many samples will be required, and how to keep the samples free from contamination. Usually patients should be instructed to take the stool sample in the morning before bathing or taking a shower. Patients should be taught how to avoid re-infection based on how the parasite is contracted when a definite diagnosis is made. For example, patients with pinworms should practice sound personal hygiene in the future such as washing hands after using the restroom and before eating, and wearing clean undergarments daily. Patients with tapeworms should avoid eating specific raw or undercooked meat or fish in the future. Health care providers should also stress that patients follow the full duration of treatment as required to eliminate the parasite.

Stool ova and parasites test see **Stool O & P test**

Stool specimen collection

Definition

Stool specimen collection is the process of obtaining a sample of a patient's feces for diagnostic purposes.

Purpose

This procedure is used to test for infectious organisms, mucus, fat, parasites, or **blood** in the stool.

Precautions

Depending on the proposed analysis of the feces, watery feces will not be suitable for conducting a test for any fat that may be present, but can be used for other analyses, such as testing for **bacteria**.

Description

A stool specimen or culture can also be called a fecal specimen or culture. A specimen of freshly passed feces of 1/2 to 1 ounce (15 g to 30 g) is collected, without contamination of urine or toilet tissue, into a small container that may have a small spoon or spatula attached inside the lid of the cup for easier collection of the sample.

Adult and older children patient can collect the specimen by passing feces into plastic wrap stretched loosely over the toilet bowl. A portion of the sample is then transferred into the supplied container.

With young children and infants wearing diapers, the diaper should be lined with plastic wrap. A urine bag can be attached to the child to ensure that the stool specimen is not contaminated with urine.

For a bedridden patient, the specimen should be collected in a bedpan lined with plastic wrap, and the nurse can transfer a portion of the feces into the appropriate container.

KEY TERMS

Barium sulfate—A water-insoluble salt used as an opaque medium for radiographic contrast.

Occult blood—Hidden blood.

Parasite—An organism that lives on or in another host.

Follow the manufacturer's guidelines if a commercial collection kit is used.

Preparation

If occult blood is suspected, the patient should be given a mild laxative and should avoid eating foods rich in meat extracts or leafy vegetables three days prior to the test. If the patient's gums bleed when brushing their teeth, the mouth should be cleansed with mouthwash and wiped with a cloth to avoid blood entering the digestive system and contaminating the stool specimen.

Certain drugs may interfere with the analysis of the specimen, and the patient should avoid ingesting products such as **antacids**, oily foods and drugs, and **antibiotics**. Barium sulfate should be excluded two weeks prior to the test, and medical procedure dyes three weeks prior to the test.

If fat in the stool is suspected, the patient will also be asked to collect the samples in pre-weighed airtight containers.

All feces passed in a 24-hour period are collected over two or three days and sent daily for analysis.

Aftercare

The patient should be made clean and comfortable.

All contents of kits, towels, plastic wrap, gloves, and bedpans should be disposed of in appropriate containers. The nurse should wash and dry his or her hands thoroughly.

Speed in testing the sample is essential, in order that an accurate result is obtained. Therefore the specimen should be sent for testing as quickly as possible.

Complications

If there is a delay in sending the specimen for testing, organisms present in the feces may die, while others may multiply, giving a false reading.

Patients should inform medical staff of any medications currently being taken as elements of the drugs may be present in the feces.

Results

The specimens are compared with normal values. Abnormal results indicate that **infection**, disease, or parasite infestation are present.

Health care team roles

The nurse should be aware of the qualities of normal feces, and note if the patient has any difficulties in passing feces. As many patients may feel uncomfortable performing this collection properly, the nurse should also educate the patient concerning the reasons for having it done.

Strep throat

Definition

Strep throat is an **infection** of the mucous membranes lining the pharynx. Sometimes the tonsils are also infected (tonsillitis). The infection is caused by group A beta-hemolytic *Streptococcus* **bacteria**, commonly known as strep.

This bacterial infection typically causes a severe **sore throat**, **fever**, and difficulty swallowing. Strep throat may also produce a rash, known as scarlet fever, and swollen glands. Untreated, it can lead to rheumatic

fever, a serious kidney disorder called glomerulonephritis, and other infections.

Description

Strep throat accounts for 5-10% of all sore throats. Although anyone can get strep throat, it is most common in school-age children. It accounts for about one quarter of sore throats in children ages five to 15. Smokers, and people who are fatigued, immunosuppressed, or who live in damp, crowded conditions are more likely to become infected. Children under age two and adults who do not have contact with children are less likely to become infected.

Strep throat occurs most frequently from November to April. The disease passes directly from person to person by coughing, sneezing, and close contact. Rarely, it may be passed through food, when a food handler infected with strep throat accidentally contaminates food by coughing or sneezing. Statistically, when one member of a household is infected, one out of every four other household members will contract strep throat within two to seven days.

Causes and symptoms

Strep infection may produce a sudden, painful sore throat one to five days after exposure to the *Streptococcus* bacteria. The **pain** is indistinguishable from sore throats caused by viral infections.

The infected patient usually feels tired and has a fever, sometimes accompanied by chills, headache, muscle aches, swollen lymph glands, and nausea. Young children may complain of abdominal pain. The tonsils appear swollen and are bright red, and may have white or yellow patches of pus. Sometimes the roof of the mouth is red or has small red spots. Often a person with strep throat has bad breath.

Though most patients display some of these common symptoms, it is possible to have the disease without any of these symptoms. Many young children complain only of a headache and stomachache, rather than the characteristic sore throat.

Occasionally, within a few days of developing the sore throat, patients may develop a fine, rough, sunburn-like rash over the face and upper body, along with a fever of 101-104°F (38.3-40°C) and bright red tongue, with a flecked, strawberry-like appearance. When a rash develops, this form of strep throat is called scarlet fever. The rash is caused by toxins released by the streptococcus bacteria. Scarlet fever is no more dangerous than strep throat, and is treated the same way. The rash disappears in about five days. One to three weeks later, patches of

skin may desquamate (peel off), as might occur with a sunburn.

Untreated strep throat can cause rheumatic fever. This is a serious illness, although it occurs rarely. The most recent outbreak appeared in the United States in the mid-1980s. Rheumatic fever occurs most often in children between the ages of five and 15, and susceptibility to it may be genetic, since it seems to run in families. Although the strep throat that causes rheumatic fever is contagious, rheumatic fever itself is not.

Rheumatic fever begins one to six weeks after an untreated streptococcal infection. The joints, especially the wrists, elbows, knees, and ankles become red, sore, and swollen. The patient develops a high fever, and possibly a rapid heartbeat when lying down, paleness, shortness of breath, and fluid retention. A red rash over the trunk may come and go for weeks or months. An acute attack of rheumatic fever lasts about three months.

Rheumatic fever can cause permanent damage to the **heart** and heart valves. It can be prevented by promptly treating streptococcal infections with **antibiotics**. It does not occur if all the streptococcus bacteria are killed within the first 10-12 days after infection.

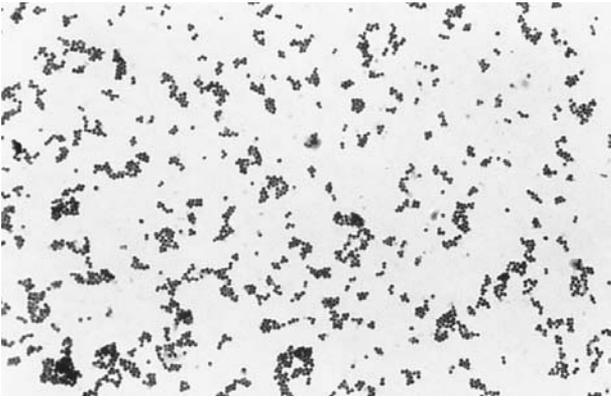

During the 1990s, outbreaks of a virulent strain of group A *Streptococcus* were reported to cause a toxic-shock-like illness and a severe invasive infection called necrotizing fasciitis, which destroys skin and muscle tissue. Although these diseases are caused by group A *Streptococci*, they rarely begin with strep throat. Usually the streptococcus bacteria enter the body through a skin wound. These infections are rare, however, since the death rate in necrotizing fasciitis is 30-50%, it is wise to promptly treat any streptococcal infection.

Diagnosis

Diagnosis of strep throat begins with a **physical examination** of the throat. The doctor will also look for signs of other illness, such as a sinus infection or bronchitis, and seek information about whether the patient has been exposed to anyone with strep throat. Patients likely to have strep throat will have a rapid strep test or **throat culture**, laboratory tests to detect the presence of bacteria.

There are two types of tests to confirm the diagnosis of strep throat. A rapid strep test determines the presence of streptococcal antigen, and results are available in about 20 minutes. The advantage of this test is the speed with which a diagnosis may be made.

The rapid strep test has a false negative rate of about 20%. For this reason, when a rapid strep test is negative, the physician may order a throat culture.

Gram stain of *Streptococci*. (Delmar Publishers, Inc. Reproduced by permission.)

For a rapid strep test or a throat culture, a physician, mid-level practitioner (i.e., nurse practitioner or physician assistant) or nurse will use a sterile swab to reach down into the throat to obtain a sample of material from the sore area. The procedure takes only a few seconds, but may cause some patients to gag.

For a throat culture, a sample of swabbed material is cultured, or grown, in the laboratory on a medium that allows laboratory technologists and technicians to accurately determine whether group A *streptococci* is present. Results are available in 24-48 hours. This test is very accurate and also detects the presence of bacteria other than *Streptococci*. Patients should be reminded by the nurse not to take antibiotics before a throat culture. Even small amounts of antibiotics can suppress the bacteria enough to mask their presence in the throat culture.

In the event that rheumatic fever is suspected, the physician will order a **blood** test. This test, called an anti-streptolysin-O test, determines whether the person has recently been infected with strep bacteria and helps to distinguish between rheumatic fever and rheumatoid arthritis.

Treatment

Strep throat is treated with antibiotics. Penicillin is the preferred medication. The typical dose for adults is Penicillin V, 250 mg by mouth, four times a day or 500 mg twice a day. Alternatively, 250 mg of erythromycin may be given four times a day. Oral antibiotics must be taken for 10 days. Patients must be advised to take the entire amount of antibiotic prescribed. They must be warned not to discontinue taking the medication when they feel better. Stopping the antibiotic early or failing to complete the prescribed course of medication can lead to a return of the strep infection. Occasionally, a single injection of benzathine penicillin G 1.2 million units IM

(intramuscularly) is given instead of 10 days of oral treatment.

About 10% of the time, penicillin is not effective against the strep bacteria. In such instances, other antibiotics such as amoxicillin (Amoxil, Pentamox, Sumox, Trimox), clindamycin (Cleocin), or a cephalosporin (Keflex, Durocef, Ceclor) may be prescribed. Erythromycin (Eryzole, Pediazole, Ilosone), another inexpensive antibiotic, is given to patients who are allergic to penicillin. Scarlet fever is treated with the same antibiotics as strep throat.

Without treatment, the symptoms of strep throat begin subsiding in four or five days. However, because of the possibility of contracting rheumatic fever, glomerulonephritis, or other infections, it is vital to treat strep throat promptly with antibiotics. If rheumatic fever does occur, it also is treated with antibiotics. Anti-inflammatory drugs are used to treat joint swelling and diuretics are used to reduce water retention. Once the rheumatic fever becomes inactive, children may continue on low doses of antibiotics to prevent a reoccurrence. Necrotizing fasciitis is treated with intravenous antibiotics.

Home care for strep throat

Patients may be taught home care measures to relieve the discomfort of their strep symptoms. They may be counseled by the nurse, mid-level practitioner, or physician to:

- Take acetaminophen or ibuprofen for pain. Aspirin should not be given to children because of its association with Reye's syndrome.
- Gargle with warm double strength tea or warm salt water, made by adding one teaspoon of salt to eight ounces of water, to relieve sore throat pain.
- Drink plenty of fluids, but avoid acidic juices like orange juice because they irritate the throat.
- Eat soft, nutritious foods like noodle soup. Avoid spicy foods.
- Avoid smoke and smoking.
- Rest until the fever is gone, then resume strenuous activities gradually.
- Use a room humidifier, as it may make sore throat sufferers more comfortable.
- Be aware that antiseptic lozenges and sprays may aggravate the sore throat rather than improve it.

Alternative treatment focuses on easing the symptoms of strep throat through herbs and botanical medicines. Honey, eucalyptus, and menthol-infused drops and syrups may all soothe the soreness of strep throat. These

treatments should never be used in place of antibiotic therapy. They should be used in addition to antibiotics, since they address symptoms rather than the underlying infection.

Prognosis

Patients with strep throat begin feeling better about 24 hours after starting antibiotics. Symptoms rarely last longer than five days.

Patients remain contagious until they have taken antibiotics for 24 hours. Children should not return to school or childcare until they are no longer contagious. Food handlers should not work for the first 24 hours after antibiotic treatment, because strep infections are occasionally passed through contaminated food. People who are not treated with antibiotics can continue to spread strep bacteria for several months.

About 10% of strep throat cases do not respond to penicillin. Patients with even a mild sore throat after a 10 days of antibiotic treatment should be advised to return to the doctor. One explanation for a persisting sore throat may be that the patient is simply a carrier of strep, and the sore throat is the result of another infectious (bacterial or viral) agent.

Timely administration of antibiotics within the first week of a strep infection acts to prevent rheumatic fever and other complications. If rheumatic fever does occur, the outcomes vary considerably. Some cases may be cured; others cause permanent damage to the heart and heart valves. In rare cases, rheumatic fever can be fatal.

Necrotizing fasciitis has mortality (death rate) of 30-50%. Patients who survive often suffer a great deal of tissue and muscle loss. Fortunately, this complication of a *Streptococcus* infection is very rare.

Health care team roles

Physicians, nurses, mid-level practitioners, and laboratory technologists are involved in the diagnosis and treatment of strep throat. In contacts with patients they can reinforce the value of adherence to prescribed treatment and can instruct patients in self-care and home care measures to relieve symptoms.

Patient education

Nurses, mid-level practitioners, and laboratory personnel have opportunities to teach patients how to minimize the risks of transmission by reinforcing the importance of personal hygiene, safe food handling, and avoiding exposures. They must also emphasize the
