PLEASE READ—IMPORTANT INFORMATION

The *Gale Encyclopedia of Nursing and Allied Health* is a medical reference product designed to inform and educate readers about a wide variety of diseases, treatments, tests and procedures, health issues, human biology, and nursing and allied health professions. The Gale Group believes the product to be comprehensive, but not necessarily definitive. While the Gale Group has made substantial efforts to provide information that is accurate, comprehensive, and up-to-date, the Gale Group makes no

representations or warranties of any kind, including without limitation, warranties of merchantability or fitness for a particular purpose, nor does it guarantee the accuracy, comprehensiveness, or timeliness of the information contained in this product. Readers should be aware that the universe of medical knowledge is constantly growing and changing, and that differences of medical opinion exist among authorities.

INTRODUCTION

The *Gale Encyclopedia of Nursing and Allied Health* is a unique and invaluable source of information for the nursing or allied health student. This collection of over 850 entries provides in-depth coverage of specific diseases and disorders, tests and procedures, equipment and tools, body systems, nursing and allied health professions, and current health issues. This book is designed to fill a gap between health information designed for laypeople and that provided for medical professionals, which may be too complicated for the beginning student to understand. The encyclopedia does use medical terminology, but explains it in a way that students can understand.

SCOPE

The *Gale Encyclopedia of Nursing and Allied Health* covers a wide variety of topics relevant to the nursing or allied health student. Subjects covered include those important to students intending to become biomedical equipment technologists, dental hygienists, dietitians, health care administrators, medical technologists/clinical laboratory scientists, registered and licensed practical nurses, nurse anesthetists, nurse practitioners, nurse midwives, occupational therapists, optometrists, pharmacy technicians, physical therapists, radiologic technologists, and speech-language therapists. The encyclopedia also covers information on related general medical topics, classes of medication, mental health, public health, and human biology. Entries follow a standardized format that provides information at a glance. Rubrics include:

Diseases/Disorders

- Definition
- Description
- Causes and symptoms
- Diagnosis
- Treatment
- Prognosis

- Health care team roles
- Prevention
- Resources
- Key terms

Tests/Procedures

- Definition
- Purpose
- Precautions
- Description
- Preparation
- Aftercare
- Complications
- Results
- Health care team roles

INCLUSION CRITERIA

A preliminary list of topics was compiled from a wide variety of sources, including nursing and allied health textbooks, general medical encyclopedias, and consumer health guides. The advisory board, composed of advanced practice nurses, allied health professionals, health educators, and medical doctors, evaluated the topics and made suggestions for inclusion. Final selection of topics to include was made by the advisory board in conjunction with the Gale editor.

ABOUT THE CONTRIBUTORS

The essays were compiled by experienced medical writers, including physicians, pharmacists, nurses, and allied health care professionals. The advisers reviewed the completed essays to ensure that they are appropriate, up-to-date, and medically accurate.

HOW TO USE THIS BOOK

The *Gale Encyclopedia of Nursing and Allied Health* has been designed with ready reference in mind.

- Straight **alphabetical arrangement** of topics allows users to locate information quickly.
- **Bold-faced terms** within entries direct the reader to related articles.
- **Cross-references** placed throughout the encyclopedia direct readers from alternate names and related topics to entries.
- A list of **Key terms** is provided where appropriate to define terms or concepts that may be unfamiliar to the student.
- The **Resources** section directs readers to additional sources of medical information on a topic.
- Valuable **contact information** for medical, nursing, and allied health organizations is included with each entry. An Appendix of Nursing and Allied Health organizations in the back matter contains an extensive list of organizations arranged by subject.
- A comprehensive **general index** guides readers to significant topics mentioned in the text.

GRAPHICS

The *Gale Encyclopedia of Nursing and Allied Health* is enhanced by over 400 black and white photos and illustrations, as well as over 50 tables.

ACKNOWLEDGMENTS

The editor would like to express appreciation to all of the nursing and allied health professionals who wrote, reviewed, and copyedited entries for the *Gale Encyclopedia of Nursing and Allied Health*.

Cover photos were reproduced by the permission of Delmar Publishers, Inc., Custom Medical Photos, and the Gale Group.

ADVISORY BOARD

A number of experts in the nursing and allied health communities provided invaluable assistance in the formulation of this encyclopedia. The advisory board performed a myriad of duties, from defining the scope of coverage to reviewing individual entries for accuracy and accessibility. The editor would like to express appreciation to them for their time and their expert contributions.

Abdominal ultrasound

Definition

Abdominal ultrasound uses high frequency sound waves to produce two-dimensional images of the body's soft tissues, which are used for a variety of clinical applications, including diagnosis and guidance of treatment procedures. Ultrasound does not use ionizing radiation to produce images, and in comparison to other diagnostic imaging modalities, it is low cost, safe, fast, and versatile.

Purpose

Abdominal ultrasound is used in the hospital radiology department and emergency department, as well as in physician offices for a number of clinical applications. Ultrasound has a great advantage over x-ray imaging technologies in that it does not damage tissues with ionizing radiation. Ultrasound is also generally far better than plain x-rays at distinguishing the subtle variations of soft tissue structures, and can be used in any of several modes, depending on the area of interest.

As an imaging tool, abdominal ultrasound generally is indicated for patients afflicted with chronic or acute abdominal **pain**; abdominal trauma; an obvious or suspected abdominal mass; symptoms of **liver** disease, pancreatic disease, gallstones, spleen disease, kidney disease and urinary blockage; or symptoms of an abdominal aortic aneurysm.

Specifically:

- Abdominal pain. Whether acute or chronic, pain can signal a serious problem—from organ malfunction or injury to the presence of malignant growths.

Ultrasound scanning can help doctors quickly sort through potential causes when presented with general or ambiguous symptoms. All of the major abdominal organs can be studied for signs of disease that appear as changes in size, shape, and internal structure.

- Abdominal trauma. After a serious accident, such as a car crash or a fall, internal bleeding from injured abdominal organs is often the most serious threat to survival. Neither the injuries nor the bleeding may be immediately apparent. Ultrasound is very useful as an initial scan when abdominal trauma is suspected, and it can be used to pinpoint the location, cause, and severity of hemorrhaging. In the case of puncture **wounds**, from a bullet for example, ultrasound can locate the foreign object and provide a preliminary survey of the damage. (**CT scans** are sometimes used in trauma settings.)
- Abdominal mass. Abnormal growths—tumors, cysts, abscesses, scar tissue, and accessory organs—can be located and tentatively identified with ultrasound. In particular, potentially malignant solid tumors can be distinguished from benign fluid-filled cysts. Masses and malformations in any organ or part of the abdomen can be found.
- Liver disease. The types and underlying causes of liver disease are numerous, though **jaundice** tends to be a general symptom. Ultrasound can differentiate between many of the types and causes of liver malfunction, and is particularly good at identifying obstruction of the bile ducts and cirrhosis, which is characterized by abnormal fibrous growths and reduced **blood** flow.
- Pancreatic disease. Inflammation and malformation of the **pancreas** are readily identified by ultrasound, as are pancreatic stones (calculi), which can disrupt proper functioning.
- Gallstones. Gallstones are an extremely common cause of hospital admissions. These calculi can cause painful inflammation of the **gallbladder** and also obstruct the bile ducts that carry digestive enzymes from the gall-

bladder and liver to the intestines. Gallstones are readily identifiable with ultrasound.

- Spleen disease. The spleen is particularly prone to injury during abdominal trauma. It may also become painfully inflamed when infected or cancerous.
- Kidney disease. The **kidneys** are also prone to traumatic injury and are the organs most likely to form calculi, which can block the flow of urine and cause further systemic problems. A variety of diseases causing distinct changes in kidney morphology can also lead to complete kidney failure. Ultrasound imaging has proven extremely useful in diagnosing kidney disorders, including blockage or obstruction.
- Abdominal aortic aneurysm. This is a bulging weak spot in the abdominal aorta, which supplies blood directly from the **heart** to the entire lower body. A ruptured aortic aneurysm is imminently life-threatening. However, it can be readily identified and monitored with ultrasound before acute complications result.
- **Appendicitis.** Ultrasound is useful in diagnosing appendicitis, which causes abdominal pain.

Ultrasound technology can also be used for treatment purposes, most frequently as a visual aid during surgical procedures—such as guiding needle placement to drain fluid from a cyst, or to guide biopsies.

Precautions

Ultrasound waves of appropriate frequency and intensity are not known to cause or aggravate any medical condition.

The value of ultrasound imaging as a medical tool, however, depends greatly on the quality of the equipment used and the skill of the medical personnel operating it. More accurate results are obtained when ultrasound is performed by a clinician skilled in sonography. Basic ultrasound equipment is relatively inexpensive to obtain, and any physician with the equipment can perform the procedure whether specifically trained in ultrasound scanning and interpretation or not. Patients should not hesitate to verify the credentials of technologists and physicians performing ultrasound scanning, as well as the quality of the equipment used and the benefits of the proposed procedure.

In cases where ultrasound is used as a treatment tool, patients should educate themselves about the proposed procedure with the help of their doctors—as is appropriate before any surgical procedure. Also, any abdominal ultrasound procedure, diagnostic or therapeutic, may be hampered by a patient's body type or other factors, such as the presence of excessive bowel gas (which is opaque

to ultrasound). In particular, very obese people are often not good candidates for abdominal ultrasound.

Description

Ultrasound includes all sound waves above the frequency of human hearing—about 20 thousand hertz, or cycles per second. Medical ultrasound generally uses frequencies between one and 10 megahertz (1-10 MHz). Higher frequency ultrasound waves produce more detailed images, but are also more readily absorbed and so cannot penetrate as deeply into the body. Abdominal ultrasound imaging is generally performed at frequencies between 2-5 MHz.

An ultrasound scanner consists of two parts: the transducer and the data processing unit. The transducer both produces the sound waves that penetrate the body and receives the reflected echoes. Transducers are built around piezoelectric ceramic chips. (Piezoelectric refers to electricity that is produced when you put pressure on certain crystals such as quartz.) These ceramic chips react to electric pulses by producing sound waves (they are transmitting waves) and react to sound waves by producing electric pulses (receiving). Bursts of high-frequency electric pulses supplied to the transducer cause it to produce the scanning sound waves. The transducer then receives the returning echoes, translates them back into electric pulses, and sends them to the data processing unit—a computer that organizes the data into an image on a television screen.

Because sound waves travel through all the body's tissues at nearly the same speed—about 3,400 miles per hour—the microseconds it takes for each echo to be received can be plotted on the screen as a distance into the body. The relative strength of each echo, a function of the specific tissue or organ boundary that produced it, can be plotted as a point of varying brightness. In this way, the echoes are translated into an image.

Four different modes of ultrasound are used in medical imaging:

- **A-mode.** This is the simplest type of ultrasound in which a single transducer scans a line through the body with the echoes plotted on screen as a function of depth. This method is used to measure distances within the body and the size of internal organs.
- **B-mode.** In B-mode ultrasound, a linear array of transducers simultaneously scans a plane through the body that can be viewed as a two-dimensional image on screen.
- **M-Mode.** The M stands for motion. A rapid sequence of B-mode scans whose images follow each other in sequence on screen enables doctors to see and measure range of motion, as the organ boundaries that produce reflections move relative to the probe. M-mode ultra-

KEY TERMS

Accessory organ—A lump of tissue adjacent to an organ that is similar to it, but which serves no important purpose, if functional at all. While not necessarily harmful, such organs can cause problems if they grow too large or become cancerous.

Benign—In medical usage, benign is the opposite of malignant. It describes an abnormal growth that is stable, treatable, and generally not life-threatening.

Biopsy—The surgical removal and analysis of a tissue sample for diagnostic purposes. Usually, the term refers to the collection and analysis of tissue from a suspected tumor to establish malignancy.

Calculus—Any type of hard concretion (stone) in the body, but usually found in the gallbladder, pancreas, and kidneys. Calculi (pl.) are formed by the accumulation of excess mineral salts and other organic material such as blood or mucous. They can cause problems by lodging in and obstructing the proper flow of fluids, such as bile to the intestines or urine to the bladder.

Cirrhosis—A chronic liver disease characterized by the degeneration of proper functioning—jaundice is often an accompanying symptom. Causes of cirrhosis include alcoholism, metabolic diseases, syphilis, and congestive heart disease.

Common bile duct—The branching passage through which bile—a necessary digestive enzyme—travels from the liver and gallbladder into the small intestine. Digestive enzymes from the pancreas also enter the intestines through the common bile duct.

Computed tomography scan (CT scan)—A specialized type of x-ray imaging that uses highly focused and relatively low energy radiation to produce detailed two-dimensional images of soft tissue structures, particularly the brain. CT scans are the chief competitor to ultrasound and can yield higher quality images not disrupted by bone or gas. They are, however, more cumbersome, time consuming and expensive to perform, and they use ionizing radiation.

Doppler—The Doppler effect refers to the apparent change in frequency of sound wave echoes returning to a stationary source from a moving target. If the object is moving toward the source, the frequency increases; if the object is moving away, the frequency decreases. The size of this frequency shift can be used to compute the object's speed—be it a car on the road or blood in an artery. The Doppler effect holds true for all types of radiation, not just sound.

Frequency—Sound, whether traveling through air or the human body, produces vibrations—molecules bouncing into each other—as the shock wave travels along. The frequency of a sound is the number of vibrations per second. Within the audible range, frequency means pitch—the higher the frequency, the higher a sound's pitch.

Ionizing radiation—Radiation that can damage living tissue by disrupting and destroying individual cells at the molecular level. All types of nuclear radiation—x rays, gamma rays and beta rays—are potentially ionizing. Sound waves physically vibrate the material through which they pass, but do not ionize it.

Jaundice—A condition that results in a yellow tint to the skin, eyes and body fluids. Bile retention in the liver, gallbladder and pancreas is the immediate cause, but the underlying cause could be as simple as obstruction of the common bile duct by a gallstone or as serious as pancreatic cancer. Ultrasound can distinguish between these conditions.

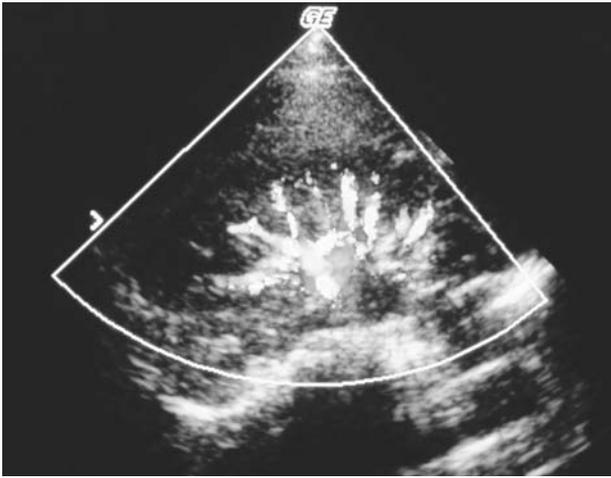

Malignant—The term literally means growing worse and resisting treatment. It is used as a synonym for cancerous and connotes a harmful condition that generally is life-threatening.

Morphology—Literally, the study of form. In medicine, morphology refers to the size, shape, and structure rather than the function of a given organ. As a diagnostic imaging technique, ultrasound facilitates the recognition of abnormal morphologies as symptoms of underlying conditions.

sound has been put to particular use in studying heart motion.

- Doppler mode. **Doppler ultrasonography** includes the capability of accurately measuring velocities of moving

material, such as blood in arteries and veins. The principle is the same as that used in radar guns that measure the speed of a car on the highway. Doppler capability is most often combined with B-mode scanning to produce

An ultrasound screen shows a patient's kidney.

Reproduced by permission.)

images of **blood vessels** from which blood flow can be directly measured. This technique is used extensively to investigate valve defects, arteriosclerosis, and **hypertension**, particularly in the heart, but also in the abdominal aorta and the portal vein of the liver.

The actual procedure for a patient undergoing an abdominal ultrasound is relatively simple, regardless of the type of scan or its purpose. Fasting for at least eight hours prior to the procedure ensures that the **stomach** is empty and as small as possible, and that the intestines and bowels are relatively inactive. This also helps the gallbladder become more visible. Prior to scanning, an acoustic gel is applied to the skin of the patient's abdomen to allow the ultrasound probe to glide easily across the skin and also to better transmit and receive ultrasonic pulses. The probe is moved around the abdomen's surface to obtain different views of the target areas. The patient will likely be asked to change positions from side to side and to hold the breath as necessary to obtain the desired views. Usually, a scan will take from 20 to 45 minutes, depending on the patient's condition and anatomical area being scanned.

Ultrasound scanners are available in different configurations, with different scanning features. Portable units, which weigh only a few pounds and can be carried by hand, are available for bedside use, office use, or use outside the hospital, such as at sporting events and in ambulances. Portable scanners range in cost from \$10,000 to \$50,000. Mobile ultrasound scanners, which can be pushed to the patient bedside and between hospital departments, are the most common configuration and range in cost from \$100,000 to over \$250,000, depending on the scanning features purchased.

Preparation

A patient undergoing abdominal ultrasound will be advised by the physician about what to expect and how to prepare. As mentioned above, preparations generally include fasting.

Aftercare

In general, no aftercare related to the abdominal ultrasound procedure itself is required. Discomfort during the procedure is minimal.

Complications

Properly performed, ultrasound imaging is virtually without risk or side effects. Some patients report feeling a slight tingling and/or warmth while being scanned, but most feel nothing at all.

Results

As a diagnostic imaging technique, a normal abdominal ultrasound is one that indicates the absence of the suspected condition that prompted the scan. For example, symptoms such as abdominal pain radiating to the back suggest the possibility of, among other things, an abdominal aortic aneurysm. An ultrasound scan that indicates the absence of an aneurysm would rule out this life-threatening condition and point to other, less serious causes.

Because abdominal ultrasound imaging is generally undertaken to confirm a suspected condition, the results of a scan often will confirm the diagnosis, be it **kidney stones**, cirrhosis of the liver, or an aortic aneurysm. At that point, appropriate medical treatment as prescribed by a patient's physician is in order.

Health care team roles

Ultrasound scanning should be performed by a registered and trained ultrasonographer, either a technologist and/or a physician (radiologist, obstetrician/gynecologist). Ultrasound scanning in the emergency department may be performed by an emergency medicine physician, who should have appropriate training and experience in ultrasonography.

Abscess

Definition

An abscess is an enclosed collection of liquefied tissue, known as pus, somewhere in the body. It is the result of the body's defensive reaction to foreign material.

Description

There are two types of abscesses, septic and sterile. Most abscesses are septic, which means that they are the result of an **infection**. Septic abscesses can occur anywhere in the body. Only **bacteria** and the body's **immune response** are required. In response to the invading bacteria, white **blood** cells gather at the infected site and begin producing chemicals called enzymes that attack the bacteria by first marking and then digesting it. These enzymes kill the bacteria and break them down into small pieces that can travel in the circulatory system prior to being eliminated from the body. Unfortunately, these chemicals also digest body tissues. In most cases, bacteria produce similar chemicals. The result is a thick, yellow liquid—pus—containing dead bacteria, digested tissue, white blood cells, and enzymes.

An abscess is the last stage of a tissue infection that begins with a process called inflammation. Initially, as invading bacteria activate the body's **immune system**, several events occur:

- Blood flow to the area increases.
- The temperature of the area increases due to the increased blood supply.
- The area swells due to the accumulation of water, blood, and other liquids.
- It turns red.
- It hurts, due to irritation from the swelling and the chemical activity.

These four signs—heat, swelling, redness, and pain—characterize inflammation.

As the process progresses, the tissue begins to turn to liquid, and an abscess forms. It is the nature of an abscess to spread as the chemical digestion liquefies more and more tissue. Furthermore, the spreading follows the path of least resistance, commonly, the tissue that is most easily digested. A good example is an abscess just beneath the skin. It most easily continues along immediately beneath the surface rather than traveling up through the outermost layer or down through deeper structures where it could drain its toxic contents. The contents of an abscess can also leak into the general circulation and produce symptoms just like any other infection. These include chills, **fever**, aching, and general discomfort.

Sterile abscesses are sometimes a milder form of the same process caused not by bacteria but by non-living irritants such as drugs. If an injected drug such as penicillin is not absorbed, it stays where it is injected and may cause enough irritation to generate a sterile abscess. Such an abscess is sterile because there is no infection involved. Sterile abscesses are quite likely to turn into

KEY TERMS

Cellulitis—Inflammation of tissue due to infection.

Enzyme—Any of a number of protein chemicals that can initiate chemical reactions at body temperature.

Fallopian tubes—Part of the internal female anatomy that carries eggs from the ovaries to the uterus.

Flora—Living inhabitants of a region or area.

Pyogenic—Capable of generating pus. *Streptococcus*, *Staphylococcus*, and bowel bacteria are the primary pyogenic organisms.

Sebaceous glands—Tiny structures in the skin that produce oil (sebum). If they become plugged, sebum collects inside and forms a nurturing place for germs to grow.

Septicemia—The spread of an infectious agent throughout the body by means of the blood stream.

Sinus—A tubular channel connecting one body part with another or with the outside.

hard, solid lumps as they scar, rather than remaining pockets of pus.

Causes and symptoms

Many different agents cause abscesses. The most common are the pus-forming (pyogenic) bacteria such as *Staphylococcus aureus*, which is a very common cause of abscesses under the skin. Abscesses near the large bowel, particularly around the anus, may be caused by any of the numerous bacteria found within the large bowel. **Brain** abscesses and **liver** abscesses can be caused by any organism that can travel there through the blood stream. Bacteria, amoebae, and certain **fungi** can travel in this fashion. Abscesses in other parts of the body are caused by organisms that normally inhabit nearby structures or that infect them. Some common causes of specific abscesses are:

- skin abscesses by normal skin flora
- dental and throat abscesses by mouth flora
- lung abscesses by normal airway flora, bacteria that cause **pneumonia** or **tuberculosis**
- abdominal and anal abscesses by normal bowel flora

Specific types of abscesses

Listed below are some of the more common and important abscesses.

- Carbuncles and other **boils**. Skin oil glands (sebaceous glands) on the back or the back of the neck are the ones usually infected. The most commonly involved bacteria is *Staphylococcus aureus*. Acne is a similar condition involving sebaceous glands on the face and back.
- Pilonidal cyst. Many people have as a birth defect a tiny opening in the skin just above the anus. Fecal bacteria can enter this opening, causing an infection and subsequent abscess.
- Retropharyngeal, parapharyngeal, peritonsillar abscess. As a result of throat infections such as **strep throat** and tonsillitis, bacteria can invade the deeper tissues of the throat and cause an abscess. These abscesses can compromise swallowing and even breathing.
- Lung abscess. During or after pneumonia, whether it's due to bacteria [common pneumonia], tuberculosis, fungi, parasites, or other bacteria, abscesses can develop as a complication.
- Liver abscess. Bacteria or amoeba from the intestines can spread through the blood to the liver and cause abscesses.
- Psoas abscess. Deep in the back of the abdomen, on either side of the lumbar spine, lie the psoas muscles. They flex the hips. An abscess can develop in one of these muscles, usually when it spreads from the appendix, the large bowel, or the fallopian tubes.

Diagnosis

The common findings of inflammation—heat, redness, swelling, and pain—easily identify superficial abscesses. Abscesses in other places may produce only generalized symptoms such as fever and discomfort. If an individual's symptoms and the results of a **physical examination** do not help, a physician may have to resort to a battery of tests to locate the site of an abscess. Usually something in the initial evaluation directs the search. Recent or chronic disease in an organ suggests it may be the site of an abscess. Dysfunction of an organ or system, for instance seizures or altered bowel function, may provide the clue. **Pain** and tenderness on physical examination are common findings. Sometimes a deep abscess will eat a small channel (sinus) to the surface and begin leaking pus. A sterile abscess may cause only a painful lump deep in the buttock where a shot was given.

Treatment

Since skin is very resistant to the spread of infection, it acts as a barrier, often keeping the toxic chemicals of an abscess from escaping the body on their own. Thus, the pus must be drained from the abscess by a physician. The surgeon determines when the abscess is ready for drainage and opens a path to the outside, allowing the pus to escape. Ordinarily, the body handles the remaining infection, sometimes with the help of **antibiotics** or other drugs. The surgeon may leave a drain (a piece of cloth or rubber) in the abscess cavity to prevent it from closing before all the pus has drained out.

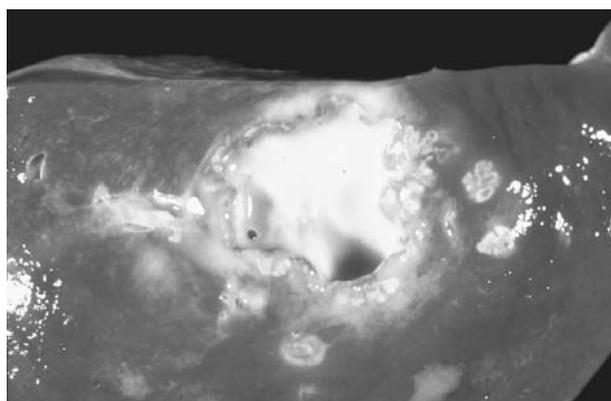

Alternative treatment

If an abscess is directly beneath the skin, it will be slowly working its way through the skin as it is more rapidly working its way elsewhere. Since chemicals work faster at higher temperatures, applications of hot compresses to the skin over the abscess will hasten the digestion of the skin and eventually result in its break down and spontaneous release of pus. This treatment is best reserved for smaller abscesses in less sensitive areas of the body such as limbs, trunk, and back of the neck. It is also useful for all superficial abscesses in their very early stages. It will “ripen” them.

Contrast **hydrotherapy**, alternating hot and cold compresses, can also help assist the body in resorption of the abscess. There are two homeopathic remedies that work to rebalance the body in relation to abscess formation, *Silica* and *Hepar sulphuris*. In cases of septic abscesses, bentonite clay packs (bentonite clay and a small amount of *Hydrastis* powder) can be used to draw an infection from the area.

Prognosis

Once an abscess is properly drained, the prognosis is excellent for the condition itself. The reason for the abscess (other diseases an individual has) will determine the overall outcome. If, on the other hand, an abscess ruptures into neighboring areas or permits the infectious agent to spill into the bloodstream, serious or fatal consequences are likely. Abscesses in and around the nasal sinuses, face, ears, and scalp may work their way into the brain. Abscesses within an abdominal organ such as the liver may rupture into the abdominal cavity. In either case, the result is life threatening. Blood **poisoning** is a term commonly used to describe an infection that has spilled into the blood stream and spread throughout the body from a localized origin. Blood poisoning, known to physicians as septicemia, is also life threatening.

An amoebic abscess caused by *Entamoeba histolytica*.
(Phototake NYC. Reproduced by permission.)

Of special note, abscesses in the hand are more serious than they might appear. Due to the intricate structure and the overriding importance of the hand, any hand infection must be treated promptly and competently.

Health care team roles

First aid providers may unknowingly initiate an abscess by using inappropriate or incorrect techniques. A physician, surgeon, physician’s assistant, or nurse practitioner usually diagnoses the presence of an abscess. Radiologists and laboratory personnel may assist in the process of establishing a diagnosis. A physician, surgeon, physician’s assistant, or nurse practitioner usually drains an abscess. Nurses provide supportive care, dress the wound, and educate patients about caring for the resulting wound. Occasionally, a physical therapist may be needed to recover lost function.

Prevention

Infections that are treated early with heat (if superficial) or antibiotics will often resolve without the formation of an abscess. It is even better to avoid infections altogether by taking prompt care of open injuries, particularly puncture **wounds**. Bites are the most dangerous of all, even more so because they often occur on the hand.

Acid-base balance

Definition

Acid-base balance can be defined as homeostasis of the body fluids at a normal arterial **blood** pH ranging between 7.37 and 7.43.

Description

An acid is a substance that acts as a proton donor. In contrast, a base, also known as an alkali, is frequently defined as a substance that combines with a proton to form a chemical bond. Acid solutions have a sour taste and produce a burning sensation with skin contact. A base is any chemical compound that produces hydroxide ions when dissolved in water. Base solutions have a bitter taste and a slippery feel. Despite variations in **metabolism**, diet, and environmental factors, the body's acid-base balance, fluid volume, and electrolyte concentration are maintained within a narrow range.

Function

Many naturally occurring acids are necessary for life. For example, hydrochloric acid is secreted by the **stomach** to assist with digestion. The chemical composition of food in the diet can have an effect on the body's acid-base production. Components that affect acid-base balance include protein, chloride, **phosphorus**, sodium, potassium, **calcium**, and magnesium. In addition, the rate at which nutrients are absorbed in the intestine will alter acid-base balance.

Cells and body fluids contain acid-base buffers, which help prevent rapid changes in body fluid pH over short periods of time, until the **kidneys** pulmonary systems can make appropriate adjustments. The kidneys and pulmonary system then work to maintain acid-base balance through excretion in the urine or respiration. The partial pressure of carbon dioxide gas (PCO₂) in the pulmonary system can be measured with a blood sample and

correlates with blood carbon dioxide (CO_2) levels. PCO_2 can then be used as an indicator of the concentration of acid in the body. The concentration of base in the body can be determined by measuring plasma bicarbonate (HCO_3^-) concentration. When the acid-base balance is disturbed, the **respiratory system** can alter PCO_2 quickly, thus changing the blood pH and correcting imbalances. Excess acid or base is then excreted in the urine by the renal system to control plasma bicarbonate concentration. Changes in respiration occur primarily in minutes to hours, while renal function works to alter blood pH within several days.

Role in human health

Production of CO_2 is a result of normal body metabolism. **Exercise** or serious infections will increase the production of CO_2 through increased respiration in the **lungs**. When oxygen (O_2) is inhaled and CO_2 is exhaled, the blood transports these gases to the lungs and body tissues. The body's metabolism produces acids that are buffered and then excreted by the lungs and kidneys to maintain body fluids at a neutral pH. Disruptions in CO_2 levels and HCO_3^- create acid-base imbalances. When acid-base imbalances occur, the disturbances can be broadly divided into either acidosis (excess acid) or alkalosis (excess base/alkali).

Common diseases and disorders

Acid-base metabolism imbalances are often characterized in terms of the $\text{HCO}_3^-/\text{CO}_2$ buffer system. Acid-base imbalances result primarily from metabolic or respiratory failures. An increase in HCO_3^- is called metabolic alkalosis, while a decrease in the same substance is called metabolic acidosis. An increase in PCO_2 , on the other hand, is known as respiratory acidosis, and a decrease in the same substance is called respiratory alkalosis.

Acidosis

Acidosis is a condition resulting from higher than normal acid levels in the body fluids. It is not a disease, but may be an indicator of disease. Metabolic acidosis is related to processes that transform food into energy and body tissues. Conditions such as diabetes, kidney failure, severe **diarrhea**, and **poisoning** can result in metabolic acidosis. Mild acidosis is often compensated by the body in a number of ways. However, prolonged acidosis can result in heavy or rapid breathing, weakness, and headache. Acidemia (arterial pH < 7.35) is an accumulation of acids in the bloodstream that may occur with severe acidosis when the acid load exceeds respiratory capacity. This condition can sometimes result in **coma**

KEY TERMS

Acid—(a) Any ionic or molecular substance that can act as a proton donor; (b) A sour-tasting substance, like vinegar; (c) A chemical compound that can react with a base to form a salt.

Acidosis—A dangerous condition where the blood and body tissues are less alkaline (or more acidic) than normal.

Alkalosis—Excessive alkalinity of the blood and body tissue.

Alkalemia—Abnormal blood alkalinity.

Base—(a) Any ionic or molecular substance that can act as a proton acceptor; (b) A bitter-tasting substance which has a soapy feel; (c) A chemical compound that can react with an acid to form a salt. A base can also be called an alkali.

Bicarbonate—A salt of carbonic acid produced by neutralizing a hydrogen ion.

Diabetic ketoacidosis—A condition characterized by excessive thirst and urination. Other symptoms may include appetite loss, nausea, vomiting, and rapid deep breathing.

Diuretic—An agent or drug that eliminates excessive water in the body by increasing the flow of urine.

Electrolyte—A substance such as an acid, bases, or salt. An electrolyte's water solution will conduct an electric current and ionizes. Acids, bases, and salts are electrolytes.

Homeostasis—An organism's regulation of body processes to maintain internal equilibrium in temperature and fluid content.

Hypochloremic alkalosis—A large loss of chloride.

Hypokalemic alkalosis—Low plasma potassium.

pH—The negative logarithm of H^+ (hydrogen) concentration.

and, if the pH falls below 6.80, it will lead to death. Diabetic ketoacidosis is a condition where excessive glucagon and a lack of insulin contribute to the production of ketoacids in the **liver**. This condition can be caused by chronic **alcoholism** and poor carbohydrate utilization.

Respiratory acidosis is caused by the lungs's failure to remove excess carbon dioxide from the body, reducing

Acid-base disturbances, causes, and compensatory mechanisms

Acid-base disturbance	Common cause	Mode of compensation
Respiratory acidosis	Respiratory depression (drugs, central nervous system trauma) Pulmonary disease (pneumonia, chronic obstructive pulmonary disease, respiratory underventilation)	Kidneys will retain increased amounts of HCO_3^- to increase pH
Respiratory alkalosis	Hyperventilation (emotions, pain, respirator overventilation)	Kidneys will excrete increased amounts of HCO_3^- to lower pH
Metabolic acidosis	Diabetes, shock, renal failure, intestinal fistula	Lungs "blow off" CO_2 to raise pH
Metabolic alkalosis	Sodium bicarbonate overdose, prolonged vomiting, nasogastric drainage	Lungs retain CO_2 to lower pH

SOURCE: Pagana, K.D. and T.J. Pagana. *Mosby's Diagnostic and Laboratory Test Reference*. 3rd ed. St. Louis: Mosby, 1997.

the pH in the body. Several conditions, including chest injury, blockage of the upper air passages, and severe lung disease, may lead to respiratory acidosis. Blockage of the air passages may be caused by bronchitis, **asthma**, or airway obstruction, resulting in mild or severe acidosis. Regular, consistent retention of carbon dioxide in the lungs is referred to as chronic respiratory acidosis. This disorder results in only mild acidosis because it is balanced by increased bicarbonate production.

The predominant symptoms of acidosis are sometimes difficult to distinguish from symptoms of an underlying disease or disorder. Mild conditions of acidosis may be asymptomatic or may be accompanied by weakness or listlessness, nausea, and vomiting. Most often, severe metabolic acidosis ($\text{pH} < 7.20$) is associated with increased respiration to compensate for a shortage of HCO_3^- . This is followed by a secondary decrease in PCO_2 that occurs as part of respiratory compensation process. Treatment options for acidosis typically require correction of the underlying condition by venous administration of sodium bicarbonate or another alkaline substance.

Alkalosis

Alkalosis is a condition resulting from a higher than normal level of base/alkali in the body fluids. An excessive loss of HCO_3^- in the blood causes metabolic alkalosis. The body can compensate for mild alkalinity, but prolonged alkalosis can result in convulsions, muscular weakness, and even death if the pH rises above 7.80. Alkalosis can be caused by drugs or disorders that upset the normal acid-base balance. Prolonged vomiting and hyperventilation (abnormally fast, deep breathing) can result in alkalosis.

The predominant symptoms of alkalosis are neuromuscular hyperexcitability and irritability. Alkalemia (abnormal blood alkalinity) increases protein binding of ionized calcium even though plasma total calcium does not change. Severe cases may induce hypocalcemia (a

low level of plasma calcium). Low plasma potassium leads to a condition called hypokalemic alkalosis. It is frequently accompanied by metabolic alkalosis, resulting in cramping, muscle weakness, polyuria, and ileus (obstruction of the intestines). Diuretic medications may cause hypokalemic alkalosis. Prolonged vomiting may induce hypochloremic alkalosis (a large loss of chloride). The kidneys may conserve bicarbonate in order to compensate for the chloride reduction. Compensated alkalosis results when the body has partially compensated for alkalosis, and has restored normal acid-base balances. However, in compensated alkalosis, abnormal bicarbonate and carbon dioxide levels persist.

Alkalosis requires correction of the underlying condition and may involve venous administration of a weak acid to restore normal balance. If the source of alkalosis is excessive drug intake, it may be appropriate to reduce intake to restore the normal acid-base balance.

Respiratory alkalosis results from decreased CO_2 levels caused by conditions such as hyperventilation (a faster breathing rate), **anxiety**, and **fever**. The pH is elevated in the body. Hyperventilation causes the body to lose excess carbon dioxide in expired air and can be triggered by altitude or a disease that reduces the amount of oxygen in the blood. Symptoms of respiratory alkalosis may include dizziness, lightheadedness, and numbing of the hands and feet. Treatments include breathing into a paper bag or a mask that induces rebreathing of carbon dioxide.

Acid-fast culture

Definition

The term acid-fast refers to a type of organism not readily decolorized by acid after staining. An acid-fast culture is the microbiological analysis of such an organism. An acid-fast culture refers to the process of detection, growth, isolation, identification, and antibiotic susceptibility testing of mycobacteria that cause pulmonary **tuberculosis** and other infections such as skin, abdominal, and disseminated (widely spread throughout many organs).

Purpose

The acid-fast culture is used to isolate *Mycobacterium tuberculosis* when tuberculosis (TB) is suspected. More recently the test has become important for the identification of other acid-fast organisms including *Mycobacterium avium* complex (MAC), *Mycobacterium bovis*, and *Mycobacterium africanum* responsible for causing tuberculosis in **AIDS** patients and other immunosuppressed persons. Antibiotic sensitivity testing performed when cultures are positive or when patients are known to have tuberculosis determines the appropriate drugs for treatment. This is essential because of the emergence of tuberculosis strains that are resistant to many of the **antibiotics** that were once effective in treating this disease. The test is also used to differentiate tuberculosis from carcinoma and bronchiectasis that may appear similar on x ray.

Precautions

Antibiotics and some sulfonamides may interfere with test results, causing the results to be falsely negative. Sufficient organisms may not be recovered to diagnose **infection** when a single culture sample is collected. Therefore, sputum cultures should be collected on three consecutive mornings.

Special safety precautions

Health care workers involved with collection and handling of specimens from patients suspected of having tuberculosis or other mycobacterial infections should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. In addition, health care personnel working with patients and handling specimens from patients suspected of having tuberculosis must be given a skin test (e.g. Mantoux or PPD test) on a regular basis. Precautions must be followed closely when handling mycobacterial specimens. The laboratory personnel who process and handle the infectious material from the patient are at greatest risk (about three times higher than other laboratory personnel) for tuberculosis infection or skin test positivity. The hazard of working in a laboratory that handles mycobacterial specimens is greatly reduced if the personnel follow proper procedures when handling and processing the specimens. All processing should take place in a biologic safety cabinet (BSC). The biologic safety cabinets used in the clinical mycobacterial laboratory are of two types: Class I, or negative-pressure cabinets, and Class II, or vertical-laminar-flow cabinets. Correct operation of these safety devices along with proper maintenance and testing of the air flow are essential to their performance. Yearly inspection of the cabinets by trained individuals is required.

Processing specimens, testing organisms, and transferring viable cultures must be carried out within the BSC. After processing specimens or working under the BSC, the area inside the cabinet is disinfected and a UV (ultraviolet) light located within the cabinet is turned on to kill any organisms on the surface of the work area as well as any airborne **bacteria**. After performing a procedure, the work area must be decontaminated with a disinfectant solution (e.g., the use of a phenol-soap mixture containing orthophenol or phenolic derivatives with an effective contact time of 10-30 minutes).

Protective clothing including gloves, fluid-proof gowns, goggles, and face mask or respirator is recommended for laboratory personnel working in the mycobacterial laboratory. Incinerators (no bunsen burners) are used within the BSC to reduce aerosoling of bacteria from infectious material while processing and culturing.

Description

Tuberculosis is an infection caused by *Mycobacterium tuberculosis*, a disease which is a major health problem worldwide. *Mycobacterium tuberculosis* is a rod-shaped bacterium characterized by acid-fastness. It is commonly transmitted via the air to the **lungs**, where it thrives, causing **fever**, cough, and hemoptysis (coughing up blood-tainted secretions). Tuberculosis is highly con-

KEY TERMS

Bronchiectasis—The formation of dilated, enlarged bronchi that results from lower respiratory tract infection.

Granuloma—Encapsulation of infected tissue caused by phagocytic cells that surround the foci of infection.

Nosocomial—An infection acquired in a hospital setting.

tagious. Disease is spread when persons cough, releasing an aerosol of organisms that are easily inhaled by others. Although deaths from tuberculosis in the United States had declined since the 1950s, recently there has been a resurgence of the disease, with the higher incidence of infection seen in certain races, in poor socioeconomic conditions, among new immigrants, in prison inmates, and in persons infected with the human **immunodeficiency** virus.

Because it takes several weeks for most *Mycobacteria* to grow in a culture, the laboratory performs an acid-fast smear first to aid in early diagnosis; however, the acid-fast smear should not be used in place of culture, as a culture is far more sensitive. An acid-fast culture can detect as few as 10 to 100 CFU/mL of sputum. The smear can provide a presumptive diagnosis of mycobacterial disease; confirm that cultures growing on media are acid-fast; and demonstrate that antibiotic treatment is effective pending follow-up culture results.

The genus *Mycobacterium* includes organisms that are obligate parasites, saprophytes (i.e., organisms that live off dead tissue), and opportunistic pathogens. Mycobacteria cause tuberculosis as well as non-tuberculous clinical conditions; therefore, mycobacteria are divided into two major groups based upon whether they cause tuberculosis (*M. tuberculosis* complex) or non-tuberculous infections (NTM). The principle pathogen causing tuberculosis in humans is *Mycobacterium tuberculosis*. It is estimated that about one third of the world's population is infected with *M. tuberculosis*. The World Health Organization reports an estimated eight million new cases and three million deaths attributable to tuberculosis each year. Tuberculosis is a leading cause of death in developing countries.

Other organisms causing human tuberculosis that are included in the *M. tuberculosis* complex are: *M. bovis* (the cause of tuberculosis in cattle and humans, as well as other carnivores); *M. bovis BCG* (a strain used as a vaccine against tuberculosis in many parts of the world); and

M. africanum (the cause of human tuberculosis in tropical Africa). *Mycobacterium tuberculosis* causes an infection that may mimic other diseases such as **pneumonia**, neoplasm, or fungal infections. Patients may be symptomatic or asymptomatic with signs of pulmonary and other organ involvement. Symptoms include night sweats, low-grade fever, anorexia, fatigue, weight loss, and a productive cough or coughing of **blood** in pulmonary tuberculosis infections. Patients with HIV are more likely to develop active tuberculosis.

It is necessary to identify the tuberculosis-causing mycobacteria by species and determine the antibiotic sensitivity or resistance-pattern for epidemiologic and **public health** information as well as for the effective treatment of infected persons. As stated earlier, about one-third of the world's population (1.7 billion persons) are infected with *M. tuberculosis*. Therefore, it is of great concern that the emergence of epidemic multidrug-resistant strains of *M. tuberculosis* has increased at the same time as the increase in HIV infections in the United States.

The primary routes of transmission for the *M. tuberculosis* complex are via inhalation of airborne droplets from an infected person; through infectious aerosols produced when processing clinical specimens for the recovery of *Mycobacteria spp.*; and by ingestion of contaminated milk from cows (or goats) infected with *M. bovis*. *M. africanum* is also transmitted by the inhalation of droplets containing infecting organisms. In all cases, close contact with infected individuals leads to the acquisition of tuberculosis infection.

The nontuberculous mycobacteria (NTM) group, which are not transmitted by person to person contact as is the *M. tuberculosis* complex, are differentiated by rate of growth (slow-growing or rapid-growing) as well as color pigmentation (the ability or inability of the colonies to change color when exposed to light). Growth patterns are divided into two main groups: slow-growers and rapid growers. Slow growers take more than seven days to grow and form colonies on solid media; rapid-growers produce colonies on solid media within three to five days. This method of classification for the NTM, by growth patterns and exposure to light, is referred to as the Runyon Classification. Some organisms in this group are considered pathogenic, and others are potentially pathogenic or non-pathogenic.

One of the most often recovered mycobacterium species in the United States belongs to the NTM group and is referred to as the *Mycobacterium avium* complex (MAC). The MAC group consists of two main species, *M. avium* and *M. intracellulare*. These two mycobacteria are very similar and are differentiated by DNA tests. The

MAC organisms are frequently isolated from immunocompromised patients, such as patients infected with HIV and patients with pre-existing pulmonary disease. MAC infections have been found to be the most common cause of NTM (nontuberculous mycobacteria) infections in humans. The NTM organisms are found in the environment (frequently recovered from water, soil, house dust, and plants) and are sometimes found colonized in the respiratory or gastrointestinal tract of healthy individuals. In AIDS patients, MAC infections may be focal or disseminated. It is theorized that the MAC organisms, acquired from the environment, colonize the respiratory tract or gastrointestinal tract before disseminating in an HIV-positive patient. Sputum and stool samples from HIV infected patients often contain MAC organisms.

Pulmonary disease in AIDS patients due to MAC cannot be distinguished clinically or by x ray from those caused by *M. tuberculosis*. Infections caused by disseminated MAC organisms in AIDS patients usually occur about one year after the diagnosis of AIDS. Also, non-AIDS patients who are white males, 45-60 years of age, typically heavy smokers, or alcohol abusers with pre-existing lung disease are good candidates for a tuberculosis-like disease also caused by MAC organisms.

An NTM, which will not grow *in vitro* (non-cultivable), is *M. leprae*. *Mycobacterium leprae* is the cause of leprosy, or Hansen's disease. This organism causes a chronic, debilitating, and disfiguring disease involving the skin, mucous membranes, and nerve tissue. There is often extensive damage to the skin (lesions) and nerves. Infectivity is low and transmission can occur from person to person through contact with infected skin; however, inhalation of nasal secretions from the infected person (close contact) appears to be the predominant mode of transmission. Leprosy in North America is rare, and most of the cases are acquired from exposure to the organism while in a tropical country. *Mycobacterium leprae* cannot be cultured on solid or liquid media *in vitro*; therefore, it is diagnosed by DNA amplification tests such as the polymerase chain reaction (PCR) using infected tissue, or mucous membrane secretions, and by observing acid-fast bacilli (using acid-fast staining procedures) in the tissue preps or skin biopsies of infected patients.

Several other NTM (non-tuberculous mycobacteria) organisms are considered potential pathogens for humans while others are rarely implicated in disease. The following NTM are considered potential pathogens and should be identified especially if recovered from immunocompromised patients:

- *Mycobacterium kansasii*: A slow grower, causing a chronic pulmonary disease resembling classic tubercu-

losis as well as cervical lymphadenitis and cutaneous diseases; tap water is the main reservoir for humans.

- *Mycobacterium haemophilum*: A slow grower, causing skin nodules and disseminated disease in immunosuppressed patients with AIDS, Hodgkins's disease, and kidney and bone marrow transplants, as well as cervical lymphadenitis in children.
- *Mycobacterium marinum*: A slow grower, causing cutaneous infections such as "swimming pool granuloma" and "fish tank granuloma" with its natural reservoir being fresh and salt water from infected fish and other marine life.
- *Mycobacterium ulcerans*: A slow grower, infecting the skin (usually after some trauma) causing nodules and ulcers to form; infection occurs mainly in tropical and temperate climates (Africa and Australia) and is rare in the United States.
- *Mycobacterium xenopi*: A slow grower, causing pulmonary infections in adults (resembling MTB complex and MAC complex). The infection is considered nosocomial, since it is recovered from hospital water storage systems and hot and cold taps quite often.
- *Mycobacterium scrofulaceum*: A slow grower responsible for cervical adenitis in children, recovered from raw milk, soil, water, and dairy products.
- *Mycobacterium szulgai*: A slow grower causing pulmonary disease similar to *M. tuberculosis*.
- *Mycobacterium fortuitum* complex: Rapid growing microorganisms which include *M. fortuitum*, *M. abscessus*, and *M. chelonae* causing infections involving surgical **wounds**, post-traumatic wound infection, otitis media, and chronic pulmonary disease.

Mycobacterium gordonae is the non-pathogenic mycobacterium most commonly recovered from patient specimens. It is found in the environment and is called the "tap water bacillus." It is only rarely implicated as a cause of human infection.

Specimen collection

Specimens to be processed for the recovery of mycobacteria are obtained and handled using specific guidelines to ensure successful growth, isolation, and identification of the causative organism. Containers must be sterile, leak-proof, and labeled properly. After collection, if the specimen cannot be processed within one hour, refrigeration is required but no longer than overnight. However, blood samples must be placed in the proper media and incubated immediately at 35-37°C.

The most often requested specimens are pulmonary specimens (secretions) which must be obtained before

any treatment (antibiotic therapy) is given. Pulmonary specimens may be obtained in several ways: spontaneously produced (expectorated) sputum; aerosol-induced sputum; bronchoscopic aspirations, washings and brushings; gastric aspirates, and lavages (washings) from patients who have swallowed sputum through the night. Saliva is not acceptable as a specimen for the recovery of mycobacteria and is usually rejected as a contaminated specimen. A series of early morning sputum specimens are recommended over a three-day period. The ideal amount of sputum specimen for processing and recovery of mycobacteria is 5-10 mL of sputum. Upon rising in the morning, the patient is instructed to cough deeply to produce sputum (expectorated sputum). A patient who is unable to bring up any sputum is given an aerosol treatment (aerosol-induced sputum) by a respiratory therapist in order to recover a sufficient amount of sputum for culture.

Other specimens requested for culture and recovery of mycobacteria are early morning, voided urine specimens; fecal specimens; tissue and body fluids (pleural, pericardial and peritoneal fluids), cerebrospinal fluid (CSF), bone marrow aspirates, and blood. Blood and stool specimens are usually cultured from AIDS patients. These specimens reveal numerous mycobacteria when infection is present in these patients. Wound or skin lesions (abscesses) require a technique using aspiration of the specimen into a syringe rather than the use of a swab to obtain the specimen.

Specimens not suitable for culture and usually rejected are 24-hour urine specimens, pooled sputum, saliva, and swabs containing pulmonary secretions. The high rate of contamination as well as the reduced rate of mycobacteria recovery in these specimens renders them unsuitable.

Specimen processing

Decontamination and digestion of sputum specimens is necessary to recover mycobacteria for culture and identification. The process of decontamination (removing unwanted bacteria) and digestion (breaking down mucous and protein) of sputum specimens is necessary to release the mycobacteria that may be present but are trapped in the mucous, and also to kill the unwanted bacteria (normal flora). Specimens from sterile body sites (blood, tissue, and body fluids, etc.) do not need the process of decontamination and digestion as do sputum samples. If the process of decontamination and digestion is not done or done improperly, recovery of mycobacteria from sputum samples is inhibited causing a false-negative report. Mucous, cells, and normal bacterial flora (from the oral cavity) entrap and enmesh the

mycobacteria in sputum. A common decontaminant is sodium hydroxide (4%) which is also used as a mucolytic agent (for liquifaction or digestion of mucous). A combination is often used which consists of N-acetyl-L-cysteine (NALC) and a lower concentration (2%) of sodium hydroxide. This combination gives a better recovery rate when used together as a mucolytic-decontaminant. Liquifaction of the thick mucous in sputum is necessary to free the mycobacteria trapped in it without harming the mycobacteria, and decontamination kills the normal flora (bacteria from the mouth, throat and oral cavity) which interfere with the recovery of mycobacteria. The final product is reduced (concentrated) from the original 5-10 mL volume, and a portion of the resulting specimen is transferred by sterile technique to either sterile solid, tube or plate media, and liquid media, while another portion is used to make several smears on glass slides for staining.

Acid fast and fluorescent staining

The smears made after the process of decontamination and digestion of sputum are stained using either an acid-fast staining procedure or a fluorochrome stain. Mycobacteria do not stain well with the Gram staining procedure used routinely in the microbiology laboratory. Specimens obtained from sterile sites (bone marrow, tissue, etc.) do not need processing and smears are made directly from the specimen onto glass **microscope** slides. Mycobacteria are slightly curved or straight bacilli, about 0.2 to 0.6 by 1.0 to 10 micrometers in size. The cell wall of mycobacteria contains a high lipid content, and is made up of long-chain, multiply cross-linked fatty acids (mycolic acids). In the acid-fast staining procedure, a basic dye, carbolfuchsin stain, is used to stain the cell wall. The long-chain mycolic acids and waxes in the mycobacteria cell wall serve to complex the carbolfuchsin. The Ziehl-Neelsen acid fast stain for mycobacteria uses heat to fix the dye in the cell wall, while the Kinyoun staining method uses an increased concentration of basic fuchsin and phenol eliminating the heat requirement. In the Ziehl-Neelsen procedure, the carbolfuchsin stain is left on the smear for five minutes while heat is applied under the slide by a bunsen burner or a hot plate. The carbolfuchsin dye penetrates the cell wall and the excess stain is washed off with a 3% acid-alcohol mixture (95% ethanol and 3% hydrochloric acid). The mycobacteria cell wall retains the dye (a red-purple color) and will not be decolorized (washed out) by the acid-alcohol, thus the term acid-fast. A second dye, methylene blue, is used to stain any background material including any other bacteria that may be present. This dye results in a light background providing good contrast to the red-purple stain of the carbolfuchsin dye, thus aid-

ing in the detection of acid-fast bacilli. If mycobacteria are present in the smear, the appearance of red-purple short or long bacilli are observed at 1000 X magnification. Some species of mycobacteria appear “beaded” while others may appear pleomorphic (a mixture of coccoid and rod shapes), or filamentous (branching of the bacillus).

Another staining method used for the detection of mycobacteria is the auramine-rhodamine fluorochrome stain. This method requires a fluorescent microscope. Smears are scanned at a lower magnification (250 X to 400 X). The fluorochrome dyes used in this procedure complex to the mycolic acids in acid-fast cell walls. The fluorescing mycobacteria are seen as bright yellow-orange bacilli against a dark background. Fluorescent stained smears can be read more rapidly than acid-fast stains, but there are drawbacks. *Mycobacteria spp.* that are rapid-growers may not appear fluorescent with these stains; artifacts may fluoresce; material on the oil objective may have floated off a previous positive smear causing a false-positive reading for the next smear examined. All positive smears from the auramine-rhodamine fluorochrome method should be confirmed using the Ziehl-Neelsen method for acid-fast bacilli.

Acid-fast bacillus (AFB) smear report

Laboratories performing staining procedures and reporting smear results must adhere to guidelines from the U.S. Department of Health and Human Services (Public Health Service, Centers for Disease Control, Atlanta). The rule for reporting acid-fast smears for mycobacteria requires scanning the smear for a minimum of 15 minutes (at least 300 oil immersion fields) before calling the slide negative for acid-fast bacilli or “No AFB seen.” The following are recommended interpretations and ways to report smear results:

- A request for another specimen or a doubtful report is the result of seeing AFB of 1-2/300 fields for the Ziehl-Neelsen (Z-N) stain and AFB of 1-2/70 fields for the auramine-rhodamine (fluorochrome) stain.
- A “1+” report for AFB seen = 1-9/100 fields for the Z-N method and 2-18/50 fields for the fluorochrome stain.
- A “2+” report for AFB seen = 1-9/10 fields for the Z-N method and 4-36/10 fields for the fluorochrome stain.
- A “3+” report for AFB seen = 1-9/field for the Z-N method and 4-36/field for the fluorochrome stain.
- A “4+” report for AFB seen = less than 9/field for the Z-N method and less than 36/field for the fluorochrome stain.

Culture media and isolation methods

Several types of media are used for the cultivation of mycobacteria, and each facility determines which ones are most appropriate for use. A combination of culture media is often used to optimize recovery of mycobacteria as well as inhibit the growth of contaminants. Mycobacteria require a pH of 6.5-6.8 for growth and grow best at higher humidity. Commercially prepared solid culture media (in tubes with screw-top caps) consist of bovine serum albumin agar-based media (Middlebrook 7H10 and 7H11) and egg-based media (Lowenstein-Jensen). Liquid media (Middlebrook 7H9) is used to subculture stock strains or as part of a system (e.g., BACTEC 12B medium, Septi-Chek AFB) to cultivate and detect growth of acid-fast bacilli. *Mycobacterium spp.* grow more rapidly in liquid media; solid media takes approximately 17 days for the isolation of acid-fast bacilli whereas liquid media takes only about 10 days. The following are descriptions of three general types of media that are most often used.

- Lowenstein-Jensen media (L-J) is an egg-potato base solid media containing malachite green (an inhibitory agent). The use of L-J media is excellent for the recovery of *M. tuberculosis* from sterile-site specimens as well as decontaminated-digested sputum specimens.
- Petraghani media is an egg-milk-potato solid medium also containing malachite green. It is primarily used for specimens from highly contaminated areas (e.g., fecal material).
- Middlebrook 7H10 media is a liquid based media containing salts, **vitamins**, cofactors, oleic acid, albumin, catalase, glycerol, and glucose. This media enhances the recovery of MAC organisms (*Mycobacteria avium* complex).

Each culture medium described above represents a nonselective formulation, but selective formulations are also used which contain antibiotics to enhance the growth of mycobacteria and suppress the growth of contaminating bacteria. The enhanced formulas are used for specimens that are highly contaminated.

All culture tubes are incubated in an atmosphere of 5-10% CO₂ (for growth enhancement) even though mycobacteria are strict aerobes. The tubed media are kept in a high humidity incubator at 35°C in the dark in a slanted position with the caps loosened (in order for CO₂ to enter the tubes and excess fluid to evaporate). For specimens obtained from skin or superficial lesions, a lower temperature (25-30°C) is required for the recovery of *M. marinum* and *M. ulcerans*. A nutritional requirement of hemin and a temperature of 30°C are needed for the recovery of *M. haemophilum* (cultured from skin

nodule specimens). If *M. xenopi* is suspected, a temperature of 42-45°C is required (cultured from hospital hot water tanks).

AFB cultures are held for six to eight weeks before reporting “No growth of AFB.” Cultures are observed daily for the first two weeks, checking for any growth or colony formation. Rapid-growing mycobacteria usually appear on non-selective media in two to three days at temperatures between 20 to 40°C. The slow-growing mycobacteria associated with disease require four to six weeks of incubation on selective media. Since the use of liquid media allows mycobacteria to grow more rapidly and is considered the most sensitive primary isolation media, the Becton Dickinson Diagnostic Instrument Systems developed the BACTEC System. The BACTEC System utilizes Liquid Middlebrook 7H12 and 7H13 in an automated radiometric culture system. The broth is placed in commercially prepared vials containing a ¹⁴C-labeled substrate (palmitic acid) used by mycobacteria, liberating radioactive carbon dioxide (¹⁴CO₂) into the upper part of the vial. The ¹⁴CO₂ liberated is detected by the BACTEC 460 (instrument) and is recorded as a “growth index” denoting growth of mycobacteria in the vial of broth. This method of growth significantly improves the isolation rate of mycobacteria compared with conventional isolation using solid tubed media. The BACTEC vials must be checked within four days of inoculation. This method detects *Mycobacteria spp.* growth in clinical specimens in less than two weeks compared to four to six weeks for conventional methods.

Non-radiometric automated systems are also available for the detection of growth and recovery of mycobacteria from clinical specimens. An example is the Septi-Chek AFB system (BBL-Becton Dickinson Microbiology Systems) that detects, isolates, rapidly identifies, and performs antibiotic susceptibility testing. This is a biphasic media system (a bottle containing liquid media and solid media) that uses growth enhancing factors and antimicrobial agents in the liquid and three different solid media on a paddle inserted in the top of the vial. This system rapidly grows, isolates, and presumptively identifies *M. tuberculosis* (i.e., differentiates it from other mycobacteria).

Identification

Based on the volume of specimens submitted, the ability of performance, and the expertise of the clinical laboratory personnel, the American Thoracic Society (ATS) and the College of American Pathologists (CAP) have recommended levels of service for clinical laboratories testing of mycobacteria. The ATS recommends

four levels of testing while the CAP lists three levels. The three levels of service recommended by CAP are:

- Level I. Specimen collection only; no identification procedures performed with all specimens sent to other qualified laboratories.
- Level II. Perform microscopy; isolate and identify and sometimes perform susceptibility tests for *M. tuberculosis*.
- Level III. Perform microscopy; isolate, identify, and perform susceptibility testing for all species of *Mycobacterium*.

Identification of *Mycobacteria spp.* by qualified clinical laboratories entails several of the following:

- Confirmation that the isolate recovered in broth or on solid media is an acid-fast organism.
- Categorize (presumptively) the isolate by phenotypic characteristics, such as colony morphology, photoreactivity, growth rate, and optimum growth temperature.
- Identification through tests based on enzyme systems of the organism, metabolic by-products, and inhibition of growth by exposure to selected biochemicals.
- Chromatographic detection of mycolic acid.
- Identification by DNA hybridization (e.g., Gen-Probe-San Diego, Calif.)
- Identification by PCR (polymerase chain reaction) tests.

The biochemical tests most often utilized are **niacin** accumulation, nitrate reduction, TCH (inhibition of growth when exposed to thiophene-2-carboxylic acid hydrazide), growth in 5% NaCl, tellurite reduction, growth on MacConkey agar, catalase, hydrolysis of Tween 80, **iron** uptake, and tests for the enzymes aryl-sulfatase, urease, and pyrazinamidase. Biochemical testing is time consuming and may take several weeks to obtain results. Molecular methods (DNA and PCR) are becoming increasingly available commercially and allow for identification and detection of mycobacteria faster, with less cost and more specificity.

Antibiotic susceptibility testing for tuberculosis

The susceptibility testing for *Mycobacteria tuberculosis* is done on a pure culture which may take two to three weeks to prepare after the initial culture has grown. Thus, a total of five to seven weeks is not uncommon before the physician finally receives an antibiotic susceptibility report for a patient with a positive MTB culture. However, rapid testing systems mentioned previously may be used for susceptibility testing, which reduces the time considerably.

Once the physician receives the initial smear report (i.e., positive AFB on smear) and the initial culture report (presumptive *M. tuberculosis* isolated), the patient is given two or more primary drugs (first-line drugs) to initiate treatment that may require six to nine months of drug therapy. The first line (primary drugs) drugs tested *in vitro* include isoniazid (INH), rifampin, pyrazinamide, ethambutol, and streptomycin. After three months of therapy, patients are again cultured. If the cultures are still positive, re-testing of different or secondary drugs is done. The second-line drugs include ethionamide, capreomycin, cycloserine, kanamycin, pyrazinamide, amikacin, ciprofloxacin, ofloxacin, rifabutin, and para-aminosalicylic acid.

The methods used for susceptibility testing are: radiometric (BACTEC System); proportional; resistance ratio (agar dilution and disk elution); and absolute concentration methods. It is important to isolate and determine the susceptibility pattern for *M. tuberculosis* because of the increase in multidrug-resistant cases in the United States.

Preparation

Prior to breakfast, the patient will be asked to provide a 5-10 mL specimen of sputum delivered into a sterile cup with a screw top lid. Obtaining an appropriate sample will require that the patient cough deeply several times to bring up the sputum. Failure to do so will result in a specimen containing saliva or post-nasal drip, which are both considered sample contaminants.

Aftercare

There are not specific requirements for care after obtaining the specimen.

Complications

There are no complications associated with this test.

Results

The acid-fast smear report will indicate “no AFB seen” if results are negative. If positive, the report should be documented as described above. For cultures, “no growth of AFB” on any medium after eight weeks is considered a negative test. Growth on any medium is tested for acid-fastness and if positive, a preliminary report of a positive culture for *Mycobacterium spp.* is submitted. A final report of the mycobacterium species identified and antibiotic susceptibility is submitted as soon as results are available. The antibiotic susceptibility report indi-

cates one of three conditions for each drug: sensitive, equivocal, or resistant.

Health care team roles

A physician orders and interprets the report for an acid-fast culture. A nurse, physician assistant, or respiratory therapist assists in sputum or sample collection. A clinical laboratory scientist/medical technologist who is specially trained in mycobacteriology performs the microbiological testing.

Activities of daily living evaluation

Definition

An activities of daily living (ADL) evaluation is an assessment of an individual's physical and sometimes

KEY TERMS

Adaptation—Altering a tool used in performing a task so that the patient is better able to function independently or with minimal assistance.

Dressing stick—A long rod with a hook attached to the end that a patient uses in place of the hands. Typically a dressing rod would be used to pull on a pair of pants or socks.

Home modification—Altering the physical environment of the home so as to remove hazards and provide an environment that is more functional for the patient. Examples of home modification include installing grab bars and no-slip foot mats in the bathroom to prevent falls.

mental skills. In the area of physical or **occupational therapy**, it reflects how well a disabled patient or someone recovering from disease or accident can function in daily life. It is also used to determine how well patients relate to and participate in their environment.

Purpose

ADL evaluations help practitioners determine how independent patients are and what skills they can accomplish on their own, as well as to gauge how independent each individual can become after intervention by a health professional. The goal of practitioners performing ADL evaluations is to help patients become as independent as possible, using appropriate adaptations if needed.

Description

Many ADL indexes exist, such as the Katz Index, Revised Kenny Self-Care Evaluation, and the Barthel Index. These indexes typically evaluate patients on their self-care skills and rate each individual according to how functional they are. Scoring is based on how independently a task can be performed and whether supervision or assistance is needed in performing the task.

Basic ADL versus Instrumental ADL

Basic activities of daily living are those skills needed in typical daily self care. An evaluation would, in part, consist of bathing, dressing, feeding, and toileting. The evaluator would examine various activities in each category to determine the patient's skill. Afterward it can be determined what, if any, changes will be necessary to allow the patient to function as independently as possible.

Instrumental activities of daily living refer to skills beyond basic self care that evaluate how individuals function within their homes, workplaces, and social environments. Instrumental ADLs may include typical domestic tasks, such as driving, cleaning, cooking, and shopping, as well as other less physically demanding tasks such as operating electronic appliances and handling budgets. In the work environment, an ADL evaluation assesses the qualities necessary to perform a job, such as strength, endurance, manual dexterity, and **pain management**.

If a person is being treated following an injury or disorder diagnosis, whether an intervention is needed depends upon how severe his or her functional ability has been affected. If an individual's ADL function is not restored, a health care professional will perform an intervention, which entails helping the individual adapt to permanent dysfunction or regain meaningful function. How well an individual must be able to perform these tasks depends upon the living setting he or she is returning to, whether it is a full custodial facility, assisted living community, or living at home on his or her own.

Complications

Returning a client to full meaningful function can be problematic for individuals who do not have the motivation to do so. A holistic approach to treatment is most important in cases such as these, and physical and occupation therapists are trained to evaluate not only the physical disability or dysfunction of an individual, but also the person's mental health and well-being. Occupational therapists can address mental health issues resulting from injury or disorder diagnosis, such as depression. However, in cases where a patient has sustained a permanent cognitive disability and is learning-impaired, it is more effective and appropriate for the occupational therapist to teach family members or a caretaker how to perform daily tasks for the patient.

Results

Interventions implemented to increase function include adaptations and home modification. Adaptations are devices that can enhance the usability of everyday items for individuals who have a limited range of motion. Home modification involves the process of making one's living environment more functional for ADL.

Adaptations

There are several ways that adaptations can be used to make common household items more functional. For example, patients commonly have a weakened grasp that is insufficient to hold heavy or small objects, so enhance-

ments such as easily gripped handles could be added to small objects, such as eating utensils or personal grooming items. Other adaptations may involve the use of unique tools to facilitate tasks, such as using a long rod with a hook at one end, known as a dressing stick, to pull on pants or socks. Adaptations may involve altering the environment to aid in other tasks, such as providing adequate lighting or magnifying lenses to compensate for a **vision** impairment.

Home modifications

Home modification has become a major area for occupational therapists to practice. In order for patients to return home or go to a group setting, the physical environment of the house or facility may have to be altered to make ADL function better. Common examples of home modifications include the installation of grab bars in the shower, toilet area and hallways; lower kitchen counters for easier access to wheelchair-bound individuals; and the elimination of potential trip points, such as loose throw rugs and slight changes in floor elevation.

Health care team roles

Occupational therapists and physical therapists are the two primary disciplines most qualified to assess ADL function and recommend the appropriate intervention and modifications in one's home and work environment. Physical therapists might focus primarily on a patient's mobility and ambulation, while the occupational therapist might focus on more specific tasks described above.

Acupressure

Definition

Acupressure is a form of touch therapy that utilizes the principles of acupuncture and Chinese medicine. In acupressure, the same points on the body are used as in acupuncture, but are stimulated with finger pressure instead of with the insertion of needles. Acupressure is used to relieve a variety of symptoms and **pain**.

Origins

One of the oldest text of Chinese medicine is the *Huang Di, The Yellow Emperor's Classic of Internal Medicine*, which may be at least 2,000 years old. Chinese medicine has developed acupuncture, acupressure, herbal remedies, diet, **exercise**, lifestyle changes, and other remedies as part of its healing methods. Nearly all of the forms of Oriental medicine that are used in the West today, including acupuncture, acupressure, **shiatsu**, and Chinese herbal medicine, have their roots in Chinese medicine. One legend has it that acupuncture and acupressure evolved as early Chinese healers studied the puncture **wounds** of Chinese warriors, noting that certain points on the body created interesting results when stimulated. The oldest known text specifically on acupuncture points, the *Systematic Classic of Acupuncture*, dates back to 282 A.D. Acupressure is the non-invasive form of acupuncture, as Chinese physicians determined that stimulating points on the body with massage and pressure could be effective for treating certain problems.

Outside of Asian-American communities, Chinese medicine remained virtually unknown in the United States until the 1970s, when Richard Nixon became the first U.S. president to visit China. On Nixon's trip, journalists were amazed to observe major operations being performed on patients without the use of anesthetics. Instead, wide-awake patients were being operated on, with only acupuncture needles inserted into them to control pain. At that time, a famous columnist for the *New York Times*, James Reston, had to undergo surgery and elected to use acupuncture for anesthesia. Later, he wrote some convincing stories on its effectiveness. Despite being neglected by mainstream medicine and the American Medical Association (AMA), acupuncture and Chinese medicine became a central to alternative medicine practitioners in the United States. Today, there are millions of patients who attest to its effectiveness, and nearly 9,000 practitioners in all 50 states.

Acupressure is practiced as a treatment by Chinese medicine practitioners and acupuncturists, as well as by massage therapists. Most massage schools in American

Therapist working acupressure points on a woman's shoulder. (Photo Researchers, Inc. Reproduced by permission.)

include acupressure techniques as part of their bodywork programs. Shiatsu massage is very closely related to acupressure, working with the same points on the body and the same general principles, although it was developed over centuries in Japan rather than in China. Reflexology is a form of bodywork based on acupressure concepts. Jin Shin Do is a bodywork technique with an increasing number of practitioners in America that combines acupressure and shiatsu principles with **qigong**, Reichian theory, and **meditation**.

Benefits

Acupressure massage performed by a therapist can be very effective both as prevention and as a treatment for many health conditions, including headaches, general aches and pains, colds and flu, arthritis, **allergies**, **asthma**, nervous tension, menstrual cramps, sinus problems, sprains, tennis elbow, and toothaches, among others. Unlike acupuncture which requires a visit to a professional, acupressure can be performed by a layperson. Acupressure techniques are fairly easy to learn, and have been used to provide quick, cost-free, and effective relief from many symptoms. Acupressure points can also be stimulated to increase energy and feelings of well-being,

reduce **stress**, stimulate the **immune system**, and alleviate **sexual dysfunction**.

Description

Acupressure and Chinese medicine

Chinese medicine views the body as a small part of the universe, subject to laws and principles of harmony and balance. Chinese medicine does not make as sharp a distinction as Western medicine does between mind and body. The Chinese system believes that emotions and mental states are every bit as influential on disease as purely physical mechanisms, and considers factors like work, environment, and relationships as fundamental to a patient's health. Chinese medicine also uses very different symbols and ideas to discuss the body and health. While Western medicine typically describes health as mainly physical processes composed of chemical equations and reactions, the Chinese use ideas like yin and yang, chi, and the organ system to describe health and the body.

Everything in the universe has properties of yin and yang. Yin is associated with cold, female, passive, downward, inward, dark, wet. Yang can be described as hot,

male, active, upward, outward, light, dry, and so on. Nothing is either completely yin or yang. These two principles always interact and affect each other, although the body and its organs can become imbalanced by having either too much or too little of either.

Chi (pronounced *chee*, also spelled *qi* or *ki* in Japanese *shiatsu*) is the fundamental life energy. It is found in food, air, water, and sunlight, and it travels through the body in channels called *meridians*. There are 12 major meridians in the body that transport chi, corresponding to the 12 main organs categorized by Chinese medicine.

Disease is viewed as an imbalance of the organs and chi in the body. Chinese medicine has developed intricate systems of how organs are related to physical and mental symptoms, and it has devised corresponding treatments using the meridian and pressure point networks that are classified and numbered. The goal of acupressure, and acupuncture, is to stimulate and unblock the circulation of chi, by activating very specific points, called pressure points or *acupoints*. Acupressure seeks to stimulate the points on the chi meridians that pass close to the skin, as these are easiest to unblock and manipulate with finger pressure.

Acupressure can be used as part of a Chinese physician's prescription, as a session of **massage therapy**, or as a self-treatment for common aches and illnesses. A Chinese medicine practitioner examines a patient very thoroughly, looking at physical, mental, and emotional activity, taking the pulse usually at the wrists, examining the tongue and complexion, and observing the patient's demeanor and attitude, to get a complete diagnosis of which organs and meridian points are out of balance. When the imbalance is located, the physician will recommend specific pressure points for acupuncture or acupressure. If acupressure is recommended, the patient might opt for a series of treatments from a massage therapist.

In massage therapy, acupressurists will evaluate a patient's symptoms and overall health, but a massage therapist's diagnostic training isn't as extensive as a Chinese physician's. In a massage therapy treatment, a person usually lies down on a table or mat, with thin clothing on. The acupressurist will gently feel and palpate the abdomen and other parts of the body to determine energy imbalances. Then, the therapist will work with different meridians throughout the body, depending on which organs are imbalanced in the abdomen. The therapist will use different types of finger movements and pressure on different acupoints, depending on whether the chi needs to be increased or dispersed at different points. The therapist observes and guides the energy flow through the patient's body throughout the session.

Sometimes, special herbs (*Artemisia vulgaris* or moxa) may be placed on a point to warm it, a process called *moxibustion*. A session of acupressure is generally a very pleasant experience, and some people experience great benefit immediately. For more chronic conditions, several sessions may be necessary to relieve and improve conditions.

Acupressure massage usually costs from \$30–70 per hour session. A visit to a Chinese medicine physician or acupuncturist can be more expensive, comparable to a visit to an allopathic physician if the practitioner is an MD. Insurance reimbursement varies widely, and consumers should be aware if their policies cover alternative treatment, acupuncture, or massage therapy.

Self-treatment

Acupressure is easy to learn, and there are many good books that illustrate the position of acupoints and meridians on the body. It is also very versatile, as it can be done anywhere, and it's a good form of treatment for spouses and partners to give to each other and for parents to perform on children for minor conditions.

While giving self-treatment or performing acupressure on another, a mental attitude of calmness and attention is important, as one person's energy can be used to help another's. Loose, thin clothing is recommended. There are three general techniques for stimulating a pressure point.

- Tonifying is meant to strengthen weak chi, and is done by pressing the thumb or finger into an acupoint with a firm, steady pressure, holding it for up to two minutes.
- Dispersing is meant to move stagnant or blocked chi, and the finger or thumb is moved in a circular motion or slightly in and out of the point for two minutes.
- Calming the chi in a pressure point utilizes the palm to cover the point and gently stroke the area for about two minutes.

There are many pressure points that are easily found and memorized to treat common ailments from headaches to colds.

- For headaches, toothaches, sinus problems, and pain in the upper body, the "LI4" point is recommended. It is located in the web between the thumb and index finger, on the back of the hand. Using the thumb and index finger of the other hand, apply a pinching pressure until the point is felt, and hold it for two minutes. Pregnant women should never press this point.
- To calm the nerves and stimulate digestion, find the "CV12" point that is four thumb widths above the navel

KEY TERMS

Acupoint—A pressure point stimulated in acupressure.

Chi—Basic life energy.

Meridian—A channel through which chi travels in the body.

Moxibustion—An acupuncture technique that burns the herb moxa or mugwort.

Shiatsu—Japanese form of acupressure massage.

Yin/yang—Universal characteristics used to describe aspects of the natural world.

in the center of the abdomen. Calm the point with the palm, using gentle stroking for several minutes.

- To stimulate the immune system, find the “TH5” point on the back of the forearm two thumb widths above the wrist. Use a dispersing technique, or circular pressure with the thumb or finger, for two minutes on each arm.
- For headaches, sinus congestion, and tension, locate the “GB20” points at the base of the **skull** in the back of the head, just behind the bones in back of the ears. Disperse these points for two minutes with the fingers or thumbs. Also find the “yintang” point, which is in the middle of the forehead between the eyebrows. Disperse it with gentle pressure for two minutes to clear the mind and to relieve headaches.

Precautions

Acupressure is a safe technique, but it is not meant to replace professional health care. A physician should always be consulted when there are doubts about medical conditions. If a condition is chronic, a professional should be consulted; purely symptomatic treatment can exacerbate chronic conditions. Acupressure should not be applied to open wounds, or where there is swelling and inflammation. Areas of scar tissue, blisters, **boils**, rashes, or **varicose veins** should be avoided. Finally, certain acupressure points should not be stimulated on people with high or low **blood pressure** and on pregnant women.

Research and general acceptance

In general, Chinese medicine has been slow to gain acceptance in the West, mainly because it rests on ideas very foreign to the scientific model. For instance, Western scientists have trouble with the idea of chi, the

invisible energy of the body, and the idea that pressing on certain points can alleviate certain conditions seems sometimes too simple for scientists to believe.

Western scientists, in trying to account for the action of acupressure, have theorized that chi is actually part of the neuroendocrine system of the body. Celebrated orthopedic surgeon Robert O. Becker, who was twice nominated for the Nobel Prize, wrote a book on the subject called *Cross Currents: The Promise of Electromedicine; The Perils of Electropollution*. By using precise electrical measuring devices, Becker and his colleagues showed that the body has a complex web of electromagnetic energy, and that traditional acupressure meridians and points contained amounts of energy that non-acupressure points did not.

The mechanisms of acupuncture and acupressure remain difficult to document in terms of the biochemical processes involved; numerous testimonials are the primary evidence backing up the effectiveness of acupressure and acupuncture. However, a body of research is growing that verifies the effectiveness in acupressure and acupuncture techniques in treating many problems and in controlling pain.

Training and certification

There are two routes to becoming trained in the skill of acupressure. The first is training in traditional acupuncture and Chinese medicine, which has many schools and certifying bodies around the country. The majority of acupressure practitioners are trained as certified massage therapists, either as acupressure or shiatsu specialists.

The Acupressure Institute provides certification and resources for acupressure practitioners. Address: 1533 Shattuck Ave., Berkeley, CA 94709, phone (510) 845-1059, website: www.acupressure.com.

The American Oriental Bodywork Therapy Association (AOBTA) certifies acupressure practitioners and has over 1,400 members. It also provides a list of schools and training programs. Address: 1010 Haddonfield-Berlin Road, Suite 408, Voorhees, NJ 08043, phone (856) 782-1616, email: AOBTA@prodigy.net.

The Jin Shin Do Foundation for Body/Mind Acupressure is an international network of teachers and practitioners. Address: 1084G San Miguel Canyon Road, Royal Oaks, CA 95076, phone (408) 763-7702.

The largest organization that certifies massage therapists, with over 40,000 members worldwide, is the American Massage Therapy Association. It also has a

member directory and lists of training programs. Website: www.amtamassage.org.

Acute kidney failure

Definition

Acute kidney failure (AKF) occurs when there is a sudden reduction in kidney function that results in nitrogenous wastes accumulating in the **blood** (azotemia).

Description

The **kidneys** are the body's natural filtration system. They perform the critical task of processing approximately 200 quarts of fluid in the bloodstream every 24 hours. Waste products like urea and toxins, along with excess fluids, are removed from the bloodstream in the form of urine. Kidney (or renal) failure occurs when kidney functioning becomes impaired somehow. Fluids and toxins begin to accumulate in the bloodstream. As fluids build up in the bloodstream, the patient with AKF may become puffy and swollen (edematous) in the face, hands, and feet. Their **blood pressure** typically begins to rise, and they may experience fatigue and nausea. Often urine output decreases drastically or is not produced at all.

Unlike **chronic kidney failure**, which is long term and irreversible, acute kidney failure is often a temporary condition. With proper and timely treatment, it can many

times be reversed, leaving no permanent or serious damage to the kidneys.

Causes and symptoms

Acute kidney failure appears most frequently as a complication of serious illness, like **heart** and/or **liver** failure, serious **infection**, **dehydration**, severe **burns**, and excessive bleeding (hemorrhage). It may also be caused by an obstruction to the urinary tract or as a direct result of kidney disease, injury, or an adverse reaction to medicine. These conditions divide AKF into three main categories: prerenal, postrenal, and intrinsic (inside) conditions.

Prerenal AKF does not damage the kidney, but can cause diminished kidney function and significantly decreased renal (kidney) blood flow. It is the most common type of acute renal failure, and is often the result of:

- dehydration
- extracellular fluid (ECF) volume depletion (or other acute fluid loss from the gastrointestinal tract, kidneys, or skin)
- drugs (NSAIDs, cyclosporine, radiopaque contrast materials, or any substance toxic to the kidneys)
- hemorrhage
- septicemia, or sepsis
- congestive **heart failure** (CHF)
- liver failure
- burns
- decreased intravascular volume (referred to as third spacing, also found in the presence of **pancreatitis**, post surgical patients, and patients with a nephrotic syndrome)

Postrenal AKF is the result of an obstruction of some kind somewhere in the urinary tract, often in the bladder or ureters (the tubes leading from the kidney to the bladder). The kidneys compensate to such a degree that one kidney can be completely obstructed and the other will maintain nearly normal kidney function for the body. The conditions that often cause postrenal AKF are:

- inflammation of the prostate gland in men (prostatitis)
- enlargement of the prostate gland (benign prostatic hypertrophy)
- bladder or pelvic tumors
- **kidney stones** (calculi)

Intrinsic AKF involves a type of kidney disease or direct injury to the kidneys. This type of AKF accounts

for 20-30% of AKF reported among hospitalized patients. Intrinsic AKF can result from:

- lack of blood supply to the kidneys (ischemia)
- use of radiocontrast agents in patients with kidney problems
- drug abuse or overdose
- long-term use of nephrotoxic medications, like certain **pain** medicines
- acute inflammation of the glomeruli, or filters, of the kidney (glomerulonephritis)
- kidney infections (pyelitis or pyelonephritis)
- infiltration by lymphoma, leukemia, or sarcoid carcinomas

Common symptoms of AKF include:

- **Anemia.** The kidneys are responsible for producing erythropoietin (EPO), a hormone that stimulates red blood cell production. If kidney disease causes shrinking of the kidney, red blood cell production is reduced, leading to anemia.
- **Bad breath or bad taste in mouth.** Urea in the saliva may cause an ammonia-like taste in the mouth.
- **Bone and joint problems.** The kidneys produce **vitamin D**, which helps the body absorb **calcium** and keeps bones strong. For patients with kidney failure, bones may become brittle. In children, normal growth may be stunted. Joint pain may also occur as a result of high phosphate levels in the blood. Retention of uric acid may cause gout.
- **Edema.** Puffiness or swelling in the arms, hands, feet, and around the eyes.
- **Frequent urination.**
- **Foamy or bloody urine.** Protein in the urine may cause it to foam significantly. Blood in the urine may indicate bleeding from diseased or obstructed kidneys, bladder, or ureters.
- **Cola-colored urine followed by oliguria** (decreased urine output) or **anuria** (no urine output)
- **Headaches.** High blood pressure may trigger headaches.
- **Hypertension, or high blood pressure.** The retention of fluids and wastes causes blood volume to increase. This makes blood pressure rise.
- **Increased fatigue.** Toxic substances in the blood and the presence of anemia may cause the patient to feel exhausted.
- **Itching.** **Phosphorus**, normally eliminated in the urine, accumulates in the blood of patients with kidney fail-

ure. An increased phosphorus level may cause the skin to itch.

- **Lower back pain.** Patients suffering from certain kidney problems (like kidney stones and other obstructions) may have pain where the kidneys are located, in the small of the back below the ribs.
- **Nausea.** Urea in the gastric juices may cause upset stomach.

Diagnosis

Kidney failure is diagnosed by a doctor, whether the patient is in the hospital or seen as an outpatient. He or she will take a complete medical history and make a thorough review of the patient's medical record, looking for exposure to nephrotoxic (medicines that can be hard on the kidneys) drugs or other clues to the patient's condition. The physician will then conduct a thorough **physical examination**, making a careful assessment of the patient's ECF volume and effective circulating blood volume (EBV). A nephrologist, a doctor that specializes in the kidney, may be consulted to confirm the diagnosis and recommend treatment options. He or she will look for a recent history of changes in body weight and try and determine whether the patient is taking in much more fluid than he or she is excreting. Capillary wedge pressure and cardiac output values are also effective tools in pinpointing the cause and extent of the AKF.

The patient that is suspected of having AKF will have blood and urine tests to determine the level of kidney function. A blood test will assess the levels of creatinine, blood urea nitrogen (BUN), uric acid, phosphate, sodium, and potassium. The kidney regulates these agents in the blood. Urine samples will also be collected, usually over a 24-hour period, to assess protein loss and/or creatinine clearance.

Determining the cause of kidney failure is critical to proper treatment. Prerenal or obstructive causes are often looked into first because they are the quickest types of AKF to treat. A full assessment of the kidneys is necessary to determine if the underlying disease is treatable and if the kidney failure is chronic or acute. X rays, **magnetic resonance imaging** (MRI), computed tomography scan (CT), ultrasound, renal biopsy, and/or arteriogram of the kidneys may be used to determine the cause of kidney failure and level of remaining kidney function. X rays and ultrasound of the bladder and/or ureters may also be needed.

Treatment

Treatment for AKF varies, since it is directed to the underlying, primary medical condition that triggered the

kidney failure. Prerenal conditions may be treated with replacement fluids given through a vein, diuretics, blood transfusion, restricted salt intake, or medications. Postrenal conditions and intrarenal conditions may require surgery and/or medication.

Frequently, patients in AKF require *hemodialysis*, *hemofiltration*, or *peritoneal dialysis* to filter fluids and wastes from the bloodstream until the primary medical condition can be controlled.

Hemodialysis

Hemodialysis involves circulating the patient's blood outside of the body through an extracorporeal circuit (ECC), or dialysis circuit. The ECC is made up of plastic blood tubing, a filter known as a dialyzer (or artificial kidney), and a dialysis machine that monitors and maintains blood flow and administers dialysate. Dialysate is a sterile chemical solution that is used to draw waste products out of the blood. The patient's blood leaves the body through the vein and travels through the ECC and the dialyzer, where fluid removal takes place.

During dialysis, waste products in the bloodstream are carried out of the body. At the same time, electrolytes and other chemicals are added to the blood. The purified, chemically-balanced blood is then returned to the body.

A dialysis "run" typically lasts three to four hours, depending on the type of dialyzer used and the physical condition of the patient. Dialysis is used several times a week until AKF has resolved.

Blood pressure changes associated with hemodialysis may pose a risk for patients with heart problems. **Peritoneal dialysis** may be the preferred treatment option in these cases.

Hemofiltration

Hemofiltration, also called continuous renal replacement therapy (CRRT), is a slow, continuous blood filtration therapy used to control acute kidney failure in critically ill patients. These patients are typically very sick and may have heart problems or circulatory problems. They cannot endure the rapid filtration rates of hemodialysis. They also frequently need **antibiotics**, **nutrition**, vasopressors, and other fluids given through a vein to treat their primary condition. Because hemofiltration is continuous, prescription fluids can be given to patients in kidney failure without the risk of fluid overload.

Like hemodialysis, hemofiltration uses an ECC. A hollow fiber hemofilter is used instead of a dialyzer to remove fluids and toxins. Instead of a dialysis machine, a blood pump makes the blood flow through the ECC. The volume of blood circulating through the ECC in

hemofiltration is less than that in hemodialysis. Filtration rates are slower and gentler on the circulatory system. Hemofiltration treatment will generally be used until kidney failure is reversed.

Peritoneal dialysis

Peritoneal dialysis may be used if the patient in AKF is stable and not in immediate crisis. In peritoneal dialysis (PD), the lining of the patient's abdomen, the peritoneum, acts as a blood filter. A flexible tube-like instrument (catheter) is surgically inserted into the patient's abdomen. During treatment, the catheter is used to fill the abdominal cavity with dialysate. Waste products and excess fluids move from the patient's bloodstream into the dialysate solution. After a certain time period, the waste-filled dialysate is drained from the abdomen, and replaced with clean dialysate. There are three types of peritoneal dialysis, which vary according to treatment time and administration method.

Peritoneal dialysis is often the best treatment option for infants and children. Their small size can make vein access difficult to maintain. It is not recommended for patients with abdominal adhesions or other abdominal defects (like a hernia) that might reduce the efficiency of the treatment. It is also not recommended for patients who suffer frequent bouts of an inflammation of the small pouches in the intestinal tract (diverticulitis).

Prognosis

Because many of the illnesses and underlying conditions that often trigger AKF are critical, the prognosis for these patients many times is not good. Studies have estimated overall death rates for AKF at 42-88%. Many people, however, die because of the primary disease that has caused the kidney failure. These figures may also be misleading because patients who experience kidney failure as a result of less serious illnesses (like kidney stones or dehydration) have an excellent chance of complete recovery. Early recognition and prompt, appropriate treatment are key to patient recovery.

Survival statistics also depend on the type of AKF the patient has, age at time of onset, and general health. If the patient has prerenal AKF, there is a good recovery prognosis, but the mortality rate is higher among those who fail to respond to diuretics and vasodilator therapy. Since 1980, age has become a risk factor that increased mortality in patients with acute tubular necrosis (ATN), an intrinsic form of AKF.

Up to 10% of patients who experience AKF will suffer irreversible kidney damage. They will eventually go on to develop chronic kidney failure or end-stage renal

KEY TERMS

Anuria—When the body ceases to make urine entirely or falls below 100 mls.

Azotemia—Too many nitrogenous compounds in the blood caused by the kidneys' failure to remove urea from the blood.

Blood urea nitrogen (BUN)—A waste product that is formed in the liver and collects in the bloodstream; patients with kidney failure have high BUN levels.

Capillary wedge pressure—The blood pressure inside of a capillary.

Cardiac output—The volume of blood pushed out by the ventricles.

Creatinine—A protein produced by muscle that healthy kidneys filter out.

Edema—The abnormal accumulation of fluid in the interstitial spaces of tissue.

Electrolytes—An element or a compound that can break into ions and conduct electrical current when melted or dissolved in water.

Erythropoietin (EPO)—A glycoprotein hormone made in the kidneys.

Extracellular fluid (ECF)—That part of body fluid made of interstitial fluid and blood plasma.

Extracorporeal—Outside of, or unrelated to, the body.

Glomeruli—The tiny structures that perform the actual mechanical filtering in the kidney.

Gout—A condition caused by error in uric acid metabolism.

Interstitial—The space between cells.

Intravascular volume—The volume of fluid inside a blood vessel.

Intrinsic—Starting from or situated inside an organ or tissue.

Ischemia—A lack of blood supply to an organ or tissue.

Lymphoma—Cancer of the lymph tissue.

Nephritis—Inflammation and abnormal functioning of the kidney.

Nephrologist—A physician who specializes in treating diseases of the kidney.

Nephrotoxic—Toxic, or damaging, to the kidney.

NSAIDs—Non-steroidal, antiinflammatory drug.

Oliguria—Abnormally low urine production.

Radiopaque agents—Dyes administered to a patient for the purposes of a radiologic study.

Sepsis—A bacterial infection of the bloodstream.

Urea—A systemic diuretic.

Vasopressors—Medications that constrict the blood vessels.

disease. These patients will require long-term dialysis or kidney transplantation to replace their lost renal functioning.

Health care team roles

The patient who suffers from AKF will come in contact with a number of different health care professionals during both the diagnosis and treatment phase of the illness. Patients will require (according to the type and severity of their condition) laboratory work, diagnostic radiology services, pharmaceutical and nutritional interventions, dialysis (in some cases), nursing care, and disease management by a nephrologist.

The medical history, taken by a physician in the emergency room, the patient's family doctor, a fellow nurse practitioner, physician's assistant (PA), or a nephrologist is the most essential tool in determining the

cause and type of AKF. The admitting physician or nephrologist will conduct a thorough physical, looking at the following areas for specific clues.

Skin. Checking the patient for areas of small, purple or red spots (petechiae), hemorrhage beneath the skin (purpura), and bluish discoloration of a fairly large area of the skin (ecchymosis) can lead to a diagnosis of an inflammatory or vascular cause for the AKF.

Eyes. Certain conditions in the eyes can point to a diagnosis of interstitial nephritis (inflammation between the cells and tissues of the kidney) or necrotizing vasculitis (inflamed **blood vessels**).

Cardiovascular and volume status. Evaluating the condition of the heart and the rest of the circulatory system plus volume status (**fluid balance**) is the most important part of diagnosing and managing AKF. Nurses and nurses' aides will measure and chart daily intake and

output (measuring how much fluid the patient takes in and how much he or she excretes in a 24-hour period of time). This is one of the best ways to get a good estimate of volume status. The pulse rate and blood pressure will be taken by the physician, nurses, and nurses' aides often in both the upright (standing or sitting on the side of the bed with legs dangling down) and supine (lying down) positions. The physician will also check the pulse in the neck, examine the heart and **lungs**, and check for edema (fluid buildup) in the arms and legs. Different combinations of the results of these assessments point to different causes for and types of AKF.

Abdomen. The physician will feel for signs of urinary tract obstruction by palpating (pressing) on the bladder and the upper corners of the abdomen that may reveal an obstruction in the ureter (tube between the kidney and the bladder) somewhere. If the entire abdomen is unusually swollen and filled with fluid (ascites), the AKF may be the result of liver failure.

Arms and legs (extremities). The physician and nursing staff will check the patients arms and legs for edema at the time of diagnosis and throughout treatment. Edema in the arms and legs is a sign of a decrease in oxygenated blood (ischemia), muscle tenderness from rhabdomyolysis (disease of the skeletal muscle), or arthritis. The presence and degree of edema is helpful in pinpointing the cause of AKF and in measuring the patient's progress with treatment.

Nervous system. The physician will assess the patient's degree of mental clarity and nerve responses, as abnormalities in these areas of the nervous system are often common symptoms of AKF. The nursing staff also monitors the patient's mental status during the course of treatment.

Laboratory personnel will draw blood and collect urine samples to help diagnose AKF and later, to evaluate treatment. Increases in BUN (blood urea nitrogen) and creatinine (substance formed from the **metabolism** of creatine) are indicators of AKF.

The **urinalysis** is the most important test run in the early stage of AKF evaluation. Significant color changes point to an intrinsic cause for AKF. Urine dipstick tests that prove positive for proteinuria (too much protein) and blood are helpful in diagnosing many causes of AKF. The different types of sediment readings from spun urine samples can further help to distinguish the cause and type of AKF. Urine electrolytes indicate how well the tubules (part of the kidney's nephron) are working.

Nurses and nurses' aides will keep track of fluids the patient takes in (intake) and eliminates (output) to help determine the type of AKF the patient is in and to help the physician manage the patient's course of treatment.

Fluid management is critical in the patient with AKF, regardless of the cause.

Patients in AKF may undergo further evaluation in the Radiology Department to determine the cause of their disease and to plan an appropriate plan of treatment. They may undergo an ultrasound examination, doppler scan, nuclear scan, MRI, renal **angiography**, or a renal biopsy. The ultrasound, doppler scan, and MRI are the least invasive of the procedures. Contrast material is injected for the angiogram and the renal biopsy requires taking tissue samples from the kidney itself. These procedures are performed by trained and licensed radiologic technologists and radiologists.

Nutrition is crucial to the effective management of the patient in AKF. The dietician will work closely with the patient, physician, nursing staff, and pharmacist to ensure proper **electrolyte balance**, whether the patient eats regular foods or is nourished by total **parenteral nutrition** (TPN, nutrients mixed and fed through a tube).

Some patients will require **kidney dialysis** that will be performed by nurses and technicians from the renal or urology department.

Since many different medications are eliminated through the kidneys, the physician works closely with the pharmacist to modify dosing and minimize the use of medications that are toxic to the kidneys.

Prevention

Since AKF can be caused by many things, prevention is difficult. Medications that may impair kidney function should be given cautiously. Patients with pre-existing kidney conditions who are hospitalized for other illnesses or injuries should be carefully monitored for kidney failure complications. Treatments and procedures that may put them at risk for kidney failure (like diagnostic tests requiring radiocontrast agents or dyes) should be used with extreme caution.

Administration of medication

Purpose

The administration of medication is often a chief responsibility of the nurse. The practice of administering

medication involves providing the patient with a substance prescribed and intended for the diagnosis, treatment, or prevention of a medical illness or condition.

Description

The central action of medication administration involves actual and complete conveyance of a medication to the patient. However, there is a wider set of practices required to achieve safe, effective patient outcomes and to prepare for and evaluate the outcome of medication administration.

Laws regarding medication administration vary from state to state. Doctors, physicians, physician assistants, nurse practitioners, and nurses are generally trained and authorized to administer medication, while other medical disciplines may have a limited responsibility in this area. In certain circumstances, unlicensed personnel may be trained and authorized to administer medication in residential care settings. State and federal laws also restrict the distribution of and access to medications that can be abused (called controlled substances). Responsibility for controlled substances includes accountability for any discarded substances, double-locked storage, and counting of medication supply at regular intervals by clinician teams.

Preparation for medication administration begins with the order for medication, in most circumstances written by the physician. Nurse practitioners and physician assistants are also often authorized to write prescriptions. State laws vary regarding these privileges. A record of orders for medication and other treatments is kept in the medical chart. Universally accepted safe clinical practice guidelines and state laws govern the components of medication orders in order to ensure consistency and patient safety. All orders should contain the patient's name, the date and time when the order is written, and the signature of the ordering clinician. Caregivers administering medication are responsible for checking that these components are present and clear. The name of the medication is accompanied by the dosage, or how much of the drug should be given; the route of administration, or how the medication should be given (ie, **intramuscular injection**); and frequency, or how often the drug is to be given. Common routes of administration are discussed below.

The most common route of administration is the oral route, or swallowing of medication. This is the easiest and safest route. The physical position and swallowing abilities of the patient should be evaluated to avoid choking. Patients may also receive medication by the buccal route (through the inner cheek or gum) or the sublingual route (under the tongue).

Administration involving a needle or syringe occurs with several drug routes. These routes are referred to as parenteral. Care must be taken to maintain asepsis with all injections and injection sites. Intramuscular medications are injected into the muscle. A special injection technique called Z-track can be used when administering intramuscular medications that can be damaging to the tissue. All intramuscular injections involve the practice of landmarking, or identifying anatomical markers that indicate the correct injection site and avoid damage to bone or nerves. Subcutaneous injections are administered under the skin. Insulin is a common medication that is usually given subcutaneously. Intradermal medications are used much less frequently than subcutaneous or intramuscular injections. They are injected into the skin. Intravenous medications are given through an intravenous line into the vein. These medications may be mixed with a large amount of solution that is being infused, given in a small solution through a port in the intravenous tubing (bolus), or attached in smaller infusion containers to the larger infusion (piggyback). In all cases of administration with a needle or syringe, rotation of injection sites is required to prevent damage to tissue. It is also important that the size of the needle is selected based on the thickness of the medication to be given and the depth of the injection, while maximizing the patient's level of comfort during insertion. Needle sticks with contaminated needles are a hazard to both health professional and patient. Care is taken to dispose of needles and syringes rapidly in impervious containers. Protective systems that sheath the needle after use are commonly used to prevent inadvertent needle sticks.

Medication can also be instilled via the mucous membranes. Asepsis must be used to avoid introduction of **infection**. Rectal or vaginal medications are most often given in suppository form and must be introduced gently to avoid tearing or bleeding of tissue. Nasal medications are often instilled via spray or drops and often involve closing one nostril and asking the patient to inhale gently. The head should be tilted back to avoid aspiration. Ear or otic medications are given in liquid form. The patient's head is tilted to the side. Instruments should never enter the ear. If the medication is not instilled correctly, the patient may experience nausea or vertigo. Eye or ophthalmic medications may be given via drops or ointment. The container for the medication should not touch the eye, and drops are introduced into the inner canthus or corner of the eye.

Inhalational medications are inhaled via the respiratory tract, most often to treat respiratory conditions. Metered dose inhalers (MDI) are often used. MDIs involve pressing a specially designed canister to release a mist.

An anesthesiologist administers drugs to a patient in surgery. (Photograph by Michelle del Guercio. Science Source/Photo Researchers. Reproduced by permission.)

Topical medications are applied to the surface of the skin. The skin needs to be cleansed and assessed for breaks before administering topical medications. Topical patches that gradually release medication need to be labeled with date and time in case a second patch is inadvertently applied without removal of the first. Ointments are applied evenly. The clinician should avoid touching the topical medication, as medications that are absorbed into the system via the skin, such as nitroglycerin paste, may affect the clinician. As with all medication techniques, asepsis must be maintained to avoid introduction of microorganisms.

Frequency of administration is most often ordered on a repeating schedule (ie, every 8 hours). At times the order may be written as a STAT (give right away) order, a one-time order (give just once) or a prn (give as needed) order. Standing orders are routine hospital orders that doctors in specialized areas prescribe on admission.

Many abbreviations are used in writing medication orders. Other common abbreviations include:

- p.o.: by mouth
- IM: intramuscular injection
- SC: subcutaneous injection
- IV: intravenous
- PR: per rectum
- h.s.: at hour of sleep (bedtime)
- ac: before meals
- pc: after meals
- q: every, ie, q 8 h means every 8 hours
- q.d.: every day
- b.i.d.: twice/day
- t.i.d.: three times/day
- q.i.d.: four times/day
- q.o.d.: every other day

Some examples of medication orders using these abbreviations are:

- digoxin 0.25 mg p.o. q.d.
- diphenhydramine 25 mg p.o. q h.s. prn.

If orders are illegible, ambiguous, or confusing, the author of the order should be consulted to clarify the order before any medication administration occurs. When the order is clear, it often needs to be transcribed to another document reserved for recording administration of medications. Health care institutions have specific policies regarding methods with which to check medication orders and ensure proper transcription. Policies also dictate parameters for order renewal or medication discontinuation. Poor penmanship, misunderstanding of penmanship, and errors in transcription often contribute to medication errors. It is increasingly common for medical facilities to use a computerized system that lowers the risk of error by reducing steps in the process and validating information automatically.

Once the order has been read and verified, the caregiver needs to evaluate the order in the context of the individual patient. Some factors to consider include:

- pharmacodynamics: how the drug works in the body
- interactions: possible effects of other medication or food on the ordered medication
- allergies: patient history of hypersensitivity to drug or drug class
- contraindications: medical conditions that preclude the use of the ordered drug
- side effects: potential adverse reactions to the drug

- toxic effects: dangerous effects that often occur due to build up of drug in body or impaired metabolism
- tolerance: certain drugs require increasing doses over time to achieve the same effect
- physiological variables: sex, age, size, and physical condition may alter how a drug is processed in the body
- diet: certain foods, liquids, or nutritional states may alter the drug's effect on the body

Due to the large number of medications available and the large body of information required for appropriate drug administration, it is important to have access to a current medication reference such as the *Physician's Desk Reference* or other reference handbooks about medication. The package insert that comes with every medication is also a good resource. Pharmacists are knowledgeable resources and can answer many questions regarding medication. It is important to be familiar with the medication ordered before attempting to administer it. Procedural manuals by the institution or medical reference publishers detail the step-by-step techniques for administering various types of medication.

The patient should be notified of the order for the drug and provided with education about the medication they are to receive. Before administration, five factors often referred to as the "five rights" should be addressed. Medication records should be on hand at time of administration to ensure safe administration.

Right patient. Identify patient by name badge or bracelet. Avoid simply asking patient's name or checking the name on the door as miscommunications can sometimes occur.

Right drug. Check record for name of drug and compare with drug on hand. As many drugs have similar spellings, this needs to be checked carefully. For prevention of error, it is often recommended that three checks of the drug to be administered are made: when reaching for the package that contains the drug, when opening the drug, and when returning the packaging to its storage area. It is also recommended that clinicians only administer drugs that they have prepared, versus those prepared by another clinician.

Right route. Check medication record for how to administer the drug and check labeling of drug to ensure it matches prescribed route.

Right dose. Compare ordered dose to dose on hand. At times, calculations may need to be performed to ascertain the correct dose. For example, a scored tablet, or one that is designed and intended for dividing, may need to be halved or quartered in order to administer the correct oral dose. This requires simple division. Common situations requiring calculation include calculation of intravenous

infusion rates and the conversion of measurement units, for example, determining how many milliliters (mL) are required to give the ordered number of milligrams.

The formula for this calculation can be applied to many situations:

- dose ordered/dose on hand x amount on hand = amount to administer

Using the above medication question, 25 mg /100 mg x 2 ml = 0.5 ml (amount to administer)

Intravenous medications also require frequent calculation. For example, an intravenous anticoagulant such as heparin may be ordered as “1000 units per hour,” and the clinician may need to calculate how many drops are needed per minute or hour based on how the intravenous solution is prepared. These calculations may vary according to the infusion equipment used, for example, varying drop factor ratings or use of a device called a buretrol that carefully measures infused medication. Often a mechanical pump is used to control intravenous infusion rates.

Right time. Verify that frequency or time ordered matches current time.

All medications should be handled to ensure that they do not come into contact with potentially contaminated objects or surfaces. Medications of any sort should not be left unattended, and patients should be observed taking the medication. This avoids the disposal, hoarding, abuse, or misuse of the medication, and assures the safety of the patient.

Documentation of medication administration is an important responsibility. The medication record tells the story of what substances the patient has received and when. Like other health care records, it is also a legal document. Various institutions have policies and procedures regarding documentation. The initials of the administering nurse or other health care provider and the time and date should be documented on the record next to the appropriate order. Other information may be required, such as location and severity of **pain** when administering a pain medicine (analgesic) or pulse rate when administering certain **heart** medications (i.e., digoxin). Patient refusals of medication also need to be documented, and the prescribing clinician should be informed.

Medication errors need to be documented as well. The prescribing clinician should be notified of errors. Institutional policies usually require filing a separate form to document errors. Errors can include administering the wrong drug, wrong dose, at the wrong time, or via the wrong route. Omissions of medication are also considered errors.

It is important to evaluate the patient following medication administration and document effect. For example, many hospitals dictate that a note be written regarding pain relief within several hours after analgesic administration. Any adverse effects from medication should be reported.

Preparation

Preparation for safe medication administration requires a background of education and hands-on training. New nurses and other professionals should be supervised until they demonstrate an appropriate level of knowledge and competent skills for independent medication administration.

Aftercare

The patient should be monitored to make sure the medication has had the desired effect.

Health care team roles

In addition to the clinician who administers medication, other members of the health care team play vital roles surrounding the medication administration process. Doctors or other prescribing clinicians are responsible for writing clear, legible orders and for monitoring the response of the patient to medication. They are also responsible for responding to potential adverse effects and concerns by the patient or other clinicians. Pharmacists are responsible for evaluating the medication order for potential problems, correctly filling the order, and monitoring the medication supply. All health care professionals are responsible for complying with medication-related policies designed to protect the patient and/or staff and for maintaining current knowledge regarding medication and medication administration.

Adolescent nutrition

Definition

Adolescence is a time of increased growth and development, in which a greater need for nutrients coincides with a change in food habits that also influences nutritional needs. Due to differences in body type, physical activity, and rate of growth, every adolescent has different nutritional needs.

Purpose

It is important to meet such needs during adolescence or ramifications may extend into adulthood. For instance, because bone mass is accumulated through young adulthood and slows dramatically thereafter, inadequate **calcium** intake may lead to weaker bones throughout life.

Precautions

During adolescence, bodies are rapidly changing and growing, which often causes teens to feel uncomfortable with themselves, especially if they are different from their peers. Teenagers are more likely to miss meals. Emotional distress may cause them to either eat too much or too little and use diet pills or supplements. Such patterns can lead to the development of eating disorders, which are characterized by unhealthy eating behaviors including starvation, induced vomiting, overusing **laxatives**, and overeating. Eating disorders usually begin between ages 14 and 20 and are estimated to be the third most common chronic disorder among adolescents. It is important to provide early intervention to avoid serious long-term complications.

Description

Due to variation in physical activity, **metabolism**, and growth rate, the nutritional needs of adolescents vary from person to person, and should be based on individual needs. However, general recommendations for adolescents can provide guidance. Caloric needs are usually based on the growth rate and level of **exercise** and should average between 2,200 and 3,000 calories per day. Protein needs are based on height. To determine individual needs, divide the RDA total of protein by the individual's height in centimeters. The average is about 0.3 gm/cm of height. Mineral needs increase during adolescence, especially for calcium and **iron**. Recommended intake of calcium is 1,300 milligrams (mg) per day; iron requirements are about 10-12 mg for males and 15 mg for females. **Zinc**, which is needed for growth and sexual development, is also needed in adequate amounts. Requirements for zinc are 15 mg for males and 12 mg for females. Vitamin needs increase during adolescence and the need for supplementation can be avoided by providing a well-balanced diet.

Complications

Adolescents may also have special needs, such as chronic illness, substance abuse problems, and **pregnancy**. Drug abuse often interferes with adequate food choices, but the effects of drugs greatly depends on the substance, amount, and the nutritional status of the adolescent. Adolescents with chronic illness may have increased or decreased needs based on individual circumstances. Pregnant teenagers have increased needs, because they are still growing and developing themselves.

Results

Poor **nutrition** in adolescence can have important health consequences in adulthood. **Obesity** and excessive fat intake increases the likelihood of being an overweight adult and puts the individual at risk for cardiovascular disease and other health problems. Substituting sodas and fruit juices for milk at this time of rapid growth and bone-building may lead to **osteoporosis** and bone **fractures** during later years. Too much sugar in the diet causes cavities. A diet heavily dependent on fast food results in decreased energy intake, excess fat and sodium, and a deficiency of calcium, riboflavin, **vitamin A**, **follic acid**, and fiber.

A healthy diet in adolescence promotes adequate growth and sexual maturity. A decreased risk of cavities, as well as **hypertension** and hyperlipidemias in older years, is closely correlated with adequate nutrition during adolescence.

Health care team roles

Dietitians play an important role in educating teenagers about eating well-balanced diets to receive the proper amounts of all the nutrients. When complications such as eating disorders are present, dietitians can also provide the nutritional information necessary to treat the disorder. However, psychologists and other mental health professionals should be consulted to assess the mental and emotional status of the individual.

Adrenal glands

Definition

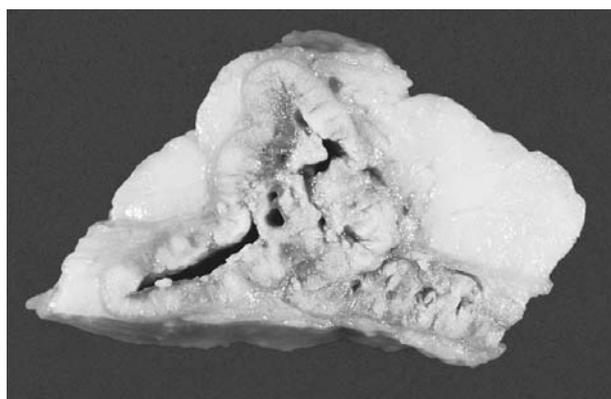

Adrenal glands produce and release several different hormones that maintain internal fluid levels, maintain sodium and potassium levels, and mediate the **stress** response.

Description

The human body contains two adrenal glands, one on top of each kidney. The gland is triangular in shape and yellowish in appearance. Subdivisions include the adrenal cortex and the medulla. The cortex is the outer layer and is responsible for the production of steroid hormones called glucocorticoids, mineralcorticoids, and androgens. The medulla forms the inner layer of the adrenal glands and releases norepinephrine and epinephrine (known commonly as noradrenaline and adrenaline) directly into the bloodstream. The adrenal cortex and medulla serve very different functions in the human body because of the different hormones that they produce and release.

Function

The adrenal cortex converts cholesterol into glucocorticoids, mineralcorticoids, and androgens. The glucocorticoids are so named due to their role in regulating body glucose levels. The major glucocorticoid produced

Cross section of human adrenal gland (triangular shape).
(Photograph by Martin M. Rotker. Phototake NYC. Reproduced by permission.)

by the adrenal is cortisol. Cortisol is also known as the stress hormone because the body releases cortisol in order to help cope with stressful situations. The immediate effects of cortisol are to increase levels of fatty acids, **proteins**, and glucose in the **blood**. Cortisol causes these increases by taking protein from muscles, fatty acids from fatty tissues, increasing gluconeogenesis (the process of making glucose), and decreasing the body's uses of glucose. Thus, in Cushing's syndrome (hyper-cortisolism), patients may experience muscle wasting (too much protein is taken from the muscles). Paradoxically, although cortisol increases the levels of free fatty acids, patients with too much cortisol over a long period of time experience an increase in fat on the upper body.

Cortisol and other glucocorticoids are also potent inhibitors of the **immune system**. Thus, it is not too surprising that synthetic glucocorticoids, like prednisone, are used to treat autoimmune diseases and allergies—diseases in which the immune system is too active. The release of cortisol is under the control of the anterior pituitary. The anterior pituitary accomplishes this by releasing the peptide hormone, adrenocorticotropin (ACTH) onto the adrenal gland.

The mineralcorticoids are so named due to their role in establishing mineral and water levels in the body. The major mineralcorticoid produced by the adrenal gland is aldosterone (although the glucocorticoid cortisol has some mineralcorticoid activity). The primary role of aldosterone is to regulate the balance of potassium, sodium, and water by affecting the absorption of all three in the kidney. Briefly, aldosterone causes the kidney to reabsorb more water and sodium, while causing potassium to be excreted in exchange for the sodium. When too much aldosterone is produced by the adrenal glands, as in primary aldosteronism, the level of potassium in the

KEY TERMS

Adrenal cortex—Outer layer of the adrenal gland that produces steroid hormones.

Adrenal medulla—Inner layer of the adrenal gland that releases adrenaline.

Androgens—Male sex hormones.

Hyperkalemia—An abnormally high level of potassium in the blood.

Hypokalemia—An abnormally low level of potassium in the blood.

Hypovolemia—An abnormally low volume of blood.

Glucocorticoid—A steroid hormone, like cortisol, that affects fat, carbohydrate, and protein levels in the blood as well as regulating the immune response.

Mineralcorticoid—A steroid hormone, like aldosterone, that regulates the excretion of salt, potassium, and water.

blood is low (hypokalemia) and the retention of sodium and water is high. Patients can experience **hypertension** and muscle weakness.

When there is too little aldosterone, potassium levels are high and there are extreme water and sodium losses. The loss of water and increased potassium levels can lead to extremely low **blood pressure** and death. A disease that might result in a loss of mineralcorticoid function is Addison's disease. In Addison's disease, the adrenals are usually at least 90% decimated before symptoms arise. The peptide, angiotensin II, and potassium levels are the main control for the release of aldosterone from the adrenals.

The adrenal glands also secrete small amounts of androgens such as testosterone. However, in the adult, that amount of androgens produced from a normally functioning adrenal gland is so small that it is unlikely to have a major effect. Nevertheless, pathology of the adrenals may result in abnormally high levels of androgens being secreted. The androgens may cause masculinization in males or females.

The adrenal medulla is really an extension of the sympathetic division of the **autonomic nervous system**. The sympathetic nervous system mediates "fight or flight" responses to environmental stimuli. Sympathetic nerves that originate in the **spinal cord** release the neu-

rotransmitter, acetylcholine, onto the adrenal glands. The adrenal glands respond by releasing dopamine, norepinephrine, and epinephrine directly into the bloodstream. Norepinephrine and epinephrine are commonly referred to as noradrenaline and adrenaline, respectively. Epinephrine makes up the majority of the substance secreted by the adrenal medulla. Circulating norepinephrine and epinephrine can increase **heart rate**, constrict **blood vessels**, dilate eye pupils, inhibit motility and digestion in the **stomach** and intestines, increase sweating, increase **metabolism**, and increase breathing. The adrenal medulla is stimulated to release norepinephrine and epinephrine under stressful situations such as **exercise** or emotional distress.

Role in human health

Thus, the adrenal glands play a significant role in mental and physical health. Not only are the adrenal glands vital for maintaining a proper balance of sodium and potassium, they mediate the body's response to stress, both short-term and long-term. In response to immediate stress, the adrenal glands produce epinephrine, norepinephrine, and the hormone cortisol. The body is prepared for flight or fight, and energy is made available for instant use. In the long term, the adrenal glands may have a negative impact on human health. Prolonged stress can produce undesirable changes in the body that range from immune system depression to fertility complications.

Diseases and disorders

Addison's disease

Addison's disease arises from a hypoactive adrenal cortex. The adrenal cortex fails to produce adequate amounts of the glucocorticoid cortisol, and sometimes the mineralcorticoid aldosterone. A lack of aldosterone causes the **kidneys** to excrete excess sodium and water while retaining potassium. This can lead to hyperkalemia (high levels of potassium), hypovolemia (low blood volume), and hypotension (low blood pressure). Hyperkalemia may cause fatal heart arrhythmias, and (severe) hypovolemia can lead to **shock** and kidney failure. Common symptoms include frequent urination, **dehydration**, fatigue, dizziness, skin discoloration, nausea, vomiting, weakness, and cold intolerance. Treatment includes oral or intravenous glucocorticoids such as prednisone, and, if necessary, administration of the oral mineralcorticoid fludrocortisone acetate to replace aldosterone. The cause of Addison's disease is not known, but in 80% of the cases there is a wasting or atrophy of the adrenal cortex.

Primary aldosteronism

Conn's syndrome is also known as primary aldosteronism. In this disease, too much of the mineralcorticoid, aldosterone, is made by the adrenal glands. The increased levels of aldosterone cause excessive potassium excretion while promoting excessive sodium and water retention. This leads to hypertension (high blood pressure) and hypokalemia (low serum potassium). Hypokalemia is an important diagnostic clue in the process of differentiating primary aldosteronism from other similar disorders. In some cases, Conn's syndrome is due to an adrenal tumor, in which case it may be surgically removed. In other cases, the diuretic drugs, spironalactone or amiloride, are given to block the effects of aldosterone.

Cushing's syndrome

The adrenal cortex is overactive in Cushing's syndrome. The adrenal cortex overproduces glucocorticoids, which can lead to high blood sugar levels and high blood pressure. Symptoms include **obesity**, muscle wasting, fatigue, irritability, excessive hair growth in women, irregular menstrual cycles, and decreased male fertility. A tumor of the adrenal gland, or an overproduction of ACTH by the pituitary, may cause Cushing's syndrome. Treatment may include **chemotherapy** or hormone-inhibiting medications.

Pheochromocytoma

Pheochromocytomas are tumors of the adrenal glands that secrete large quantities of norepinephrine and epinephrine. The most common symptom is extremely high blood pressure. Treatment is usually surgical removal of the tumor.

Adrenocortical hormone tests

Definition

Adrenocortical hormone tests measure levels of aldosterone and cortisol (also known as hydrocortisone) in **blood** and urine. These hormones are synthesized from cholesterol by the action of several enzymes. The cells responsible are located in the outer part (cortex) of the **adrenal glands**, two small organs, one sitting just above each kidney. As steroid hormones, they are an important part of the body's **endocrine system** and help to regulate body functions. The adrenal cortex also produces many other steroid hormones including androgens, primarily dehydroepiandrosterone (DHEA) and androstenedione, that are converted to testosterone and dihydrotestosterone.

Aldosterone, a mineralcorticoid, helps regulate the amounts of sodium and potassium in the blood and, because fluid follows sodium, helps maintain **fluid balance** and blood volume, which, in turn, affect **blood pressure**.

Cortisol, a glucocorticoid, helps regulate the **metabolism of proteins, fats, and carbohydrates**, especially glucose (sugar). Specifically, cortisol helps convert amino acids (subunits of proteins) into glucose within the **liver**. It raises blood sugar levels by stimulating the release of glucose from cellular glucose stores and simultaneously acts to inhibit insulin, which moderates glucose transport into the cells. Cortisol also has a number of anti-inflammatory effects, including suppressing the **immune system** and reducing **fever**.

Purpose

Aldosterone measurement is used to detect aldosteronism (hyperaldosteronism), which is the excess secretion of the hormone by the adrenal glands. It is also used to detect those cases of hypoaldosteronism that occur in the absence of a low cortisol.

The cortisol test is performed on patients who are suspected to have malfunctioning adrenal glands. It is considered to be the best indicator of adrenal activity. Blood and urine cortisol measurements, together with the determination of ACTH levels, are the three most important tests in the investigation of Cushing's syndrome (overproduction of cortisol) and Addison's disease (underproduction of cortisol). Additional tests called simulation and suppression tests may be needed to detect disease in difficult cases, or to distinguish between the causes.

Precautions

Adrenocortical function tests may be done on serum or urine. The nurse or phlebotomist performing venipuncture should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. Cortisol levels in blood are subject to diurnal variation. Test results must be evaluated with regard to the time of day the blood was collected. Physicians will determine if patients whose fluid balance may already be compromised by illness can undergo 24-hour urine tests. Physicians will also determine if patients can discontinue taking drugs that control sodium and potassium levels and fluid balance prior to testing. These tests are sometimes performed by a method called radioimmunoassay (RIA) that tags test reagents with radioactive iodide. RIA based tests may be contraindicated for patients who have had recent procedures using radiation or who have had radioactive drugs administered, because results may be altered and unreliable.

Description

Aldosterone

Aldosterone is produced by the outer area of the adrenal cortex called the zona glomerulosa. Aldosteronism, an increased secretion of aldosterone, can be primary (a malfunction in the adrenal glands or in aldosterone secretion itself) or secondary (caused by another condition). Excessive aldosterone production results in the retention of sodium, and subsequently in fluid retention and high blood pressure (**hypertension**). Because potassium can be lost in this process, muscle weakness is also a frequent symptom. Primary aldosteronism is most often caused by an adrenal tumor (adenoma) a condition referred to as Conn's syndrome. Primary aldosteronism can also be idiopathic (of unknown origin) or congenital. Secondary aldosteronism is more common and occurs as a consequence of non-adrenal conditions characterized by severe imbalances in sodium and potassium with resulting fluid imbalance, such as congestive **heart failure**, cirrhosis (liver disease) with fluid in the abdominal cavity (ascites), certain kidney diseases, excess potassium (hyperkalemia), a sodium-depleted diet, and the toxemia of **pregnancy**. To differentiate primary aldosteronism from secondary aldosteronism, a plasma renin test should be performed at the same time as the aldosterone assay. Renin, an enzyme produced in the **kidneys**, is typically elevated in secondary aldosteronism and reduced in primary aldosteronism.

Hypoaldosteronism is characterized by low serum sodium, **dehydration**, and high serum potassium (hyperkalemia). Hypoaldosteronism can occur in Addison's dis-

ease, which usually is caused by autoimmune damage to the adrenal cortex. Addison's disease is marked by decreased glucocorticoids and is detected by tests for deficient cortisol production. However, hypoaldosteronism may also occur in the absence of low glucocorticoids. This condition may result from decreased renin production by the kidney, heparin treatment, and a deficiency of an enzyme needed to produce aldosterone. In such cases, serum aldosterone and **plasma renin activity** must be measured to establish the diagnosis.

Cortisol

Cortisol and the other glucocorticoid hormones are produced in the zona fasciculata and reticularis of the cortex. Overproduction of glucocorticoids (cortisol) by the adrenal cortex is called Cushing's syndrome. Excessive cortisol production leads to high blood glucose levels, sodium retention, **obesity**, and excessive hair growth. Because cortisol production can suppress the immune system, excess levels may also cause chronic **infection** in some patients.

The release of cortisol is controlled by circulating levels of a pituitary hormone, adrenocorticotrophic hormone (ACTH). In a complex process, the hypothalamus manufactures corticotropin-releasing hormone (CRH), which, in turn, stimulates the **pituitary gland** to produce ACTH. While ACTH stimulates the adrenal glands to produce cortisol, rising levels of cortisol act by negative feedback to inhibit further production of CRH and ACTH. Disturbances in this elaborate feedback mechanism can be caused by certain types of **stress**, such as physical trauma, infection, extreme heat or cold, exhaustion from strenuous **exercise**, and extreme **anxiety**. When normal feedback becomes uncoordinated as a result of one of these conditions, excessive amounts of ACTH and, in turn, cortisol will be released. For this reason, cortisol levels in blood can vary considerably with time, a phenomenon called pulse variation.

Cushing's syndrome has four causes. The majority of cases result from the use of cortisol and related compounds for immunosuppression and treatment of inflammatory diseases. This is called iatrogenic hypercortisolism. The next most prevalent cause is Cushing's disease, also called pituitary Cushing's. This results from adenomas of the pituitary gland that secrete ACTH. Less commonly, Cushing's syndrome is caused by adrenal adenoma or carcinoma or by ACTH secreting tumors located outside the pituitary (ectopic ACTH).

Primary Addison's disease results from damage to the adrenal cortex. The most common causes are autoimmune disease and infection. Secondary Addison's disease is caused by a pituitary deficiency of ACTH. These two

conditions can often be differentiated by measuring both cortisol and ACTH. In primary Addison's disease the ACTH will usually be increased because the functional pituitary gland is responding to low blood levels of cortisol. In secondary Addison's disease, both cortisol and ACTH levels will be low.

Measurement

Cortisol is routinely measured by most laboratories. The most common method used is enzyme immunoassay. Aldosterone levels are far lower and require a more sensitive method, typically chemiluminescent immunoassay or radioimmunoassay. Measurement of cortisol intermediates such as 11-dexocortisol and 17-hydroxyprogesterone are used in conjunction with cortisol for the diagnosis of congenital adrenal hyperplasia. In this condition, an enzyme deficiency in the synthetic pathway of cortisol leads to low cortisol and accumulation of one or more steroid intermediates above the block. These compounds are measured by RIA. ACTH is typically measured by RIA because of its low concentration in plasma. Plasma renin is usually measured by determining the activity of the enzyme (renin activity) rather than by immunoassay of the hormone mass because the latter method measures both the active and inactive forms. In the assay, renin acts on angiotensinogen to produce angiotensin I, which is then measured by RIA.

Adrenocortical hormone tests are typically performed on blood plasma or 24-hour urine samples. When performed on blood, physicians may request that tests be performed on two samples, each drawn at a different time, to account for fluctuations in hormone levels at different times during the day (diurnal variation).

Tests for aldosterone are performed on blood plasma or on a 24-hour urine specimen. Levels of aldosterone peak in early morning and are at half that level by afternoon, making the time of drawing a blood sample significant. To help ensure a more reliable evaluation, two samples may be drawn for testing, one in early morning (8 AM) and one mid-afternoon (4 PM). Diet and posture (upright or lying down) may also cause aldosterone levels to fluctuate, so that a single blood sample may miss increased or decreased levels and may not accurately reflect hormone production. Because a 24-hour urine specimen reflects hormone production over an entire day, it will usually provide a more reliable aldosterone measurement. Elevated blood levels should ideally be confirmed with a 24-hour urine test.

Since posture and body position affect aldosterone production, hospitalized patients should remain in an upright position (at least sitting) for two hours before blood is drawn. Occasionally blood will be drawn before

Normal findings for aldosterone assay

Blood test

Supine	3–10 ng/dl (0.08–0.30 nmol/L)
Upright	
Adult female	5–30 ng/dl (0.14–0.80 nmol/L)
Adult male	6–22 ng/dl (0.17–0.61 nmol/L)
Newborn	5–60 ng/dl
1 week–1 year	1–160 ng dl
1–3 years	5–60 ng/dl
3–5 years	<5–80 ng/dl
5–7 years	5–70 ng/dl
7–11 years	<5–50 ng/dl
11–15 years	<5–50 ng/dl
24-hour urine test	2–80 µg/24 hr (5.5–72.0 nmol/24 hr)

and after the patient gets out of bed. Nonhospitalized patients (outpatients) should arrive at the laboratory in time to maintain an upright position for at least two hours.

Cortisol can be measured in both blood plasma and urine. Blood levels of cortisol are most reliably measured in the morning at 8 AM, in the afternoon at 4 PM, or in the evening at 10 PM. Levels of cortisol normally peak in the morning and decline gradually during the day, reaching the lowest level in the early hours of the next day. It is important to note, however, that when the normal cycle of activity and sleep (circadian rhythm) is reversed, as in night-shift work, cortisol levels will reverse also. Physicians often order blood plasma cortisol rather than a 24-hour urine collection because the earliest sign of adrenal malfunction is sometimes the loss of diurnal variation, even though cortisol levels are not yet elevated. For example, individuals with Cushing's syndrome often exhibit peak plasma cortisol levels in the morning with no decline as the day progresses. Cortisol levels may also be elevated during pregnancy, in the presence of physical and emotional stress, and with the administration of certain drugs. A 24-hour urine test for cortisol will reflect cortisol production over the entire period of collection.

Cortisol is bound in the plasma by cortisol binding protein (transcortin) and other proteins such as albumin. Very little of the plasma cortisol is free, but when cortisol is produced in excess, the binding proteins become saturated, and excess free cortisol is excreted in the urine. Measurement of 24-hour urinary free cortisol is not influenced by serum binding protein levels and is not subject to the diurnal variation (pulse variation) seen with serum total cortisol measurements. Therefore, it is somewhat more sensitive than measurement of total

serum cortisol in detecting persons with Cushing's syndrome.

Both aldosterone and cortisol (and other hormones, such as adrenomedullary hormones) are sometimes measured with blood samples from the adrenal veins, particularly when the existence of a tumor is suspected and surgery may be an option. This procedure, called adrenal venography, is performed by an angiographer in the radiology department, although the cortisol test is still performed in the clinical laboratory. Testing adrenal vein samples helps confirm the presence of adrenal tumors by allowing blood to be drawn through a catheter from the right and left adrenal glands. High levels on one side will confirm the presence of a tumor on that side. Normal levels on both sides indicates a non-adrenal source for the patient's condition. This is a specialized rather than a standard sample collection procedure and preparation for the procedure is not discussed below.

Adrenocorticotrophic hormone (ACTH) test

Although difficult to measure, ACTH aids in the differential diagnosis of the cause of Cushing's syndrome and in distinguishing primary from secondary Addison's disease. Approximately half of persons with Cushing's disease (pituitary Cushing's) have a normal ACTH level and half will have an elevated level. Most persons with adrenal tumors will have low (less than 10 picograms/L) or undetectable ACTH in the plasma owing suppression by cortisol. Most persons with ectopic ACTH secreting tumors will have elevated levels in excess of 200 pg/L. Persons with primary Addison's disease will usually have high ACTH levels (greater than 150 picograms/L) caused by negative feedback (low cortisol) while those with secondary Addison's disease will have low or normal ACTH levels owing to pituitary failure or hypothalamic suppression.

Stimulation and suppression tests

Because measurement of cortisol may not be definitive for the diagnosis of Cushing's syndrome or Addison's disease, several stimulation and suppression tests are available. Some of these tests are used to establish a diagnosis while others are used to help distinguish the cause of the disease. The most commonly used suppression test for Cushing's syndrome is the dexamethasone suppression test. Dexamethasone is a powerful synthetic analog of cortisol and will normally inhibit the pituitary release of ACTH, and thus suppress cortisol secretion. In the low dose overnight dexamethasone suppression test 1 mg of dexamethasone is given orally at midnight and the 8 AM cortisol is measured. The cortisol level is suppressed in normals and will be less than 5

micrograms/dL. Persons with Cushing's syndrome will usually show no suppression and the plasma cortisol will be 10 micrograms/dL or higher. In the high dose overnight dexamethasone suppression test the patient is given 8 mg (other doses are sometimes used) of dexamethasone at midnight. A blood sample is collected at 8 AM and cortisol is measured. Persons with Cushing's disease show a suppression in cortisol production of at least 50% of their baseline (i.e., the initial cortisol level without the drug). Persons with adenoma or ectopic ACTH tumors remain unsuppressed. In addition to dexamethasone suppression tests, metyrapone stimulation tests and corticotropin releasing hormone (CRH) stimulation tests are sometimes used for difficult cases. The former measures the ACTH reserve of the pituitary gland and the latter measures the ACTH response to hypothalamic stimulation. Patients with Cushing's disease (pituitary Cushing's) usually have an exaggerated response (increased ACTH) to both tests. Persons with adenoma or ectopic ACTH tumors do not respond with increases over the baseline in either test.

A sensitive screening test for Addison's disease is the rapid Cosyntropin stimulation test. The patient's 8 AM cortisol is measured and followed by intravenous administration of 250 micrograms of synthetic ACTH. Plasma cortisol is measured at 30 and 60 minutes after administration of the drug. Normal individuals produce a twofold increase in the baseline ACTH level while persons with either primary or secondary Addison's disease show a subnormal response.

Preparation

Fasting is not required for aldosterone blood or urine tests. The patient should maintain a normal sodium diet (approximately 3 g/day) for at least two weeks before either test. The testing physician should decide if drugs that alter sodium, potassium, and fluid balance (e.g., diuretics, antihypertensives, steroids, oral contraceptives) should be withheld. The test will be more accurate if these are discontinued for a period of at least two weeks before the test. Renin inhibitors (e.g., propranolol) should not be taken one week before the test, unless permitted by the physician. The patient should avoid licorice for at least two weeks before the test, because of its aldosterone-like effect. Because strenuous exercise and stress can increase aldosterone levels, these should be avoided as well. Two blood samples are often drawn for aldosterone evaluation, one in the early morning and one mid-afternoon.

Fasting is not required for cortisol blood or urine tests, although cortisol levels may increase after a meal and patients should not eat for at least a two-hour period

KEY TERMS

Adrenal glands—The adrenal glands are paired triangular structures located immediately above and loosely attached to each kidney. The inner portion is called the adrenal medulla and the outer portion is called the adrenal cortex.

Adrenocortical hormones—Adrenocortical hormones are steroid hormones produced and released by the adrenal cortex. They are important in regulating certain body functions, especially fluid balance, blood pressure, and fat metabolism.

Adrenocorticotrophic hormone (ACTH)—ACTH is a pituitary hormone that directly controls the rate of release of cortisol and is also needed to maintain production of aldosterone by the adrenal glands.

Aldosterone—Aldosterone is a steroid hormone released by the adrenal cortex. It helps balance fluid levels and blood pressure by regulating the amounts of sodium and potassium in the blood.

Corticotropin-releasing hormone (CRH)—CRH is produced by the hypothalamus and, in a complex process, serves to stimulate the pituitary gland to produce ACTH.

Cortisol—Cortisol is a steroid hormone released by the adrenal cortex in response to stimulation by ACTH. It helps regulate the release of amino acids from muscles and convert them to glucose for use as energy. It releases fatty acids from body tissue for use as energy by muscles, allowing circulating glucose to be reserved for use by the brain.

Glucocorticoid—A glucocorticoid (cortisol) is released by the adrenal cortex to help regulate the release and utilization of glucose.

Hyperaldosteronism—Hyperaldosteronism, known also as aldosteronism, is the excess secretion of the hormone aldosterone by the adrenal glands. It may be caused by an adrenal tumor or may occur secondary to non-adrenal conditions such as congestive heart failure, cirrhosis of the liver, certain kidney diseases, excess potassium, a sodium-depleted diet, and toxemia of pregnancy.

Mineralcorticoid—A mineralcorticoid (aldosterone) is released by the adrenal cortex to help regulate mineral levels in the blood, especially sodium and potassium.

prior to testing. For cortisol tests on blood or urine, the testing physician may discontinue the patient's regular medications for up to two weeks prior to testing. Drugs that may increase levels of cortisol include estrogen, oral contraceptives, amphetamines, cortisone, and spironolactone (Aldactone). Drugs that may decrease cortisol levels include androgens, aminoglutethimide, betamethasone, and other steroid medications, as well as danazol, lithium, levodopa, metyrapone and phenytoin (Dilantin). The patient may eat a normal diet but must not eat for at least two hours before blood samples are drawn, since cortisol levels may rise after meals. Two blood samples are usually drawn for cortisol evaluation, one in the early morning and one mid-afternoon.

The clinical laboratory will provide instructions and containers for patients collecting their own 24-hour urine samples for the measurement of aldosterone or cortisol. Patients should be advised to avoid touching the preservative, if any, in the collection container. If the preservative comes in contact with the skin, the area should be rinsed with water immediately. Collection should begin in the morning on any day except Friday or Saturday to ensure that samples will be delivered to the laboratory on a work day. Urine samples must be refrigerated continuously in the patient's home or in the nursing facility. The

specimen should be delivered to the laboratory promptly at the end of the 24-hour period.

Aftercare

Following venipuncture for blood plasma hormone tests, the nurse or phlebotomist drawing the sample should inspect the venipuncture site to make sure that the wound has closed and no bleeding is present. The site should be covered with an adhesive bandage. There is no notable aftercare for patients undergoing 24-hour urine hormone tests. Patients can be reminded to resume foods and medications (according to the physician's orders) that were restricted prior to testing.

Complications

Complications for blood hormone tests are minimal, but may include slight bleeding from the venipuncture site, fainting or feeling lightheaded after venipuncture, or the development of a hematoma (blood accumulating under the puncture site). There are no complications for the urine test, although patients should be instructed to drink clear fluids regularly to maintain fluid balance while collecting the 24-hour urine specimen. Adrenal

venography used to obtain adrenal vein samples has many potential complications, including allergic reactions to iodinated dye used in the procedure, adrenal hemorrhage, blood clots, and infection. This procedure is usually reserved for pre-surgical patients with suspected adrenal tumors and is not discussed here in detail.

Results

Aldosterone

Normal results for the aldosterone assay are laboratory-specific and vary according to test methodology used and the source of the specimen. Blood plasma levels, urine levels, and adrenal vein levels will be different. Results will also vary between patients depending upon average sodium intake, time of day, source of specimen, age, sex, and posture. Reference ranges are shown below for radioimmunoassay, the most common assay method for aldosterone.

Reference ranges for blood plasma levels:

- Supine (lying down): 3-10 ng/dL.
- Upright (sitting for at least two hours): Female: 5-30ng/dL; Male: 6-22 ng/dL.

Reference ranges for urine: 2-80 micrograms/24 hr.

Abnormal results. Increased levels of aldosterone are found in Conn's disease (aldosterone-producing adrenal tumor), and in Bartter's syndrome (overexcretion of potassium, sodium, and chloride by the kidneys resulting in low blood levels of potassium and high blood levels of aldosterone and renin). Elevated levels are also seen in secondary aldosteronism (in primary conditions such as congestive **heart** failure, cirrhosis of the liver, certain kidney diseases, hyperkalemia, a sodium-depleted diet, and toxemia of pregnancy), stress, and malignant hypertension.

Decreased levels of aldosterone are found in aldosterone deficiency, steroid therapy, high-sodium diets, certain antihypertensive therapies, and Addison's disease (an autoimmune disorder also involving abnormal cortisol and ACTH levels).

Cortisol

Normal results for the cortisol assay are laboratory-specific and vary according to the test methodology used and the source of the specimen. Blood serum levels, urine levels, and adrenal vein levels will be different.

Reference ranges for blood serum levels:

- Adults (8 A.M.): 6-28 micrograms/dL; adults (4 P.M.): 2-12 mcg/dL.

- Child 1-6 years (8 A.M.): 3-21 mcg/dL; child 1-6 years (4 P.M.): 3-10 mcg/dL.
- Newborn: 1/24 mcg/dL.

Reference ranges for urine (free cortisol):

- Adult: 10-100 micrograms/24 hr.
- Adolescent: 5-55 mcg/24 hr.
- Child: 2-27 mcg/24 hr.

Abnormal results. Increased levels of cortisol are found in Cushing's syndrome, hyperthyroidism (excess thyroid activity), obesity, ACTH-producing tumors, pregnancy, and high levels of physical or emotional stress.

Decreased levels of cortisol are found in Addison's disease, conditions of hypothyroidism (reduced thyroid activity), and **hypopituitarism** (diminished pituitary activity).

Drugs that may increase the levels of cortisol include estrogen, oral contraceptives, amphetamines, cortisone, and spironolactone (Aldactone). Drugs that may decrease the levels of cortisol include androgens, aminoglutethimide, betamethasone, other steroid medications, danazol, lithium, levodopa, metyrapone, and phenytoin (Dilantin).

Health care team roles

The testing physician will typically instruct the patient about preparatory steps for adrenocortical hormone tests, making recommendations for diet and for discontinuing medications. A nurse or a phlebotomist will perform a venipuncture to obtain blood samples. The phlebotomist or nurse should mark the laboratory slip with the time each blood sample was drawn and indicate any medications the patient may be taking. Laboratories will provide containers for urine collection and should help ensure compliance by providing written instructions for 24-hour urine collection. Laboratory technologists or nursing staff interacting with the patient may gently question the patient at the time of the blood test or urine collection to make sure they have discontinued medications prior to the test according to their doctor's instructions. When the 24-hour urine collection is completed, health care providers may remind the patient to resume medications if the testing physician has instructed them to do so. Measurements of adrenal hormones are performed by clinical laboratory scientists/medical technologists. Results are interpreted by a physician. In most cases, an endocrinologist is usually consulted.

Patient education

Patients must be instructed regarding changes in medications or diet, sources of sodium in the diet, and

maintaining an upright position prior to testing. Outpatients who will be collecting their urine specimens at home should have written instructions for the 24-hour urine collection. Health care providers should also encourage the patient to drink clear fluids regularly throughout the urine collection process.

Training

Laboratory technologists performing adrenocortical hormone tests will have studied biochemistry, enabling them to understand the role of these hormones in the body and the chemical basis for expression of the hormones in body fluids. Hands-on clinical laboratory training will prepare technologists to perform radioimmunoassay or other methods of measuring aldosterone and cortisol in blood and urine. Nursing personnel responsible for patients undergoing hormone testing for will understand the critical nature of preparation for these tests and help to encourage patient compliance. They will note any areas of non-compliance and inform the testing physician. Laboratory and nursing staff will be responsible for noting abnormal results and calling them to the attention of physicians.

Adrenocorticotrophic hormone test see
Pituitary hormone tests

Adrenomedullary hormone tests

Definition

Adrenomedullary hormone tests measure levels of the hormones epinephrine, norepinephrine, and dopamine found in **blood** and urine. This group of tests also includes urine tests for the catabolic products (break-down products) of these hormones, known alternately as metabolites. Epinephrine, norepinephrine, and dopamine, collectively called catecholamines, are manufactured by chromaffin cells in the medulla (center) of the **adrenal glands** and are derived from the amino acid tyrosine. They help ready the body for the “fight-or-flight” response, also known as the alarm reaction. When adrenomedullary hormones are released at times of **stress**, the **heart** beats stronger and faster, **blood pressure** rises, blood flow is increased to the **brain** and muscles, and the **liver** releases glucose (sugar) as energy the body can readily use. Simultaneously, the rate of breathing increases, airways in the **respiratory system** widen, and digestive activity slows. These reactions quickly direct more oxygen and fuel to the brain, heart, and **skeletal muscles**, the organs most active in responding to stress.

The adrenomedullary hormone tests (also called catecholamines, dopamine, norepinephrine, epinephrine, or adrenalin tests) may be performed on blood or urine specimens. Urine tests are also used to measure the metabolites vanillylmandelic acid (VMA), metanephrine and normetanephrine, and homovanillic acid (HVA). Catecholamines are released from the adrenal gland in pulses causing blood levels to be quite variable. Measurements of catecholamines and their metabolites in 24-hour urine samples are generally preferred because they are not subject to pulse variation.

Purpose

Only small amounts of adrenomedullary hormones are found in the urine of healthy people. Excessive levels may be secreted in conditions that affect hormone production, such as pheochromocytoma (a tumor of the chromaffin cells of the adrenal gland) and rare tumors of the nervous system (neuroblastomas, ganglioneuroblastomas, and ganglioneuromas). Elevated hormone levels often result in constant or intermittent high blood pressure (**hypertension**). Episodes of high blood pressure may be accompanied by symptoms such as headache, sweating, palpitations, and **anxiety**. The adrenomedullary hormone test can be ordered to help determine if high blood pressure is related to abnormal hormone secretion

and to either exclude a tumor as the underlying cause or to identify the type of tumor that may be increasing hormone levels.

Description

Adrenomedullary hormone tests are typically performed by medical technologists in the clinical laboratory on either blood plasma or 24-hour urine samples. If performed on blood, the test may require drawing one or two samples, depending on the physician's request. The objective may be to measure changes in adrenomedullary hormone production over a specific time period or in certain conditions, such as changes in temperature, posture, diet, or medications. The first blood sample will usually be drawn after the patient has been lying down in a warm, comfortable environment for at least 30 minutes. If a second sample is needed, the patient will be asked to stand for 10 minutes before the blood is drawn. Instead of a venipuncture, which can be stressful for the patient and can actually increase adrenomedullary hormone levels in the blood, a catheter (a small plastic tube-like device) may be inserted in a vein 24 hours in advance. This allows the blood sample to be collected without the stress of needle puncture at the time of the test.

Because blood levels of adrenomedullary hormones commonly go up and down in response to factors such as temperature, stress, postural change, diet, smoking, **obesity**, and certain drugs, abnormally high blood levels should be confirmed with a 24-hour urine test. It is also important to consider that hormone secretion from a tumor may not be steady, but may occur periodically during the day. Consequently, an elevation in hormone levels potentially could be missed if only the blood test is performed. By contrast, the urine test requires that all urine passed during a 24-hour period must be collected by the patient or a healthcare professional, ensuring that the urine specimen reflects hormone production over an entire day.

The recommended procedure for measuring catecholamines and their metabolites is chromatography. High-performance liquid chromatography with electrochemical detection (HPLC-EDC) or liquid chromatography with mass spectrometry detection (LC-MS) are both sensitive and specific and have the advantage of being able to measure epinephrine, norepinephrine, and dopamine simultaneously. HPLC-EDC is also the method of choice for simultaneous measurement of VMA and HVA, although this procedure requires different extraction and separation conditions than are used for catecholamines. VMA can also be measured by a column-diazo method that is free of interference from dietary vanillin. The VMA is extracted from the urine

and isolated on a silica gel column. The column is washed to remove interfering substances and the VMA is eluted and reacted with a diazonium salt to form a purple colored complex. Metanephrines are most often measured by HPLC-EDC or by gas chromatography-mass spectrometry. Immunoassay and radioenzymatic assays are also used for the measurement of catecholamines and metanephrines. These methods require enzymatic conversion to a derivative before measuring the catecholamine or metabolite.

Precautions

There are no notable precautions with either blood or urine tests for adrenomedullary hormones. Physicians will determine if restrictions for the tests are appropriate for patients being treated with medications for high blood pressure or heart disease. When blood is used, **universal precautions** should be followed for the prevention of transmission of bloodborne pathogens.

Preparation

Physicians will instruct patients to discontinue use of certain medications for up to two weeks before the test or will write orders to this effect for patients in nursing facilities. Drugs that may increase catecholamine levels include **caffeine**, nicotine, levodopa, lithium, amphetamine, clonidine, erythromycin, insulin, methyl dopa, tetracyclines, and nitroglycerin. Drugs that may decrease catecholamine levels include clonidine, imipramine, MAO inhibitors, phenothiazines, salicylates, and reserpine. The patient should fast (nothing to eat or drink) for 10 to 24 hours before the blood test and should cease smoking for 24 hours before testing. Other restrictions may be required either by individual physicians or by the laboratory, depending on the tests requested. Vigorous physical **exercise** and emotional stress should be avoided before the test to prevent alteration of test results by increasing secretions of epinephrine and norepinephrine.

The clinical laboratory will provide instructions and containers for patients collecting their own 24-hour urine samples. Catecholamines and their metabolites are rapidly degraded above pH 2.0. Therefore, 10 mL of 6N hydrochloric acid or concentrated sulfuric acid will be present in the container. Patients should be advised to avoid touching the preservative in the collection container. If the preservative comes in contact with the skin, the area should be rinsed with water immediately. Collection should begin in the morning on any day except Friday or Saturday to ensure that samples will be delivered to the laboratory on a work day. Urine samples must be refrigerated continuously in the patient's home or in the nurs-

ing facility. The specimen should be delivered to the laboratory promptly at the end of the 24-hour period.

Aftercare

Following venipuncture for blood plasma hormone tests, the laboratory technologist, nurse, or phlebotomist drawing the sample should inspect the venipuncture site to make sure that the wound has closed and no bleeding is present. The site should be covered with an adhesive bandage. There is no notable aftercare for patients undergoing 24-hour urine hormone tests. Patients can be reminded to resume foods and medications that were restricted prior to testing.

Complications

Complications from drawing blood are minimal and may include slight bleeding from the venipuncture site, fainting, or lightheadedness after the blood sample is drawn. Blood may accumulate under the puncture site (hematoma) if pressure is not applied to the site immediately after drawing blood. There are no complications for the urine test, although patients must avoid touching the preservative in the collection containers.

Results

Reference ranges are laboratory-specific and vary with age and according to the test methodology used. Normal values for blood and urine tests are different. High performance liquid chromatography (HPLC) is the most common test method. Other methods especially spectrophotometric and fluorometric determinations are less specific and give higher results. Urinary levels are influenced by renal function and it has become customary to report urinary catecholamines and their metabolites per gram of creatinine excreted especially when a random urine is used. Typical adult values for HPLC blood and urine tests follow.

Reference ranges for blood plasma hormone levels:

- Supine (lying down): Epinephrine less than 50 picograms per milliliter (pg/mL), norepinephrine less than 410 pg/mL, and dopamine less than 30 pg/mL.
- Standing: Values for blood specimens taken when the subject is standing are higher than the ranges for supine posture for epinephrine (less than 140 pg/mL) and norepinephrine (less than 1700 pg/mL), but not for dopamine.

Reference ranges for urine hormone levels:

- Epinephrine: 0.5 to 20 micrograms per 24 hours (mcg/24 hrs) or 0 to 20 micrograms per gram creatinine.

- Norepinephrine: 15 to 80 mcg/24 hrs or 0-45 mcg per gram creatinine.
- HVA: 65 to 400 mcg/24 hrs or 0 to 8 mg per gram creatinine.
- Total catecholamines: 14 to 110 mcg/24 hrs.
- VMA: 2 to 7 milligrams(mg)/24 hrs or 0 to 6 mg per gram creatinine.
- Metanephrine: 24 to 96 mcg/24 hrs or 0 to 300 mcg per gram creatinine.
- Normetanephrine: 75 to 375 mcg/24 hrs or 0 to 400 mcg per gram creatinine.

Elevated levels of the individual adrenomedullary hormones can indicate different conditions and/or causes, depending on which hormone or combination of hormones is elevated:

- Pheochromocytoma most commonly causes an increase in norepinephrine, metanephrines, and VMA although other catecholamines may also be increased. Measurement of 24-hour urinary metanephrines is considered the most sensitive test for this condition. When both metanephrines and VMA are used, the test approaches 100% in its clinical sensitivity. Neuroblastomas most frequently produce dopamine, norepinephrine, HVA, and VMA. HVA is the most specific marker since it is least likely to be increased in pheochromocytoma. The sensitivity with HVA alone is about 70%. The recommended initial tests for neuroblastoma includes both HVA and VMA to increase diagnostic sensitivity.
- Elevations of catecholamines and their metabolites are possible with, but do not directly confirm, thyroid disorders, low blood sugar (hypoglycemia), or heart disease.
- Electroshock therapy, or shock resulting from hemorrhage or exposure to toxins, can raise hormone levels.
- In the patient with normal or low baseline hormone levels, failure to show an increase in the sample taken after standing suggests an **autonomic nervous system** dysfunction (the division of the nervous system responsible for the automatic or unconscious regulation of internal body functioning).
- In the absence of a tumor or other clinical findings, elevated adrenomedullary hormones may indicate prolonged stress or acute anxiety. They may also be elevated during serious physical illness.

Health care team roles

A physician orders adrenomedullary hormone tests and will typically instruct the patient about preparatory

KEY TERMS

Catabolic—Catabolism and catabolic refer to the breakdown of complex substances in the body into simpler ones, which are called catabolic products.

Catecholamines—A collective term for the major adrenomedullary hormones epinephrine, norepinephrine, and dopamine. Catecholamines are known to be elevated in the presence of certain tumors, in severe stress, strenuous exercise, acute anxiety, and serious illness.

Dopamine—A precursor of epinephrine and norepinephrine. It is a neurotransmitter (transmits impulses between cells) primarily found in the brain.

Epinephrine—Also called adrenalin, is a naturally occurring hormone released by the medulla of the adrenal glands in response to signals from the sympathetic nervous system. These signals are triggered by stress, exercise, or by emotions such as fear.

Ganglioneuroma—A tumor composed of mature nerve cells.

Homovanillic acid (HVA)—A catabolic product or metabolite of the major adrenomedullary hormone dopamine.

Metanephrine—A catabolic product or metabolite of the adrenomedullary hormones epinephrine and norepinephrine.

Neuroblastoma—A rare tumor of the adrenal glands or sympathetic nervous system. Neuroblastomas can range from being benign (relatively harmless) to malignant.

Norepinephrine—A hormone secreted by nerve endings of the sympathetic nervous system and by the adrenal medulla. It is a neurotransmitter whose primary function is to help maintain constant blood pressure by stimulating certain blood vessels to constrict when blood pressure falls below normal.

Normetanephrine—A catabolic product or metabolite of the adrenomedullary hormone norepinephrine and epinephrine.

Pheochromocytoma—A tumor that originates from the overproduction of powerful adrenomedullary hormones by the chromaffin cells of the adrenal glands.

Vanillylmandelic acid—A product of catabolism of the adrenomedullary hormones metanephrine and normetanephrine.

steps required. A laboratory technologist, nurse, or a phlebotomist (someone specifically trained in venipuncture technique) will perform a venipuncture to obtain blood samples, collecting blood in a tube that contains anticoagulant. If two samples are drawn, this may take about 45 minutes. Health care providers may help encourage the patient to remain quiet and calm prior to the test and between the drawing of samples. Laboratories will provide containers for urine collection and should help ensure compliance by providing written instructions for 24-hour urine collection. Laboratory technologists or nursing staff interacting with the patient may gently question the patient at the time of the blood test or urine collection about fasting or about having discontinued the use of caffeine, nicotine, prohibited foods and medications prior to the test. Testing is performed by a clinical laboratory scientist/medical technologist.

Patient education

Because tests for adrenomedullary hormones are especially sensitive, patient compliance with restrictions is essential. It is important for outpatients undergoing the adrenomedullary hormone tests to receive written

instructions regarding dietary restrictions, changes in medications, and instructions for 24-hour urine collection. These instructions can be prepared by the laboratory and supplied to physicians and nursing units in health care facilities. Urine collection instructions should be written in a step-wise manner. Laboratory and nursing staff can explain each step, reminding the patient to refrigerate the urine at all times and deliver the container to the laboratory promptly at the end of the 24-hour period. Health care providers should also encourage the patient to drink clear fluids regularly throughout the urine collection process.

Training

Laboratory technologists performing adrenomedullary hormone tests will have undergone education and training in biochemistry, enabling them to understand the role of these hormones in the body and the chemical basis for expression of the hormones in body fluids. Hands-on clinical laboratory training will prepare technologists to perform HPLC or other methods of measuring adrenomedullary hormones in blood and urine. Nursing personnel responsible for patients undergoing testing for

adrenomedullary hormones must understand the critical nature of the preparation for these tests and help to encourage patient compliance. Laboratory and nursing staff will be responsible for noting abnormal results and calling them to the attention of physicians.

Adult day care

Definition

Adult day care describes programs, services, and facilities intended to assist physically or mentally impaired adults who might otherwise require institutionalization, allowing them to remain in the community. It is generally considered an alternative to institutional long-term care and rehabilitation.

Description

There are two general types of adult day care programs—a medical model and a social model. The medical model provides comprehensive medical, therapeutic, and rehabilitation day treatment. The social model offers supervised activities, peer support, companionship, and recreation. Both models assist older adults and those with chronic conditions to remain as independent as possible, for as long as possible.

Programs organized along the medical model lines are often called adult day health care to distinguish them from social programs. Adult day health care programs

offer health services such as physician visits, nursing care, and podiatry, as well as rehabilitation services such as physical, occupational, and speech therapy in a secure environment. This model of adult day care is offered to clients with a variety of chronic medical conditions including:

- adults with **Alzheimer’s disease**, other dementias, or depression
- patients recovering from stroke or head or **spinal cord** injuries
- patients with chronic diseases such as diabetes or cardiovascular disease
- adults with developmental disabilities such as Down syndrome
- adults suffering from mental illnesses
- frail older adults requiring nursing care and assistance daily living activities

The social model of adult day care emphasizes supervised group activities such as crafts, gardening, music, and **exercise**. Participants in this model may require some assistance with the activities of daily living (e.g., eating, bathing, dressing) but they generally do not require skilled nursing care. Like adult day health care facilities, these social programs generally provide transportation and a midday meal for clients, as well as caregiver support groups, information and referral services, and community outreach programs.

In 2005, there will be an estimated 36 million Americans aged 65 or older. According to U.S. Department of Labor statistics, the fastest growing segment of older adults is the population age 85 and older. About 80% of the frail elderly remain in the community and are cared for by relatives, most commonly by adult daughters. Today, however, an increasing number of women aged 35 to 54 are in the workforce and unable to care for aging parents or disabled adult children at home.

Though the clients of adult day care are the adults who attend the programs daily or several times each week, adult day care also meets the needs of families and other caregivers. Before women entered the workforce, they were available to care for relatives at home. Today, adult day care provides a secure, alternative source of care for women who work outside the home. It also offers respite, or much needed breaks, for caregivers. Older adults caring for spouses, or children caring for aging parents find adult day care helps ease the burden of caring for an ill, confused, or disabled family member.

The first adult day care centers opened in England during the 1940s and 1950s. Established by psychiatric hospitals, these centers were designed to reduce the fre-

KEY TERMS

Alzheimer's disease—Progressive dementia characterized by worsening memory and other cognitive impairment.

Geriatrician—Physician specializing in the care and treatment of older adults.

quency of hospital admissions. The first adult day care centers in the United States appeared during the early 1970s, and today there are more than 4,000 services and centers. Most centers and programs operate during business hours, Monday through Friday, but some offer weekend and evening care.

According to a 1997 survey conducted by the National Adult Day Service Association (NADSA), 34 states offer licensure of adult day care, but only 25 require licensure. Adult day care services or programs may be affiliated with hospitals, **nursing homes**, home health agencies, or senior centers, but many are unaffiliated, independent programs. They may be located in storefronts, senior centers, community health and medical centers, and nursing homes.

Among centers responding to the NADSA survey, the average enrollment (number of clients) was about 40; the average client age was 76; and about three quarters of clients lived with family. Nearly 80% of adult day centers offered nursing services, and approximately 90% are not-for-profit. Fees ranged from \$1 to \$200 per day, with an average of \$28 to \$43 dollars per day. As of 2001, **Medicare** does not pay for any type of adult day care; however, in 35 states, **Medicaid** can be used to pay for adult day care.

Viewpoints

Though fees for adult day care vary widely, the service is generally considered cost effective when compared with the cost of institutional care, such as skilled nursing facilities or even home health care. More importantly, adult day care enables older adults, persons with physical disabilities, and those with cognitive impairments to maintain their independence. Research has demonstrated that adult day care also reduces the risks and frequency of hospitalization for older adults. Adult day care satisfies two requirements of care; it provides a secure, protected environment and is often the least restrictive setting in which care may be delivered.

Quality and standards of care vary from state to state and from one center or program to another. NADSA and

the National Council on the Aging have developed standards and benchmarks for care, but adherence to these standards is voluntary. NADSA is currently developing a certification program for adult day center administrators and directors; there is already a certification process for program assistants. Since no uniform national standards exist, it is difficult for consumers to know whether a program or center is staffed by qualified personnel or provides appropriate services.

Generally, quality adult day care centers or programs conduct thorough assessments of each client and develop individualized plans of care and activities to meet the needs of the impaired, disabled, or frail older adults. The plans for each client describe objectives in terms of improvement or maintenance of health status, functional capabilities, and emotional well being. Centers must have high caregiver to client ratios to ensure safety, supervision, and close attention. Further, all personnel and volunteers should be qualified, trained, and sensitive to the special needs of the client population. For example, centers and services for persons with Alzheimer's disease or other dementias must take special precautions to ensure that clients can not wander away from the facility.

Professional implications

The aging population in the United States, the increasing incidence of Alzheimer's disease, and rising popularity of adult day care have created new and additional opportunities for health professionals and other care-giving and service personnel.

Along with nurses, physical, occupational, and speech therapists, adult day care centers employ:

- administrators, program, and activity directors
- recreational therapists and assistants
- health aides and program aides
- bus and van drivers
- social workers and counselors
- teachers and trainers

Advanced practice nurses

Definition

Advanced practice nurses are typically those nurses prepared at the master's or doctoral level, and they fall into four categories of clinicians: clinical nurse specialists, certified **registered nurse** anesthetists, nurse practitioners, and certified nurse-midwives.

Description

Clinical nurse specialists

Clinical nurse specialists (CNSs) are licensed registered nurses (RNs) with additional master's or doctorate-level training in CNS. These advanced practice nurses are clinical experts in theory-based or research-based nursing, focusing on specific specialty areas.

CNSs have broadened patient care roles because of their advanced training. In some states, they have the authority to prescribe medications.

CNSs assume many roles within the health care delivery system. While many are in the clinical setting, others work as educators, administrators, consultants, researchers, change agents, and case managers. CNSs can become specialized in the areas of adult psychiatry, child psychology, community health, home health, gerontology, and medical-surgical, as well as oncology, perinatal critical care, critical care, and rehabilitation. Some nurses in areas of specialty certification classify themselves as CNSs, others use the umbrella term of advanced practice nursing

In March 2000, the number of RNs prepared to practice in at least one advanced practice role was estimated to be about 7.3% of the total RN population. The largest group among the advanced practice nurses was the nurse

practitioners, followed by the CNSs. These two groups together made up about 80% of all advanced practice nurses. Although about 36.9% of the CNSs were employed in nursing, only about 24% were practicing under the position title of CNS. Nearly 25% of CNSs reported working in **nursing education** positions.

Certified registered nurse anesthetist

Nurse anesthesia is the oldest of the advanced nursing specialties. These advanced clinical nurses, called certified registered nurse anesthetists (CRNAs), administer about 65% of the anesthetics given to patients annually in the United States.

Nurse anesthetists make up the third largest group of advanced practice nurses, and were the first professional group in the United States to provide anesthesia services in the 1800s. Their role in surgery is to keep patients as comfortable, **pain** free, and safe as possible. Nurse anesthetists perform patient physical assessments; take part in preoperative teaching; develop, prepare, and implement the anesthesia plan; select, obtain, and administer anesthesia and other medications and fluids needed to manage the anesthetic; maintain anesthesia throughout the operation and manage the patient's airway and pulmonary status; respond as necessary to emergency situations ensuring **airway management**, administering emergency fluids or medications, and performing cardiac life support techniques; and follow patients through recovery and into the patient care unit. Essentially, they take care of patients before, during, and after having surgery or giving birth.

CRNAs can sub-specialize in pediatric, obstetric, cardiovascular, plastic, dental, or neurosurgical anesthesia. Some have credentials in critical care nursing and respiratory care.

Nurse practitioner

Nurse practitioners (NPs) are registered nurses who have advanced academic and clinical experience. Because of this additional training, NPs can diagnose and manage common and chronic illnesses, independently or as part of a health care team. Nurse practitioners often can provide primary care previously offered only by doctors and, in many states, they prescribe medications. While in many cases NPs work in collaboration with physicians, NPs have the authority to practice without a physician collaboration or supervision in 18 states.

NPs perform physical exams; diagnose and treat many acute illnesses and injuries; provide immunizations; manage high **blood pressure**, diabetes, and other chronic conditions; order and interpret x rays and other lab tests; and counsel and educate patients about how

they can live healthy lifestyles. NPs focus much of their practice on health maintenance, disease prevention, **patient education**, and counseling. While they have a strong emphasis on primary care, NPs practice in a wide variety of specialties, including neonatology, ob-gyn, pediatrics, school health, family and adult health, mental health, **home care**, geriatrics, and acute care.

Certified nurse-midwife

Certified nurse-midwives (CNMs) focus on the independent management of women's health care, particularly on **pregnancy**, **childbirth**, the postpartum period, care of the newborn and the family planning, and gynecological needs of women. They have the authority to write prescriptions. CNMs deliver babies in all types of health care settings, as well as in private homes, and provide primary health care to women, often helping them to realize personal fulfillment through labor and birth. CNMs work independently and in collaboration with other health care providers. They also teach and conduct research.

The trend seems to be that more people are choosing CNMs. As of 1998, there were nearly 278,000 CNM-attended births in the United States. About 400 nurse-midwives pass the national certification exam each year. The practice of nurse-midwifery is legal in all states and the District of Columbia. These advanced practice nurses have prescription-writing ability in 50 states and jurisdictions. Ninety percent of all visits to CNMs are for primary and preventive care. Seventy percent of that was for care during pregnancy and after birth, while 20% was for care outside of the maternity cycle.

Work settings

Clinical nurse specialists

CNSs work in the acute care, long-term care, and intermediate care settings. They work in clinical education within health care facilities, as well as in nursing education programs as faculty teaching nursing. Other settings in which CNSs work include outpatient and ambulatory care, private practice, home health, physician office practice, sub-acute care, government or military service, community health centers, health care administration, private industry (working for drug companies or manufacturers, in managed care and other areas of the private sector), and nurse-managed centers. Within these categories, CNSs work in assisted living facilities; specialized hospital areas, such as **cardiac catheterization** labs; correctional facilities; dialysis units; parish nursing; and psychiatric hospitals.

Certified registered nurse anesthetist

Nurse anesthetists can work with an physician anesthesiologist, independently or in groups as providers of anesthetics. They work as part of a medical team or independently in any setting in which anesthesia is given, including doctors' and dentists' offices, pain clinics, operating rooms of hospitals, and ambulatory surgery settings. CRNAs who work independently or in groups might have contracts with physicians or hospitals. Some CRNAs work in private practices, while others choose the public sector or the U.S. military. They work in universities as instructors and in research settings as investigators, collaborators, consultants, assistants, interpreters, and researchers. CRNAs also work in surgical and obstetric environments in MRI units, cardiac catheterization labs, and **lithotripsy** units. In these environments, they provide consultation and implementation of respiratory and ventilatory care, manage emergency situations, and start or participate in airway maintenance, ventilation, and tracheal intubation during **CPR**.

Nurse practitioner

Nurse practitioners work in metropolitan area clinics and hospitals, as well as in rural areas, inner cities, and medically underserved locations. They work in schools, caring for children, and in **nursing homes** and assisted living facilities, caring for the elderly and others. NPs work in pediatric, family health, women's health, and other specialty settings. Some work in private practices or in nurse-run group practices.

Certified nurse-midwife

CNMs work in clinical practice in public, university, and military hospitals. They also work in health maintenance organizations, private practices, and birthing centers. Many practice in public health clinic, and some provide home birth services. More than 50% of CNMs work most often in the office or clinic environment, listing a hospital or physician practice as their employer.

Education and training

Clinical nurse specialists

Nurses must have a baccalaureate degree or its equivalent to enroll in a CNS program. To use the title of CNS, the CNS must have a minimum of a master's degree from an education program that prepares CNSs. The training is graduate-level education. Some universities have a fast track program whereby they will accept individuals who do not have a baccalaureate and move them into a master's program. CNSs also take a certifica-

tion exam in a specialty, offered by one of the nationally recognized certification entities.

CNS students go through advanced theory and practice training, revolving around the three areas of influence that impact on direct patient care, supervising direct patient care, and patient care systems.

The American Nurses Credentialing Center certifies CNSs as adult psychiatric, child psychology, community health, home health, gerontology, and medical-surgical CNSs. There also are other certifying bodies, including the Rehabilitation Nursing Certification Board, Oncology Nursing Certification Corporation, and American Association of Critical Care Nurses Certification.

The doctoral-level CNS typically focuses on research.

Certified registered nurse anesthetist

Nurse anesthetists are registered nurses who complete two to three years of higher education, beyond the bachelor's of nursing degree or other appropriate baccalaureate degree. They attend accredited nurse anesthesia education programs, covering all areas of anesthesia. After completing an accredited program, nurse anesthetists must pass a national certification exam to obtain the CRNA designation.

The education for a **nurse anesthetist** involves about 24 to 36 months of graduate course work. It includes classroom and clinical experience.

In most cases, to be accepted into an accredited school, those who aspire to become nurse anesthetists must have an appropriate four-year degree, an RN license, and at least one year of acute care nursing experience, which varies by program.

Nurse practitioner

NPs receive their advanced educations through programs that award master's degrees. RNs who aspire to become NPs should have extensive clinical experience before applying to an NP program. NP programs include the components of an intensive preceptorship under the direct supervision of a physician or experienced NP and instruction in nursing theory. An increasing number of nurses are becoming prepared as both NPs and CNSs. Those prepared in both roles are more likely to function as nurse practitioners.

Certified nurse-midwife

CNMs are educated in the two disciplines of nursing and midwifery. They must possess evidence of certification according to the requirements of the American College of Nurse-Midwives. Being an RN is a require-

ment to become a certified nurse-midwife. In some cases, those with baccalaureate degrees in other fields are considered. Upon graduation, CNMs can receive MS (master's of science), MSN (master's of science in nursing), MPH (master's of **public health**) degrees or a doctoral degree. About 68% of CNMs have master's degrees, while 4% have doctoral degrees. There are also those who graduate with a certificate or from a nurse-midwifery education program. However, the number of states and employers who require master's-prepared CNMs is increasing. Once in the program, student CNMs receive labor and delivery experience in different types of settings. They must pass a national certification exam to call themselves CNMs.

Advanced education and training

All advanced practice nurses with master's degree can go on to get their doctorate degrees. Often, those with doctorate-level training go into research, administration, or teaching at the university level.

Future outlook

The outlook is good for all types of nurses, especially those at the RN level or higher. It is projected that if current trends continue, demand will exceed supply of RNs by about 2010. It is possible that as many as 114,000 jobs for full-time-equivalent RNs are going to go unfilled nationwide by 2015. This is due to a growing elderly population with mounting health care needs, an aging RN workforce, the expansion of primary care, and technological advances that require more highly trained nurses.

There is a growing demand for RNs with advanced clinical skills. Almost all who graduate have jobs waiting for them.

Aerobic testing see **Endurance testing**

Aerosol drug administration

Definition

Aerosol drug administration is the administration of a drug via air particles delivered by an appropriate device that is inhaled and absorbed into the patient's body via the **lungs**.

Purpose

Aerosol administration of drugs is indicated in circumstances where rapid absorption and localization effects of the drug are required to produce the appropriate response. Aerosol administration methods are most commonly used in asthmatic conditions or specific lung conditions that cause difficulty in breathing. Diseases including **emphysema**, **asthma**, chronic obstructive pulmonary disease (COPD), and other similar conditions warrant and necessitate the use administration of drugs by this route of administration.

Precautions

Aerosol administration in itself is generally a safe practice, as long as the health care provider or client is well educated in its use. It is contraindicated in conditions where complete obstruction of the airway is present, as the administration route is completely blocked. Such conditions, however, are usually resolved rapidly in emergency situations.

Description

Aerosol drug administration, also known as inhalation therapy, or in some cases, nebulized drug therapy, is the method by which drugs are dispersed into the lungs or bronchial airways in the form of tiny droplets—often

bound to water, oxygen, or another gaseous substance. Drugs are generally delivered by two means. The first is via a device called a nebulizer. The nebulizer is a mechanical pump (of which there are many types) that produces a fine mist in which the drug is dispersed via an appropriate nebulizer-compatible face mask. This fine mist is inhaled deep into the lungs for maximum effect. The second method of delivery is via a hand-held, nebulized aerosol device. These devices, also known as “puffers,” use the effects of a pressurized gas to create and disperse the drug into a fine mist or spray, which is then inhaled.

Both methods of aerosol inhalation are very effective when used correctly. In cases of extreme breathlessness or dyspnea (labored or difficult breathing), the mechanical pump nebulizers are generally more effective, as they disperse the drug over a longer time period; this, in turn, gives the recipient a longer time period, allowing the airways to open more effectively.

In terms of medical treatment costs and medication costs, aerosol drug administration is relatively inexpensive. Nebulized therapy via a mechanical pump is usually completed within five to ten minutes. Delivery of drug via hand-held devices is completed within a few seconds.

Procedure for effective mechanical pump nebulization

- The nebulizer solution and equipment specific to the type of pump being used should be prepared. If necessary, the instruction guides should be consulted. (Detailed instruction is beyond the scope of this guide due to the vast number and variety of pumps available.)
- An appropriate face mask is obtained.
- The recipient should be placed in a comfortable, upright position that is greater than 45 degrees. This will enable maximum breathing efficiency. A hospital bed with an adjustable backrest, or a chair with good back support, is adequate. The comfort of the recipient should be ensured and maintained throughout the procedure.
- The client should be reassured. Often, when a patient is suffering from breathing difficulty, he or she becomes anxious and frightened. The nurse should do his or her best to relax and reassure the patient as much as possible. When relaxed, the airway has the best chance of recovery, and inhalation of the nebulized drug is assured.
- When patient is comfortable and in a suitable position, the nebulizer pump can be turned on. The nurse must

confirm that a steady mist is flowing from the mask or application device.

- When a steady flow of mist is achieved, the nurse should fit the mask or application device correctly to the patient's face or trachea (if applicable).
- While nebulization and delivery of drug is occurring, the patient should be monitored for signs of reaction to the drug and for improvements or deterioration in breathing patterns.
- Once the procedure is complete, the patient's oxygen saturation level should be measured, if equipment is available. This measurement should be recorded and reported along with any other documentation.
- The recipient should be asked if the medication has had a positive effect. If not, further advice or orders should be sought from the physician.
- The nurse should provide education about delivery of the drug by inhalation to the recipient. He or she should also answer questions the recipient may have.

Procedure for inhalation from hand-held devices

- Again, there are many devices available that operate in different manners. A detailed description of each, however, is beyond the scope of this guide.
- For effective delivery of drug from these type of devices, it is essential that the medication is prepared properly, using the instructions supplied with the device.
- Once the medication has been prepared, the recipient must hold his or her lips one to two inches (3-5 cm) from the open mouth. The patient needs to breathe in deeply (powdered-drug-type devices), or breathe in deeply while depressing the canister (for canister/barrel type devices); this will allow the drug to be inhaled deeply into the airways and lung tissue.
- Positive responses should be observed or measured by the nurse.
- All data, as appropriate, must be recorded by the nurse. If treatment is not effective, further advice or orders should be sought.

Preparation

Generally, there are no specific pretreatment procedures, except for the set-up of equipment used for the procedure. The recipient generally requires no personal preparation in common use of this procedure.

Aftercare

Recipients should be monitored for signs of positive response to the drug. It is important to rinse the mouth

following inhalation therapy, as drug residue can remain in the mouth and cause oral problems and tooth decay in some instances.

Complications

Complications are almost always related to the type of drug being delivered. Complications may also arise due to drug **overdose**. It is important in a hospital or clinic emergency environment, particularly with asthma sufferers, that the health care provider assess how much, and what type of medication, has been administered prior to the patient's arrival in the emergency department, to avoid such complications.

Results

Anticipated outcome for symptom-relieving drugs

In a lung or breathing condition, the desired outcome from symptom-relieving aerosol drugs is a complete cessation of such symptoms or at least an improvement in symptoms following completion of the treatment. Failure to relieve symptoms indicates ineffective drug delivery, incorrect drug choice or strength, or deterioration of the patient's condition.

Anticipated outcome for preventive drugs

While more difficult to measure (as effects can be both short- or long-term), the goal of using preventive medications via this specific delivery route is to prevent or reduce presentation of symptoms. A reduction in the occurrence of symptoms, or a complete cessation of associated symptoms, indicates a successful preventive treatment regime.

Health care team roles

The health care team roles for successful treatment include:

- All equipment used in the procedure should be maintained and used according to the manufacturers' specifications.
- All treatment options must be explained to the patient.
- The recipient should be monitored during delivery of inhalation therapy.
- All events and observations for the procedure should be recorded.
- The recipient must be educated in all aspects of his or her condition, including the reasons for the use of specific treatments and drugs.

Aging and the aged

Definition

Aging is the process of growing older, a process that includes physical changes and, sometimes, mental changes. “The aged” refers to elderly people, those who have reached an advanced age.

Description

The concept of aging and the aged has changed, as record numbers of people around the world are living longer, a trend expected to continue throughout the twenty-first century and beyond.

The word “elderly” used to refer to an older person, generally someone age 65 or older. At the beginning of the twentieth century, 65 was considered an advanced age. The life expectancy for a baby born in 1900 was 51 years for a girl and 48 years for a boy. That year, approximately one in 25 Americans was over 65.

By the 1930s, legislation set older adults apart from the rest of American society. Social Security laws declared that people had to retire from work by age 65. The ruling affected about 7.5 million people during the 1930s.

At the end of the twentieth century, the older population had increased 10 times since 1900. In 2000, approximately 35 million people age 65 and older accounted for 13% of America’s population, according to *Older Americans 2000: Key Indicators of Well-Being*, a

2000 report from the Federal Interagency Forum on Aging Related Statistics. According to the report, by 2030 70 million Americans will be 65 or older.

Since the late twentieth century, the age group growing fastest in many countries has been the “very old” or the “oldest old.” Opinions vary about the age classification for this group. The United States federal government defines this group as people 85 and older. The United Nations (U.N.) classifies people 80 and older in this demographic group.

The oldest age group includes the rapidly increasing number of centenarians, people age 100 or older. In the United States, the number of centenarians is projected to grow from about 60,000 in 2000 to some 2 million by the middle of the twenty-first century.

The demographic revolution

Advances in areas such as health care, medicines like **antibiotics**, and **nutrition** during the twentieth century mean that more people are living longer. An American baby born at the turn of the twenty-first century is expected to live nearly 30 years longer than one born a century earlier, according to *Older Americans 2000*.

The increase in life expectancy during the late twentieth century is believed to be as high or higher than any increase from recorded time until 1900. In many countries, one out of 10 people was 60 or older in 2000, according to *The Ageing of the World’s Population*, a 2000 report from the U.N. Division for Social Policy and Development. The ratio of people over 60 was projected to change to one out of five in 2050 and one out of three in 2150, according to the report.

At the same time that more people are living longer, people around the world are having fewer children. The lower birth rate is attributed to the availability of family planning methods. The combination of a growing older population and a declining birth rate has produced a demographic revolution that the U.N. predicts will continue into subsequent centuries.

These demographic trends affect what the U.N. calls the “old-age dependency balance,” the relationship between the number of people age 65 and older and the number of working people age 15 to 64.

Traditionally in the United States, younger workers have supported older people through wage deductions for programs such as Social Security. During the first half of the twenty-first century, the U.N. estimated that the old-age dependency ratio will double in more developed areas and triple in less developed areas.

With a smaller pool of workers, organizations around the world are studying methods to ease the

Commonly used instruments for geriatric patients

Instrument	Administered by	Answered by	Score range (poor–good)
Folstein mini mental state	Interviewer	Subject	0–30
Katz activities of daily living	Interviewer	Proxy	0–6
Lawton instrumental activities of daily living	Interviewer, self-administered	Proxy or subject	9–27
Tinetti balance & gait evaluation	Interviewer, self-administered	Subject	0–28
Yesavage geriatric depression scale	Interviewer, self-administered	Subject	15–30

dependency burden. One method of accomplishing this is to help older adults remain healthy and independent for as long as possible. Not only does this benefit the aging person, but health care costs are also reduced.

The demographic revolution has political, social, and economic significance. Of primary concern is how to provide health care for the growing number of older people, especially those 85 and older. Generally, the oldest old need more health services than younger people.

The aging process

It used to be thought that as people aged, their bodies became “worn out” over time and then they died. As the body deteriorates, a person may experience signs of aging, resulting in the need for dentures or the presence of a chronic disease. Although methods of prolonging life are well-known, opinions vary about why people age.

A range of factors is thought to contribute to aging, either alone or in combination. For example, a healthy person whose parents led long lives could expect to live many years. The probability of a long life would be increased if the population receives adequate health care, and modifies unhealthy lifestyle behaviors.

FACTORS AFFECTING THE AGING PROCESS. Factors that affect the aging process include:

- **Heredity.** A person whose parents and grandparents lived to an advanced age could expect to live longer. On the other hand, a person could inherit the susceptibility to a disease that shortens life. In addition, **stress** affects health, and the ability to cope with stress is also believed to be inherited.
- **Senescence.** Theories about aging focus on the reason cells stop dividing and age. Some scientists believe that cells begin to age when a person is fully grown. Others theorize that excess DNA accumulates and obstructs cell activity. Another theory is based on the effect of chemical compounds called free radicals on the system. The compounds located in the body and the environ-

ment can accelerate conditions such as **heart** attacks and diabetes.

- **Physiology.** The collective functioning of the body’s components affects how long a person lives.
- **Biology.** Traditionally, women live longer than men. Scientists believe this is due to the female sex hormones.
- **Lifestyle.** The choices a person makes when younger can affect health later in life. A person who smoked cigarettes, took drugs, did not eat nutritionally, or failed to get enough **exercise** or sleep may suffer poor health years later. For example, smoking is attributed to numerous conditions ranging from **cancer** to gum diseases.
- **Psychological factors.** Feelings of self-confidence are linked to a longer life. Conversely, low self-esteem and negative attitudes about being old may impair health. This can lead to feelings of depression and loneliness.

PHYSICAL SIGNS OF AGING. How a person ages varies, however, the aging process includes some general characteristics such as:

- Lowering of the basal **metabolism** (the rate of energy production in the body cells). People may tire more easily and be more sensitive to changes in the weather.
- Reduction of strength, endurance, and ability.
- Change in eyesight. People who wear glasses may experience **presbyopia**, a form of farsightedness. Bifocals or reading glasses allow the person to read print that appears too small. Other aging people who never needed corrective lenses may need to wear eyeglasses. Some older people may be diagnosed with eye conditions such as **glaucoma** and **cataracts**.
- Change in **hearing**. Generally, older people have more difficulty hearing high tones but can hear low tones. A hearing aid may be prescribed.
- **Dental changes.** Gums may recede, and this can lead to tooth decay. Lack of proper **oral hygiene** earlier in life may result in the removal of all or some of the natural teeth. Dentures may be required.

Leading causes of death in persons 65 and older

Cause of death	Number of deaths	Percentage of all deaths in those ≥ 65 years old
All causes	1,542,493	100.0
Heart disease	594,858	38.6
Malignant neoplasms, including neoplasms of lymphatic and hematopoietic tissues	345,387	22.4
Cerebrovascular diseases	125,409	8.1
Chronic obstructive pulmonary disease and associated conditions	72,755	4.7
Pneumonia and influenza	70,485	4.6
Diabetes mellitus	35,523	2.3
Accidents and adverse effects	26,213	1.7
Motor vehicle accidents	7,210	0.5
All other accidents and adverse effects	19,003	1.2
Nephritis, nephrotic syndrome, and nephrosis	17,306	1.1
Atherosclerosis	17,158	1.1
Septicemia	15,351	1.0
All other causes	222,048	14.4

SOURCE: National Center for Health Statistics, 1993.

- **Osteoporosis** (a condition characterized by reduced bone density and brittle bones). This condition, more common in women, can lead to bone fractures.
- Muscle strength and body tone may diminish.
- Organ function may slow down.
- As skin ages, cells hold less water, and there is less fat tissue. Skin becomes dry and wrinkled.
- Hair loses its pigment (color) and turns white or gray.
- Sexual desire and ability may decrease. Drugs such as Viagra allow men to perform, and products such as lubricants can help women.
- Reproduction. Aging men can still father children. After **menopause**, women are usually unable to bear children.
- The senses of **taste**, touch, and **smell** may diminish over time.

MENTAL SIGNS OF AGING. Generally, age has little effect on the mind. While it is true that older people do not learn as quickly, once something is learned, the information is retained more accurately. However, the **brain** like the body, must be exercised. That exercise can take the form of learning something new. However, most adults, not just the aging, may experience **anxiety** about returning to classes. People who teach adults effectively

make their students feel welcome. They also realize that adults remember more of what is relevant to them.

As people advance in age, they may experience **memory** loss. This is frequently treatable. In addition, a stimulated mind is thought to help avoid the memory loss that has been associated with aging. Emotional health can affect physical health, with conditions such stress, loneliness, and depression leading to illness in people of all ages.

DEMENTIA AND ALZHEIMER'S DISEASE. One-third or more people age 85 and older have moderate or severe memory impairment. Memory loss can be a symptom of **Alzheimer's disease**, a progressive condition that is not reversible. Before more was known about Alzheimer's, the disease was thought to be a natural symptom of aging. It is still not easy to diagnose and can be mistaken for **dementia**. Although many of those diagnosed with Alzheimer's are older than 65, the disease also affects people in their 40s and 50s. There was no known cure as of the spring of 2001.

AGE-RELATED HEALTH CONDITIONS. Advanced age doesn't cause disease in itself, but the possibility that some chronic conditions will develop increases as a person ages. These conditions include arthritis and other musculoskeletal disorders that could affect mobility.

However, the prevalence of arthritis and other chronic diseases like **hypertension**, heart disease, cancer, diabetes, and stroke varies by ethnicity in the United States. Furthermore, an ongoing healthy lifestyle can help prevent illness and disease later in life. For an older adult, that lifestyle should include exercise, a proper diet to avoid malnutrition, and vaccinations such as flu shots.

Viewpoints

Retirement brings many changes to aging people. After working throughout their lives, they may want to relax and get into a routine of sitting and watching television. They may experience a loss of identity after defining themselves by their work for so many years.

The aging lifestyle

After retirement, it is crucial to overall health for a person to find hobbies, social activities, or interests that challenge both mind and body. Most cities in the United States have senior centers that offer lunch programs where people can socialize. Center classes range from line dancing to journal writing. In addition, volunteer opportunities for older adults include serving with law enforcement and as tutors. Many older people remain socially active through contact with friends, family, and neighbors. In addition, more older people are physically active.

Agism and activism

For centuries, cultures including the Native Americans, Samoans, and Chinese honored the older members of their societies. These people respected their elders for their wisdom and experience. However, negative attitudes about the aged date back to ancient times. The Greek philosopher Socrates cited his age as one reason that he planned to commit suicide by taking hemlock. He was 70 years old.

Furthermore, some primitive societies regarded the aged and ailing as burdens. In some situations, people were murdered or given assistance in committing suicide. Assisted suicide was the subject of much debate during the late twentieth century and remains an issue in the twenty-first century, with people divided about whether or not a person has the right to choose to die.

Health issues are just one factor for those who view older people as a burden to society. Negative stereotypes about the aged include the view that they are useless because they don't work and therefore don't contribute to society. This prejudice against older people is known as agism, sometimes spelled "ageism." This negative attitude can be traced in part to the fact that older people are visual reminders of aging and death. In addition, during the second half of the twentieth century, the media celebrated youth as a valued commodity. The appearance of an older person was seen as a rarity, as when Renee Russo appeared in the 1999 movie, *The Thomas Crown Affair*. Much was made of the fact that she was in her 40s.

Older people took a stand during the 1970s. Maggie Kuhn founded the Gray Panthers, a group that continues to fight agism. The American Association of Retired Persons campaigned and continues to advocate for older people. Both groups champion older adults as vital people with much to contribute to society.

The older population of the late twentieth century now includes Baby Boomers. The first Boomers turned 50 in the late 90s, and this group is expected to vigorously campaign for the rights of the aging and the aged.

Furthermore, with mandatory retirement abolished, people in their 90s and 100s worked at jobs that they enjoyed in 2000, according to the *New York Times*. However, that same year, agism surfaced after the U.S. presidential election. Disputed election results in Florida led to jokes on TV and the Internet about the incompetence of older voters.

National trends

While older people may share a chronological age, they vary according to their ethnic heritage, economic

status, interests, and education. Some are healthy and active; others are frail and not as active. According to *Older Americans 2000*, the ethnic make-up of people age 65 and older in 2000 was 84% non-Hispanic white, 8% non-Hispanic black, 6% Hispanic, 2% non-Hispanic Asian and Pacific Islander, and less than 1% American Indian and Alaska native. Population percentages are predicted to change by the year 2050 to 64% non-Hispanic white, 16% Hispanic, 12% non-Hispanic black, 7% non-Hispanic Asian and Pacific Islander, and less than 1% American Indian and Alaska native.

The report indicated that older Americans in 2000 were better educated than older people in 1950. The higher education level "positively" influenced health and socio-economic status.

People age 85 and older are the most likely to live in **nursing homes**. About three-fourths of nursing home residents are women, which reflects their predominance in the population.

A NATIONAL MODEL. Government, the medical community, and numerous organizations are studying issues associated with the ever-increasing aging population. An overview of the issues facing the aging and the aged is demonstrated by the scope of the activities of the U.S. Department of Health and Human Services (HHS) in 2000. Programs and projects included research on the aging process, aging and disease, Alzheimer's, and the relationship between the aging and society. Other HHS activities included a seniors nutrition program, and services and studies related to care at home and long-term care facilities.

International trends

Globally, the average lifespan increased by 20 years during the last half of the twentieth century, according to the U.N. At the end of the century, a 60-year-old woman living in a developed region could expect to live 22 years longer. A man that age could expect to live 18 years longer. In a less developed region, a woman who reaches age 60 could expect to live 16 years longer, while a 60-year-old man in that area could expect to live 14 years longer.

A sampling of other international trends includes:

- People age 60 and older accounted for one in five Europeans and one in 20 Africans in 2000. In developing countries, the growth of the aging population is more rapid than in developed countries. Therefore, developing countries have less time to adjust to the expansion of their aging populations.
- In developing countries, older people continue to work. In Zimbabwe, 82% of men and 70% of women age 60

KEY TERMS

Chronic disease—A condition lasting a long time.

Cognitive—Able to know or perceive.

Geriatrics—The branch of medicine concerned with the prevention, diagnosis, and treatment of conditions in aging people and the aged.

Gerontology—The study of the aging process and conditions associated with this process.

and older worked during the year 2000. Some non-wage earners worked at home caring for children, worked on farms, or did other household projects that allowed other relatives to work for pay.

- More than 25% of people age 75 and older live in China and India.
- In many Asian and African countries, more than half of women age 60 and older are widowed. Only 10–20% of men in that age group outlived their spouses.
- Women outlive men almost everywhere. At age 60, there are 99 men for every 100 women. By age 90, there are only 69 men for every 100 women.

A EUROPEAN MODEL. Concern about promoting health and preventing illness led the European Commission to start the Megapoles Project in 1997. Part of the project involved looking at the elderly in the capital cities of Amsterdam, Athens, Brussels, Copenhagen, Dublin, Helsinki, Lisbon, London, Madrid, Oslo, Stockholm, and Vienna. The review, “Growing Old in Metropolitan Areas” (GOMA), found three major issues in those cities:

- Prevention of social isolation and loneliness. The goals include promoting individual self-confidence that would lead to a more positive perception by others.
- Early detection of dementia, Alzheimer’s disease, and the implementation of a project to provide individual competence. The project involves the elderly, their relatives, and caregivers.
- Providing a safer environment that protects older people from accidental **falls**, road traffic, and “firm vigilance” towards violence directed at the elderly.

A 2001 report on GOMA included examples of successes. Cities such as Vienna have day centers that offer therapeutic and health promotion services. Stockholm has a special bus with wheelchair ramps that transports seniors to their destinations after morning rush hour. Furthermore, programs in London reach out to older people

who may feel isolated for various reasons, for example, a lack of language skills. Intergenerational projects can serve three groups targeted by Megapoles Project: the elderly, the disadvantaged, and youth and young families. For example, one facility serves as a day center for the elderly and a kindergarten. Young and old interacted and socialized.

Another London project linked older people to social services through their milkman. This was aimed at people who didn’t leave their homes. Isolation can lead to impaired mobility and cognitive skills, so the milkman “casually” checks in daily and may encourage visits from social service workers. This delivery person calls for help if milk isn’t taken indoors.

Furthermore, senior centers in Madrid and Helsinki provide information about topics such as health, nutrition, exercise, and home safety.

IMPLICATIONS ACROSS BORDERS. The GOMA report acknowledged that not all senior projects can be exported to other cities. And for those living in the United States, most programs are recognizable. Handicapped-accessible public transportation is required by law. National, state, and city agencies are concerned with the elderly. Senior centers in many cities offer health programs, physical activities, and classes.

The GOMA report maintained that dialog throughout the world about the aged and implementation of programs for this group are crucial. The goal of dialog and programs is to help the aged feel secure, socially integrated, and mentally healthy. Not only do these dialogs and programs benefit the aging population, they provide some relief to health providers and caregiving institutions.

Professional implications

In 1965 the federal government created **Medicare**, a health insurance program for people age 65 and older. In 1999, Medicare spending totaled \$181 million for the 39 million older and disabled people enrolled in the program.

The cost of health care for the aging population is among the issues that will be debated throughout the twenty-first century as the old-age dependency burden shifts to fewer younger people. This could lead to further discussion of health care rationing, i.e. whether the decision to provide some health care should be limited because of a person’s advanced age. This issue was discussed in an article titled “Does Ageism Affect Health Care Rationing?” (found on the Novartis Foundation web site <www.healthandage.com>). The author cited an incident described in a 1998 issue of the medical journal, the

Lancet. Both articles concerned an 88-year-old woman who stopped breathing three minutes after admission to a hospital emergency room. At issue was whether the woman should be revived since the admitting physician thought she would die anyway. The doctor revived the woman, who was still doing well several years later.

The Novartis Foundation writer pointed out that rationing wouldn't have been an issue with a younger patient. The writer maintained that age should not be an issue when determining whether to provide health care. The author warned that this issue is complex. In some cases, a patient may face a lingering death.

Debate will continue about **euthanasia**, mercy killing, and the right-to-die. Opponents of these procedures fear that patients may be pressured to end their lives. In some cases, this pressure may be based on rising health care costs.

Such debates will affect some members of the medical profession as they are faced with patients and families needing guidance. In addition, the shift to an ever-growing older population will affect health care in the twenty-first century.

On a more positive note, strategies to delay illness later in life benefit the elderly and help keep costs down. For example, delaying the onset of Alzheimer's disease by five years would cut its incidence in half and result in a saving of \$50 billion annually in the United States.

This preventive treatment should focus on patients of all ages. The healthcare team should emphasize to patients that aging is an ongoing process, so that lifelong preventive measures such as diet and exercise are the best tools for long-term health.

Treating the older patient

For the older patient, the goal of treatment is to help a patient remain physically, mentally, and socially active for as long as possible. To achieve this goal:

- Patients above the age of 60 should have an annual comprehensive health assessment.
- Vitamins and inoculations are important.
- Patients should be advised that **calcium** from sources such as milk and dairy products is crucial for fighting osteoporosis and keeping teeth and bones strong.
- Diet should maintain the recommended body weight, so that a patient is not overweight or too thin. A low-fat diet is recommended because aging results in a lessening of fat-digesting enzymes.
- Patients should be reminded that regular exercise produces benefits that include well-being, good circulation, and good respiration. Exercise helps a person

maintain coordination and mobility. Even if a person is in a wheelchair or bed, exercise will produce beneficial results.

- Early treatment to help prevent or lessen a risk of conditions such as cataracts or glaucoma.

The future

Since the aging population is growing and continues to increase, all health care professionals and staffs should receive geriatric training. The demographic trend also creates a demand for people with expertise in gerontology and geriatrics. Other career opportunities include work in long-term care facilities, health education for the aged, and home health care.

In addition, working with the aged prompts people in the nursing and allied health fields to take a look at their lives and those of their relatives. In doing so, they can make adjustments so that they can attempt to live long and healthy lives.

AIDS

Definition

Acquired immune deficiency syndrome (AIDS) is an infectious disease caused by the human **immunodeficiency virus (HIV)**. AIDS is the advanced form of **infection** caused by HIV and typically only manifests itself after a long latency period after initial HIV infection. AIDS is a fatal disease for which there is currently no cure.

Description

First recognized in the United States in 1981, AIDS is considered one of the most devastating **public health** problems in recent history. The Centers for Disease Control and Prevention (CDC) has estimated that, as of June 2000, between 800,000 and 900,000 people in the United States were HIV-positive, and 312,000 were living with AIDS. Of adult AIDS cases, 47–53% were believed to have contracted HIV from same sex male intercourse, 25–31% from intravenous drug use, and 10% from heterosexual contact. There are an estimated 40,000 new HIV infections each year in the U.S. The Joint United Nations Program on HIV/AIDS estimates that, worldwide during the year 2000, an estimated 3 million people had died of AIDS, and 34.7 million adults

and 1.4 million children were living with HIV/AIDS. Approximately 95% of persons with HIV/AIDS were living in developing countries.

Risk factors

HIV/AIDS can be transmitted in several ways. The various routes of transmission (and associated risk factors) include:

- Sexual contact. Persons at greatest risk are those who do not practice safe sex (sex with a condom), those who are not monogamous, those who engage in anal intercourse, and those who have sex with a partner with symptoms of advanced HIV infection and/or other sexually transmitted diseases (STDs). In the United States and Europe, most cases of sexually transmitted HIV infection arise via same sex contact, whereas in Africa the disease is spread primarily through heterosexual intercourse.
- Transmission in **pregnancy**. High-risk mothers include women who use intravenous drugs, women who have sex with bisexual men, women who are married to men who have an abnormal **blood** condition called **hemophilia** (a condition requiring blood transfusions), and women living in areas with a high rate of HIV infection among heterosexuals. The chances of transmitting HIV from mother to child are higher in women who are in advanced stages of the disease. Breast feeding increases the risk of transmission by 10%-20%, and vaginal delivery doubles the risk of transmitting HIV to the child. Zidovudine (AZT) given to the mother during pregnancy and given to the baby soon after delivery have been shown to decrease the risk of HIV transmission to the child.
- Exposure to contaminated blood or blood products. With the introduction of blood product screening in the mid-1980s, the incidence of HIV transmission in blood transfusions has dropped to 1 in 100,000. Among users of intravenous drugs, risk increases with the duration of injection use, the frequency of needle sharing, the number of persons who share a needle, and the number of AIDS cases in the local population.
- Exposure of health care professionals to infected blood. Studies have shown that 0.32% of highly exposed health care workers have become infected with HIV through occupational exposure. Needle injuries are the most common exposure route. Risk factors for contracting HIV from a needle injury include a deep injection, a needle that has been used in an artery or vein, blood visibly apparent on the needle prior to injury, and blood from a patient with end-stage AIDS. There is evidence that administration of zidovudine (AZT) to the

injured worker soon after HIV exposure decreases risk of infection.

HIV is not transmitted by handshakes, coughing, sneezing, or other casual non-sexual contact. There is currently no evidence that HIV can be transmitted through bloodsucking insects such as mosquitoes.

AIDS in women

HIV remains an important cause of death and illness in women. In the US, AIDS was the fifth leading cause of death among women aged 25-44 in 1998. In 1999, 32% of new HIV diagnoses were in women. Although HIV infected women have been observed to die earlier than men, it is believed that this difference in survival rates is caused by differences in access to care and delayed treatment rather than biological differences in disease progression.

AIDS in children

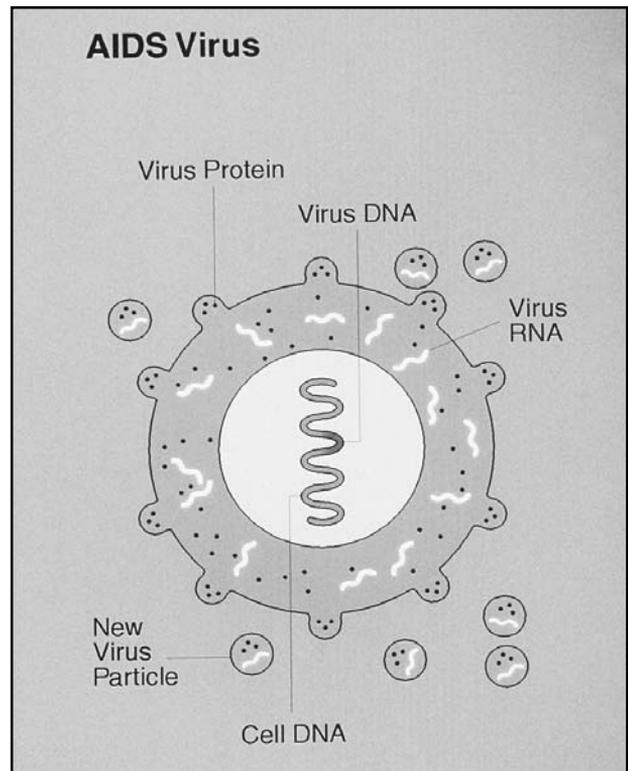

Since AIDS can be transmitted from an infected mother to the child during pregnancy, during the birth process, or through breast milk, all infants born to HIV-positive mothers are a high-risk group. In 1999, 78% of new HIV cases in women were in females of childbearing age. Without prenatal intervention, between 20-40% of children born to HIV-positive women will become infected with the virus.

AIDS is one of the 10 leading causes of death in children between one and four years of age. The interval between exposure to HIV and the development of AIDS is shorter in children than in adults. Infants infected with HIV have a 20-30% chance of developing AIDS within a year and dying before age three. In the remainder, AIDS progresses more slowly; the average child patient survives to seven years of age. Some survive into early adolescence.

Causes and symptoms

Because HIV destroys **immune system** cells, AIDS is a disease that can affect any of the body's major organ systems. HIV attacks the body through three disease processes: immunodeficiency, autoimmunity, and nervous system dysfunction.

Immunodeficiency describes the condition in which the body's **immune response** is damaged, weakened, or is not functioning properly. In AIDS, immunodeficiency results from the way that the virus binds to a protein called CD4, which is found on the surface of certain subtypes of white blood cells, including helper T cells, macrophages, and monocytes. Once HIV attaches to an immune system cell, it can replicate within the cell and

The AIDS virus. (National Institutes of Health. Reproduced by permission.)

kill the cell in ways that are still not completely understood. In addition to killing some lymphocytes directly, the AIDS virus disrupts the functioning of the remaining CD4 cells. Because the immune system cells are destroyed, many different types of infections and cancers that take advantage of a person's weakened immune system (opportunistic) can develop.

Autoimmunity is a condition in which the body's immune system produces antibodies that work against its own cells. Antibodies are specific **proteins** produced in response to exposure to a specific, usually foreign, protein or particle called an antigen. In this case, the body produces antibodies that bind to blood platelets that are necessary for proper blood clotting and tissue repair. Once bound, the antibodies mark the platelets for removal from the body, and they are filtered out by the spleen. Some AIDS patients develop a disorder, called immune-related thrombocytopenia purpura (ITP), in which the number of blood platelets drops to abnormally low levels.

HIV also infects some susceptible cells in the **central nervous system**. The exact mechanism of HIV entry into the **brain** is unknown. Possible modes of entry across the blood-brain barrier include HIV entry as a single cell-free viral particle (virion), entry via infected

monocyte or lymphocyte, and infection of endothelial cells (cells forming brain border). Regardless of the mechanism, evidence suggests that the cerebral spinal fluid is seeded with HIV very early in the infection process.

Although not all patients will follow them precisely, the course of AIDS generally progresses through the three stages (acute retroviral syndrome, latency period, and late-stage AIDS) that follow.

Acute retroviral syndrome

Acute retroviral syndrome is a term used to describe a group of symptoms that can resemble mononucleosis and that may be the first sign of HIV infection in 50-70% of all patients and 45-90% of women. The symptoms may include **fever**, fatigue, muscle aches, loss of appetite, digestive disturbances, weight loss, skin rashes, headache, and chronically swollen lymph nodes (lymphadenopathy). Approximately 25-33% of patients will experience a form of **meningitis** during this phase in which the membranes that cover the brain and **spinal cord** become inflamed. Acute retroviral syndrome develops between one and six weeks after infection and lasts for two to three weeks. Blood tests during this period will indicate the presence of virus (viremia) and the appearance of the viral p24 antigen in the blood.

Latency period

After the HIV virus enters a patient's lymph nodes during the acute retroviral syndrome stage, the disease becomes latent for as many as 10 years or more before symptoms of advanced disease develop. During latency, the virus continues to replicate in the lymph nodes, where it may cause one or more of the following conditions.

PERSISTENT GENERALIZED LYMPHADENOPATHY (PGL). Persistent generalized lymphadenopathy, or PGL, is a condition in which HIV continues to produce chronic painless swellings in the lymph nodes during the latency period. The lymph nodes that are most frequently affected by PGL are those in the areas of the neck, jaw, groin, and armpits. PGL affects between 50-70% of patients during latency.

CONSTITUTIONAL SYMPTOMS. Many patients will develop low-grade fevers, chronic fatigue, and general weakness. HIV may also cause a combination of food malabsorption, loss of appetite, and increased **metabolism** that contribute to the so-called AIDS wasting or wasting syndrome.

OTHER ORGAN SYSTEMS. At any time during the course of HIV infection, patients may suffer from a yeast infection in the mouth called thrush, open sores or ulcers,

or other infections of the mouth; **diarrhea** and other gastrointestinal symptoms that cause malnutrition and weight loss; diseases of the **lungs** and **kidneys**; and degeneration of the nerve fibers in the arms and legs. HIV infection of the nervous system leads to general loss of strength, loss of **reflexes**, and feelings of numbness or burning sensations in the feet or lower legs.

Late-stage AIDS

Late-stage AIDS is usually marked by a sharp decline in the number of CD4+ lymphocytes, followed by a rise in the frequency of opportunistic infections and cancers. Doctors monitor the number and proportion of CD4+ lymphocytes in the patient's blood in order to assess the progression of the disease and the effectiveness of different medications. About 10% of infected individuals never progress to this overt stage of the disease.

OPPORTUNISTIC INFECTIONS. Once the patient's CD4+ lymphocyte count falls below 200 cells/mm³, the patient is at risk for a variety of opportunistic infections. The infectious organisms may include the following:

- **Fungi.** The most common fungal disease associated with AIDS is *Pneumocystis carinii* **pneumonia** (PCP). About 70%-80% of AIDS patients will have at least one episode of PCP prior to death. PCP is the immediate cause of death in 15-20% of AIDS patients. It is an important measure of a patient's prognosis. Other fungal infections include a yeast infection of the mouth (candidiasis or thrush) and cryptococcal meningitis.
- **Protozoa.** Toxoplasmosis is a common opportunistic infection in AIDS patients that is caused by a protozoan. Other diseases in this category include amebiasis and cryptosporidiosis.
- **Mycobacteria.** AIDS patients may develop **tuberculosis** or MAC infections. MAC infections are caused by *Mycobacterium avium-intracellulare*, and occur in about 40% of AIDS patients.
- **Bacteria.** AIDS patients are likely to develop bacterial infections of the skin and digestive tract.
- **Viruses.** AIDS patients are highly vulnerable to cytomegalovirus (CMV), herpes simplex virus (HSV), varicella zoster virus (VZV), and Epstein-Barr virus (EBV) infections. Another virus, JC virus, causes progressive destruction of brain tissue in the brain stem, cerebrum, and cerebellum (multifocal leukoencephalopathy or PML), which is regarded as an AIDS-defining illness by the Centers for Disease Control and Prevention.

AIDS DEMENTIA COMPLEX AND NEUROLOGIC COMPLICATIONS. AIDS **dementia** complex is a late complication of the disease. It is unclear whether it is caused by

the direct effects of the virus on the brain or by intermediate causes. AIDS dementia complex is marked by loss of reasoning ability, loss of **memory**, inability to concentrate, apathy and loss of initiative, and unsteadiness or weakness in walking. Some patients also develop seizures. There are no specific treatments for AIDS dementia complex.

MUSCULOSKELETAL COMPLICATIONS. Patients in late-stage AIDS may develop inflammations of the muscles, particularly in the hip area, and may have arthritis-like pains in the joints.

ORAL SYMPTOMS. In addition to thrush and painful ulcers in the mouth, patients may develop a condition called hairy leukoplakia of the tongue. This condition is also regarded by the CDC as an indicator of AIDS. Hairy leukoplakia is a white area of diseased tissue on the tongue that may be flat or slightly raised. It is caused by the Epstein-Barr virus.

AIDS-RELATED CANCERS. Patients with late-stage AIDS may develop Kaposi's sarcoma (KS), a skin tumor that primarily affects homosexual men. KS is the most common AIDS-related malignancy. It is characterized by reddish-purple blotches or patches (brownish in persons with darker skin) on the skin or in the mouth. About 40% of patients with KS develop symptoms in the digestive tract or lungs. KS may be caused by a herpes virus-like sexually transmitted disease agent rather than HIV.

The second most common form of **cancer** in AIDS patients is a tumor of the **lymphatic system** (lymphoma). AIDS-related lymphomas often affect the central nervous system and develop very aggressively.

Invasive cancer of the cervix is an important diagnostic marker of AIDS in women.

Diagnosis

Because HIV infection produces such a wide range of symptoms, the CDC has drawn up a list of 34 conditions regarded as defining AIDS. The physician will use the CDC list to decide whether the patient falls into one of these three groups:

- definitive diagnoses with or without laboratory evidence of HIV infection
- definitive diagnoses with laboratory evidence of HIV infection
- presumptive diagnoses with laboratory evidence of HIV infection

Physical findings

Almost all the symptoms of AIDS can occur with other diseases. The general **physical examination** may

range from normal findings to symptoms that are closely associated with AIDS. These symptoms are hairy leukoplakia of the tongue and Kaposi's sarcoma. When the doctor examines the patient, he or she will look for the overall pattern of symptoms rather than any one finding.

Laboratory tests for HIV infection

BLOOD TESTS (SEROLOGY). The first blood test for AIDS was developed in 1985. At present, patients who are being tested for HIV infection are usually given an enzyme-linked immunosorbent assay (ELISA) test for the presence of HIV antibody in their blood. Positive ELISA results are then tested with a Western blot or immunofluorescence (IFA) assay for confirmation. The combination of the ELISA and Western blot tests is more than 99.9% accurate in detecting HIV infection within four to eight weeks following exposure. Indeterminate test results are possible (positive ELISA but non-confirmatory Western blot result) if the tests are given within the window period after infection (up to eight weeks after infection, but may be longer). In these indeterminate cases, the ELISA and Western blot should be repeated every three months until a definitive result is made. The patient should be considered HIV positive until proven otherwise. The polymerase chain reaction (PCR) test can be used to detect the presence of viral nucleic acids in the very small number of HIV patients who have false-negative results on the ELISA and Western blot tests.

OTHER LABORATORY TESTS. In addition to diagnostic blood tests, other blood tests are used to track the course of AIDS in patients that have already been diagnosed, including blood counts, viral load tests, p24 antigen assays, and measurements of β_2 -microglobulin (β_2M).

Doctors will use a wide variety of tests to diagnose the presence of opportunistic infections, cancers, or other disease conditions in AIDS patients. Tissue biopsies, samples of cerebrospinal fluid, and sophisticated imaging techniques, such as **magnetic resonance imaging** (MRI) and computed tomography scans (CT) are used to diagnose AIDS-related cancers, some opportunistic infections, damage to the central nervous system, and wasting of the muscles. Urine and stool samples are used to diagnose infections caused by parasites. AIDS patients are also given blood tests for **syphilis** and other sexually transmitted diseases.

Diagnosis in children

Diagnostic blood testing in children older than 18 months is similar to adult testing, with ELISA screening confirmed by Western blot. Younger infants can be diagnosed by direct culture of the HIV virus, PCR testing, and p24 antigen testing.

KEY TERMS

Acute retroviral syndrome—A group of symptoms resembling mononucleosis that often are the first sign of HIV infection in 50-70% of all patients and 45-90% of women.

AIDS dementia complex—A type of brain dysfunction caused by HIV infection that causes difficulty thinking, confusion, and loss of muscular coordination.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—Any substance that stimulates the body to produce antibody.

Autoimmunity—A condition in which the body's immune system produces antibodies in response to its own tissues or blood components instead of foreign particles or microorganisms.

CD4—A type of protein molecule in human blood, sometimes called the T4 antigen, that is present on the surface of 65% of immune cells. The HIV virus infects cells that have CD4 surface proteins, and as a result, depletes the number of T cells, B cells, natural killer cells, and monocytes in the patient's blood. Most of the damage to an AIDS patient's immune system is done by the virus' destruction of CD4+ lymphocytes.

Hairy leukoplakia of the tongue—A white area of diseased tissue on the tongue that may be flat or slightly raised. It is caused by the Epstein-Barr virus and is an important diagnostic sign of AIDS.

Hemophilia—Any of several hereditary blood coagulation disorders occurring almost exclusively in males. Because blood does not clot properly, even minor injuries can cause significant blood loss that may require a blood transfusion, with its associated minor risk of infection.

Human immunodeficiency virus (HIV)—A transmissible retrovirus that causes AIDS in humans. Two forms of HIV are now recognized: HIV-1, which causes most cases of AIDS in Europe, North and South America, and most parts of Africa; and HIV-2, which is chiefly found in West African patients. HIV-2, discovered in 1986, appears to be less virulent than HIV-1 and may also have a longer latency period.

Immunodeficient—A condition in which the body's immune response is damaged, weakened, or is not functioning properly.

Kaposi's sarcoma—A cancer of the connective tissue that produces painless purplish red (in people with light skin) or brown (in people with dark skin) blotches on the skin. It is a major diagnostic marker of AIDS

Latent period—Also called incubation period, the time between infection with a disease-causing agent and the development of disease.

Lymphocyte—A type of white blood cell that is important in the formation of antibodies and that can be used to monitor the health of AIDS patients.

In terms of symptoms, children are less likely than adults to have an early acute syndrome. They are, however, likely to have delayed growth, a history of frequent illness, recurrent ear infections, a low blood cell count, failure to gain weight, and unexplained fevers. Children with AIDS are more likely to develop bacterial infections, inflammation of the lungs, and AIDS-related brain disorders than are HIV-positive adults.

Treatment

Because AIDS is a fatal disease, AIDS therapies focus on improving the quality and length of life for AIDS patients by slowing or halting the replication of the virus, and treating or preventing infections and cancers

that take advantage of a person's weakened immune system. No vaccine is effective in preventing HIV infection.

Treatment for AIDS covers four considerations:

TREATMENT OF OPPORTUNISTIC INFECTIONS AND MALIGNANCIES. Most AIDS patients require complex long-term treatment with medications for infectious diseases. This treatment is often complicated by the development of resistance in the disease organisms. AIDS-related malignancies in the central nervous system are usually treated with radiation therapy. Cancers elsewhere in the body are treated with **chemotherapy**.

PROPHYLACTIC TREATMENT FOR OPPORTUNISTIC INFECTIONS. Prophylactic treatment is treatment that is given to prevent disease. AIDS patients with a history of *Pneumocystis pneumonia*; with CD4+ counts below 200

KEY TERMS CONTINUED

Lymphoma—A cancerous tumor in the lymphatic system that is associated with a poor prognosis in AIDS patients.

Macrophage—A large white blood cell, found primarily in the bloodstream and connective tissue, that helps the body fight off infections by ingesting the disease-causing organism. HIV can infect and kill macrophages.

Monocyte—A large white blood cell that is formed in the bone marrow and spleen. About 4% of the white blood cells in normal adults are monocytes.

***Mycobacterium avium* (MAC) infection**—A type of opportunistic infection that occurs in about 40% of AIDS patients and is regarded as an AIDS-defining disease.

Non-nucleoside reverse transcriptase inhibitors—A newer class of anti-retroviral drugs that work by inhibiting the reverse transcriptase enzyme necessary for HIV replication.

Nucleoside analogue reverse transcriptase inhibitors—The first group of effective anti-retroviral medications. They work by interfering with HIV synthesis of its viral DNA.

Opportunistic infection—An infection by organisms that usually do not cause infection in people with healthy functioning immune systems.

Persistent generalized lymphadenopathy (PGL)—A condition in which HIV continues to produce chronic painless swellings in the lymph nodes during the latency period.

***Pneumocystis carinii* pneumonia (PCP)**—An opportunistic infection caused by a fungus that is a major cause of death in patients with late-stage AIDS.

Progressive multifocal leukoencephalopathy (PML)—A disease caused by a virus that destroys white matter in localized areas of the brain. It is regarded as an AIDS-defining illness.

Protease inhibitors—A new class of anti-retroviral drugs used to treat AIDS that works by preventing the HIV protease enzyme from generating new functioning HIV viruses.

Protozoan—A single-celled, usually microscopic organism that is eukaryotic and, therefore, different from bacteria (prokaryotic).

Retrovirus—A virus that contains a unique enzyme called reverse transcriptase that allows it to replicate within new host cells.

T cells—Lymphocytes that originate in the thymus gland. T cells regulate the immune system's response to infections, including HIV. CD4 lymphocytes are a subset of T lymphocytes.

Thrush—A yeast infection of the mouth characterized by white patches on the inside of the mouth and cheeks.

Viremia—The measurable presence of virus in the bloodstream that is a characteristic of acute retroviral syndrome.

Wasting syndrome—A progressive loss of weight and muscle tissue caused by the AIDS virus.

cells/mm³ or 14% of lymphocytes; weight loss; or thrush should be given prophylactic medications. The three drugs given are trimethoprim-sulfamethoxazole, dapsone, or pentamidine in aerosol form.

ANTI-RETROVIRAL TREATMENT. In recent years researchers have developed drugs that suppress HIV replication, as distinct from treating its effects on the body. These drugs fall into three classes:

- **Nucleoside reverse transcriptase inhibitors (NRTIs).** These drugs work by looking very similar to the molecules acted upon by the HIV enzyme reverse transcriptase. Reverse transcriptase binds to these drugs, which in turn stop the viral replication process. These drugs include zidovudine, didanosine (ddi), zalcitabine (ddC),

stavudine (d4T), lamivudine (3TC), and abacavir (ABC).

- **Non-nucleoside reverse transcriptase inhibitors (NNRTIs).** These drugs de-activate the HIV enzyme reverse transcriptase. This class of drugs includes nevirapine (NVP), delavirdine (DLV), and efavirenz (EFV).

Protease inhibitors. A new class of drugs, protease inhibitors are effective against HIV strains that have developed resistance to nucleoside analogues and are used in combination with them. These compounds include saquinavir (SQV), ritonavir (RJV), indinavir (IDV), nelfinavir (NFV), and amprenavir (APV).

New combinations of therapies are also being developed, primarily to improve adherence. Trizivir for the treatment of HIV in adults and adolescents is a fixed-

Risk of acquiring HIV infection by entry site

Entry site	Risk virus reaches entry site	Risk virus enters	Risk inoculated
Conjunctiva	Moderate	Moderate	Very low
Oral mucosa	Moderate	Moderate	Low
Nasal mucosa	Low	Low	Very low
Lower respiratory	Very low	Very low	Very low
Anus	Very high	Very high	Very high
Skin, intact	Very low	Very low	Very low
Skin, broken	Low	High	High
Sexual:			
Vagina	Low	Low	Medium
Penis	High	Low	Low
Ulcers (STD)	High	High	Very high
Blood:			
Products	High	High	High
Shared needles	High	High	Very high
Accidental needle	Low	High	Low
Traumatic wound	Modest	High	High
Perinatal	High	High	High

SOURCE: Hopp, J.W. and E.A. Rogers. *AIDS and the Allied Health Professions*. Philadelphia: F.A. Davis Co., 1989.

dose combination of abacavir, zidovudine, and lamivudine. Another combination therapy, Combivir, combines lamivudine and zidovudine. Both Trizivir and Combivir are combinations of NRTIs that combine drugs into a single dosage, making it easier for patients to comply with their dosage regimens.

Treatment guidelines for these agents are continually being modified as new medications are developed and introduced. Guidelines for when to start anti-retroviral therapy have been published separately by the International AIDS Society—United States and U.S. Department of Health and Human Services. These guidelines are very similar and base their recommendations on a patient's CD4 counts, viral load, and clinical symptoms.

In terms of specific treatment approaches, the January 2000 guidelines from the U.S. Department of Health and Human Services suggest two strategies for initial treatment, both of which use combinations of drugs: two nucleosides and a protease inhibitor, or two nucleosides and a non-nucleoside drug. Over time, treatment changes may be required; factors that must be considered when changing treatment regimens include drug toxicity, clinical symptoms, viral load, CD4 counts, adherence to current and future medications, and other viable treatment options.

STIMULATION OF BLOOD CELL PRODUCTION. Because many patients with AIDS suffer from abnormally low levels of both red and white blood cells, they may be given medications to stimulate blood cell production.

Epoetin alfa (erythropoietin) may be given to anemic patients. Patients with low white blood cell counts may be given filgrastim or sargramostim.

Treatment in women

Treatment of pregnant women with HIV is particularly important because anti-retroviral therapy has been shown to reduce transmission to the infant by 65%.

Prognosis

No cure for AIDS has been discovered. Treatment stresses aggressive combination drug therapy for those patients with access to the expensive medications and who tolerate them adequately. The use of these multi-drug therapies, called highly active antiretroviral therapies or HAART, has significantly reduced the numbers of deaths in the United States resulting from AIDS. The data is still inconclusive, but the potential exists to prolong life indefinitely using these and other drug therapies to boost the immune system, keep the virus from replicating, and ward off opportunistic infections and malignancies.

Prognosis after the latency period depends on the patient's specific symptoms and the organ systems affected by the disease. Patients with AIDS-related lymphomas of the central nervous system die within two to three months of diagnosis; those with systemic lymphomas may survive for eight to ten months.

Health care team roles

The physician oversees the treatment strategy and patient evaluation for patients who are HIV-positive and/or have AIDS. Adherence to treatment is a critical aspect of clinical care in AIDS, and nurses play a key role in educating patients and providing them with adherence tools. Nurses, social workers, and psychologists can also be trained as HIV counselors to advise patients about HIV testing and, if necessary, to assist and guide patients in adjusting to a life with HIV. During end-stage AIDS, nurses, social workers, and other hospice workers ensure that patients do not experience unnecessary **pain** and discomfort.

Prevention

As of 2000, there is no vaccine effective against HIV/AIDS. Several vaccines are being investigated, however, both to prevent initial HIV infection and as a therapeutic treatment to prevent HIV from progressing to full-blown AIDS.

Several types of prevention programs have been found to be effective in reducing sexual transmission of HIV. These include:

- targeted education for at-risk groups, emphasizing preventive practices such as condom use, monogamy, and HIV testing prior to beginning a sexual relationship
- counseling with or without testing for HIV and other sexually transmitted diseases
- education programs in institutions such as the military, prisons, and the workplace
- greater access to condoms

Preventive measures for other modes of transmission include:

- Making clean needles more available and discouraging intravenous drug users from sharing needles.
- Encouraging health care professionals to take all necessary precautions by wearing gloves and masks when handling body fluids.
- Encouraging health care institutions to provide safer medical devices such as self-sheathing needles and retracting and/or needleless intravenous systems.
- Informing individuals who are planning to undergo major surgery that they can donate blood in advance to prevent a risk of infection from a blood transfusion. (However, blood and blood products are carefully monitored.)
- Encouraging testing for HIV infection if there has been suspected exposure to HIV. If HIV infection is confirmed, sexual partners should be informed and, if necessary, receive medical attention.

AIDS counseling

Definition

AIDS counseling is a specialized branch of counseling or social work that deals with the prevention of the disease and the treatment of clients who have been diagnosed with human **immunodeficiency** virus (HIV) or acquired immunodeficiency syndrome (AIDS).

KEY TERMS

AIDS—Acquired immunodeficiency syndrome, caused by infection with HIV.

BSW—Baccalaureate degree in social work.

HIV—Human immunodeficiency virus, a pathogen that gradually destroys the immune system and eventually causes death.

Lay person—Person who performs a job effectively with little or no special training.

Long-term care—A facility that provides nursing and basic needs care when a client is no longer able to receive that care at home.

MSW—Master's degree in social work.

Needs assessment—Interview conducted by a counselor with client and family, to review charts and interview other health workers to determine what specific services are required by client.

Description

The AIDS epidemic created a specialized niche for the treatment of the disease. Counselors and social workers who work in this particular field help clients who are directly affected by HIV and AIDS meet their personal, medical, financial and emotional needs. They also educate both patients and the public about the disease.

AIDS counselors teach the general public about the causes and risk factors of AIDS, and the steps necessary to prevent HIV **infection**. Education is also required for the people who have already been infected with HIV. AIDS counselors teach their clients how to prevent the spread of the disease via safe sexual practices, responsible **prenatal care**, and treatment for drug addiction.

Education about the disease, although very important, is only a small part of AIDS counseling. Because AIDS affects a wide spectrum of the population, counseling needs are as varied as those of the clients. AIDS counseling may cover substance abuse, mental health problems, preparation for death, medication and treatment approaches, financial needs, prenatal care, child care, family dynamics, and homelessness. Some of these needs require licensed professionals such as physicians, pharmacists, and psychologists to help the client; others simply require a caring lay person to help the client find the right services.

Social workers are highly involved in AIDS counseling because of the nature of their profession. Social

workers act as advocates for patient's rights, arrange for community support, make arrangements for patients to go to long-term care facilities, find funds to pay for housing and medication, link the patients to social service and community outreach programs, arrange and lead support groups, plan for **home care**, and counsel the patients and their families.

Work settings

AIDS counselors work in a variety of locations, including hospitals, community outreach clinics, **public health** clinics, **hospices**, or mental health and substance abuse facilities.

AIDS counselors work varying hours, depending upon the requirements of the facility in which they work. Often the hours are 8 A.M. to 5 P.M., Monday through Friday, but counselors or social workers may be required to work evenings or weekends, and may be on call for hospices and hospitals.

Education and training

Professional counselors are required to have at least a master's degree in counseling, although education, training, and licensing requirements vary from state to state. Psychologists must have a master's degree or a Ph.D in psychology. Professional counselors are required to have 900 hours of field work or an internship.

The minimum educational requirement for social workers is a bachelor's degree in social work (BSW). However, people who hold a undergraduate degrees in another discipline such as psychology or sociology may also qualify for entrance-level jobs in AIDS counseling.

BSW programs prepare students for direct care of clients. Students who major in social work must complete 400 hours of supervised field work in addition to courses in social work practice, social work policies, human behavior and social environment, research methods, social work values and ethics, study of populations at risk, and the promotion of social justice.

An advanced degree is the standard for many positions in social work including positions within the field of health care. A master's degree in social (MSW) allows the social worker to be certified for clinical and supervisory work.

Advanced education and training

The National Association of Social Workers requires social workers to complete 90 hours of continuing education classes every three years to continue their certification in the profession. Licensed professionals with

advanced degrees may be required to complete more than 90 hours of continuing-education classes.

Future outlook

AIDS counseling is a growing profession. The national Bureau of Labor Statistics predicts that growth will continue at a rate exceeding that for other occupations until at least 2008. There are several reasons why AIDS counseling continues to grow:

- increased awareness of AIDS and increased funding for prevention and treatment
- advanced medical treatment of AIDS patients
- longer life expectancy of patients
- growth of home health care and agencies now serving AIDS patients
- replacement of workers seeking career change
- stress and burnout among counselors and social workers, causing them to leave profession
- increase in population of people living with AIDS

AIDS tests

Definition

AIDS tests, short for acquired **immunodeficiency** syndrome tests, cover a number of different procedures used in the diagnosis and treatment of HIV-infected patients. Tests that measure antibodies to the human immunodeficiency virus (HIV) are called AIDS serology tests. Serology is the branch of immunology that deals

with the identification and measurement of antibodies in serum which indicate the presence of disease or immunity to disease. Serum is the normally clear light yellow noncellular portion of **blood** that forms after the sample is allowed to clot. Some AIDS tests measure HIV antigens or nucleic acid rather than antibodies produced in response to HIV **infection**. AIDS tests evaluate the presence of HIV in blood serum, and the effects of HIV infection on the patient's **immune system**.

Purpose

AIDS serology tests have several uses. Some AIDS tests are used to diagnose patients or confirm a diagnosis; others are used to measure the progression of the disease or the effectiveness of specific treatment regimens. Some AIDS tests can also be used to screen blood donations for safe use in transfusions.

In order to understand the different purposes of the blood tests used for AIDS patients, it is helpful to understand how HIV infection affects the immune system. HIV is a retrovirus that enters the blood stream of a new host in the following ways:

- sexual contact, including oral and anal intercourse
- entry of HIV infected body fluids (such as blood or urine) through a cut or break in the skin
- transmission during **pregnancy**
- using or being pricked by a needle that had previously been used by or on an infected person
- transfusion of infected blood products

A retrovirus is a virus that contains two identical strands of RNA and a unique enzyme called reverse transcriptase that converts the viral RNA to DNA within the host cell. Another viral enzyme called integrase inserts this proviral DNA into the host cell genome. Other viral **proteins** control the process of transcription which forms RNA copies of the inserted DNA, production of structural viral proteins, assembly of immature virus particles, maturation, and release (budding) from the host cell. The entire process takes 12-24 hours.

The primary host cell for HIV is the T helper cell. The HIV envelope contains a glycoprotein called gp120, which binds to a surface molecule on the T helper cell called CD4. Other types of lymphocytes which lack the CD4 molecule are not infected. In addition to T helper cells, HIV can infect phagocytic cells (macrophages, monocytes, and dendritic cells) which serve as reservoirs and spread the virus throughout the body. The virus can also infect certain tissue cells such as **neurons**, which in part accounts for some of the underlying pathology of HIV disease.

HIV disease begins as a flu-like illness two to six weeks after infection which subsides without treatment. Antibodies to the viral envelope appear eight to 12 weeks after infection. Most patients enter a phase of clinical latency, which on average lasts eight to 10 years. This is followed by gradual loss of CD4 positive lymphocytes (T helper cells). T helper cells produce a substance called interleukin-2 (IL-2), which stimulates other cells (T cells and B cells) in the human immune system to respond to infections. Without the IL-2, the **immune response** collapses and patients become susceptible to a wide range of infections. Depletion of T helper cells signals the onset of opportunistic infections, malignancy, **dementia**, and a constellation of other diseases associated with AIDS.

There are no medical restrictions on administering AIDS tests. Most tests are performed on blood, but a screening test using urine is available. Health care professionals should always follow standard precautions recommended by the Centers for Disease Control (CDC) to reduce the possibility of accidental needlestick injury or exposure to the patient's blood and body fluids. This includes wearing latex gloves, washing hands before and following venipuncture, and using disposable needles and safety devices.

Description

Diagnostic tests

Diagnostic blood tests for AIDS are usually given to persons in high-risk populations, pregnant females, health care and public service workers who have been exposed to HIV, or those who have symptoms associated with AIDS. The condition of testing positive for HIV antibody in the blood is called seroconversion, and persons who are HIV-positive are called seroconverters.

AIDS tests used to diagnose infection fall into two categories, screening tests and confirmatory tests. It is possible to diagnose HIV infection by isolating the virus from the blood. However, viral culture is expensive, not widely available, and time consuming. Screening tests detect the presence of antibodies to several HIV antigens. These tests are inexpensive, widely available, and accurate in detecting 99.9% of HIV infections. However, approximately 0.2% of persons without HIV infection will test positive. In order to eliminate these false positives, persons should be tested in duplicate and positive results followed by a confirmatory test.

ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA). This test is the most commonly used method to screen blood for transfusions as well as to diagnose patients. An ELISA test for HIV works by attaching two or more HIV antigens to a plastic well or beads. A sample of the

patient's blood serum is added and incubated. If antibodies to HIV antigens are present, they will bind to the tube, or bead. After washing to remove excess proteins, an anti-human immunoglobulin conjugated to an enzyme is added. After incubation, excess antibody is washed away and a chemical called a substrate is added. The enzyme reacts with the substrate to form a colored product that indicates a positive test.

The latest generation of ELISA tests are 99.5% sensitive to HIV. Occasionally, the ELISA test will be positive for a patient without symptoms of AIDS from a low-risk group. Because this result is likely to be a false positive, the ELISA must be repeated *on the same sample of the patient's blood*. If the second ELISA is positive, the result should be confirmed by the Western blot or other confirmatory test.

WESTERN BLOT (IMMUNOBLOT). The Western blot or immunoblot test is used as a reference procedure to confirm the diagnosis of HIV infection. In Western blot testing, HIV antigens of different size are purified from HIV cultures and separated from each other by the process of electrophoresis. (In electrophoresis, protein molecules are suspended in a gel and separated by applying an electric current through the gel.) The HIV antigens are transferred to a nylon membrane or nitrocellulose filter. The patient's serum is added to this, and if antibodies are present they will bind to the corresponding viral antigens. The membrane is washed and anti-human immunoglobulin conjugated to an enzyme is added. After washing again, the color-developing substrate is added, which causes colored bands to appear where the serum antibodies are attached to the membrane. Western blots can detect antibodies to several HIV antigens, but results must be interpreted with caution because antibodies produced against other **viruses** may cross-react. A test is considered positive when antibodies are seen against antigens from at least two of the three major HIV antigens (p24, gp41, and gp120/160).

When used in combination with ELISA testing, Western blot testing is 99.9% specific. It can, however, yield false negatives in patients with very early HIV infection and in those infected by HIV-2. In some patients the Western blot yields indeterminate results.

IMMUNOFLUORESCENCE ASSAY (IFA). This method is sometimes used to confirm ELISA results instead of the Western blot test. An IFA test detects the presence of HIV antibody in a sample of the patient's serum by incubating the serum with H9 cells infected with HIV virus. The cells are grown in tissue culture and transferred to glass slides, which are frozen. After incubating with the patient's serum, the slide is washed to remove the serum and fluorescein-conjugated anti-human immunoglobulin

is added. After incubation, the unbound conjugate is removed by washing the slide. The slide is examined using a fluorescent **microscope**. The conjugate causes the HIV-infected cells coated with antibody to have a green fluorescence. This test can detect antibody of the IgM class that is produced within seven to 10 days after infection.

RADIOIMMUNOPRECIPITATION ASSAY (RIPA). A third confirmatory HIV testing method is the radioimmunoprecipitation assay (RIPA). This test also uses H9 lymphocytes infected with HIV. The cells are grown in tissue culture media containing radioactive methionine. This causes the viral antigens to be radioactive. A lysate is prepared from the cultured cells and incubated with serum. If antibodies are present in the serum they will bind to the radioactive viral antigens. These radioactive immune complexes are isolated onto sepharose beads coated with Staphylococcal protein-A. The beads are precipitated and tested for radioactivity, the presence of which indicates a positive test.

VIRAL LOAD TESTS. Tests for viral load measure the amount of virus in the blood either by quantifying nucleic acid or p24 antigen (p24 antigen capture assay). They may be used as confirmatory tests for HIV infection, but are more often used to determine the progression of HIV disease to AIDS and to determine the onset of drug resistance, both of which are signaled by an increase in the concentration of circulating viruses. The nucleic acid based tests for viral load include the reverse transcriptase-polymerase chain reaction (RT-PCR) test, branched DNA signal amplification method (bDNA), and the nucleic acid sequence-based amplification method (NASBA). DNA amplification methods can detect as little as 50 copies of viral RNA per mL of plasma and can detect infection during the “window phase,” when antibody levels are too low to produce a positive test result. In the RT-PCR assay, guanidinium isothiocyanate is added to the patient’s serum or plasma. The RNA is precipitated with isopropanol, and the RNA is resuspended and incubated in a medium containing reverse transcriptase, heat stable DNA polymerase (Taq polymerase), oligonucleotide primers tagged with **biotin**, and nucleotide triphosphates. The reverse transcriptase produces a double stranded DNA copy of the viral RNA. This DNA copy serves as the template for the polymerase chain reaction. Heat is used to separate the target DNA strand, a process known as denaturation. The temperature is lowered and the primers bind to the target sequence, a process called annealing. Heat stable DNA polymerase fills in the sequence by adding nucleotide triphosphates to the 3’ end of the primer, a process called extension. This makes a new copy of the double stranded DNA. The cycle is repeated, making use of the newly synthesized

DNA molecule as a template. If the process is repeated 30 times there will be over one billion copies of the target DNA. The amplified DNA, called amplicons, are denatured into single strands and are detected by means of an enzyme-conjugated DNA probe which hybridizes to the amplicons.

P24 ANTIGEN CAPTURE ASSAY. The p24 antigen capture assay is also used to measure viral load. Found in the viral core of HIV, p24 is a protein that can be measured by enzyme immunoassay. Generally, p24 is detected early in infection (before antibody production) but then falls to undetectable levels shortly after antibody production. The p24 assay is useful in detecting HIV infection before seroconversion, and for this reason it is used along with ELISA when testing donor blood for HIV. A return to detectable levels occurs when the virus becomes activated. Therefore, the test is used to identify patients who have become unresponsive to antiviral therapy and to indicate progression to AIDS. The test is not a useful screening test for HIV, since only about 20-30% of patients are positive in the early stages of HIV infection. Beads coated with monoclonal antibodies against p24 antigen are mixed with serum and incubated. After washing to remove unbound serum proteins, the beads are mixed with a second antibody to p24 derived from a rabbit. The beads are washed again, and an enzyme-conjugated anti-rabbit immunoglobulin is added. A final wash step is performed and substrate is added. The amount of color formed is proportional to the p24 antigen level of the serum.

BLOOD DONOR TESTING. Blood donated for transfusion is tested for HIV-1 and HIV-2 by ELISA, p24 antigen capture, and RT-PCR. For the latter, donor samples are pooled and tested for the presence of virus. This process detects the rare donors units that are negative for anti-HIV but potentially infective. This process has reduced the window phase from 22 days (ELISA alone) down to 11 days. It is estimated that the risk of receiving a transfusion of HIV positive blood in the United States is less than 1 in 562,500 when ELISA and p24 antigen testing are both used.

In 1999, the U.S. Food and Drug Administration (FDA) approved an HIV home testing kit. The kit contains multiple components, including material for specimen collection, a mailing envelope to send the specimen to a laboratory for analysis, and provides pre- and post-test counseling. It uses a finger prick process for blood collection. The results are obtained by the purchaser through a toll-free telephone number using a personal identification number (PIN). Post-test counseling is provided over the telephone by a licensed counselor. The only kit approved by the FDA as of 2001 was the Home Access test system.

KEY TERMS

Antibody—A protein in the blood that identifies and helps remove disease organisms or their toxins. Antibodies are secreted by B cells. AIDS diagnostic tests work by demonstrating the presence of HIV antibody in the patient's blood.

Antigen—Any substance that stimulates the body to produce antibodies.

B cell—A type of white blood cell derived from bone marrow. B cells are sometimes called B lymphocytes. They secrete antibody and have a number of other complex functions within the human immune system.

CD4—A type of protein molecule in human blood that is present on the surface of 65% of human T cells. CD4 is a receptor for the HIV virus. When the HIV virus infects cells with CD4 surface proteins, it depletes the number of T cells, B cells, natural killer cells, and monocytes in the patient's blood. Most of the damage to an AIDS patient's immune system is done by the virus' destruction of CD4+ lymphocytes. CD4 is sometimes called the T4 antigen.

Complete blood count (CBC)—A routine analysis performed on a sample of blood taken from the patient's vein with a needle and vacuum tube. The measurements taken in a CBC include a white blood cell count, a red blood cell count, the red cell distribution width, the hematocrit (ratio of the volume of the red blood cells to the blood volume),

and the amount of hemoglobin (the blood protein that carries oxygen).

Electrophoresis—A method of separating complex protein molecules suspended in a gel by running an electric current through the gel.

Enzyme-linked immunosorbent assay (ELISA)—A diagnostic blood test used to screen patients for AIDS or other viruses. The patient's blood is mixed with antigen attached to a plastic tube or bead surface. A sample of the patient's blood serum is added, and excess proteins are removed. A second antibody coupled to an enzyme is added, followed by a chemical that will cause a color reaction that can be measured by a special instrument.

Human immunodeficiency virus (HIV)—A transmissible retrovirus that causes AIDS in humans. Two forms of HIV are now recognized: HIV-1, which causes most cases of AIDS in Europe, North and South America, and most parts of Africa; and HIV-2, which is chiefly found in West African patients. HIV-2, discovered in 1986, appears to be less virulent than HIV-1, but may also have a longer latency period.

Immunofluorescent assay (IFA)—A blood test sometimes used to confirm ELISA results instead of using the Western blotting. In an IFA test, HIV antigen is mixed with a fluorescent compound and then with a sample of the patient's blood. If HIV antibody is present, the mixture will fluoresce when examined under ultraviolet light.

Prognostic tests

In addition to tests for viral antigens and antibodies, other blood tests are needed to evaluate and manage patients with HIV disease. The most important of these is the CD4 positive lymphocyte count. This test measures the number of T helper cells in the blood. A CD4 count of less than 200/microL or 14% of the total lymphocyte count in a person who is HIV positive constitutes a diagnosis of AIDS. A falling CD4 positive lymphocyte count parallels a rise in viral replication and correlates with both a risk of opportunistic infection and drug resistance in patients receiving highly active antiviral therapy (HAART).

It is important for doctors treating AIDS patients to measure the CD4 positive lymphocyte count on a regular

basis. Experts consulted by the U.S. Public Health Service recommend the following frequency of serum testing based on the patient's CD4+ level:

- CD4+ count more than 600 cells/microL: Every six months.
- CD4+ count between 200-600 cells/microL: Every three months.
- CD4+ count less than 200 cells/microL: Every three months.

When the CD4+ count falls below 200 cells/microL, the doctor will put the patient on a medication regimen to protect him or her against opportunistic infections.

BETA₂-MICROGLOBULIN (β₂M). Beta₂-microglobulin is a protein found on the surface of all human cells with a nucleus. It is released into the blood when a cell dies.

KEY TERMS CONTINUED

Lymphocyte—A type of white blood cell that is important in the formation of antibodies. Doctors can monitor the health of AIDS patients by measuring the number or proportion of certain types of lymphocytes in the patient's blood.

Macrophage—A large white blood cell, found primarily in the bloodstream and connective tissue, that helps the body fight off infections by ingesting the disease organism. HIV can infect and kill macrophages.

Monocyte—A large white blood cell that is formed in the bone marrow and spleen. About 4% of the white blood cells in normal adults are monocytes.

Opportunistic infection—An infection that develops only when a person's immune system is weakened, as happens to AIDS patients.

Polymerase chain reaction (PCR)—A test performed to evaluate false-negative results to the ELISA and Western blot tests. In PCR testing, numerous copies of a gene are made by separating the two strands of DNA containing the gene segment, marking its location, using DNA polymerase to make a copy, and then continuously replicating the copies. The amplification of gene sequences that are associated with HIV allows for detection of the virus by this method.

Retrovirus—A virus that contains a unique enzyme called reverse transcriptase that allows it to replicate within new host cells.

Seroconversion—The change from HIV-negative to HIV-positive status during blood testing. Persons who are HIV-positive are called seroconverters.

Serology—The analysis of the contents and properties of blood serum.

Serum—The part of human blood that remains liquid when blood cells form a clot. Human blood serum is clear light yellow in color.

T cells—Lymphocytes that originate in the thymus gland. T cells regulate the immune system's response to infections, including HIV. CD4 lymphocytes are a subset of T lymphocytes.

Viral load test—A new blood test for monitoring the speed of HIV replication in AIDS patients. The viral load test is based on PCR techniques and supplements the CD4+ cell count tests.

Western blot—A technique that is used to confirm ELISA results. HIV antigen is purified by electrophoresis and attached by blotting to a nylon or nitrocellulose filter. The patient's serum is reacted against the filter, followed by treatment with developing chemicals that allow HIV antibody to show up as a colored patch or blot. If the patient is HIV-positive, there will be stripes at specific locations for two or more viral proteins. A negative result is blank.

WBC differential—A white blood cell count in which the technician classifies the different white blood cells by type as well as calculating the number of each type. A WBC differential is necessary to calculate the absolute CD4+ lymphocyte count.

Although rising blood levels of $\beta_2\text{M}$ are found in patients with cancer and other serious diseases, a rising $\beta_2\text{M}$ blood level can be used to measure the progression of AIDS.

GENOTYPIC DRUG RESISTANCE TEST. Genotypic testing can help determine whether specific gene mutations, common in people with HIV, are causing drug resistance and drug failure. The test looks for specific genetic mutations within the virus that are known to cause resistance to anti-viral drugs. For example the drug 3TC, also known as lamivudine (Epivir), is not effective against strains of HIV that have a mutation at a particular position, known as M184V, in their reverse transcriptase enzyme. If the genotypic resistance test shows a mutation at position M184V, it is likely that person is resistant to 3TC and not likely to respond to treatment. Genotypic

tests are only useful when the patient is already taking antiviral medication, and the viral load is greater than 1,000 copies per mL of plasma. The cost of the viral drug resistance testing is usually between \$300 and \$500, and is usually not covered by insurance plans, including Medicare.

PHENOTYPIC DRUG RESISTANCE TESTING. Phenotypic testing directly measures the *in vitro* sensitivity of a patient's HIV strains to particular drugs and drug combinations. The test measures the concentration of a drug required to inhibit viral replication by 50% and 90%. This is the same method used by researchers to determine whether a drug might be effective against HIV before using it in human clinical trials. Phenotypic testing is a more direct measurement of resistance than genotypic testing. Unlike genotypic testing, phenotypic

testing does not require a high viral load, but it is recommended that persons already be taking **antiretroviral drugs**. The cost is between \$700 and \$900 and is usually not covered by insurance plans, including Medicare.

AIDS serology in children

Children born to HIV-infected mothers may acquire the infection through the mother's placenta or during the birth process. Public health experts recommend the testing and monitoring of all children born to mothers with HIV. Diagnostic testing in children older than 18 months is similar to adult testing, with ELISA screening confirmed by Western blot. Younger infants can be diagnosed by direct culture of the HIV virus, PCR testing, and p24 antigen testing. These techniques allow a pediatrician to identify 50% of infected children at or near birth, and 95% of cases in infants three to six months of age.

Preparation

In addition to diagnostic testing for HIV infection, many laboratory tests are important to the proper management and treatment of patients with HIV disease and AIDS. These include the **complete blood count** (CBC), cultures and serological tests for opportunistic infections, Pap smear for cervical cancer, imaging studies, nerve conduction studies, and tests for nutritional status.

Preparation and aftercare are important parts of AIDS diagnostic testing. Doctors are now advised to take the patient's emotional, social, economic, and other circumstances into account and to provide counseling before and after testing. Patients are generally better able to cope with the results if the doctor has spent some time with them before the blood test explaining the basic facts about HIV infection and testing. Many doctors now offer this type of informational counseling before performing the tests.

Complications

The risks of AIDS testing are primarily related to disclosure of the patient's HIV status rather than to any physical risks connected with blood testing. Some patients are better prepared to cope with a positive diagnosis than others, depending on their age, sex, health, resources, belief system, and similar factors.

Results

Normal results for ELISA, Western blot, IFA, and PCR testing are negative for HIV antibody.

Normal results for CD4+ lymphocytes: 500-1200/microL, 34-67% of all lymphocytes.

The following abnormal results of AIDS tests indicate progression of the disease:

- Percentage of CD4 positive lymphocytes: less than 14% of all lymphocytes.
- CD4+ lymphocyte count: less than 200 cells/microL.
- Viral load test: Levels more than 5000 copies/mL.

Health care team roles

Nurses and phlebotomists (workers who draw blood) are usually the health care professional that draw the blood for AIDS tests. However, it is the physician that recommends specific treatment and prescribes needed medication. HIV tests are performed by clinical laboratory scientists, CLS (NCA) or medical technologists, MT (ASCP). It is often the role of a trained counselor to tell the patient the test results. Regardless of the results, nurses, health care educators, and counselors often are responsible for educating the patient about safe sex practices and risk factors for contracting HIV, along with the possible need for periodic repeat testing.

Air embolism *see* **Gas embolism**

Airway management

Definition

Airway management involves ensuring that the patient has a patent airway through which effective ventilation can take place.

Purpose

An obstructed airway means that the body is deprived of oxygen. If ventilation is not reestablished,

brain death will occur within minutes. The primary purpose of airway management is to provide a continuously open airway along with a continuous source of oxygen. When a patient is critically ill and requires an artificial airway and mechanical ventilation, it is the responsibility of the healthcare professionals caring for the patient to ensure that the airway is secure.

Another goal of airway management is to provide an artificial airway that is as close to the patient's natural airway as possible. This may mean mechanically performing physiological functions such as humidifying inspired air and removing secretions.

Precautions

Airway management is a necessity for any patient who has an artificial airway. If the patient is restless or agitated, it is recommended that activities such as suctioning or endotracheal tube care be postponed until either the patient is calm or a sedative has been given. This is to avoid inadvertent removal of the airway. However, if the patient's respiratory status is unstable, suctioning or repositioning the endotracheal tube should be done if it will stabilize the patient.

Description

Airway management consists of much more than just keeping the breathing tube in the correct position. The tube must be managed so that it allows optimal ventilation with the fewest complications.

Humidification

Humidification of inspired air normally takes place in the upper respiratory tract. When this area is bypassed by an artificial airway (such as an endotracheal or tracheostomy tube), humidification must be performed outside the body. If supplemental oxygen is used, it will require humidification to prevent drying and irritation of the respiratory tract and to facilitate removal of secretions. There are humidification devices available that can be attached to oxygen flow meters or **ventilators**.

Suctioning

Suctioning consists of inserting a sterile catheter into the endotracheal or tracheostomy tube in order to remove secretions. This is an extremely important part of caring for a patient with an artificial airway, since the reflex of coughing, which would normally remove these secretions, is not effective. The patient will experience respiratory distress if the tube is obstructed by sputum. Suctioning should be performed only when the patient

KEY TERMS

Bag-valve-mask device—Device consisting of a manually compressible bag containing oxygen and a one-way valve and mask that fits over the mouth and nose of the patient.

Endotracheal tube—Tube inserted into the trachea via either the oral or nasal cavity for the purpose of providing a secure airway.

Hypoxemia—Abnormal deficiency of oxygen in the arterial blood.

Oxygen flow meter—Meter attached to a oxygen source that controls the amount of supplemental oxygen the patient receives.

Pulse oximeter—Noninvasive machine that measures the amount of hemoglobin that is saturated with oxygen.

Tracheostomy tube—Surgically created opening in the trachea for the purpose of providing a secure airway. This is used when the patient requires long-term ventilatory assistance.

Ventilator (mechanical ventilation)—Device used to provide assisted respiration and positive pressure breathing.

needs it; however, the need should be assessed at least every two hours.

A number of studies have been done to find ways to minimize the complications of suctioning. Equipment should be sterilized to decrease the risk of **infection**. There are now closed suction systems available that are attached to the ventilator tubing on one end and to the artificial airway on the other. The catheter remains protected inside a sterile plastic sleeve that is changed every 24 hours. This system limits the amount of times the tubing must be disconnected from the airway, thus reducing exposure of the trachea to environmental contaminants.

Suctioning causes oxygen deprivation for the time that the suction is applied. Hypoxemia can be minimized by preoxygenating the patient with 100% oxygen prior to suctioning and between each pass of the suction catheter. (This can be done by either pushing the 100% oxygen button on the ventilator or by using a bag-valve-mask device.) The patient's pulse oximetry should be monitored while suctioning. The duration of each suction pass should be limited to 10 seconds and the number of passes should be limited to three or less if possible. This decreases hypoxemia and airway trauma. Studies have

shown that using intermittent suction is no more beneficial than continuous suction.

Installation of a small amount of saline prior to suctioning was a common procedure in the past. It was thought that saline helped to loosen secretions and to facilitate their removal, but studies have shown this is not the case. On the contrary, saline installation has been shown to increase infection rates and to cause decreased oxygen levels for longer periods than suctioning without saline use. This procedure is no longer regarded as beneficial.

Preparation

Preparation for airway management includes explaining all procedures that will be performed to the patient. Often, patients who are receiving mechanical ventilation are kept sedated or even paralyzed to facilitate optimal ventilation. The level of sedation should be assessed. If patients are not receiving continuous infusions of a sedating drug, they may have a physician's order for sedation as needed. If they are agitated, they should be given the prescribed dose of sedation prior to performing any airway-related procedures, to ensure that the airway is not inadvertently removed.

Patients receiving mechanical ventilation also often have bilateral soft wrist restraints applied to prevent accidental removal of the artificial airway. It is recommended that these be securely fastened before starting an airway-related procedure, or that another healthcare professional be at the bedside to help calm and hold the patient. Also, all needed supplies should be at the bedside prior to starting a procedure, so as to not cause excess discomfort or **stress** for the patient.

Aftercare

After the procedure is finished, the patient should be reassured if necessary and their respiratory status should be reassessed. The insertion point of the airway should be confirmed to be at the same place as prior to the procedure, unless the purpose was to change the depth of the tube. If the airway has been manipulated since suctioning, the patient may require suctioning again. Any waste should be disposed of in the garbage or in a biohazard container if there is a large amount of **blood**. Prior to the healthcare professional leaving the room, the patient should be made comfortable, further sedation or **pain** medication should be administered as needed and the patient should be confirmed to be stable.

Complications

The greatest risk of airway management is that the airway may be inadvertently removed, causing the

patient to have respiratory distress. Procedures that require manipulating the airway may cause fear or agitation for patients if they feel that they do not have control over their breathing. If the patient becomes combative, it can be very difficult to finish the procedure without disturbing the airway.

Results

The anticipated outcomes of airway management are a continuously open airway through which effective ventilation can take place, and prevention of infection.

Health care team roles

The nurse and respiratory therapist are equally responsible for monitoring and managing artificial airways. Both perform sterile suctioning and both document their assessment of the patient's respiratory status. The respiratory therapist is generally responsible for managing the ventilator, adding humidification, and changing ventilator tubing.

If the patient is accidentally extubated (the airway is removed), both the nurse and respiratory therapist must assist in reinsertion. This is usually done by an anesthesiologist, a certified **registered nurse anesthetist (CRNA)**, a medical resident, or another physician. The respiratory therapist is generally responsible for ventilating the patient with a bag-valve-mask device until reintubation (reinsertion of the airway), while the nurse gathers equipment, administers medications, and monitors the patient's pulse oximetry, **vital signs**, and cardiac rhythm.

The nurse and respiratory therapist are also responsible for finding alternative means for the patient to communicate. Artificial airways are inserted through the vocal cords, making speaking impossible. The patient should be encouraged to try alternative methods such as mouthing words, writing, or pointing to letters, words, or pictures on a communication board. Communicating with these patients takes great patience and creativity, as well as dedication to helping them feel like their needs are being met.

Alcoholic paralysis

Definition

Alcohol **paralysis**, or alcohol-related neurological disease, is an umbrella term for a wide variety of nervous system disorders that are directly caused by the ingestion of toxic amounts of alcohol.

These can be grouped into four categories:

- effects of acute alcohol intoxication
- withdrawal from alcohol
- diseases and neurological damage related to **alcoholism**
- **fetal alcohol syndrome**

Description

Effects of acute intoxication

Alcohol, or ethanol, has long-demonstrated direct toxic effects on nerve and muscle cells. Depending on which nerve and muscle pathways are involved, alcohol can have far-reaching effects on different parts of the **brain**, peripheral nerves, and muscles. When a person drinks alcohol, it is absorbed by **blood vessels** in the **stomach** lining and flows rapidly throughout the body and brain. Ethanol freely crosses the blood-brain barrier that ordinarily keeps large molecules from escaping from the **blood** vessel to the brain tissue. Drunkenness, or intoxication, may occur at blood alcohol concentrations of as low as 50-150 mg per 100 milliliters (0.02-0.05 oz per qt) in what are usually called social drinkers. Sleepiness, stupor, **coma**, or even death from respiratory depression and low **blood pressure** occur at progressively higher concentrations.

Although alcohol is broken down by the **liver**, the toxic effects from a high dose of alcohol are most likely a direct result of alcohol itself rather than of its breakdown products. The fatal dose varies widely because people who drink heavily develop a tolerance to the effects of alcohol with repeated use. In addition, alcohol tolerance results in the need for higher levels of blood alcohol to achieve intoxicating effects, which increases the likelihood that habitual drinkers will be exposed to high and potentially toxic levels of ethanol. This is particularly true when binge drinkers fail to eat, because fasting decreases the rate of alcohol clearance and causes even higher blood alcohol levels.

Recent research indicates that alcohol's toxicity may be a component of violence and aggression. A National Institute on Alcohol Abuse and Alcoholism (NIAAA) study showed that an estimated 86 percent of homicide offenders, 37 percent of assault offenders, 60 percent of sexual offenders, and 13 percent of child abusers were drinking at the time of the offense. Forty-two percent of violent crimes reported to police involved alcohol, and 51 percent of victims interviewed believed that the person who had assaulted them had been drinking.

A December 1999 NIAAA study suggests that because they absorb and metabolize alcohol differently than men, women may be more susceptible to its adverse effects. This was based on **magnetic resonance imaging** (MRI) studies of the brains of alcoholic women, compared with both non-alcoholic women and alcoholic men. Imaging showed that the brain regions involved in coordinating brain functions were markedly smaller in the alcoholic women than either of the other two groups.

Two separate studies, conducted in February and August of 2000, proposed and showed evidence that even early drinking can seriously affect **memory**. Researchers at Duke University and the University of California both found that adolescence, especially between the ages of 15 and 16, are important years in brain development, and this development is adversely affected by alcohol and drug use. It is as yet unknown whether such impairment is reversible.

Withdrawal

When a chronic alcoholic suddenly stops drinking, withdrawal of alcohol leads to a syndrome of increased excitability of the **central nervous system**, called *delirium tremens* or "DTs." Symptoms begin six to eight hours after abstinence, and are most pronounced 24-72 hours after abstinence. They include body shaking (tremulousness), insomnia, agitation, confusion, hearing voices or seeing images that are not really there (such as crawling bugs), seizures, rapid **heart** beat, profuse

sweating, high blood pressure, and **fever**. Alcohol-related seizures are reported in approximately 15 percent of alcoholics, and the chance of having seizures, as well as the severity of the seizures, increases with the number of withdrawal incidences. In structural imaging, it was found that alcoholics that had had seizures showed shrinkage on both sides of the brain behind the frontal lobe.

Diseases and brain damage related to alcoholism

Wernicke-Korsakoff syndrome is caused by deficiency of the B-vitamin **thiamine**, and can also be seen in people who don't drink but have some other cause of thiamine deficiency, such as chronic vomiting, that prevents the absorption of this vitamin. Patients with this condition have the sudden onset of Wernicke encephalopathy; the symptoms include marked confusion, delirium, disorientation, inattention, memory loss, and drowsiness. Examination reveals abnormalities of eye movement, including jerking of the eyes (nystagmus) and double **vision**. Problems with balance make walking difficult. People may have trouble coordinating their leg movements, but usually not their arms. If thiamine is not given promptly, Wernicke encephalopathy may progress to stupor, coma, and death.

If thiamine is given and death averted, Korsakoff's syndrome may develop in some patients, who suffer from memory impairment that leaves them unable to remember events for a period of a few years before the onset of illness (retrograde amnesia) and unable to learn new information (anterograde amnesia). Most patients have very limited insight into their memory dysfunction and have a tendency to make up explanations for events they have forgotten (confabulation).

Severe alcoholism can cause cerebellar degeneration, a slowly progressive condition affecting portions of the brain called the anterior and superior *cerebellar vermis* causing a wide-based gait, leg incoordination, and an inability to walk heel-to-toe in tightrope fashion. The gait disturbance usually develops over several weeks, but may be relatively mild for some time, and then suddenly worsen after binge drinking or an unrelated illness.

Fetal alcohol syndrome

Fetal alcohol syndrome (FAS) occurs in infants born to alcoholic mothers when prenatal exposure to ethanol retards fetal growth and development. Alcohol is a known teratogen (an agent capable of causing physical abnormalities in developing fetuses) that affects both the infant's body and brain. It can cause this damage across the entire **pregnancy**, not just the first trimester. Affected infants often have a distinctive appearance with a thin

upper lip, flat nose and mid-face, short stature and small head size. Almost half are mentally retarded, and most others are mildly impaired intellectually or have problems with speech, learning, and behavior.

Up to three births of every thousand in the industrialized countries of the world will produce a child born with FAS. This condition is considered more apt to occur following continuous, heavy alcohol intake by the mother, but has also been seen following intermittent or binge drinking. A study by Dr. John W. Olney, of Washington University School of Medicine, found that because brain cells building the connections necessary for memory, learning and thought begin to develop in the sixth month in-utero, one brief (four-hour) drinking binge during that period of time can damage millions of developing cells.

Causes and symptoms

Acute excess intake of alcohol can cause drunkenness (intoxication) or even death, and chronic or long-term abuse leads to potentially irreversible damage to virtually any level of the nervous system. Any given patient with long-term alcohol abuse may have no neurologic complications, a single alcohol-related disease, or multiple conditions, depending upon the genes they have inherited, how well nourished they are, and other environmental factors, such as exposure to other drugs or toxins.

Neurologic complications of alcohol abuse may also result from nutritional deficiency, because alcoholics tend to eat poorly and may become depleted of thiamine or other **vitamins** important for nervous system function. Persons who are intoxicated are also at higher risk for **head injury** or for compression injuries of the peripheral nerves. Sudden changes in blood chemistry, especially sodium, related to alcohol abuse may cause central pontine myelinolysis, a condition of the brainstem in which nerves lose their myelin coating. Liver disease complicating alcoholic cirrhosis may cause **dementia**, delirium, and movement disorder.

Alcoholic myopathy, or weakness secondary to breakdown of muscle tissue, is also known as alcoholic rhabdomyolysis or alcoholic myoglobinuria. Males are affected by acute (sudden onset) alcoholic myopathy four times as often as females. Breakdown of muscle tissue (myonecrosis) can come on suddenly during binge drinking or in the first days of alcohol withdrawal. In its mildest form, this breakdown may cause no noticeable symptoms, but may be detected by a temporary elevation in blood levels of an enzyme found predominantly in muscle, called the MM fraction of creatine kinase.

The severe form of acute alcoholic myopathy is associated with the sudden onset of muscle **pain**, swelling, and weakness; a reddish tinge in the urine caused by myoglobin, a breakdown product of muscle excreted in the urine; and a rapid rise in muscle enzymes in the blood. Symptoms usually worsen over hours to a few days, and then improve over the next week to 10 days as the patient is withdrawn from alcohol. Muscle symptoms are usually generalized, but pain and swelling may selectively involve the calves or other muscle groups. The muscle breakdown of acute alcoholic myopathy may be worsened by crush injuries, which may occur when people drink so much that they compress a muscle group with their body weight for a long time without moving, or by withdrawal seizures with generalized muscle activity.

In patients who abuse alcohol over many years, chronic alcoholic myopathy may develop. Males and females are equally affected. Symptoms include painless weakness of the limb muscles closest to the trunk and the girdle muscles, including the thighs, hips, shoulders, and upper arms. This weakness develops gradually, over weeks or months, without symptoms of acute muscle injury. Muscle atrophy, or decreased bulk, may be striking. The nerves of the extremities may also begin to break down, a condition known as alcoholic peripheral neuropathy, which can add to the person's difficulty in moving. Symptoms of peripheral neuropathy, too, typically develop slowly, over a period of months.

The way in which alcohol destroys muscle tissue is still not well understood. Proposed mechanisms include muscle membrane changes affecting the transport of **calcium**, potassium, or other **minerals**; impaired muscle energy **metabolism**; and impaired protein synthesis. Alcohol is metabolized (broken down) primarily by the liver, with a series of chemical reactions in which ethanol is converted to acetate. Acetate is metabolized by skeletal muscle, and alcohol-related changes in liver function may affect skeletal muscle metabolism, decreasing the amount of blood sugar available to muscles during prolonged activity. Because not enough sugar is available to supply needed energy, muscle protein may be broken down as an alternate energy source. However, toxic effects on muscle may be a direct result of alcohol itself rather than of its breakdown products.

Although alcoholic peripheral neuropathy may contribute to muscle weakness and atrophy by injuring the motor nerves controlling muscle movement, alcoholic neuropathy more commonly affects sensory fibers. Injury to these fibers can cause tingling or burning pain in the feet, which may be severe enough to interfere with walking. As the condition worsens, pain decreases but numbness increases.

KEY TERMS

Abstinence—Refraining from the use of alcoholic beverages.

Atrophy—A wasting or decrease in size of a muscle or other tissue.

Cerebellum—The part of the brain involved in coordination of movement, walking, and balance.

Degeneration—Gradual, progressive loss of nerve cells.

Delirium—Sudden confusion with decreased or fluctuating level of consciousness.

Delirium tremens—A complication that may accompany alcohol withdrawal. The symptoms include body shaking (tremulousness), insomnia, agitation, confusion, hearing voices or seeing images that are not really there (hallucinations), seizures, rapid heart beat, profuse sweating, high blood pressure, and fever.

Dementia—Loss of memory and other higher functions, such as thinking or speech, lasting six months or more.

Myoglobinuria—Reddish urine caused by excretion of myoglobin, a breakdown product of muscle.

Myopathy—A disorder that causes weakening of muscles.

Neuropathy—A condition affecting the nerves supplying the arms and legs. Typically, the feet and hands are involved first. If sensory nerves are involved, numbness, tingling, and pain are prominent, and if motor nerves are involved, the patient experiences weakness.

Thiamine—A B vitamin essential for the body to process carbohydrates and fats. Alcoholics may suffer complications (including Wernicke-Korsakoff syndrome) from a deficiency of this vitamin.

Wernicke-Korsakoff syndrome—A combination of symptoms, including eye-movement problems, tremors, and confusion, that is caused by a lack of the B vitamin thiamine and may be seen in alcoholics.

Diagnosis

The diagnosis of alcoholic paralysis depends largely upon the practitioner taking a thorough history and finding characteristic symptoms in patients who abuse

alcohol. Other possible causes should be excluded by the appropriate tests, which may include blood chemistry, **thyroid function tests**, brain MRI or computed tomography (CT) scan, and/or cerebrospinal fluid analysis.

Acute alcoholic myopathy can be diagnosed by finding myoglobin in the urine and increased creatine kinase and other blood enzymes released from injured muscle. The surgical removal of a small piece of muscle for microscopic analysis (muscle biopsy) shows the scattered breakdown and repair of muscle fibers. Doctors must rule out other acquired causes of muscle breakdown, which include the abuse of drugs such as heroin, cocaine, or amphetamines; trauma with crush injury; the depletion of phosphate or potassium; or an underlying defect in the metabolism of **carbohydrates** or **lipids**. In chronic alcoholic myopathy, serum creatine kinase often is normal, and muscle biopsy shows atrophy, or loss of muscle fibers. **Electromyography** (EMG) may show features characteristic of alcoholic myopathy or neuropathy.

Treatment

Acute management of alcohol intoxication, delirium tremens, and withdrawal is primarily supportive, to monitor and treat any cardiovascular or **respiratory failure** that may develop. In delirium tremens, fever and sweating may necessitate treatment of fluid loss and secondary low blood pressure. Agitation may be treated with benzodiazepines such as chlordiazepoxide, beta-adrenergic antagonists such as atenolol, or alpha 2-adrenergic agonists such as clonidine. Because Wernicke's syndrome is rapidly reversible with thiamine, and because death may intervene if thiamine is not given promptly, all patients admitted for acute complications of alcohol, as well as all patients with unexplained encephalopathy, should be given intravenous thiamine.

Withdrawal seizures typically resolve without specific anti-epileptic drug treatment, although status epilepticus (continual seizures occurring without interruption) should be treated vigorously with injections of phenytoin (Dilantin), diazepam (Valium), or phenobarbital. Acute alcoholic myopathy with myoglobinuria requires monitoring and maintenance of kidney function, and correction of imbalances in blood chemistry including potassium, phosphate, and magnesium levels.

Chronic alcoholic myopathy and other chronic conditions are treated by correcting associated nutritional deficiencies and maintaining a diet adequate in protein and carbohydrate. The key to treating any alcohol-related disease is helping the patient overcome alcohol addiction. Behavioral measures and social supports may

be needed in patients who develop broad problems in their thinking abilities (dementia) or remain in a state of confusion and disorientation (delirium). People with walking disturbances may benefit from **physical therapy** and assistive devices. Doctors may also prescribe drugs to treat the pain associated with peripheral neuropathy.

Prognosis

Complete recovery from Wernicke's syndrome may follow prompt administration of thiamine. However, repeated episodes of encephalopathy or prolonged alcohol abuse may cause persistent dementia or Korsakoff psychosis. Most patients recover fully from acute alcoholic myopathy within days to weeks, but severe cases may be fatal due to **acute kidney failure** or disturbances in heart rhythm secondary to increased potassium levels. Recovery from chronic alcoholic myopathy may occur over weeks to months of abstinence from alcohol and correction of malnutrition. Cerebellar degeneration and alcoholic neuropathy may also improve to some extent with abstinence and balanced diet, depending on the severity and duration of the condition.

Prevention

Prevention requires abstinence from alcohol. Persons who consume small or moderate amounts of alcohol might theoretically help prevent nutritional complications of alcohol use with dietary supplements including B vitamins. Historically, it is known that the incidence of neurological damage to people afflicted with alcoholism was even greater before bakeries began to enrich bread with vitamins and minerals. However, proper **nutrition** cannot protect against the direct toxic effect of alcohol or of its breakdown products. Patients with any alcohol-related symptoms or conditions, pregnant women, and patients with liver or neurologic disease should abstain completely. Based upon several recent studies, persons with family history of alcoholism or alcohol-related conditions may be considered at increased risk for both alcoholism and the neurologic complications of alcohol use.

Health care team roles

Because alcohol is the most widely abused drug in our society, there is a prevalence of people with alcohol-related consequences in all treatment settings. Nearly every member of the health care team, across a broad spectrum of places including hospitals, **nursing homes**,

clinics and even homes will be involved with the patient with alcohol-related neurological disease.

- Physicians, especially primary care physicians, have long been the front line of diagnosis and care for alcoholics, long before a neurologist (a physician who specializes in diseases of the nervous system) becomes involved. In the past education regarding alcoholism was not considered to be adequate, but this has changed considerably over the past two decades. Health care providers should take a comprehensive drinking history as part of any initial examination of a patient, and be aware that people suffering from alcoholism, a disease of denial, often say they drink less than they actually do.
- Nurses will be involved in the day to day treatment of people with alcohol-related neurological disease who are temporarily unable, or no longer able at all, to care for themselves. This may involve caring for and monitoring people in withdrawal or DT's, as well as providing supportive physical and emotional care, which may include administering medications, monitoring **vital signs** (blood pressure and pulse), providing fluids either by mouth or intravenously, preventing injuries during seizures or from **falls**, and encouraging sobriety through a calm, non-judgmental attitude.
- Physiotherapists may often become involved in helping the person with an alcohol-related neurological condition to restore their ability to walk safely. This may involve repetitively practicing various steps and providing encouragement to the person.
- Certified alcoholism counselors (CACs) can help the alcoholic patient to come to terms with this most baffling, difficult disease. The CAC can provide information not only on the disease of alcoholism, but the many programs available to help deal with it, including Alcoholics Anonymous and Rational Recovery.

Alcoholism

Definition

Alcoholism is the popular term for alcohol abuse and alcohol dependence. The hallmarks of both of these disorders involve repeated life problems that can be directly tied to a person's abuse of alcohol. Alcoholism has serious consequences, affecting an individual's health and personal life, as well as having a negative impact on society at large. Alcoholism is the use of alcohol in any harmful way.

Description

The effects of alcoholism are quite far reaching. Alcohol affects every body system, causing a wide range of health problems. Such problems include poor **nutrition**, **memory** disorders, difficulty with balance and walking, **liver** disease (including cirrhosis and hepatitis), high **blood pressure**, weakness of muscles (including the **heart**), disturbances of heart rhythm, anemia, clotting disorders, weak immunity to infections, inflammation and irritation along the entire gastrointestinal system, acute and chronic problems with the **pancreas**, low **blood** sugar, high blood fat content, interference with reproductive fertility, and weak bones.

On a personal level, alcohol can be responsible for marital and other relationship difficulties, depression, unemployment, **child abuse**, and general family dysfunction.

Alcoholism causes or contributes to a variety of severe social problems: homelessness, murder, suicide, injury, and violent crime. Alcohol is a contributing factor in 50% of all deaths due to motor vehicle accidents. In fact, more than 100,000 deaths occur each year due to the effects of alcohol, of which 50% are due to injuries of some sort. In the United States, the annual economic cost of alcoholism and alcohol abuse is estimated at more than \$160 billion.

Causes and symptoms

There are probably a number of factors that work together to cause a person to become an alcoholic. Genetic studies have demonstrated that close relatives of an alcoholic are more likely to become alcoholics themselves. This risk appears to hold true even for the child adopted away from his or her biological family at birth and raised in a non-alcoholic adoptive family—with no knowledge of the biological family's difficulties with alcohol. More research is being conducted to determine whether genetic factors can account for differences in

alcohol **metabolism**, thereby increasing the risk of an individual becoming an alcoholic—or whether the involvement of genetics is less direct, perhaps producing personality traits that render people susceptible to alcoholism. Many investigators believe that environmental factors, such as availability and acceptance of alcohol, peer pressure, or stressful lifestyle are at least as important as genetic factors. At the time of this writing in early 2001, researchers were seeking the location of specific genes that affect susceptibility to alcoholism.

The symptoms of alcoholism can be broken down into two major categories, symptoms of acute alcohol abuse and symptoms of long-term alcohol abuse.

Immediate (acute) effects of alcohol abuse

Alcohol exerts a depressive effect on the **brain**. The blood-brain barrier does not prevent alcohol from entering the brain, so the brain-alcohol level will quickly become equivalent to the blood-alcohol level. Alcohol's depressive effects result in difficulty walking, poor balance, slurred speech, and generally poor coordination (i.e., accounting, in part, for the increased likelihood of injury). At higher alcohol levels, a person's breathing and heart rates will be slowed, and vomiting may occur, with a high risk of the vomit being inspired (breathed) into the **lungs**; this can result **pneumonia**, or in choking and death (especially if the person is unconscious). Extremely high blood alcohol levels may result in **coma** and death.

Effects of long-term (chronic) alcoholism

Long-term abuse of alcohol affects virtually every organ system of the body:

- Nervous system. An estimated 30-40% of all men in their teens and twenties have experienced alcoholic blackouts, which occur when drinking a large quantity of alcohol. This can also result in loss of memory of the time surrounding the episode of drinking. Alcohol is well known to cause sleep disturbances, so that overall sleep quality is affected. Numbness and tingling may occur in the arms and legs. Two syndromes, which can occur together or separately, are known as Wernicke's and Korsakoff's syndromes. Both are due to the low thiamin levels found in the blood of alcoholics. Wernicke's syndrome results in disordered eye movements, very poor balance and difficulty walking; Korsakoff's syndrome severely affects memory, preventing new learning from taking place.
- Gastrointestinal system. Alcohol causes loosening of the muscular ring that prevents the stomach's contents from re-entering the esophagus. Therefore, the acid from the **stomach** can flow backwards into the esophagus, thereby burning those tissues and causing **pain**

and bleeding. Inflammation of the stomach can also result in bleeding and pain, and decrease the appetite. A major cause of severe, uncontrollable bleeding (hemorrhage) in an alcoholic is the development of enlarged (dilated) **blood vessels** within the esophagus, called esophageal varices. These varices are actually developed in response to liver disease, and are extremely prone to bursting and hemorrhaging. **Diarrhea** is also a common affect of alcohol abuse due to alcohol's effect on the pancreas. Another condition, inflammation of the pancreas (**pancreatitis**) can be a serious and painful consequence of alcoholism. Throughout the intestinal tract, alcohol interferes with the absorption of nutrients, creating a malnourished state. Alcohol is broken down (metabolized) in the liver, which is profoundly affected by consistently high alcohol levels. Alcohol interferes with a number of important chemical processes that also occur in the liver. As a result, the liver begins to enlarge and fill with fat (i.e., fatty liver), fibrous scar tissue interferes with the liver's normal structure and function (cirrhosis), and the liver may become inflamed (hepatitis).

- Blood alcohol can cause changes to all types of blood cells. Red blood cells become abnormally large. The number of white blood cells (WBCs) (important for fighting infections) decreases, resulting in a weakened **immune system**. This places alcoholics at increased risk for infections; it is thought to account, in part, for the increased risk of **cancer** in alcoholics (i.e., ten times the normal risk). Platelets and blood clotting factors are negatively affected, causing an increased risk of hemorrhage.
- Heart. Small amounts of alcohol can cause a drop in blood pressure. With increased use, however, alcohol begins to move blood pressure into a dangerously high range. High levels of **fats** circulating in the bloodstream increase the risk of heart disease. Heavy drinking results in an increase in heart size, weakening of the heart muscle, abnormal heart rhythms, and risk of the formation of blood clots within the chambers of the heart. These factors greatly increase the risk of stroke, which can occur if a blood clot from the heart enters the circulatory system, goes to the brain, and blocks one of its blood vessels.
- Reproductive system. Heavy drinking has a negative effect on fertility in both men and women. It decreases testicle and ovary size, thereby interfering with both sperm and egg production. When an alcoholic woman becomes pregnant, she assumes the great risk of giving birth to a baby who has **fetal alcohol syndrome**. This causes distinctive facial defects, lowered IQ, and behavioral problems.

Diagnosis

Two different types of trouble with alcohol are identified. The first is called alcohol dependence, and refers to a person who is physiologically dependent on the use of alcohol. According to the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV)*, an individual must have three of the following traits to be diagnosed with alcohol dependence:

- Tolerance, meaning that a person becomes accustomed to a particular dose of alcohol and must increase the dose in order to obtain the desired effect.
- Withdrawal, meaning that a person experiences unpleasant physical and psychological symptoms when he or she does not drink alcohol.
- The tendency to drink more alcohol than one intends (i.e., once an alcoholic starts to drink, he or she finds it difficult to stop).
- Being unable to avoid drinking or stop drinking once started.
- Having large blocks of time taken up by alcohol abuse.
- Choosing to drink at the expense of other important tasks or activities.
- Drinking despite evidence of negative effects on one's health, relationships, education, or job.

Under DSM-IV, a diagnosis of alcohol abuse requires that one of the following four criteria is met within a 12-month period. Because of drinking, a person repeatedly:

- Fails to live up to his or her most important responsibilities.
- Physically endangers himself, herself, or others (e.g., by drinking when driving).
- Gets into trouble with the law.
- Experiences difficulties in relationships or jobs.

Diagnosis is often brought about when family members relate the alcoholic's difficulties to a physician. A physician may become suspicious when a patient suffers repeated injuries or begins to experience medical problems that seem related to alcohol abuse. Alcohol abuse is so widespread that some estimates suggest that about 20% of a physician's patients will be alcoholics.

Diagnosis is aided by the answers to questionnaires that try to determine what aspects of a person's life may be affected by his or her abuse of alcohol. Determining the exact quantity of alcohol that a person drinks is much less important than learning how drinking affects his or her relationships, jobs, educational goals, and family life. In fact, because the metabolism of alcohol (how the body

KEY TERMS

Blood-brain barrier—A membrane that separates the circulating blood from reaching the brain and the fluid that surrounds it and the spinal cord. It prevents many damaging substances from reaching the brain, but alcohol is able to cross the barrier.

Dependence—A state in which a person requires a steady amount of a particular drug in order to avoid experiencing symptoms of withdrawal.

Detoxification—The phase of treatment during which a patient stops drinking and is monitored and cared for while he or she experiences withdrawal from alcohol.

Relapse—A return to a disease state, after recovery appeared to be occurring; in alcoholism, relapse refers to a patient beginning to drink alcohol again after a period of avoiding alcohol.

Tolerance—A phenomenon whereby a drug abuser becomes physically accustomed to a particular quantity of alcohol (or dosage of a drug), and requires ever-increasing quantities in order to obtain the same effects.

Withdrawal—Those signs and symptoms experienced by a person who has become physically dependent on a drug, experienced upon decreasing the drug's dosage or discontinuing its use.

breaks down and processes alcohol) is so unique, the quantity of alcohol consumed is not a criterion for diagnosing either alcohol dependence or alcohol abuse.

One very simple tool for beginning to diagnose alcoholism is the CAGE questionnaire. It consists of four questions, with the first letters of each key word spelling the word CAGE:

- Have you ever tried to *Cut* down on your drinking?
- Have you ever been *Annoyed* by anyone's comments about your drinking?
- Have you ever felt *Guilty* about your drinking?
- Do you ever need an *Eye-opener* (a morning drink of alcohol) to start the day?

There are other, longer lists of questions that help to determine the severity and effects of a person's alcohol abuse. Given the evidence of genetic involvement in alcoholism, it is important to ascertain whether any relative of the person has ever suffered from alcoholism.

Physical examination may reveal signs suggestive of alcoholism: evidence of old injuries; a visible network of enlarged veins just under the skin around the navel (called caput medusae); fluid in the abdomen (ascites); yellowish tone to the skin; decreased testicular size; and poor nutritional status. Lab work may reveal an increase in the size of red blood cells; abnormalities in WBCs (responsible for fighting **infection**) and platelets (particles responsible for clotting); and an increase in certain liver enzymes.

Treatment

Treatment of alcoholism has two parts. The first step in the treatment of alcoholism, called detoxification, involves helping the person stop drinking and ridding his or her body of the harmful (toxic) effects of alcohol. Because the person's body has become accustomed to alcohol, he or she will need to be supported through withdrawal. Withdrawal will be different for different patients, depending on the severity of the alcoholism (as measured by the quantity of alcohol ingested daily and the length of time the patient has been an alcoholic). Withdrawal symptoms can range from mild to life-threatening. Mild withdrawal symptoms include nausea, aches, diarrhea, difficulty sleeping, sweats, **anxiety**, and trembling. This phase is usually over in about three to five days. More severe effects of withdrawal can include hallucinations, seizures, an unbearable craving for more alcohol, confusion, **fever**, fast heart rate, high blood pressure, and delirium (a fluctuating level of consciousness). Patients at highest risk for the most severe symptoms of withdrawal (referred to as delirium tremens) are those with other medical problems, including malnutrition, liver disease, or Wernicke's syndrome. Delirium tremens usually begins approximately three to five days after the patient's last drink, progressing from the more mild symptoms to the more severe, and may last a number of days.

Patients going through only mild withdrawal are simply monitored carefully to ensure that more severe symptoms do not develop. However, no medications are necessary. Treatment of a patient suffering the more severe effects of withdrawal may require sedating medications to relieve the discomfort of withdrawal and to avoid the potentially life-threatening complications of high blood pressure, fast heart rate, and seizures. Benzodiazepines are helpful in those patients suffering from hallucinations. If the patient is nauseated, fluids may need to be given through a vein (intravenously), along with some necessary sugars and salts. It is crucial that thiamin be included in the fluids, because of its usu-

ally quite low in alcoholic patients. Further, thiamin deficiency can lead to Wernicke-Korsakoff syndrome.

After cessation of drinking has been accomplished, the next steps involve helping the patient avoid ever taking another drink. This phase of treatment is referred to as rehabilitation. The best programs incorporate the family into the therapy; it has no doubt been severely affected by the patient's drinking. Some therapists believe that family members, in an effort to deal with their loved one's drinking problem, sometimes develop patterns of behavior that unintentionally support or "enable" the patient's drinking. This situation is referred to as "codependence," and must be addressed in order to successfully treat a person's alcoholism.

Sessions led by peers, where recovering alcoholics meet regularly and provide support for each other's recoveries, are considered to be among the best methods of preventing a return to drinking (relapse). Perhaps the most well-known group of this kind is called Alcoholics Anonymous, which uses a "12-step" model to help people avoid drinking. These steps involve recognizing the destructive power that alcohol has held over the alcoholic's life, looking to a higher power for help in overcoming the problem, and reflecting on the ways in which the abuse of alcohol has hurt others and, if possible, making amends to those people.

There are also medications that may help an alcoholic avoid returning to drinking. These have been used with varying degrees of success. Disulfiram (Antabuse) is a drug that, when mixed with alcohol, causes a very unpleasant reaction that includes nausea and vomiting, diarrhea, and trembling. Naltrexone (Revia) and acamprosate (**calcium** acetylhomotaurinate) seem to be helpful in limiting the effects of a relapse. None of these medications would be helpful unless the patient is also willing to work very hard to change his or her behavior.

Alternative treatments can be a helpful adjunct for the alcoholic patient once the medical danger of withdrawal has passed. Because many alcoholics have very stressful lives (whether because of or leading to the alcoholism is sometimes a matter of debate), many of the treatments for alcoholism involve dealing with and relieving **stress**. These include massage, **meditation**, and hypnotherapy. The malnutrition of long-term alcohol abuse is addressed by nutrition-oriented practitioners, with careful attention being given to a healthy diet and the use of nutritional supplements, such as **vitamins** A, B complex, and C—as well as certain fatty acids, amino acids, **zinc**, magnesium, and selenium. Herbal treatments include milk thistle (*Silybum marianum*), which is thought to protect the liver against damage. Other herbs believed to be helpful for the patient suffering through

withdrawal include lavender (*Lavandula officinalis*), skullcap (*Scutellaria lateriflora*), chamomile (*Matricaria recutita*), peppermint (*Mentha piperita*), yarrow (*Achillea millefolium*), and valerian (*Valeriana officinalis*). Acupuncture is believed to both decrease withdrawal symptoms and to help improve a patient's chances for continued recovery from alcoholism.

Prognosis

Recovery from alcoholism is a lifelong process. In fact, the person who has suffered from alcoholism is encouraged to refer to himself or herself ever after as "a recovering alcoholic," never a recovered alcoholic. This is because most researchers in the field believe that one can never fully recover from alcohol because the vulnerability to alcoholism is still part of the individual's biological and psychological makeup. The potential for relapse (returning to illness) is always there, and must be acknowledged and respected. Statistics suggest that, among middle-class alcoholics in stable financial and family situations who have undergone treatment, 60% or more can be successful at an attempt to stop drinking for at least a year, and many for a lifetime.

Health care team roles

The International Nurses Society on Addictions (IntNSA) says that it is appropriate for nurses to assess patients for alcohol-related problems in any setting, and to initiate discussion of such problems with not only the patient, but also the family, significant others, and appropriate members of an interdisciplinary health team. Nurses have a responsibility to educate and counsel alcoholic patients, their families, and significant others. Nurses with special knowledge or experience in the subject can play an important role in educating both the community and fellow health-care professionals. General-care nurses might wish to seek help or advice from a clinical specialist in alcoholism. According to IntNSA, the nurse's role in treating alcoholism is not restricted to psychiatric and mental health nursing, as it involves every other clinical nursing specialty. It is important that nurses be aware of community resources so that they can make appropriate treatment referrals. IntNSA offers Certified Addiction Registered Nurse certification to nurses who pass rigorous testing.

Prevention

Prevention must occur at a relatively young age, since the first experience with alcohol intoxication usually occurs during the teenage years. It is particularly important that teenagers who are at high risk for alco-

holism—those with a family history of alcoholism, early or frequent abuse of alcohol, a tendency to drink to drunkenness, alcohol abuse that interferes with school work, a poor family environment, or a history of domestic violence—are educated about alcohol and its long-term effects. How this is best achieved, without irritating the youngsters and losing their attention, is a matter of debate and study.

Allergies

Definition

Allergies are abnormal reactions of the **immune system** that occur in response to otherwise harmless substances.

Description

Allergies are among the most common of medical disorders. About one quarter of all Americans suffer from some form of allergy, such as **asthma**, allergic rhinitis

(hay fever), or atopic dermatitis (eczema). Allergy is the single largest reason for school absence; allergic rhinitis alone is responsible for two million school day absences annually. Allergies cause one out of nine physician visits and are responsible for significant losses of productivity in the workplace.

An allergy is a type of immune reaction. Normally, the immune system responds to **bacteria**, **viruses**, or particles—such as pollen or dust—by producing antibodies (specific **proteins**) capable of binding to antigens (identifying molecules) on the foreign particle. The interaction between the antibody and antigen sets off a series of reactions designed to protect the body from **infection**. When this same series of reactions is triggered by harmless, everyday substances, it is known as an allergy, and the offending substance is called an allergen.

Allergens enter the body through four main routes: the airways, skin, gastrointestinal tract, and the circulatory system.

- Airborne allergens cause the sneezing, runny nose of allergic rhinitis. Airborne allergens can also affect the lining of the **lungs**, causing asthma, or the conjunctiva of the eyes, causing conjunctivitis (pink eye).
- Allergens in food may cause itching and swelling of the lips and throat, cramps, and **diarrhea**. When absorbed into the bloodstream, they may cause urticaria (**hives**) or more severe reactions such as swelling of the skin, mucous membranes, organs, and **brain** (angioedema). Some food allergens may cause **anaphylaxis**, a potentially life-threatening condition marked by tissue swelling, airway constriction, and a sudden drop in **blood pressure**.
- Allergens that come in direct contact with the skin can cause reddening, itching, and blistering (contact dermatitis). Skin reactions can also occur from allergens introduced through the airways or gastrointestinal tract. This reaction is known as atopic dermatitis or eczema.
- Injection of allergens, from insect **bites and stings** or drug administration, can introduce allergens directly into the circulatory system. There they may cause system-wide responses (including anaphylaxis), as well as local reactions of swelling and irritation at the injection site.

Individuals with allergies are not equally sensitive to all allergens. For example, some may have severe allergic rhinitis but no food allergies, others are extremely sensitive to nuts but not to any other food. Allergies may worsen over time. For example, childhood ragweed allergy may progress to year-round dust and pollen allergy. On the other hand, an individual may lose allergic sensitivity. Infant or childhood atopic dermatitis almost always disappears with advancing age. More commonly,

an individual's apparently diminished sensitivity may instead be attributable to reduced exposure to allergens or an increased tolerance for allergy symptoms.

Causes and symptoms

Causes

Mast cells involved in allergic reactions capture and display an antibody, called immunoglobulin E (IgE), that binds to allergens. After the allergen is bound, mast cell granules release a variety of potent chemicals, including histamine, that are responsible for some of allergic symptoms.

Immunologists distinguish allergic reactions into two main types: immediate hypersensitivity reactions, which are mainly mast cell-mediated and occur within minutes of contact with allergen, and delayed hypersensitivity reactions, mediated by T cells (a type of white **blood** cells) and occurring hours to days after exposure.

Inhaled or ingested allergens usually cause immediate hypersensitivity reactions. Allergens bind to IgE antibodies on the surface of mast cells, which release the contents of their granules onto neighboring cells, including **blood vessels** and nerve cells. Histamine binds to the surfaces of these other cells through special proteins called histamine receptors. Interaction of histamine with receptors on blood vessels causes increased leakage, thereby producing fluid collection, swelling, and redness. Histamine also stimulates **pain** receptors, making tissue more sensitive and irritable. Symptoms last from one to several hours following contact.

In the upper airways and eyes immediate hypersensitivity reactions cause the runny nose and itchy, blood-shot eyes typical of allergic rhinitis. In the gastrointestinal tract these reactions lead to swelling and irritation of the intestinal lining, causing the cramping and diarrhea typical of food allergy. Allergens that enter the circulatory system may cause hives, angioedema, anaphylaxis, or atopic dermatitis.

Allergens on the skin usually cause delayed hypersensitivity reaction. Roving T cells contact the allergen, setting in motion a more prolonged **immune response**. This type of allergic response may develop over several days following contact with the allergen, and symptoms may persist for a week or more.

THE ROLE OF INHERITANCE. While allergy to specific allergens is not inherited, the likelihood of developing some type of allergy seems to be, at least for many people. If neither parent has allergies, then the chances of a child developing allergy is approximately 10–20%; when one parent has allergies, it is 30–50%; and when both have allergies, it is 40–75%. Allergy patients share a

genetic predisposition to produce higher levels of IgE in response to allergens. Those who produce more IgE will develop a stronger allergic sensitivity.

COMMON ALLERGENS. The most common airborne allergens are the following:

- plant pollens
- animal fur and dander
- body parts from house mites (microscopic creatures found in all houses)
- house dust
- mold spores
- cigarette smoke
- solvents
- cleaners

Common food allergens include the following:

- nuts, especially peanuts, walnuts, and Brazil nuts
- fish, mollusks, and shellfish
- eggs
- wheat
- milk
- food additives and preservatives

The following types of drugs commonly cause allergic reactions:

- penicillin or other antibiotics
- flu vaccines
- tetanus toxoid vaccine
- gamma globulin

Common causes of contact dermatitis include:

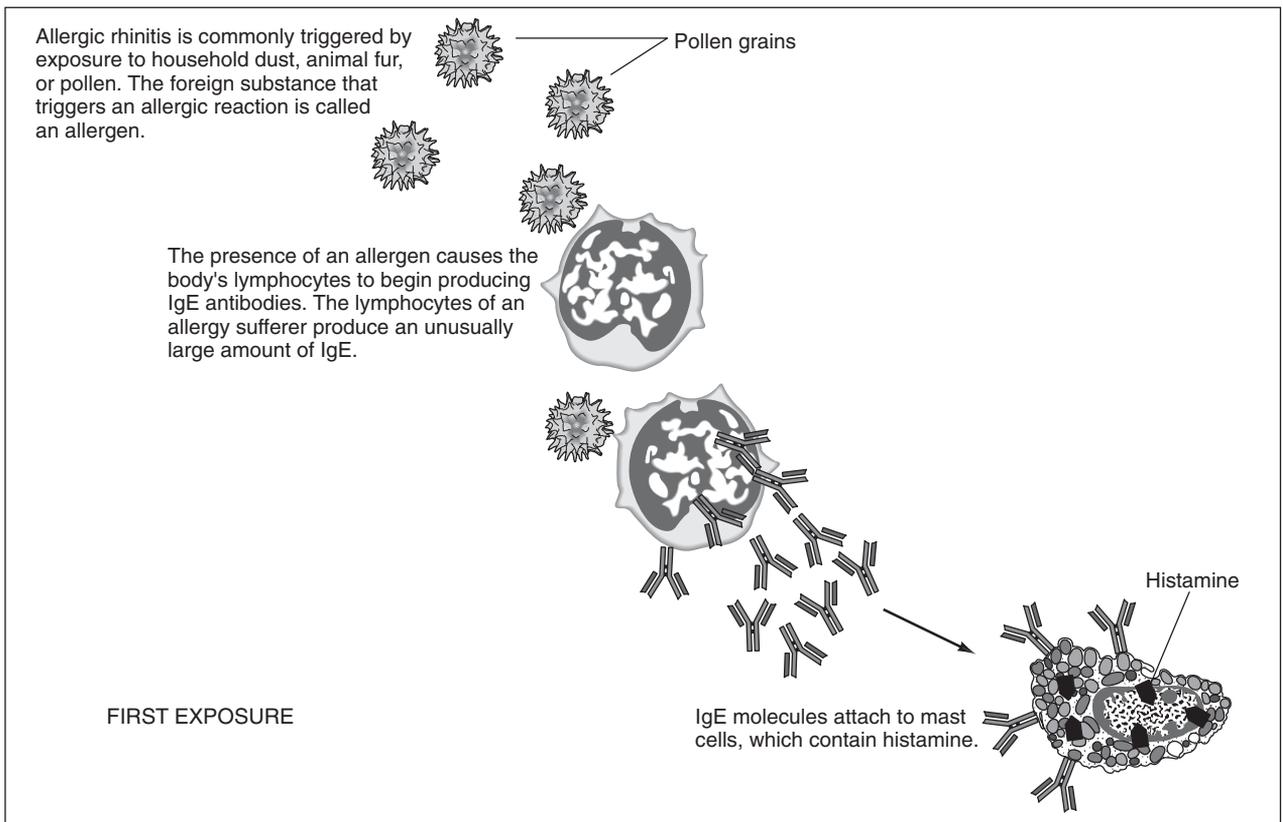

- poison ivy, oak, and sumac
- nickel or nickel alloys
- latex

Insects and other arthropods whose bites or stings typically cause allergy include:

- bees, wasps, and hornets
- mosquitoes
- fleas
- scabies

Symptoms

Symptoms depend on the specific type of allergic reaction. Allergic rhinitis is characterized by an itchy, runny nose, often with a scratchy or irritated throat due to post-nasal drip. Allergic conjunctivitis (inflammation of

The allergic response. (Illustration by Hans & Cassidy.)

the thin membrane covering the eye) causes redness, irritation, and increased tearing in the eyes. Asthma causes wheezing, coughing, and shortness of breath. Symptoms of food allergies depend on the tissues most sensitive to the allergen and whether it is spread systemically by the circulatory system. Gastrointestinal symptoms may include swelling and tingling in the lips, tongue, palate or throat, and nausea, cramping, diarrhea, and gas. Contact dermatitis is marked by reddened, itchy, weepy skin blisters.

Systemic reactions may occur from any type of allergen, but are more common following ingestion or injection of an allergen. Skin reactions include hives and angioedema (a deeper and more extensive skin reaction) involving more extensive fluid collection. Anaphylaxis is marked by airway constriction, blood pressure drop, widespread tissue swelling, **heart** rhythm abnormalities, and, in some cases, loss of consciousness.

Diagnosis

Allergies may often be diagnosed by taking a detailed medical history, matching the onset of symptoms to the exposure to possible allergens. **Allergy tests** may be used to identify potential allergens. These tests usually begin with prick tests or patch tests that expose the skin

to small amounts of allergen to observe the response. Reaction will occur on the skin even if the allergen is normally encountered in food or in the airways.

RAST testing, performed by a laboratory technologist, is a blood test that measures the level of reactive IgE antibodies in the blood. Provocation tests, most commonly done with airborne allergens, present the allergen directly through the route normally involved. Food allergen provocation tests require abstinence from the suspect allergen for two weeks or more, followed by ingestion of a measured amount.

Treatment

A variety of prescription and over-the-counter drugs are available for treatment of immediate hypersensitivity reactions. Most work by decreasing the ability of histamine to provoke symptoms. Other drugs counteract the effects of histamine by stimulating other systems or reducing immune responses in general.

Drugs

ANTIHISTAMINES. **Antihistamines** block the histamine receptors on nasal tissue, decreasing the effect of

histamine released by mast cells. They may be used after symptoms appear, though they may be even more effective when used before symptoms appear. A wide variety of antihistamines are available.

Some antihistamines produce drowsiness as a major side effect. These include:

- diphenhydramine (Benadryl and generics)
- chlorpheniramine (Chlor-trimeton and generics)
- brompheniramine (Dimetane and generics)
- clemastine (Tavist and generics)

Antihistamines that do not cause drowsiness are available by prescription and include the following:

- astemizole (Hismanal)
- loratidine (Claritin)
- fexofenadine (Allegra)
- azelastin HCl (Astelin)

Hismanal has the potential to cause serious heart arrhythmia when taken with the antibiotic erythromycin, the antifungal drugs ketoconazole and itraconazole, or the antimalarial drug quinine. Exceeding the recommended dose of Hismanal may also cause arrhythmia.

DECONGESTANTS. Decongestants constrict blood vessels to counteract the effects of histamine. Nasal sprays, applied directly to the nasal lining and oral systemic preparations are available. Decongestants are stimulants and may cause increased heart rate and blood pressure, headaches, and agitation. Use of topical decongestants for longer than several days can cause loss of effectiveness and rebound congestion, in which nasal passages become more severely swollen than before treatment.

TOPICAL CORTICOSTEROIDS. Topical **corticosteroids** reduce mucous membrane inflammation and are available by prescription. Allergies tend to worsen as the season progresses because the immune system becomes sensitized to particular antigens and can produce a faster, stronger response. Topical corticosteroids are especially effective at reducing this seasonal sensitization because they work more slowly and last longer than most other medication types. As a result, they are best started before allergy season begins. Side effects are usually mild, but may include headaches, nosebleeds, and unpleasant **taste** sensations.

MAST CELL STABILIZERS. Cromolyn sodium prevents the release of mast cell granules, thereby preventing the release of histamine and other chemicals contained in them. It acts as a preventive treatment if it is begun several weeks before the onset of the allergy season. It also may be used for year round allergy prevention.

Cromolyn sodium is available as a nasal spray for allergic rhinitis and in aerosol (a suspension of particles in gas) form for asthma.

Immunotherapy

Immunotherapy, also known as desensitization or allergy shots, alters the balance of antibody types in the body, thereby reducing the ability of IgE to cause allergic reactions. Immunotherapy is preceded by allergy testing to determine the precise allergens responsible. Injections involve very small but gradually increasing amounts of allergen, over several weeks or months, with periodic boosters. Full benefits may take as long as several years to achieve, and are not seen at all in about one in five patients. Patients are monitored closely following each shot because of the small risk of anaphylaxis.

Bronchodilators

Because allergic reactions involving the lungs cause the airways or bronchial tubes to narrow (as in asthma), bronchodilators, which cause the smooth muscle lining the airways to dilate, can be very effective. Some bronchodilators used to treat acute asthma attacks include adrenaline, albuterol, or other adrenergic stimulants, most often administered as aerosols. Theophylline, naturally present in coffee and tea, is another drug that produces bronchodilation. It is usually taken orally, but in a severe asthma attack it may be administered intravenously. Other drugs, including steroids, are used to prevent asthma attacks and in the long-term management of asthma.

Treatment of contact dermatitis

Calamine lotion applied to affected skin can reduce irritation. Topical corticosteroid creams are more effective, though overuse may lead to dry and scaly skin.

Treatment of anaphylaxis

The emergency condition of anaphylaxis is treated with injection of adrenaline, also known as epinephrine. Patients prone to anaphylaxis in response to food or insect allergies often carry an “Epi-pen” containing adrenaline in a hypodermic needle. Prompt injection may prevent a more serious reaction from developing.

Prognosis

Allergies may improve over time, although they often worsen. While anaphylaxis and severe asthma are life threatening, other allergic reactions are not. Learning to recognize and avoid allergy-provoking situations allows most patients with allergies to lead normal lives.

KEY TERMS

Allergen—A substance that provokes an allergic response.

Allergic rhinitis—Inflammation of the mucous membranes of the nose and eyes in response to an allergen; also known as hay fever.

Anaphylaxis—Increased sensitivity caused by previous exposure to an allergen that can result in blood vessel dilation and smooth muscle contraction. Anaphylaxis can result in sharp blood pressure drops and difficulty breathing.

Angioedema—Severe non-inflammatory swelling of the skin, organs, and brain that can also be accompanied by fever and muscle pain.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—A foreign protein to which the body reacts by making antibodies.

Asthma—A lung condition where the airways become constricted due to smooth muscle contraction, causing wheezing, coughing, and shortness of breath.

Atopic dermatitis—Inflammation of the skin as a result of exposure to airborne or food allergens; also known as eczema.

Conjunctivitis—Inflammation of the thin lining of the eye called the conjunctiva.

Contact dermatitis—Inflammation of the skin as a result of contact with a substance.

Delayed hypersensitivity reactions—Allergic reactions mediated by T cells that occur hours to days after exposure.

Granules—Small packets of reactive chemicals stored within cells.

Histamine—A chemical released by mast cells that activates pain receptors and causes cells to become leaky.

Immune hypersensitivity reaction—Allergic reactions that are mediated by mast cells and occur within minutes of allergen contact.

Mast cells—A type of immune system cell found in the lining of the nasal passages and eyelids, with an antibody called immunoglobulin type E (IgE) on its cell surface; mast cells release histamine from intracellular granules.

Health care team roles

Diagnosis and effective management of allergy symptoms involves cooperation and collaboration between the patient and an interdisciplinary team of health care professionals. The patient's primary care physician or pediatrician, allergy and immunology specialists, laboratory technologists, respiratory therapists, pharmacists, pharmacy assistants, and health educators are involved in helping patients and families gain an understanding of how to prevent effectively manage symptoms.

Patient education

Nurses, respiratory therapists, and health educators help patients learn how to prevent and manage allergy symptoms. They teach patients how to distinguish mild allergy symptoms from those requiring immediate medical attention. Pharmacists and pharmacy assistants may offer additional instruction about medication use and reiterate the importance of adhering to prescribed treatment.

Prevention

Avoiding allergens is the best means of limiting allergic reactions. For food allergies, there is no effective treatment except avoidance. By determining the allergens that cause reactions, most patients can learn to avoid allergic reactions from food, drugs, and contact allergens such as poison ivy or latex. Airborne allergens are more difficult to avoid, although keeping dust and animal dander from collecting in the house may limit exposure. Cromolyn sodium can prevent mast cell degranulation, thereby limiting the allergic response.

Allergy tests

Definition

Allergy tests may be of two general types. *In vivo* tests that measure the **immune response** to an agent called an allergen that induces an allergic (atopic) reaction, and *in vitro* tests that measure the antibodies that mediate an allergic response. Such antibodies are those of the immunoglobulin E class (IgE) which have epsilon heavy chains which attach to mast cells.

Purpose

Allergy tests are performed to determine the cause of a person's allergic reaction. An allergic reaction is caused by the production of specific IgE antibodies against one or more antigens. Those antigens that elicit IgE production are termed allergens and are usually harmless substances. Some common allergens are described below.

- house dust mites and their waste
- hair, dander, and saliva of animals with fur or feathers
- cockroaches and their waste
- weed, grass, and tree pollens
- mold and mildew spores
- stinging insects such as bees, wasps, yellow jackets, hornets, and fire ants
- drugs such as penicillin, and sulfa drugs
- foods such as eggs, milk, nuts, and seafood
- ingredients found in dyes, cosmetics, and latex

Precautions

While allergy tests are safe for most people, there is always a possibility that the subject will experience a severe allergic reaction to an allergen used for *in vivo* testing. For this reason, the subject should be exposed to the lowest dose of allergen in the first phase of testing. *In vitro* **blood** tests are particularly appropriate for persons who have a history of severe allergy. *In vitro* testing may also be more appropriate for persons taking **antihistamines**, neuroleptics, or antidepressants, and for those with skin conditions all of which may interfere with skin test results.

Description

An allergic reaction is caused when a person's **immune system** produces IgE antibodies in response to a foreign antigen (allergen). IgE molecules are tightly

bound to the surface of mast cells (and basophils in blood). These cells contain granules that have a high concentration of histamine and other substances that are responsible for the allergic reaction. Upon subsequent exposure to the same antigen, an immediate (type 1) hypersensitivity reaction called the atopic or allergic reaction ensues. The allergen binds to the IgE and the crosslinking of antigen and antibody molecules causes the mast cell to degranulate. The histamine and other allergic mediators are released and cause local swelling (**edema**) and redness (vasodilation). These reactions occur immediately and may be sufficient in intensity to cause constriction of the bronchi and **shock**. Such a systemic response to an allergen is called an anaphylactic reaction. Allergens most often responsible for anaphylactic reactions are insect bites and penicillin in persons who are allergic to these agents.

Allergies may be seasonal or chronic depending upon the exposure to the allergen. An allergy may be influenced by factors such as emotional **stress**, fatigue, **infection**, air pollution, and weather changes that can cause day to day variation in the severity of symptoms. These triggering factors add to what doctors call the "allergic load," the amount of allergens the body can tolerate at any given time without the occurrence of symptoms.

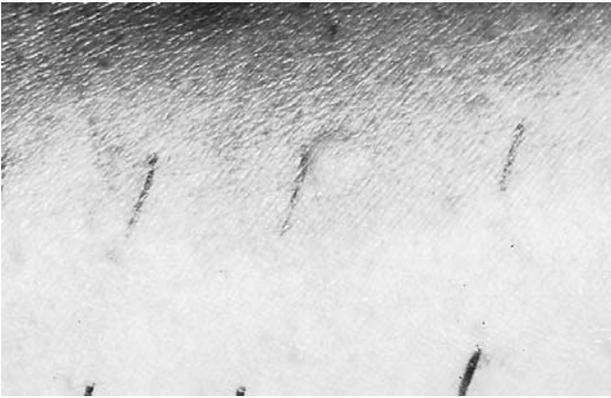

Allergies can manifest themselves in several ways. Conditions commonly caused by allergies include rhinitis, **asthma**, contact dermatitis, allergic **gastritis**, urticaria (**hives**), and conjunctivitis. Allergy tests are used to identify the allergen(s) responsible for the allergy. Once the allergen is known, avoidance and desensitization (**subcutaneous injection** of allergen extract) can be added to the treatment modality.

Types of allergy tests

IN VIVO TESTING. Known as a skin or scratch test, this method is most commonly performed by pricking the skin at multiple sites. Each site is tested by scratching the skin surface with a sterile needle laden with an allergen extract or placing allergen extract on the skin and then pricking the skin with a needle.

The advantages of this testing method include speed (results are immediately available), cost-effectiveness, and a high degree of sensitivity. The disadvantages of this method include patient discomfort, a high incidence of false positives, interference from antihistamines, other drugs and skin conditions.

IN VITRO TESTING. Immunoassays that measure total and specific IgE antibodies are used for *in vitro* allergy testing. The most commonly used method for specific IgE testing is called the RAST test (radioallergosorbent test). This test is a variation of an indirect antiglobulin

A close-up of a patient's arm after allergy testing. (Custom Medical Stock Photo. Reproduced by permission.)

test. The allergen is bound to a solid phase such as a plastic test tube or disc. Serum is added and incubated with the allergen. If IgE antibodies specific for the allergen are present, these bind to the tube or disc. The tube is washed, and anti-human IgE tagged with radioactive iodide is added. This attaches to the allergen-antibody complexes. After incubation, the tube is washed again, and its radioactivity is measured. The amount of radioactivity is directly proportional to the IgE concentration. This can be quantified by comparing the radioactivity of the test to standards. Standards consist of a specific IgE of known concentration (e.g., anti-birch) that is reacted with the respective purified allergen (birch extract). The RAST test can be prepared as a screening test by combining groups of allergens onto a single disc. Results are compared to a low-level IgE standard which serves as a positive cutpoint. Radioactivity above the standard indicates a positive test for allergy, and subsequent tests are performed using the individual allergens to determine the cause of a positive screen.

The immunoassay most commonly used for measuring total IgE is called the PRIST test (paper radioimmunosorbent test). This test is a double antibody sandwich type radioimmunoassay in which the IgE is the antigen. Total IgE in serum can also be determined by immunoassay methods. A positive test for total IgE indicates a diagnosis of allergy when allergic symptoms are present. However, serum IgE levels may be increased in persons with parasitic infections and malignant diseases in the absence of allergy.

In vitro tests have the advantage of being sensitive and specific although they are somewhat less sensitive than skin tests. The reagent quality is highly consistent from lot to lot. The methods are more reproducible and accuracy can be monitored with quality control. *In vitro* methods can be used for persons who are being treated

with antihistamines and other medications. One venipuncture replaces multiple skin scratches that are painful and not well tolerated by young children. Disadvantages of *in vitro* tests are higher costs and longer turnaround time than skin tests (specific IgE tests require 1-2 days before results are available because of long incubation times).

OTHER TESTING. Provocation testing may be performed to positively identify suspected allergens after preliminary skin testing. A purified preparation of the allergen is inhaled or ingested in increasing concentrations to determine if it will provoke a response.

Inhalation testing is performed only after a patient's lung capacity and response to the medium used to dilute the allergen has been determined. Once this has been determined, the patient inhales increasingly concentrated samples of a particular allergen, followed each time by measurement of the exhalation capacity. Only one allergen is tested per day.

Provocation testing with food is more tedious than inhalation testing. First the suspect food is removed from the patient's diet for two weeks; then the patient eats a single portion of the suspect food and is monitored for a reaction.

A double-blind food challenge may also be used for diagnosis of food allergy. During this test, various foods, some of which are suspected of inducing an allergic reaction, are each placed in individual capsules; the patient swallows a capsule and is then watched to see if a reaction occurs. Persons with a history of severe allergic food reactions cannot be tested this way.

Preparation

Skin testing is preceded by a brief examination of the skin. The patient should refrain from using allergy medications for at least 48 hours before testing.

Immunoassay and RAST tests require a sample of blood, which is obtained via venipuncture by a nurse or phlebotomist following standard precautions for the prevention of transmission of bloodborne pathogens.

Aftercare

Patients receiving skin tests should be monitored for 30 minutes following testing, and treated promptly should they develop signs of a severe allergic reaction. Occasionally, a delayed anaphylactic response may occur that will require immediate care; therefore, **patient education** regarding how to recognize delayed **anaphylaxis** is vital. The generalized redness and swelling that may occur in the skin test area will usually resolve within a

day or two. More severe reactions may require topical or antihistamine therapy.

Inhalation tests may cause delayed asthma attacks, even if the antigen administered in the test initially produced no response. Severe initial reactions may justify close professional observation for at least 12 hours after testing.

Complications

Intradermal testing may inadvertently result in the injection of the allergen into the circulation, with an increased risk of adverse reactions. Inhalation tests may provoke an asthma attack. Exposure to new or unsuspected allergens in any test carries the risk of anaphylaxis.

Results

Skin testing

Lack of redness or swelling on a skin test indicates no allergic response. A wheal (an area of redness and swelling) exceeding 7 mm in diameter or larger than the histamine control, has a higher diagnostic value than smaller wheals.

Immunoassay testing

SPECIFIC IGE. Quantitative specific IgE cutoffs are the lowest radioactivity levels encountered in the highest dilution of standard used. The IgE level may be reported in RAST units, or as positive, equivocal, or negative.

TOTAL IGE. The upper limit of normal for total IgE is highly age dependent for children. The upper limit increases over the first 10 years, then levels off. The cutoff for adults varies with the test methodology. For the PRIST test the cutoff is approximately 25 kU/L IgE when the standard used is traceable to the 2nd International Reference Preparation of the World Health Organization.

Inhalation testing

In an inhalation test, the exhalation capacity should remain unchanged. Following allergen inhalation, reduction in exhalation capacity of more than 20%, and for at least 10-20 minutes, indicates a positive reaction to the allergen.

Food testing

In a food challenge, no symptoms should occur. Gastrointestinal symptoms within 24 hours following the ingestion of a suspected food allergen indicates a positive response.

KEY TERMS

Allergen—A substance that provokes an allergic response.

Anaphylaxis—Increased sensitivity caused by previous exposure to an allergen that can result in blood vessel dilation (swelling) and smooth muscle contraction. Anaphylaxis can result in shock caused by a sharp fall in blood pressure.

Antibody—A specific protein produced by the immune system in response to a specific foreign protein or particle called an antigen.

Antigen—A foreign protein to which the body reacts by making antibodies.

Histamine—A chemical released by mast cells that causes vasodilation and bronchial constriction.

Mast cells—A tissue analog of the blood basophil, mast cells are prevalent near small blood vessels in the skin, membranes, and bone marrow. Mast cells bind a type of antibody called immunoglobulin E (IgE) on their surface, and participate in the allergic response by releasing histamine from intracellular granules.

Health care team roles

Allergy tests are ordered by a physician. Skin tests and inhalation tests are performed in a doctor's office by a nurse or healthcare worker specially trained to administer the test. A physician, nurse, or physician assistant should monitor patient for signs of anaphylaxis for 30 minutes after testing.

In vitro allergy tests are performed by clinical laboratory scientists CLS(NCA)/medical technologists MT(ASCP). Results are interpreted by a physician usually a specialist in immunologic and allergic diseases.

Alzheimer's disease

Definition

Alzheimer's disease (AD) is the most common form of **dementia**, a neurologic disease characterized by a progressive loss of mental ability severe enough to interfere with normal activities of daily living, lasting at least six months, and not present from birth. AD usually occurs in old age and is marked by a decline in cognitive functions such as remembering, reasoning, and planning.

Description

A person with AD usually has a gradual decline in mental functions, often beginning with slight **memory** loss, followed by losses in the ability to maintain employment, to plan and execute familiar tasks, and to reason and **exercise** judgment. Communication ability, mood, and personality may also be affected. Most people who have AD die within eight years of their diagnosis, although that interval may be as short as one year or as long as 20 years. AD is the fourth leading cause of death in adults after **heart** disease, **cancer**, and stroke.

In 2001, four million Americans have been diagnosed with AD. That number is expected to grow to as many as 14 million by the middle of the twenty-first century as the baby-boomer population ages. These numbers may be seriously underestimated due to new research that suggests mild cognitive impairment may be early stages of AD.

While a small number of people in their 40s and 50s develop the disease (called early-onset AD), AD predominantly affects the elderly. AD affects about 10% of all people over the age of 65 and nearly half of those over 85. Slightly more women than men are affected with AD, since women tend to live longer and occupy a larger proportion of the most affected age groups.

The costs for caring for loved ones with AD is considerable, and has been estimated at approximately \$174,000 per person over the course of the disease. More than 70% of people with AD are cared for at home at an estimated annual cost of \$196 billion. These costs are not supplemented by outside sources. If patients are cared for by paid home caregivers or are placed in **nursing homes**, the total annual out-of-pocket costs by families or third party payees account for \$83 billion and \$32 billion respectively.

Causes and symptoms

Causes

The cause of Alzheimer's disease is unknown. Some strong leads have been found through recent research, however, and these have also given some theoretical support to several new experimental treatments.

AD affects **brain** cells responsible for learning, reasoning, and memory. Autopsies of people with AD indicate that these regions of the brain become clogged with two abnormal structures, neurofibrillary tangles and senile plaques. Neurofibrillary tangles are twisted masses of protein fibers inside nerve cells (**neurons**). Senile plaques are composed of parts of neurons surrounding a group of brain **proteins** called beta-amyloid deposits. While it is not clear exactly how these structures cause problems, some researchers now believe that their formation is responsible for the mental changes of AD, presumably by interfering with the normal communication between neurons in the brain. Drugs approved by the Food and Drug Administration (FDA) increase the level of chemical signaling molecules in the brain, known as neurotransmitters, to make up for this decreased communication ability.

What triggers the formation of plaques and tangles is unknown, although there are several possible candidates. Restriction of **blood** flow may be part of the problem, perhaps accounting for the beneficial effects of estrogen, which increases blood flow in the brain. However, studies in 2001 do not show estrogen as a protection against the development of AD.

Highly reactive molecular fragments called free radicals damage cells of all kinds, especially brain cells, which have smaller supplies of protective antioxidants

thought to protect against free radical damage. **Vitamin E** is one such antioxidant, and its use in AD is showing some benefit.

Several genes have been implicated in AD, including the gene for amyloid precursor protein (APP) responsible for producing amyloid. Mutations in this gene are linked to some cases of the relatively uncommon early-onset forms of AD. Other cases of early-onset AD are caused by mutations in the gene for another protein, presenilin. AD eventually affects nearly everyone with **Down syndrome**, caused by an extra copy of chromosome 21. Other mutations on other chromosomes have been linked to other early-onset cases.

Potentially the most important genetic link was discovered in the early 1990s on chromosome 19. A gene on this chromosome, apoE, codes for a protein involved in transporting **lipids** into neurons. ApoE occurs in at least three forms: apoE2, apoE3, and apoE4. Each person inherits one apoE from each parent, and therefore can either have one copy of two different forms or two copies of one. Compared to those without ApoE4, people with one copy are about three times as likely to develop late-onset AD, and those with two copies are almost four times as likely to do so. Despite this important link, not everyone with apoE4 develops AD, and people without it can still have the disease. Why apoE4 increases the chances of developing AD is not known.

Promising research in 2001 has discovered a protein, apoptosis-inducing factor, that kills cells by disrupting the genetic material at their cores. This discovery could lead to drugs that could turn off this protein that triggers apoptosis or biologically regulated cell death, which is important in **fetal development** but is also implicated in stroke, heart disease, and AD. It is thought that this protein runs out of control and shuts off otherwise healthy cells.

There are several risk factors that seem to increase a person's likelihood of developing the disease. The most significant one is, of course, age; older people develop AD at much higher rates than younger ones. Another risk factor is having a family history of AD, Down syndrome, or **Parkinson's disease**. People who have had head trauma or hypothyroidism may manifest the symptoms of AD sooner.

Many environmental factors have been suspected of contributing to AD, but population studies generally have not borne these out. A study in early 2001, however, showed a specific link between aluminum in drinking water and the incidence of AD. Other suspected risk factors were other pollutants in drinking water, aluminum in any form, and mercury in **dental fillings**. To date, none

of these other factors has been shown to cause AD or to increase its likelihood.

Lifestyle factors, moreover, may prove to be better indicators of risk. Lack of stimulation, mentally and physically, between the ages of 20 and 60 seems linked to the incidence of AD. Studies have not shown, though, that a sedentary lifestyle early in life causes AD or whether it is a marker for the incidence of the disease.

Another study of African Americans and their Nigerian counterparts shows AD appearing more often in the American population than the African one. Researchers suggest that environmental or cultural factors may play a role in the formation of AD. Here, physical activity or diet may play a part.

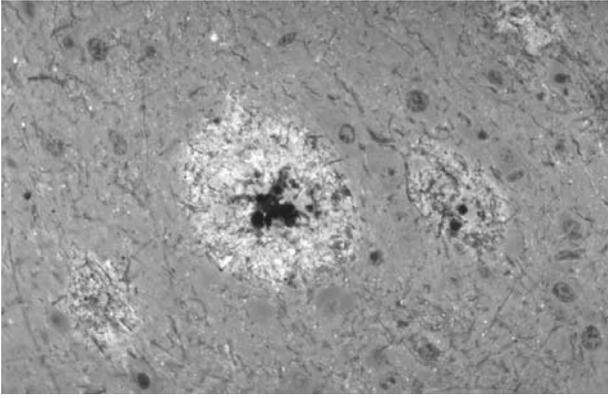

Symptoms

The symptoms of Alzheimer's disease begin gradually, usually with memory lapses. Occasional memory lapses are common to everyone and do not, by themselves, signify any change in cognitive function. The person with AD may begin with only the routine sort of memory lapse—forgetting where the car keys are—but progresses to more profound or disturbing losses such as forgetting how to even drive a car. Being lost or disoriented on a walk around the neighborhood becomes more likely as the disease progresses. A person with AD may forget the names of family members, or forget what was said at the beginning of a sentence by the end of the sentence.

As AD progresses, other symptoms appear, including inability to perform routine tasks, loss of judgment, and personality or behavior changes. Some patients have trouble sleeping and may suffer from confusion or agitation in the evening, known as sunseting. In some cases, people with AD repeat the same ideas, movements, words, or thoughts, a behavior known as perseveration. There may be delusional thinking or even hallucinations. In the final stages people may have severe problems with eating, communicating, and controlling their bladder and bowel functions.

The Alzheimer's Association has developed a list of 10 warning signs of AD. A person with several of these symptoms should see a physician for a thorough evaluation:

- memory loss that affects job skills
- difficulty performing familiar tasks
- problems with language, as in word-find problems or inappropriate word substitutions
- disorientation about time and place
- poor or decreased judgment

Diseased tissue from the brain of an Alzheimer's patient showing senile plaques within the brain's gray matter.

(Photograph by Cecil Fox, Photo Researchers, Inc. Reproduced by permission.)

- problems with abstract thinking
- misplacing things
- changes in mood or behavior
- changes in personality
- loss of initiative

Other types of dementia, including some that are reversible, can cause similar symptoms. It is important for the person with these symptoms to be evaluated by a professional who can weigh the possibility that the symptoms may have another cause. Approximately 20% of those originally suspected of having AD actually have some other disorder; about half of these cases are treatable.

Diagnosis

Diagnosis of Alzheimer's disease is complex and may require visits to several different specialists over several months before a determination can be made. With new diagnostic tools and criteria, it is possible to make a provisional diagnosis that is about 90% accurate. A positive confirmation of these findings can be made only through **autopsy**.

Early diagnosis is essential in helping the patient and the family make decisions about treatment, long-term care, and financial matters. Finding out that a loved one's behavior is based on a degenerative mental disease can help a family avoid unnecessary anger and feelings of impotence when dealing with the progression of the disease.

There are two diagnoses the clinical team can make for a patient. They are probable AD or possible AD. Probable AD is determined when physicians and psychiatrists rule out all other disorders that might produce similar symptoms. A diagnosis of possible AD is made when

AD is considered the primary reason for the symptoms but is complicated with the presence of another disorder that might confuse the general progression of the disease.

Diagnosis for AD begins with the elimination of other physical and psychological causes for the patient's behavior. This is done through a multi-step process that tests for other disorders and measures the amount of deficit the patient is experiencing.

Patient history

A detailed medical history should be taken, noting a list of the patient's medicines (prescription and over the counter), **vitamins**, and herbs. Since there are many pharmaceuticals that can cause the same mental changes as AD, a careful review of the patient's medication, alcohol, and herbal use is important. If the patient's symptoms are related to any of these, most likely the condition can be reversed through adjustments in the patient's medications or herbal use. Any illicit drugs should also be reported.

Next, the physician should take a detailed report of any changes in the patient's mental functioning and memory. This will determine the mode of onset of symptoms, the progression of the deficits, and the impact of the impairment on daily functioning.

Physical exam and lab tests

AD-like symptoms can also be provoked by other medical conditions, including tumors, **infection**, thyroid malfunctioning, and dementia caused by mild strokes (multi-infarct dementia). These possibilities must be ruled out through blood screens, urine tests, electroencephalographs (EEGs), and a variety of imaging techniques.

A genetic test for the ApoE4 gene is available, but is not used for diagnosis, since possessing even two copies does not ensure that a person will develop AD.

Cognitive functioning evaluation

Several types of oral and written tests are used in AD diagnosis and disease progression, including tests of mental status, language ability, functional ability, memory, and concentration. In the early stages of the disease, the results of these tests are usually normal. It should be noted that the widely-used Mini-Mental State Examination (MMSE) may not be accurate for highly educated or poorly educated individuals, or cultural minorities.

Neuropsychiatric evaluation

A detailed cognitive evaluation can be done by a psychologist or psychiatrist. These tests of memory and

mental functioning provide a quantitative measure of the patient's deficits.

One of the most important parts of the diagnostic process is the evaluation of depression and delirium, since these can be present with AD or may be mistaken for it. (Delirium involves a decreased consciousness or awareness of one's environment.) Depression and memory loss are both common in the elderly, and the combination of the two can often be mistaken for AD. Depression can be treated with drugs, although some antidepressants can worsen dementia if it is present, further complicating both diagnosis and treatment.

Imaging studies

Several imaging techniques can assess brain function and pathology, thus eliminating these as causes of the patient's symptoms. Most frequently used imaging scans are **magnetic resonance imaging (MRI)** or computed tomography (CT) scans, which detect structural changes in the brain. Brain function can be assessed through MRI, **positron emission tomography (PET)**, and single-photon emission CT (SPECT). These tests help rule out stroke, subdural hematoma, and **brain tumor** as possible causes for the patient's symptoms.

Treatment

Alzheimer's disease is currently incurable, though a number of pharmaceuticals and **home care** strategies can manage the disease. The mainstay of AD treatment continues to be good nursing care, providing both physical and emotional support, as the patient gradually is able to do less independently and whose behavior becomes more erratic. Modifications of the home to increase safety are often necessary. Creative strategies to help the patient stay as independent as possible are also indicated. The caregiver also needs support to minimize anger, despair, and burnout.

Drugs

Donepezil hydrochloride (Aricept), rivastigmine (Exelon), and galantamine (Reminyl) have been approved for use in AD treatment. These drugs increase the levels of the neurotransmitter acetylcholine in the brain, thereby increasing the communication ability of the remaining neurons. They do this by inhibiting the enzymes, acetylcholinesterase and butylcholinesterase, which normally break down acetylcholine and butylcholine released by neurons. These drugs modestly increase attention span, concentration, mental acuity, and information processing. Tacrine (Cognex), the first drug used, is no longer used due to the risk of **liver** toxicity.

All cholinesterase inhibitors have mild gastric side effects such as nausea and vomiting.

The antioxidant, vitamin E, is also thought to delay AD onset because it prevents neuron damage caused by free radicals. Vitamin E therapy, in combination with cholinesterase inhibitors, has become a practice standard in the treatment of AD.

Drugs that have been found ineffective are Selegiline (used in the treatment of Parkinson's disease), prednisone, and the anti-inflammatory NSAID diclofenac. Estrogen, once thought to be the keystone in treatment and prevention of AD in women, was found to be ineffective in mitigating symptoms in 2001. There is still some discussion about estrogen's ability to delay the onset of AD.

Depression may be treated with selective serotonin reuptake inhibitors (SSRIs) such as citalopram and sertraline. Physicians may also prescribe typical antipsychotics for agitation, aggression, or hallucinations, such as olanzapine, quetiapine, or risperidone. It should be noted that AD patients have more side effects from most medications, especially psychoactive drugs, and care should be taken in their selection.

Alternative treatment

Several substances are currently being tested for their ability to slow the progress of Alzheimer's disease. Among them are ginkgo extract, derived from the leaves of the Ginkgo biloba tree, and huperzine A, from the moss Huperzia serrata. Ginkgo extract has antioxidant, anti-inflammatory, and neuroprotective effects and has been used for many years in China and is widely prescribed in Europe for treatment of circulatory problems. It has been shown to modestly improve cognitive function. Huperzine A is a natural cholinesterase inhibitor. It is reported to produce greater improvement than the synthetic cholinesterase inhibitors and has few side effects. Since neither herbal is regulated, they may have inconsistent levels of their active ingredients per dosage.

Nursing care and safety

The person with Alzheimer's disease will gradually lose the ability to dress, groom, feed, bathe, or use the toilet without help; in the late stages of the disease, the individual may be unable to move or speak. In addition, the person's behavior becomes increasingly erratic. A tendency to wander may make it difficult to leave the patient unattended for even a few minutes, which would make even the home a potentially dangerous place. In addition, some patients may exhibit inappropriate sexual behaviors.

Nursing care required for AD patients is simple enough to learn. The difficulty for many caregivers comes in the constant but unpredictable nature of the demands put on them. Additionally, the personality changes presented in AD can be heartbreaking for family members as a loved one deteriorates, seeming to become a different person. Not all AD patients develop negative behaviors: some become gentle, spending increasing amounts of time in dream-like states.

A loss of grooming skills may be one of the early symptoms of AD. Mismatched clothing, unkempt hair, and decreased interest in personal hygiene become more common. Caregivers, especially spouses, may find these changes socially embarrassing and difficult to cope with. The caregiver will begin to assume more and more grooming duties for the patient as the disease progresses.

Ensuring proper **nutrition** for the AD patient may require using a colored plate to focus the patient's attention on the food. Finger foods may be preferable to those foods requiring utensils. Later, the caregiver may need to feed the patient. As movement and swallowing become difficult, a feeding tube may be placed into the **stomach** through the abdominal wall, which will require special attention.

For many caregivers, incontinence becomes the most difficult problem to deal with at home, and is a principal reason for pursuing nursing home care. In the early stages, limiting fluid intake and increasing the frequency of toileting can help. Careful attention to hygiene is important to prevent skin irritation and infection from soiled clothing.

Safety will become of prime importance. In all cases, a person diagnosed with AD should not be allowed to drive, because of the increased potential for accidents and the increased likelihood of wandering far from home while disoriented. In the home, grab bars in the bathroom, bed rails on the bed, and clutter-free passageways can greatly increase safety. Electrical appliances should be unplugged and put away when not in use, and matches, lighters, knives, or weapons should be stored out of reach. The hot water heater temperature should be set lower to prevent accidental scalding. A list of emergency numbers, including the poison control center and the hospital emergency room, should be posted by the phone.

A calm, structured environment with simple orientation aids such as calendars and clocks may reduce **anxiety** and increase safety. Labeling cabinets and drawers may keep the patient's attention focused. Scheduling meals, bathing, and other activities at regular times and places will provide emotional security and routine, since unfamiliar places and activities can be disorienting for the patient. Sleep disturbances may be minimized by

keeping the patient engaged in activities during the day, offering structure and providing physical activities.

Care for the caregiver

Family members or others caring for a person with AD have a difficult and stressful job, which becomes harder still as the disease progresses. It is common for caregivers to develop feelings of anger, resentment, guilt, and hopelessness, in addition to the sorrow they feel for their loved one and for themselves. Depression is an extremely common consequence of being a full-time caregiver for an AD patient. Support groups are an important way to deal with the **stress** of caregiving. The location and contact numbers for AD caregiver support groups are available from the Alzheimer's Association; they may also be available through a local social service agency, the patient's physician, or pharmaceutical companies that manufacture the drugs used to treat AD. Medical treatment for depression may be an important adjunct to group support.

Outside help, nursing homes, and governmental assistance

Most families eventually need outside help to relieve some of the burden of around-the-clock care for an AD patient. Personal care assistants, either volunteer or paid, may be available through local social service agencies. Adult daycare facilities are becoming increasingly common. Meal delivery, shopping assistance, or respite care may be available as well.

Providing the total care required by a person with late-stage AD can become an overwhelming burden for a family, even with outside help. At this stage, many families consider nursing home care. This decision is often one of the most difficult for the family, since it is often considered an abandonment of the loved one and a failure of the family. Counseling with a physician, clergy, or other trusted adviser may ease the difficulties of this transition. Selecting a nursing home may require a difficult balancing of cost, services, location, and availability. Keeping the entire family involved in the decision may help prevent further stress from developing later on.

Several federal government programs may ease the cost of caring for a person with AD, including Social Security Disability, **Medicare**, and Supplemental Security Income. Each of these programs provides some assistance for care, medication, or other costs, but none of them will pay for nursing home care indefinitely. **Medicaid** is a state-funded program that may provide for some or all of the cost of nursing home care, although there are important restrictions. Details of the benefits and eligibility requirements of these programs are avail-

able through the local Social Security or Medicaid office, or from local social service agencies. Long-term care insurance can also be another option, if taken out prior to the diagnosis.

Prognosis

Alzheimer's disease can weaken the aging body, making it more susceptible to life-threatening infections such as **pneumonia**. In the late stages of the disease, autonomic body functions may be impaired, the patient falling into a **coma**, and death following. In addition, other diseases common in old age—cancer, stroke, and heart disease—may lead to more severe consequences in a person with AD. On average, people with AD live eight years past their diagnosis, with a range from one to 20 years.

Health care team roles

Treatment of AD is a team effort, involving primary care physicians, nurses, imaging and laboratory technicians, gerontology specialists, psychiatrists, psychologists, nursing staff, and caregivers. Physicians order tests that aid in the diagnosis and treatment of AD. These experts must educate the patient and the caregivers in the nature of the disease and its progression, although this burden usually falls on the nursing staff. Nurses are also the first line of access to medical care and support groups. Social workers, counselors, and support group facilitators may also provide emotional support, practical advice, and information about community resources. Special Alzheimer's disease facilities may be used for either respite day care or as permanent long-term care placements.

Prevention

There is currently no proven way to prevent Alzheimer's disease, though some of the drug treatments may delay the development of the disease. The most likely current candidate is estrogen. However, staying active mentally and physically throughout life may be key to prevention.

KEY TERMS

Acetylcholine—One of the substances in the body that helps transmit nerve impulses.

Dementia—Impaired intellectual function that interferes with normal social and work activities.

Donepezil hydrochloride (Aricept)—A drug that increases the brain level of the neurotransmitter acetylcholine, which is given once a day to treat AD.

Ginko—An herb from the Ginko biloba tree that some alternative practitioners recommend for the treatment of AD.

Neurofibrillary tangle—Twisted masses of protein inside nerve cells that develop in the brains of people with AD.

Senile plaque—Structures composed of parts of neurons surrounding brain proteins called beta-amyloid deposits and found in the brains of people with AD.

Sunsetting—Confusion or agitation in the evening.

Tacrine (Cognex)—A drug that may help improve memory in people with mild to moderate cases of AD.

Ambulatory electrocardiography

Definition

Ambulatory **electrocardiography** (ECG or EKG) is the continuous monitoring on an outpatient basis of the electrical activity of the **heart**, with a device called a Holter monitor, while the patient undergoes their usual daily activities.

Purpose

Ambulatory EKG has the ability to detect a number of heart problems that do not show up during standard electrocardiography tests in a doctor's office or during a **stress test** (electrocardiography performed during **exercise**, also in a doctor's office or EKG laboratory). It is commonly used in the evaluation of palpitations (unpleasant awareness of the heartbeats) or **syncope** (fainting) or to detect electrical symptoms of cardiac ischemia, a deficiency of oxygen to the heart due to reduced **blood** flow. This disease is sometimes called "silent" ischemia because there are often no outward symptoms of the oxygen deprivation.

Because ambulatory EKG involves 24 hour monitoring, it is also particularly useful in detecting conditions that occur periodically, such as during sleep or at times of emotional or physical **stress**. The test can be used to screen for arrhythmias (abnormal heartbeats) and is routinely done in patients after myocardial infarctions that resulted in decreased function of the left ventricle. Ambulatory EKG can also detect transient arrhythmias in patients with idiopathic (unknown cause) dilated cardiomyopathy, hypertrophic cardiomyopathy or congestive **heart failure**.

The long-term nature of the test makes it useful in evaluating the effectiveness of medications used to control irregular heartbeats or arrhythmia or the effectiveness of other cardiac treatments. Because of the compact nature of the device, this test was used by astronauts on

the space shuttle to study how the heart adapts to the weightlessness of space.

Precautions

There are no particular precautions for this test.

Description

Ambulatory electrocardiography, also called continuous ambulatory electrocardiography or Holter monitoring, involves being attached to a portable recorder for 24 to 48 hours. The electrical signals are generally recorded on a magnetic tape for later review. To begin the test, an electrodiagnostic technician attaches five adhesive electrodes to the skin of the chest. Typically, electrodes are placed under each collarbone and each bottom rib, and several electrodes are placed across the chest in a rough outline of the heart. Wires snap onto each of these electrodes and connect them to a small recorder that looks like a wearable radio. The electrodes detect the heart's electrical pattern throughout the day and will store information in the recording box for doctors to interpret later. A small purse with a shoulder strap is used to hold this recorder or it is placed on a belt around the waist.

During the test, patients perform normal activities except they cannot take showers or baths and should avoid electric blankets while wearing the monitor. Often patients are given a small diary to record their various activities, such as exercise, eating, sleeping, straining, breathing too hard (hyperventilating), and any stressful situations. The patient also notes the time and circumstances of any symptoms—especially chest **pain**, dizziness, shortness of breath, heart palpitations, and any other signs of heart trouble. Some Holter monitors allow patients to record their symptoms electronically, highlighting the portion of the electrocardiogram recorded while the symptoms are occurring. Additionally, some monitors can also perform **electroencephalography** (EEG), a measurement of the electrical activity of the **brain**. These dual monitors can be useful in the diagnosis of unexplained loss of consciousness (syncope).

A device similar to a Holter monitor, called an event or loop recorder, can be used to perform ambulatory EKG when the symptoms are very periodic. Generally, these devices have only two electrodes and are the size of a beeper. The event recorder can continuously monitor the heartbeat, but will permanently store the patient's heartbeat only after the patient has pushed a button that freezes the recording process. The device can only store about 30 seconds to two minutes of signal. The button system does allow physical symptoms to be directly correlated with the electrical signals of the heart during the event. Stored

signals can be sent through the telephone to the doctor for analysis.

Additionally, because events often last more than a minute and electrodes can be rapidly positioned, the patient can attach to the machine only when a cardiac event occurs. The continuous monitoring issue is completely avoided with newer devices, such as a credit card-sized monitor that is pressed to the chest wall only when the patient detects symptoms.

Preparation

Patients are asked not to apply creams or lotions to the chest before the test, as this may inhibit the attachment of the electrodes. Sometimes the chest will be shaved of hair to improve electrode function. Wearing loose, comfortable clothing will also make the monitoring process easier.

Aftercare

The electrodes are removed after the monitoring period is completed and the patient may return to normal activities. Results are generally available a few days after the test is complete.

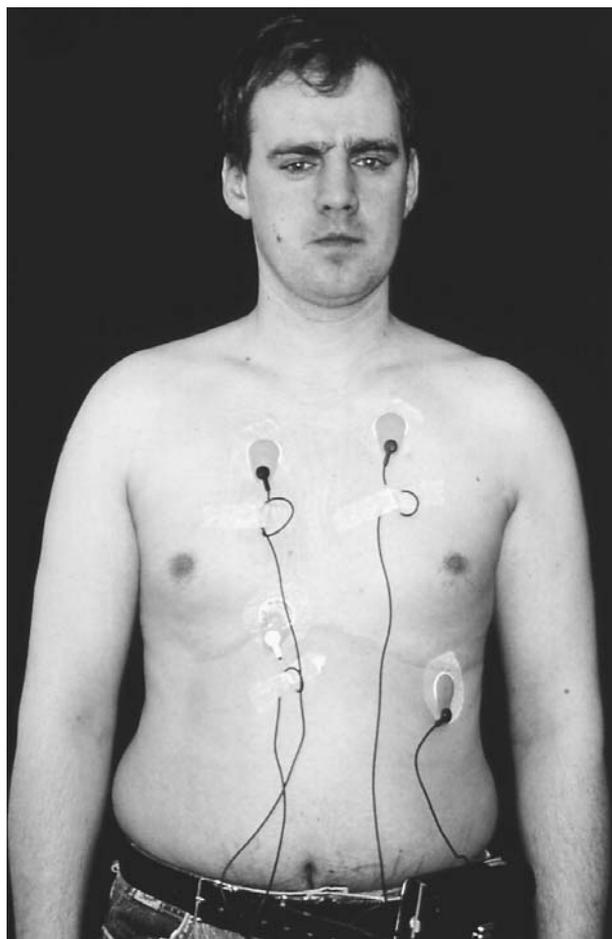

Complications

The only limitations to these monitoring procedures is the need to have recorded the heartbeat during an abnormal event. There are no physical complications that result from the monitoring.

Results

A standard ambulatory EKG will record all the beats of the heart for the period that the device is connected to the patient, while an event recorder will have signals recorded only for a short period after the event button was depressed. Computers are often used as a first stage review the lengthy tapes produced by standard ambulatory EKG testing. The program will highlight abnormal rhythms or abnormal signal shape for closer inspection by the doctor. Some standard monitors are equipped with an event button that highlights electrical output during symptoms. This helps the doctor correlate symptoms with electrical signals, similar to what occurs with a event recorder.

“Silent” ischemia is detected by a change in the shape of the heartbeat signal. In electrocardiography, the five different waves seen in a normal heartbeat are labeled PQRST. Reduced oxygen to the heart often changes the shape of the ST portion of the electrical signal.

A male patient wears electrodes attached to his chest, which are connected to a Holter monitor at his waist.

(Photograph by Dr. P. Marazzi, Photo Researchers, Inc. Reproduced by permission.)

If the purpose of the test is screening for arrhythmias, the recording will be reviewed for any atypical electrical patterns. Among the abnormal patterns that can be seen are transient bradycardia (sporadic abnormally slow heartbeats), atrial fibrillation (rapid, unproductive contraction of the atria), atrial tachycardia (abnormally fast beating of the atria), and paroxysmal supraventricular tachycardia (PSVT), a sporadic fast heartbeat that starts above the ventricles.

If the test is performed to evaluate a treatment, the doctor or technician will scan the record for a return to normal rate and graphic shape of heartbeats.

Health care team roles

Specially trained assistants known as electrocardiograph technicians often prepare patients for ambulatory EKG testing in larger hospital and cardiology group

KEY TERMS

Arrhythmia—An abnormal rhythm of the heart, if transient (periodic) it is often diagnosed using ambulatory EKG.

Cardiomyopathy—A disease of the muscle of the heart.

Ischemia—A lack of oxygen to a tissue, cardiac ischemia is often due to clogging of the coronary arteries.

Palpitation—An unpleasant awareness of the heart beating, can also encompass skipped beats or rapid beats.

Syncope—A loss of consciousness, fainting, a condition that can be caused by heart disease.

practice settings. In small settings, nurses and medical assistants set up the test. A doctor, often aided by a computer, usually does the final interpretation of the tracing.

Training

Many persons learn how to perform ambulatory EKG monitoring through on the job training. However, training programs for EKG work in general, that includes ambulatory techniques, are available through out-sourcing companies or in vocational and community colleges. The usual length of these college-based programs is 465 hours (four months). Program content includes classroom instruction in anatomy and physiology with an emphasis on the cardiac and vascular system, **medical terminology**, cardiovascular medications, patient care techniques, interpretation of cardiac rhythm, **medical ethics**, and a clinical practicum.

American sign language

Definition

ASL is an autonomous linguistic system independent of English. It is a visual/spatial/gestural language that is very expressive and dependent on visual cues of the hands, body and face. ASL contains all the features that are part of a unique communication system: it is symbolic and systematic; it has its own morphology and syntax; and there is a community of users of ASL. ASL is understood to be the "natural" language of deaf people, especially those who are second or third generation deaf. In large part because of its visual and spatial nature, there is no standardized written form of ASL.

Description

In its most basic form ASL originated in the United States in the late 1700s. Over the next two centuries it was transformed into a true language that has been taught to many deaf people. Laurent Clerc and Thomas Gallaudet adapted approximately 60% of Abbe de l'Epee's French Sign Language (FSL) to conform to American customs and manners and incorporated the basic ASL already in use in 1817. Clerc and Gallaudet also opened the American Asylum, the first school for the deaf in North America based on the goal of teaching ASL. Over the centuries the topic of teaching ASL has been quite controversial, with some believing that it should not be taught to deaf children. For example, influential people such as Alexander Graham Bell stressed the importance of oral communication in children who are deaf. Others, however, such as E.M. Gallaudet (nephew of Tomas Gallaudet) were strong proponents of the continued teaching of ASL. From this support of ASL, a deaf community and culture evolved across North America where approximately 2 million members of the deaf community share in the use of this language.

Linguistic structure

Like all other languages, ASL uses arbitrary symbols as its "words." Word order (syntax) of ASL varies according to emphasis, giving the user many expressive possibilities. Information about nouns, subjects or objects, is incorporated into directional verbs by the use of classifiers, and facial/bodily expressions are used as grammatical markers. The syntax of ASL is more closely related to the Navajo language than to the syntax of English. The small meaning units of ASL (its morphology), such as past tense or plural markers, are different

from other languages. ASL does not provide tense marking for each verb in a sentence; rather the tense is marked at the beginning of the conversation and requires no further marking.

Acquisition of ASL

DEAF CHILDREN OF DEAF PARENTS. Only 10% of all deaf children are born to deaf parents, and these children are clearly a minority in the deaf population. However these children have a linguistic advantage over deaf children of **hearing** parents. Deaf children of deaf parents have an accessible language available to them from an early age. Consequently, they develop language at about the same rate as their hearing counterparts. Deaf parents often sign in front of their deaf infants and may often enlarge their children's signs just as hearing parents elongate spoken words in "baby talk." When ASL is acquired first and speech second by these children it is called bilingual acquisition.

DEAF CHILDREN OF HEARING PARENTS. Deaf children of hearing parents typically begin **language acquisition** later as a result of parents not knowing that their child is deaf, often until the child is two to four years old. Therefore, a manual form of language is not used in front of the infant, nor is the child receiving another type of effective communication training, because the infant cannot hear information presented orally. After diagnosis, some of these children may eventually first learn a manual coding of English in the home along with speech. This type of bilingualism is known as bimodal presentation and acquisition. Other deaf children of hearing parents begin to learn ASL soon after diagnosis and learn the language quickly when they are in an environment promoting the use of ASL.

ASL and deaf culture

Deaf culture is "a social, communal, and creative force of, by and for deaf people based on American Sign Language." Deaf culture, however, is not restricted to deaf people; families, friends and advocates of the deaf community may also be a part of deaf culture. Deaf/ASL culture arose during the civil-rights era in the 1960's. It involves deaf people partaking in "visual literature" (for example, ASL poetry, plays, story telling, or humor) as well as, sports and many other physical and visual activities. As a result, the psychosocial basis of deaf culture is understood to mean that deaf people, especially those attending residential schools, regardless of mode of communication taught in the school, will seek out other deaf people and use sign language as a primary mode of communication.

ASL and education

Across North America the majority of deaf children attend public schools. Some of these children may rely on lip reading and other people as note takers, while others may have an ASL interpreter in the classroom. A significant minority of deaf children attend residential schools where communication philosophies vary. Some promote the use of sign language (most often signed English, and fewer, ASL) while others may promote oral communication. However, most children attending residential schools do learn ASL, often from their peers, rather than, or in addition to, their teachers. It is important to note that for deaf children, ASL, as well as signed English, appear to serve, equally well, the same roles in thinking as spoken language does for hearing children.

Implications in healthcare

In the last decade advocates in both the United States and Canada have been promoting better laws that provide ways for deaf people to access health care services more easily in hospitals and government settings. Currently hospitals in the United States are required to provide Tele-Type (TTY) telephone machines that allow deaf patients to make calls, as well as to provide ASL interpreters upon request. Further, the rights of the deaf patient are promoted by hospital regulations that demand that all efforts are to be taken to ensure communication between patients and staff and that the needs of the deaf patient are being met. The above have yet to become laws in Canada. However, efforts are made to provide TTYs and interpreters for Canadian deaf patients. Advocates for the Canadian deaf community continue to push for the implementation of the same laws that protect the American deaf community.

Americans with Disabilities Act

Definition

The Americans with Disabilities Act (ADA) was a bill passed by the United States Congress signed into law by President George Bush on July 26, 1990.

Description

The purpose of the ADA was to make society more accessible to people with disabilities. The ADA applies to qualified individuals with disabilities who (1) have physical or mental impairments that substantially limit one or more major life activities; (2) have a record of such impairments; or (3) are regarded as having such impairments. In addition, the ADA protects persons from discrimination based on an association or relationship with an individual with a disability.

A qualified individual with a disability is defined as a person who meets legitimate skill, experience, education, or other requirements for a position, and who is able to perform the essential functions of the position with or without reasonable accommodation. Requiring that an individual be capable of performing essential functions assures that such an individual will not be disqualified simply due to an inability to perform marginal job functions. If the individual is qualified to perform essential job functions, except for limitations caused by a disability, the employer must consider whether the individual could perform these functions with a reasonable accommodation. A written job description, prepared prior to advertising or interviewing applicants for a job, may be considered evidence of the job's essential functions.

Examples of major life activities may include seeing, **hearing**, speaking, walking, breathing, performing manual tasks, learning, self-care, and working. The ADA covers, for instance, individuals with epilepsy, **paralysis**, HIV, **AIDS**, substantial hearing or **vision** impairment, mental retardation, or specific learning disabilities. It also covers the individual with a record of a disability—for example, a person who has recovered from **cancer** or mental illness.

The ADA protects individuals who are regarded as having a substantially limiting impairment, even though they may not have such an impairment. For example, the ADA protects a qualified individual with a physical disfigurement from being denied employment because an employer is concerned how customers or coworkers might react.

The ADA also protects individuals from company or organization actions based on assumptions that an employee/member's relationship with a person with a disability would affect his or her job performance, and from actions resulting from bias or misinformation concerning certain disabilities. For example, the ADA protects a person whose spouse has a disability from being denied employment because the employer assumes that the applicant would require excessive leave to care for the spouse. The individual who is involved in volunteer work with people who have AIDS is also protected from employment discrimination by the ADA, if such discrimination is motivated by that relationship or association.

Civil rights protections similar to other legislation that provides protection on the basis of race, color, sex, national origin, age, and religion are also provided by the ADA; it also guarantees equal opportunity for individuals with disabilities in public accommodations, employment, transportation, government services, and telecommunications. Discrimination in all employment practices, including job application procedures, hiring, firing, advancement, compensation, training, recruitment, advertising, tenure, layoff, leave, fringe benefits, and all other employment-related activities, is controlled by the ADA.

With regard to both private and public sector employment, including state and local government services, companies with 15 or more employees are also subject to the ADA. Specifically, businesses must accommodate employees or customers with disabilities unless doing so represents an undue hardship or a direct threat to the health or safety of others.

Although the ADA is intended to protect those with disabilities from discrimination, employers are not expected to give preference to a qualified applicant with a disability over other applicants. An employer remains free to select the most qualified applicant available and to make decisions based on reasons unrelated to a disability.

Financial assistance for employers

To enable smaller employers to make reasonable accommodations, a special tax credit is available. A tax credit of up to \$5,000 per year for accommodations, made to comply with the ADA, may be taken by an eligible small business. A full tax deduction of up to \$15,000 per year is available to any business for expenses incurred during the removal of qualified architectural or transportation barriers. Covered expenses include removing barriers created by steps, narrow doors, inaccessible parking spaces, restroom facilities, and transportation vehicles.

Enforcement

The ADA's employment provisions are enforced under the same procedures now applicable to race, color, sex, national origin, and religious discrimination under title VII of the Civil Rights Act of 1964 and the Civil Rights Act of 1991. Available remedies include hiring, reinstatement, promotion, back pay, front pay, restored benefits, reasonable accommodation, attorneys' fees, expert witness fees, and court costs. Compensatory and punitive damages also may be available in cases of intentional discrimination or where an employer fails to make a good faith effort to provide a reasonable accommodation.

Viewpoints

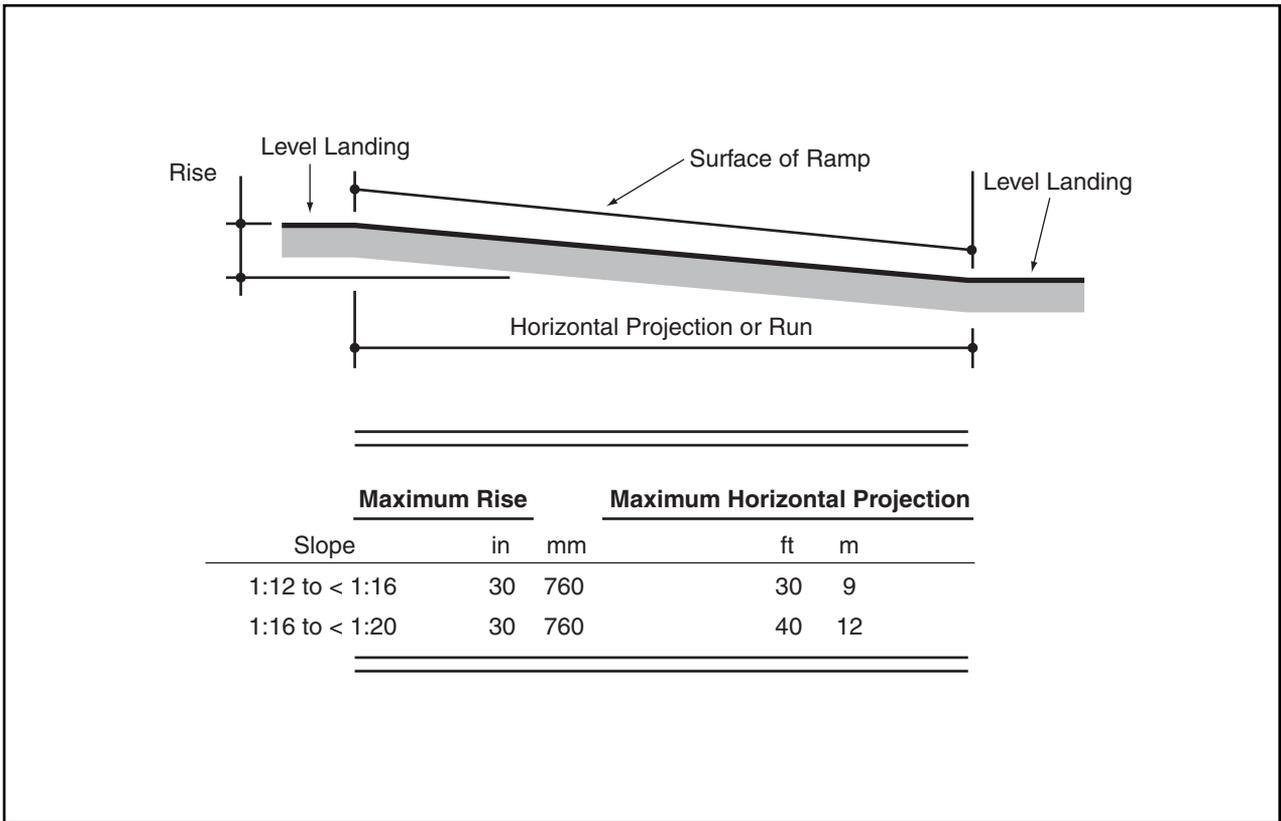

Despite the ADA's laudable intentions, it is not without critics. It is pointed out by those who find fault with the ADA that its definitions are too broad, vague, or ill-defined. Others suggest that unnecessary litigation has been spawned by the ADA, which has not been effective in moving those with disabilities from welfare to the workforce, and requires employers to shoulder burdensome costs to accommodate individuals with disabilities despite available tax credits available from the federal government.

American Disabilities Act defenders point out an example of a recent study reporting that companies' insurance costs rarely rise because of hiring individuals with disabilities. Obvious benefits generated by the ADA are also observed by supporters. Among these benefits are increased attention to pervasive discrimination against and widespread unemployment of people with disabilities, and their willingness and potential to contribute to society. Stereotypes about people with disabilities have been revealed by studies. It is clear that people with disabilities are hired less and fired more than other employees.

Professional implications

Medical examinations

According to the ADA, employers may conduct employee medical examinations when there is evidence of a job performance or safety problem, when it is required by federal law, when it is necessary to determine an individual's fitness to perform a particular job, or when voluntary examinations are part of employee health programs. However, information from medical examinations must be kept confidential. According to the ADA,

Wheelchair ramp measurements are regulated to keep the incline from being too steep. (Illustration by Argosy. Courtesy of Gale Group.)

testing for illegal drug use is not considered part of a medical examination.

An employer may not ask or require an applicant to take a medical examination before extending a job offer. Furthermore, pre-employment inquiries about a disability or the nature or severity of a disability cannot be made by an employer. However, questions may be asked by the employer about the individual’s ability to perform specific job functions. In addition, an individual with a disability may be asked by an employer to describe or demonstrate how he or she would perform such functions.

An employer may qualify a job offer based on a satisfactory post-offer medical examination or medical inquiry, provided this is required of all employees in the same job category. A post-offer examination or inquiry does not have to be job related.

In the event that a post-offer medical examination or inquiry reveals a disability and the individual is not hired, the reason for the rejection must be job related. An employer must show that reasonable accommodations were not available to enable the individual to perform the essential job functions, or that such accommodations

would have imposed an undue hardship. A post-offer medical examination may disqualify an individual. If the employer can demonstrate that a direct threat in the workplace—that is, that a significant risk or substantial harm to the health or safety of the individual would also pose a direct threat in the workplace—a significant risk of substantial harm to the health or safety of the individual or others that cannot be eliminated or reduced below the direct threat level through reasonable accommodation. Such a disqualification must be job related and consistent with business necessity. In addition, an individual with a disability who is able to perform essential job functions may not be disqualified due to speculation that the disability may cause a risk of future injury.

Reasonable accommodation

A reasonable accommodation is any modification or adjustment to a job or the work environment that enables a qualified applicant or employee with a disability to participate in the application process or to perform essential job functions. A reasonable accommodation includes adjustments to assure that a qualified individual with a

disability is provided with the same employment rights and privileges extended to employees without disabilities.

Reasonable accommodation may include making existing facilities used by employees readily accessible to, and usable by, an individual with a disability. In addition, it may involve restructuring a job; modifying work schedules; acquiring or modifying equipment; providing qualified readers or interpreters; or appropriately modifying examinations, training, or other programs. Reasonable accommodation also may include reassigning a current employee to a vacant position for which he or she is qualified, if the person is unable to do the original job because of a disability even with an accommodation. However, an employer is not obligated to find a position for an applicant who is not qualified for the position sought, nor are employers required to lower quality or quantity standards as an accommodation.

Appropriate accommodation decisions must be based on the facts in each case—that is, whether the accommodation will provide an opportunity for a person with a disability to achieve the same level of performance and the potential to enjoy benefits equal to those of a person without a disability. However, the accommodation does not have to ensure equal results or provide exactly the same benefits.

An employer is only required to accommodate a known disability of a qualified applicant or employee. The requirement is typically initiated by a request from an individual with a disability. Accommodations must be made on an individual basis since the nature and extent of a disabling condition and the requirements of a job vary with each case. If the individual does not request an accommodation, the employer is not obligated to provide one except where an individual's known disability impairs the ability to know of, or effectively communicate a need for, an accommodation obvious to the employer. If an appropriate accommodation is requested by a person with a disability (but not suggested by the employer, who cannot "suggest" this), the employer and the individual should work together to identify one. There are a number of resources that provide assistance without cost.

An employer is not required to make an accommodation if it would impose an undue hardship on the employer's business. Undue hardship is defined as an "action requiring significant difficulty or expense." This includes the nature and cost of the accommodation in relation to the size, resources, nature, and structure of the employer's operation. Undue hardship is determined on an individual basis. In general, a larger employer with greater resources would be expected to make accommo-

dations requiring greater effort or expense than a smaller employer with fewer resources.

If an accommodation represents an undue hardship, the employer must try to identify another accommodation that will not pose such a hardship. Also, if the cost of an accommodation would impose an undue hardship on the employer, the individual with a disability should be given the option of paying that portion of the cost that would constitute an undue hardship or provide the accommodation.

The employer is obligated to provide access for an individual applicant to participate in the job application process, and for an individual employee with a disability to perform the essential functions of the job, including access to a building, the work site, necessary equipment, and all facilities used by employees.

However, an employer is not required to make existing facilities accessible until an employee with a disability needs an accommodation. The employer does not have to make changes to provide access in places or facilities that will not be used by that individual for employment-related activities or benefits.

Testing

Accommodations may be needed to assure that tests or examinations measure the actual ability of an individual to perform job functions, rather than reflect limitations caused by the disability. Tests should be given to people who have sensory, speaking, or manual impairments in a manner that does not require the use of the impaired skill, unless the test is designed to measure a job-related skill.

Amino acid disorders screening

Definition

Amino acid disorders screening is performed to detect inherited and acquired disorders in amino acid **metabolism**. Tests are most commonly done in the neonatal period.

Purpose

Twenty of the 100 known amino acids are the main building blocks for human **proteins**. Of these 20 amino acids, ten (essential amino acids) are not made by the body and must be acquired through diet. Proteins regulate every aspect of cellular function. The goal of amino acid disorder screening is early detection and intervention. Errors of amino acid metabolism range from asymptomatic or benign to life-threatening. In some cases, management by dietary restriction of the amino acid(s) involved can prevent damage or symptoms.

Precautions

All neonates should be screened for the most prevalent aminoacidurias within a few days of birth. Usually this includes tests for phenylketonuria, tyrosinemia, lysinemia, maple syrup urine disease, and homocystinuria using a dried spot of **blood** collected on a paper card. When an infant displays symptoms such as failure to thrive, repeated vomiting, or nervous system impairment and an amino acid disorder is suspected, testing may be done on either plasma or urine. The patient should be fasting for the blood test. Blood samples are usually collected by heel puncture. The nurse or phlebotomist should observe **universal precautions** for the

prevention of transmission of bloodborne pathogens when collecting the sample. Blood samples show considerable variance depending upon the time of sampling, and urine testing avoids this problem. Urine testing should be performed on a first morning voided sample or a 24-hour urine sample. Some drugs may affect the results of amino acid tests by certain methods of analysis. Any medications being given to the patient should be reported to the laboratory performing the test. **Antibiotics** will adversely affect the growth of the bacterium used in the Guthrie bioassay test for phenylalanine. Mothers of breastfeeding infants should report any medications they are taking, since these can pass from mother to child in breast milk.

Description

An enzyme deficiency that blocks the metabolism of an amino acid is called a primary aminoaciduria. An error in absorption or transport of an amino acid is called a secondary aminoaciduria. Both primary and secondary aminoacidurias may be inherited (congenital) or acquired. Aminoacidurias may be grouped into two types, overflow and renal, based on the mechanism by which the amino acids accumulate. In the overflow type, the plasma level of one or more amino acids will be increased (aminoacidemia). The most common overflow type is phenylketonuria (PKU). The incidence of PKU varies with race and ethnic origin and there are 5 different forms of the disease. The most prevalent is type I which occurs in approximately 1 in 10,000 births in the United States, and accounts for about 50% of PKU cases. Because of its high prevalence all states screen newborns for PKU. This condition is caused by an inherited deficiency of the enzyme phenylalanine hydroxylase. The enzyme is needed to convert phenylalanine to tyrosine. Phenylalanine accumulates in the plasma and is oxidized by phenylalanine transaminase to phenylpyruvic acid which is excreted in the urine. Phenylpyruvic acid is a ketoacid, hence the name phenylketonuria. Mental retardation occurs as a consequence of PKU, but can be prevented by withholding phenylalanine from the diet. There are many other primary aminoacidurias. Several are caused by enzyme deficiencies of the urea cycle. These give rise to increased blood ammonia levels and an increase of one or more amino acids.

In renal type aminoacidurias, one or more amino acids are excreted in excess in the urine but plasma levels are not increased. Some renal type aminoacidurias are inherited, but many are acquired or secondary to other diseases. A common inherited renal type aminoaciduria is cystinuria which results from a defect in the reabsorption of dibasic aminoacids by the kidney.

Measurement

Newborn screening for PKU, tyrosinemia, lysinemia, maple syrup urine disease, and homocystinuria are often performed on a spot of whole blood collected from a heelstick. The test most often used is a bioassay called the Guthrie test. The test is based upon the ability of blood with an excess of the respective amino acid to overcome the effect of a specific inhibitor of the bacterium *B. subtilis*. For example, *B. subtilis* requires phenylalanine for growth. The growth of a culture of the organism can be prevented by adding thienylalanine to the culture medium. However, if excessive phenylalanine is present in the blood, it will overcome the effect of the inhibitor permitting the organism to grow. An alternative screening procedure for excessive phenylalanine that can be performed on a blood spot is the measurement of fluorescence after extraction and reaction with a reagent containing ninhydrin.

Young children with acidosis (accumulation of acid in the body), severe vomiting and **diarrhea**, or urine with an abnormal color or odor, are also tested for abnormal levels of amino acids. The most widely used method is high-performance liquid chromatography because it separates and quantifies all amino acids in the sample. Urine is usually the preferred specimen since it will detect both overflow and renal type aminoacidurias. The most common approach is to separate the amino acids on an ion exchange column using stepwise elution by changing the pH of the mobile phase. As amino acids emerge from the column they are reacted with ninhydrin and the absorbance of derivative formed is measured using a photometric detector.

Preparation

Before the blood test, the patient must not eat or drink for at least four hours. Failure to fast will alter the results of the test. The patient should eat and drink normally before the urine test.

Aftercare

The patient may feel discomfort when blood is drawn from a heel capillary or vein. Bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure should be applied to the puncture site until the bleeding stops to reduce bruising. Warm packs can also be placed over the puncture site to relieve discomfort.

Complications

There are no particular risks associated with either blood or urine tests for amino acids. Occasionally minor bruising may occur at the site where the blood was taken.

KEY TERMS

Amino acid—An organic compound containing both an amino group and an acidic carboxyl group; amino acids are the basic building blocks of proteins.

Aminoacidopathy—A condition involving abnormal amino acid levels in the blood or urine.

Chromatography—A family of laboratory techniques that separate mixtures of chemicals into their individual components.

Enzyme—A biological catalyst that increases the rate of a chemical reaction without being used up in the reaction.

Metabolism—The sum of all the chemical and energy reactions that take place in the human body.

Results

Guthrie test results are reported as either positive or negative. Results of quantitative assay for each amino acid should be compared to age-related reference ranges. Representative normal ranges for phenylalanine are shown below.

- Guthrie test: Negative or less than 2 mg/dL.
- Plasma: neonate 1.2-3.4 mg/dL (40-110 micromol/L) (premature infant 2.0-7.5 mg/dL).
- Urine: neonate 1.2-1.7 mg/day (0-200 micromol/gram creatinine).

Health care team roles

Amino acid tests are ordered and interpreted by a physician. The heel stick or venipuncture is performed by a nurse or phlebotomist. Amino acid analysis is performed by a clinical laboratory scientist/medical technologist. If an aminoacidopathy is suspected, the family is typically referred to a genetic counselor to discuss prognosis and recurrence risks. DNA tests are available for prenatal testing of some aminoacidurias.

Amniocentesis

Definition

Amniocentesis is an optional but reliable procedure offered to pregnant women in order to obtain more information about a developing fetus in the second trimester of **pregnancy**. It is primarily offered to pregnant women who are at increased risk, based on their age, family history, or other factor, of having a child with a genetic condition. Amniocentesis provides accurate information about fetal chromosomes or the likelihood of certain physical abnormalities. Additional specialized studies may be performed on an as-needed basis. Women who undergo amniocentesis typically do so either to obtain reassurance about fetal well-being or, if the results are abnormal, to plan for the remainder of their **prenatal care**. The procedure is associated with a slightly increased chance for pregnancy loss.

Purpose

Amniocentesis has been considered a standard of obstetrical care since the 1970s. It is not, however, offered to all pregnant women. The American College of Obstetricians and Gynecologists (ACOG) recommends that amniocentesis be offered to all expectant mothers age thirty-five and older. This age cut-off has been selected because advancing maternal age is associated with an increasing risk of having a baby with a numeri-

cal chromosome abnormality. At age 35, this risk is approximately one in 200 births roughly equivalent to the risk of pregnancy loss associated with amniocentesis.

Amniocentesis is performed for the following reasons:

- Detection of structural chromosome abnormalities or an increased number of chromosomes in the fetus when the mother is in a high risk group. This includes a maternal age of 35 or more; a mother who is known to carry an abnormal chromosome such as a 21/14 translocation; family history of chromosome abnormalities; a genetic disease such as sickle cell anemia for which a DNA test is available; or abnormal triple marker screening test for **Down syndrome** (i.e., a low serum alpha fetoprotein or estriol or a high chronic gonadotropin level).
- Determination of the sex of the fetus when the mother is a carrier of an X-linked genetic disease such as **hemophilia**.
- Confirmation of an elevated maternal serum alpha fetoprotein result. Alpha fetoprotein is increased in amniotic fluid in pregnancies associated with open neural tube defects such as spina bifida and several other abnormalities that allow the fluid to leak from the fetus into the amniotic fluid.
- To evaluate the severity of hemolytic disease of the newborn (HDN). In this condition, maternal antibodies, usually anti-Rho (D), cross the placenta and facilitate destruction of Rh positive fetal red **blood** cells.
- Evaluation of fetal lung maturity (FLM). **Respiratory distress syndrome** results from collapse of the infant's **lungs** during expiration if the level of pulmonary surfactants is insufficient. This may occur immediately after birth especially in premature deliveries and when the mother is a diabetic. Measurement of surfactants excreted by the fetus into the amniotic fluid is used to determine the maturity of the fetal lungs.

Evaluation studies of HDN and FLM are performed in the second half of pregnancy, whereas tests for alpha fetoprotein (AFP), chromosome karyotyping, and abnormal genes are performed during the first half of pregnancy, typically between weeks 15 and 18.

Precautions

Amniocentesis is associated with a slightly increased chance of pregnancy loss (approximately 0.5%). Each woman should discuss the potential risks and benefits of amniocentesis with a doctor or genetic counselor and make her own decision about whether or not she desires this testing.

Early amniocentesis, or procedures performed before the thirteenth week of pregnancy, has been associated with an increased risk of clubfoot and of procedure-related pregnancy loss. When collecting amniotic fluid **universal precautions** should be followed for the prevention of transmission of bloodborne pathogens. Bloody fluid or fluid containing meconium may interfere with the tests for amniotic fluid bilirubin performed to evaluate the severity of HDN. These substances may also interfere with the interpretation of some FLM tests such as the L:S ratio (which is used to determine the level of the fetus's lung development). Some tests such as the amniotic fluid bilirubin test and alpha fetoprotein test must be interpreted with regard to gestational age.

Description

According to the National Center for Health Statistics (NCHS), 112,776 amniocentesis procedures were performed in the United States in 1998, the most recent year for which data is available. The annual birth rate that year was approximately 3.9 million infants. Thus, approximately 3% of pregnant women in the United States had this procedure performed. It is likely that this is an underestimate. The NCHS obtains information from birth certificates registered in each state and the District of Columbia. Although almost all deliveries are registered in the United States, records are still submitted with incomplete information. It is also not possible to know how many amniocentesis procedures were performed for **genetic testing**, as compared to other indications, as this information is not requested.

Normal persons have a total of 46 chromosomes in each body cell, with the exception of sperm or egg cells that should have only 23. As women get older, there is an increased risk of producing an egg cell with an extra chromosome. This leads to an egg cell with 24 chromosomes rather than the normal 23. Pregnancies with an abnormal number of chromosomes are referred to as aneuploid. Aneuploidy results in a conceptus with either too much or too little genetic material. This, in turn, leads to abnormal development. Aneuploidy results from failure of the chromatids to separate either during meiosis or in the germ line cells of the embryo. Common effects of aneuploidy include an increased risk for pregnancy loss or, in living fetuses, for mental retardation and physical abnormalities.

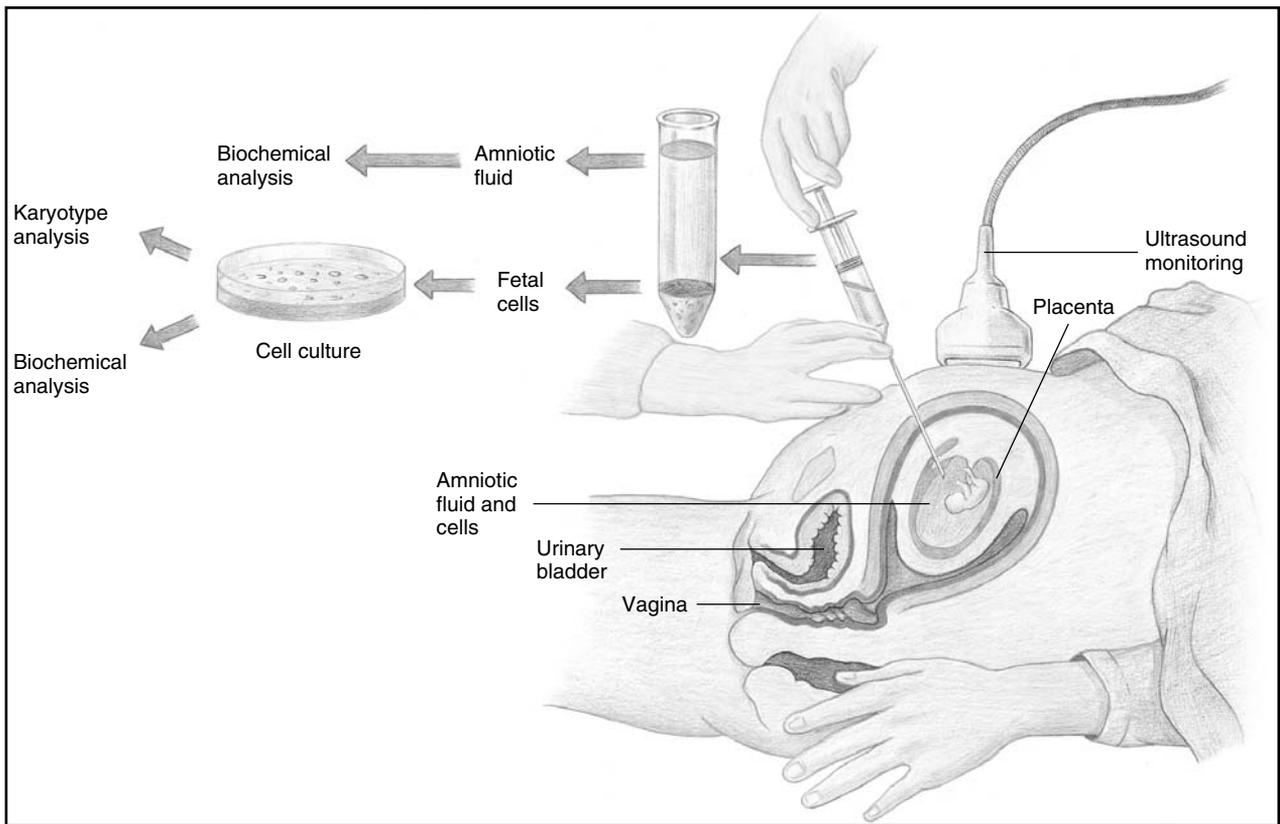

Down syndrome is the most common form of aneuploidy in live born infants, occurring in approximately one in 800 births, regardless of maternal age. The most common form of Down syndrome is 21 trisomy. One of the gametes contains an extra chromosome number 21 resulting in three number 21 chromosomes following fer-

tilization. In women who are 35 years old, the risk of having a child with Down syndrome is higher, roughly one in 385 at delivery. It is important to realize that Down syndrome is not the only chromosome abnormality that may occur. Other numerical abnormalities are possible, yielding genetic conditions that may be either more or less severe than Down syndrome. Thus, a woman is often at risk, based solely on her age, of having a child with any type of chromosome abnormality. At age 35, this total risk is approximately one in 200. By age 40, this risk has increased to one in 65, and, at age 45, this risk is one in 20. These numbers reflect the risk at the time of delivery.

Women younger than 35 years may also have children with chromosomal or other genetic disorders. Therefore, other indications for amniocentesis or other forms of prenatal diagnosis include a family history of or a previous child with a known genetic condition, abnormal prenatal screening results, such as ultrasound or a blood test, or one parent with a previously identified structural chromosome rearrangement. All of the above may make it more likely for a couple to have a child with a genetic condition.

Amniocentesis is the most common invasive prenatal diagnosis technique offered to pregnant women. Its safety and accuracy are well-established, and it is generally considered the standard by which other prenatal diagnosis techniques are measured. To perform the procedure, a doctor inserts a thin needle into the mother's uterus and the amniotic sac. A continuous ultrasound evaluation is typically used so that the doctor can avoid touching either the baby or the umbilical cord with the needle. The amniotic sac is made up of two membranes: the inner amnion and the outer chorion. The amnion and chorion both develop from the fertilized egg. They are initially separate but begin to fuse early in pregnancy. This fusion is usually completed by approximately the fourteenth to fifteenth week of pregnancy.

Amniocentesis is usually performed in the second trimester, usually during weeks fifteen to eighteen (mid-trimester). The amniotic sac holds the fetus suspended within the amniotic fluid, an almost colorless fluid that protects the fetus from harm, helps maintain a consistent temperature, and prevents the fetus, or parts of it, from becoming attached to the amnion. The amniotic fluid is produced and absorbed by the fetus and the mother throughout pregnancy. Fetal cells, primarily derived from the skin, **digestive system**, and urinary tract, are suspended within the fluid. A smaller number of cells from the amnion and placenta are also present. Finally, the fetus produces a number of different chemical substances that also pass into the amniotic fluid. One of these substances is bilirubin, a breakdown product of hemoglobin.

Amniocentesis is performed at 16–18 weeks of pregnancy. (Delmar Publishers, Inc. Reproduced by permission.)

Bilirubin in amniotic fluid is measured to determine the extent of fetal red cell destruction in HDN. Pulmonary surfactants are used in some higher-risk pregnancies to assess fetal lung maturity, and alpha-fetoprotein is used to screen for certain structural birth defects.

It is possible to perform amniocentesis in a twin pregnancy. Amniocentesis in some higher-order pregnancies, such as triplets, has also been reported. In a **multiple pregnancy**, it is important to ensure that a separate sample of amniotic fluid is obtained from each fetus. To accomplish this, a doctor injects a small amount of harmless blue dye into the amniotic sac of the first baby after a sample has been withdrawn. The dye will temporarily tinge the fluid blue-green. A second needle is inserted into the next amniotic sac with ultrasound guidance. If the fluid withdrawn is pale yellow, a sample from the next fetus has been successfully obtained. Since monoamniotic twins share the same amniotic sac, the second sample will be blue.

Chorionic villus sampling

Mid-trimester amniocentesis has been available for nearly thirty years. **Chorionic villus sampling (CVS)** has been available in the United States since the 1980s.

CVS is usually performed between ten and twelve weeks of pregnancy. It involves the removal of a small sample of the developing placenta, or chorionic villi. It has been an attractive alternative to amniocentesis, particularly for those women who desire both testing and results earlier in their pregnancies. Some of the benefits of earlier testing include reassurance sooner in pregnancy and fewer physical complications following first trimester pregnancy termination, for those couples with abnormal babies who choose this option. CVS is, however, associated with a higher risk of **miscarriage** than mid-trimester amniocentesis and because it is performed earlier than amniocentesis more fatal chromosome abnormalities are detected that would not come to term. At experienced centers, this risk is approximately 1% (or one in 100).

Early amniocentesis

Early amniocentesis is performed before the thirteenth completed week of pregnancy. It has been considered investigational for many years. The results of the largest early amniocentesis trial, published in 1998, have, however, caused physicians worldwide to reconsider the benefit and risks of this earlier procedure. The Canadian Early and Mid-trimester Amniocentesis Trial (CEMAT)

is the largest, multi-center, randomized clinical trial of early amniocentesis conducted to date. The purpose of the trial was to examine and compare the safety and accuracy of early amniocentesis (EA) versus mid-trimester amniocentesis (MTA). In order to accomplish this, 4,374 pregnant women were identified and enrolled in the study. Ultrasound was performed in the first trimester to confirm the gestational age of all pregnancies. Computer randomization was used to evenly divide the women into either the EA or MTA groups. Ultimately, 1,916 women underwent EA and 1,775 women had MTA. Follow-up was obtained on nearly all pregnancies. Two striking conclusions were reached: EA is associated with an increased incidence of clubfoot and an increased risk of procedure-related pregnancy loss. EA was also linked to an increased number of laboratory culture failures (no growth of cells and no results) compared to MTA. The total waiting time for results was slightly longer in the EA group. This is not entirely a surprise. A smaller amount of fluid is obtained when EA is performed. Hence, there are fewer cells, and culture times take longer.

Chromosome tests

Genetic testing is available on amniotic fluid obtained by amniocentesis. The most common test is a complete analysis of the fetal chromosomes called karyotyping. This procedure detects only those chromosome abnormalities that produce either a structurally abnormal chromosome (e.g., a long or short arm deletion) or aneuploidy. It does not detect mutations within genes that are responsible for specific diseases or inborn errors of **metabolism** (e.g., **cystic fibrosis**). However, many DNA based tests are available that will detect disease genes that are caused by point mutations (single base substitutions) within the genes.

After a sample of amniotic fluid is obtained, the cytogenetic laboratory isolates the cells, referred to as amniocytes, out of the fluid. The cells are placed into two or more containers filled with liquid nutrients, establishing different cultures in which the cells will continue to grow. The cells are cultured anywhere between seven to 10 days before the actual analysis begins. Culture time can be reduced to five to six days by growing a monolayer of fetal cells directly onto a coverglass. Culture is performed in order to obtain sufficient metaphase cells and to synchronize the growth of the cells. Cells in metaphase are selected for analysis because at this stage the chromatids have duplicated but not separated and the individual chromosomes are most visible under the **microscope**.

Once there appears to be an adequate number of cells to study, the cultures are harvested. Harvesting prevents additional cell growth and stops the cells at whatever point they were in the cell cycle. Cells are washed, exposed to hypotonic saline, and fixed with methanol and acetic acid. The cells are spread on a glass slide, heat fixed and treated with trypsin and stained with Giemsa or other chromosome stain. Smears are examined under 400x magnification and the modal chromosome count is recorded. Large clear metaphase cells are selected for photography or image analysis using chromosome-sorting software. Chromosomes are classified by size, centromere position, banding pattern, secondary constriction, and satellite appendages. The karyotype or chromosome map that results identifies translocations, aneuploidy, deletions, and other abnormalities in the appearance of the chromosomes. Typically, chromosome results are available within seven to 14 days after amniocentesis. Results may be delayed by slow-growing cultures. This rarely reflects an abnormal result but does extend the time until final results are available.

Many laboratories now perform a technique called fluorescence in situ hybridization (FISH) into their chromosome studies. This adjunct testing provides limited information about certain chromosomes within one to two days after amniocentesis. It does not replace a complete chromosome study using amniocyte cultures. In fact, FISH results are often reported as preliminary, pending confirmation by cultured results. They can, however, be very useful, particularly when there is already a high level of suspicion of a fetal chromosome abnormality.

FISH is performed using a small sample of uncultured amniotic fluid cells. Special molecular tags consisting of single-stranded DNA that are attached (covalently conjugated) to fluorescent dyes are used. Each tag is bound to a different combination of dyes. When excited by ultraviolet light, the fluorochromes emit visible light of characteristic colors. Tags are available that recognize a specific segment of DNA from chromosomes 13, 18, 21, X, and Y. Abnormalities of these five chromosomes account for nearly 95% of all chromosomal abnormalities. The cells are prepared onto slides as described for karyotyping, denatured to separate the DNA strands, and the probe mixture is added. Each probe hybridizes with the complementary DNA sequence of the target chromosome. When the fetal cells are examined under a fluorescent microscope, a small spot of a specific color will appear on each of these chromosomes. If an extra autosomal chromosome is present, three colored spots appear within the nucleus of the cell instead of two. In addition to determining sex, FISH detects extra sex chromosomes such as 47,XXY which is responsible for Klinefelter syndrome or the absence of one sex chromosome, and 45,X0

which is responsible for Turner syndrome. Other chromosomal abnormalities will not be detected unless a full chromosome evaluation on cultured cells is performed.

A new fluorescent mapping technique called spectral karyotyping (SKY) is available to aid in identifying chromosomes. A DNA probe specific for each chromosome is tagged with between one to five fluorescent dyes. Hybridization between the tag and DNA of the specific chromosome produces a unique color for each one. Using fluorescent microscopy, and a color camera, the karyotype showing each of the 24 different colored chromosomes is constructed. Chromosomes in which translocations occur are bi-colored. The color coding facilitates the identification of the regions of each of the chromosomes involved.

DNA tests are offered to those couples who, based on their family history or other information, are at increased risk of having a child with a single gene, or Mendelian, disorder. Testing for disease genes is primarily accomplished using the polymerase chain reaction (PCR). This technique permits a small segment of DNA within a gene to be amplified exponentially. Within two hours, the target DNA sequence can be copied over one million times, yielding sufficient DNA to identify with a radiolabeled or enzyme-conjugated probe. An example of this technique has been applied extensively to the prenatal diagnosis of cystic fibrosis. There are over 200 different point mutations identified in the CF gene, a segment of 27 coding regions called exons. Various probes may be used to identify most of these. For example, approximately 85% of all CF genes can be identified in the North American white population. DNA tests are available for **sickle cell disease**, **muscular dystrophy**, retinoblastoma, hyperlipoproteinemia, Huntington's chorea, Tay-Sachs disease, congenital adrenal hyperplasia, hemophilia, and many other conditions.

Biochemical testing of amniotic fluid is performed using the same methods as are applied to other body fluids. For example, fluorescence polarization and thin layer chromatography are techniques used to measure pulmonary surfactants. Bilirubin in amniotic fluid is analyzed by direct absorbance measurement using a scanning or diode array spectrophotometer. Bilirubin absorbs light maximally at 450 nm, and if present in the amniotic fluid, it will produce an absorbance peak at this wavelength. Hemoglobin contributes to the absorbance peak by also absorbing light at this wavelength. The interference from hemoglobin can be corrected by measuring its absorbance peak at 410 nm. The contribution of hemoglobin to the 450 nm peak is equal to 5% of its absorbance at 410 nm. Therefore, the 5% of the absorbance at 410 nm is subtracted from the absorbance

at 450 nm to determine the corrected absorbance which is proportional to bilirubin concentration.

Alpha fetoprotein in amniotic fluid is measured by a sandwich type enzyme immunoassay, the same method used for maternal blood. AFP is a protein made by the fetal **liver**. It passes out of the fetus and enters both the amniotic fluid and the mother's blood. Screening for open neural tube defects, abnormal openings in the fetal head or **spinal cord**, or ventral wall defects, openings along the abdominal wall, can be performed by measuring AFP during the fifteenth to twentieth weeks of pregnancy. An unusually high level of serum AFP does not necessarily indicate a problem with **fetal development**, but is cause for some concern. A high AFP level in amniotic fluid will detect up to 98% of all openings on the fetal body that are not covered by skin. Further studies may be suggested if the AFP is high. Most initial AFP results are available within two to three days after amniocentesis.

Preparation

The usual precautions concerning sterility of the injection site and sterility of equipment and the hands of those who will come into contact with a woman must be taken during amniocentesis.

Counseling must be offered to a woman or couple to ensure that they fully understand the results of an amniocentesis test. Counseling should be offered prior to the procedure so that a woman or couple can understand the procedure and slight risk of miscarriage that is associated with amniocentesis.

Aftercare

Physical care after an amniocentesis procedure involves the site of needle insertion. It should be kept clean and dry. Covering the puncture site with a sterile bandage is usually sufficient.

Mental care after an amniocentesis may be more important than physical care. Many women or couples require emotional support and reassurance while they are waiting for test results. Those receiving abnormal results often require ongoing support while they weigh options and make decisions that are appropriate for them. Some may require long-term support as they adjust to the outcomes of their decisions.

Complications

Women who have had an amniocentesis often describe it as uncomfortable, involving some mild pressure or **pain** as the needle is inserted. Fewer women

KEY TERMS

Alpha fetoprotein—A protein found in amniotic fluid that is commonly used to screen for certain structural birth defects.

Amnion—A thin, transparent membrane that holds the fetus in the amniotic fluid. The amniotic sac is sometimes called the bag of waters.

Anesthetic—Drug used to temporarily cause loss of sensation in an area of the body. An anesthetic may either be general, associated with a loss of consciousness, or local, affecting one area only without loss of consciousness. Anesthetics are administered via inhalation, topical application or needle injection.

Aneuploid—A fetus with an abnormal number of chromosomes.

Chorion—The outer membrane of the amniotic sac. Chorionic villi develop from its outer surface early in pregnancy. The villi establish a physical connection with the wall of the uterus. The chorionic villi eventually develop into the placenta.

Chromosome—A linear thread of genetic material contained within every cell. Humans have 46 chromosomes arranged into 23 distinct pairs. Each parent contributes one set of chromosomes, or 23, to a child. Changes in the total number of chromosomes, the shape and size (structure) of a chromosome or the contents of a chromosome may lead to abnormalities in the amount of genetic material. These abnormalities often lead to abnormal physical and mental development.

Conceptus—The product of conception, or the union of a sperm and egg cell at fertilization.

Cystic fibrosis—An inherited disease characterized by repeated lung infections, functional abnormalities of the pancreas, and an elevated level of salt in sweat. Individuals with cystic fibrosis require long-term aggressive medical care. Survival into adulthood is common, in part due to advances in treatment. Death, however, is frequently caused by respiratory failure. Although cystic fibrosis is more common among Caucasians, it has been reported in individuals of other races.

Down syndrome—A genetic condition characterized by moderate to severe mental retardation, a characteristic facial appearance, and, in some indi-

viduals, abnormalities of some internal organs. Down syndrome is always caused by an extra copy of chromosome 21, thus there are three rather than the normal two. For this reason, Down syndrome is also known as trisomy 21.

Fetus—The term used to describe a developing human infant from approximately the third month of pregnancy until delivery. The term embryo is used prior to the third month.

Fibroid—A non-cancerous tumor of connective tissue. It is made up of elongated, threadlike structures, or fibers, which usually grow slowly and are contained within an irregular shape. Fibroids are firm in consistency but may become painful if they start to break down or apply pressure to areas within the body. They frequently occur in the uterus and are generally left alone unless growing rapidly or causing other problems. Surgery is needed to remove fibroids.

Sickle cell anemia—An hereditary form of anemia due to abnormal sickle-shaped red blood cells. As a result, the cells cannot efficiently carry oxygen to body tissues. Common clinical features of sickle cell anemia include severe pain in the joints and abdomen, swelling of the tops of hands and feet, and fever. Sickle cell anemia is frequently found among individuals with ancestors who lived in central Africa.

Tay-Sachs disease—An inherited biochemical disease caused by lack of a specific enzyme in the body. In classical Tay-Sachs disease, previously normal children become blind and mentally handicapped, develop seizures, and rapidly decline. Death often occurs between the ages of three to five years. Tay-Sachs disease is common among individuals of eastern European Jewish background but has been reported in other ethnic groups.

Trimester—A three-month period. Human pregnancies are normally divided into three trimesters: first (conception to week 12), second (week 13 to week 24), and third (week 25 until delivery).

Uterus—A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes an embryo or fetus from the time the fertilized egg is implanted until birth.

describe it as extremely painful. A local anesthetic may be used to numb the upper layer of the mother's skin prior to testing. This medicine has no effect on the fetus, but may help the mother feel more comfortable during the procedure. An experienced physician can, on average, perform amniocentesis in approximately one to two minutes.

Common complaints after amniocentesis include mild abdominal tenderness at the site of needle insertion or mild cramping. These usually go away within one to two days. More serious complications are significantly less common but include leakage of amniotic fluid, vaginal bleeding, or uterine **infection**. These complications are estimated to occur in less than 1% of pregnancies. In some women, complications after amniocentesis may lead to a miscarriage, or loss of the pregnancy. A woman's background risk of having a miscarriage, without amniocentesis, is approximately 2-3% in her second trimester. In experienced hands, the risk for an amniocentesis-related pregnancy loss is estimated to be an additional 0.25-0.50%, or roughly one in every 200-400 pregnancies.

Much attention is often paid to the physical side effects of amniocentesis. However, it is important to also emphasize some of the emotional side effects of amniocentesis. Many of these are also applicable to other forms of prenatal diagnosis.

The offer of prenatal testing is associated with increased **anxiety**. This appears to be true whether a woman knew prenatal testing would be offered to her during the pregnancy or if it comes about unexpectedly, as is usually the case following abnormal screening results. Women to whom genetic amniocentesis is presented must consider the perceived benefits of testing, such as the reassurance that comes when results are normal, and compare them to the possible risks. Examples of potential risks include not only the risk of a complication after testing but also the potential burden of knowing that she will have a child with a serious disability or chronic medical condition. The nature of the child's possible diagnosis is also important. For example, could it lead to an early death, be more subtle and cause few outward signs of a problem, or be somewhere in between? There are few treatments available to correct the hundreds of known genetic disorders. Couples may wish to consider whether or not they would consider a termination of the pregnancy if a serious abnormality were detected. The definition of serious is often a matter of personal opinion. A couple's value system and family history, including that of other pregnancies and their outcomes, all influence their decision regarding amniocentesis. Ideally, a woman and her partner will have discussed at least some of these issues with each other and with either the

woman's doctor or a genetic counselor prior to testing. The choice to have amniocentesis depends on many factors and should remain a personal decision.

Results

It is important to emphasize that normal results from tests performed on amniotic fluid do not necessarily guarantee the birth of a normal infant. Each couple in the general population faces a risk of roughly 3-4% of having a child with any type of congenital birth defect. Many of these will not be detected with tests performed on amniotic fluid samples obtained by amniocentesis. Babies with birth defects are often born into families with no history of genetic disorders.

Chromosome karyotyping is interpreted according to standardized nomenclature, International System of Cytogenetic Nomenclature (ISCN). The system describes the number of chromosomes, the sex chromosomes, and then any abnormalities seen in specific chromosomes using a numerical system to identify banding characteristics. Bands are numbered starting at the centromere. Standardized symbols and abbreviations describe the type of abnormality. For example, a + sign designates an extra chromosome and 47,XY,+21 designates a male with an extra chromosome 21. The designation 46,XX,t(3:5)(q21;p15.2) means that the subject is a female with a normal number of chromosomes. There is a translocation (exchange) between chromosomes three and five involving band 21 of the long arm of number three and band 15.2 of the short arm of chromosome five.

Amniotic fluid is normally clear or slightly turbid. The concentration of AFP is reported as multiples of the median (MOM). Normal values are dependent upon the sampling time. For example, the median AFP at 15 weeks is 16.3 micrograms per mL and at 20 weeks is 8.1 micrograms per mL. Bilirubin is also time-dependent normally decreasing during gestation. The concentration should be below 0.075 mg/dL at 20 weeks and below 0.025 mg/dL at 40 weeks (full term).

An L:S ratio of 2.0 or higher correlates with fetal lung maturity. Lecithin greater than 0.10 mg/dL also correlates with fetal lung maturity.

Health care team roles

Actual samples of amniotic fluid or placenta are obtained by persons with specialized training. These are usually obstetricians or gynecologists with additional training. Sonographers assist in amniocentesis. Specially trained nurses prepare women for amniocentesis. Cytogenetic technologists, CLSp(CG) perform cell culture, karyotyping, and DNA analysis of fetal cells.

Clinical laboratory scientists/medical technologists perform biochemical testing, and may also perform DNA and some molecular tests on fetal cells from the fluid. Pathologists with special training in genetics interpret results. Obstetricians or geneticists provide results to a woman or couple and discuss treatment options that may be available. Genetic counselors and other mental health professionals may provide additional support and counseling to a woman or couple after the results of amniocentesis have been returned.

Amylase and lipase tests

Definition

Amylase and lipase tests are performed to aid in the differential diagnosis of acute abdominal **pain**. Amylase and lipase are digestive enzymes made by the **pancreas**. An enzyme is a protein that accelerates a biochemical

KEY TERMS

Amylase—A digestive enzyme made primarily by the pancreas and salivary glands.

Enzyme—A substance made and used by the body to speed up specific chemical reactions which might otherwise not happen, or might happen only slowly.

Lipase—A digestive enzyme made primarily by the pancreas.

Pancreatitis—Inflammation of the pancreas.

reaction. Both enzymes are members of the hydrolase class, which means that they split a substrate by the addition of water. Amylase catalyzes the hydrolysis of starch forming maltose. The maltose can be converted to glucose by other enzymes. Lipase splits triglycerides, forming glycerol and fatty acids as the final product.

Purpose

Epigastric pain and abdominal tenderness associated with acute **appendicitis** is difficult to distinguish from acute **pancreatitis**. Serial measurements of amylase and lipase are used to exclude a diagnosis of acute pancreatitis when results are within normal limits. One or both enzymes may be increased in acute pancreatitis, but neither enzyme is specific. In addition to acute pancreatitis, amylase is increased mumps, some malignancies, ectopic **pregnancy**, alcoholic **liver** disease, peptic ulcers, intestinal obstruction, and renal failure. Lipase is increased in renal failure, intestinal obstruction and liver disease. Use of both enzymes increases diagnostic sensitivity and specificity to around 90%. Acute pancreatitis is highly likely when the plasma amylase is increased to more than twofold normal and lipase is increased more than fivefold normal. When plasma amylase is increased, but the lipase is normal, a nonpancreatic condition is almost always the cause. When amylase is increased more than twofold and lipase is increased but less than fivefold, renal failure, pancreatitis, intestinal obstruction, peptic ulcer disease, and acute pancreatitis are possible causes.

In acute pancreatitis, plasma amylase becomes elevated two to 12 hours after an episode of acute abdominal pain. Levels peak in 12-72 hours, usually reaching two to six times the upper limit of normal, then return to normal by four days. Amylase is a small protein and is excreted in urine in significant quantities. Urinary amylase rises in parallel with plasma amylase, but reaches higher levels and remains elevated for seven to 14 days.

Renal excretion of amylase is increased in pancreatitis, and the ratio of amylase to creatinine clearance is a more specific test for acute pancreatitis than is plasma amylase. Lipase in plasma becomes abnormal four to eight hours following an episode of acute pancreatitis, reaches a peak level two to 50 times normal in approximately one day, and remains elevated for seven to 10 days. Recently, serum and urine levels of trypsinogen-2 have been shown to be very sensitive and specific indicators of pancreatitis, but assays are not yet widely available.

Precautions

Blood for measurement of amylase and lipase is collected by venipuncture. The nurse or phlebotomist should follow standard precautions for the prevention of transmission of bloodborne pathogens. Amylase and lipase should not be used as screening tests for future pancreatic disease. Neither enzyme is likely to be elevated in chronic pancreatitis because enzyme production is decreased by chronic disease. Up to 1% of persons have increased plasma amylase owing to formation of a complex between amylase and immunoglobulins. This condition is termed macroamylasemia and it occurs more frequently in the older population. Plasma amylase is elevated above normal, but urinary amylase is low in this condition. The presence of natural amylase inhibitors in the diet may decrease plasma amylase activity. Drugs that may increase amylase include morphine, phenformin, ethanol, and contraceptives. Lipase may be increased by ethanol, codeine, and narcotics. Results are dependent upon the method used and normal values may vary significantly between laboratories.

Description

Amylase and lipase tests are usually performed on a blood sample, but amylase testing can also be performed on urine. Enzymes are usually measured by determining the rate of product formation under controlled pH and temperature. Measurements are reported as units of activity rather than in mass units. Reference methods for amylase and lipase are labor intensive and difficult to automate. There are several methods for measuring amylase and lipase each with its own advantages and disadvantages. A common method of measuring amylase is based upon the hydrolysis of a synthetic glucose polymer that is labeled at one end with p-nitrophenol. The amylase splits the substrate into various subunits of glucose. Subunits consisting of three glucose molecules are hydrolyzed by an enzyme in the reagent, alpha-glucosidase, forming glucose and p-nitrophenol. The activity of amylase is proportional to the rate of p-nitrophenol formation. This is determined by measuring the amount of light that the

reaction mixture absorbs at 405 nm over a fixed time interval. Lipase is often measured using a cascade of coupling enzyme reactions that yield a colored product. Lipase is incubated with a synthetic diglyceride substrate and splits it forming a monoglyceride and a fatty acid. The monoglyceride is split by an enzyme in the reagent, monoglyceride esterase, to yield glycerol. The glycerol is converted to glycerol-3-phosphate by the enzyme glycerol kinase which attaches a phosphate from adenosine triphosphate (ATP). The glycerol-3-phosphate is oxidized by another enzyme, glycerol phosphate oxidase (GPO), forming dihydroxyacetone phosphate and hydrogen peroxide. In the final step, peroxidase catalyzes the oxidation of a dye by the hydrogen peroxide forming a pink product. The rate of absorbance (color) increase at 500 nm is measured, and is proportional to lipase activity.

Preparation

No special preparation is necessary for a person undergoing an amylase or lipase test. Urinary amylase is frequently measured using a timed urine sample. The patient should be given a urine container with instructions for collecting the urine at home. The urine should be refrigerated until it is brought to the laboratory.

Aftercare

Discomfort or bruising may occur at the puncture site, or the person may feel dizzy or faint. To reduce bruising, pressure should be applied to the puncture site until the bleeding stops. Applying warm packs to the puncture site relieves discomfort.

Complications

Amylase and lipase tests are not associated with complications.

Results

The normal range will vary depending upon the method used. Results shown below are representative of the methods described above performed at 37 degrees C.

- Plasma amylase: 70-200 U/L.
- Plasma lipase: 7-58 U/L.
- Urine amylase: Less than 1200 U/L.
- Amylase creatinine clearance ratio: 1-4%.

Health care team roles

A physician orders and interprets tests for amylase and lipase. A nurse or phlebotomist usually collects

blood for amylase and lipase tests by venipuncture. A nurse educates the patient on the proper collection and storage of a urine sample, and may also take a drug history to identify medications which might interfere with the testing. Drug interference is usually caused by inducing the release of the enzyme from an organ or tissue. Amylase and lipase tests are performed by a clinical laboratory scientist, CLS(NCA)/ medical technologist, MT(ASCP) or clinical laboratory technician, CLT(NCA) or medical laboratory technician, MLT(ASCP).

Anaerobic bacteria culture

Definition

An anaerobic **bacteria** culture is a method used to grow anaerobes from a clinical specimen. Obligate anaerobes are bacteria that can live only in the absence of oxygen. Obligate anaerobes are destroyed when exposed to the atmosphere for as briefly as 10 minutes. Some anaerobes are tolerant to small amounts of oxygen. Facultative anaerobes are those organisms that will grow with or without oxygen. The methods of obtaining specimens for anaerobic culture and the culturing procedure are performed to ensure that the organisms are protected from oxygen.

Purpose

Anaerobic bacterial cultures are performed to identify bacteria that grow only in the absence of oxygen and which may cause human **infection**. If overlooked or killed by exposure to oxygen, anaerobic infections result in serious consequences such as amputation, organ failure, sepsis, **meningitis**, and death. Culture is required to

Anaerobic culture equipment: (A) anaerobic jar with generating packet and indicator; (B) technologist working with anaerobic culture. (Delmar Publishers, Inc. Reproduced by permission.)

correctly identify anaerobic pathogens and institute effective antibiotic treatment.

Precautions

It is crucial that the health care provider obtain the sample for culture via **aseptic technique**. Anaerobes are commonly found on mucous membranes and other sites such as the vagina and oral cavity. Therefore, specimens likely to be contaminated with these organisms should not be submitted for culture (e.g., a throat or vaginal swab).

Some types of specimens should always be cultured for anaerobes if an infection is suspected. These include abscesses, bites, **blood**, cerebrospinal fluid and exudative body fluids, deep **wounds**, and necrotic tissues. The specimen must be protected from oxygen during collection and transport and must be transported to the laboratory immediately. The health care team member who performs the collection should follow **universal precautions** for the prevention of transmission of bloodborne pathogens.

Description

Anaerobes are normally found within certain areas of the body but result in serious infection when they have access to a normally sterile body fluid or deep tissue that is poorly oxygenated. Some anaerobes normally live in the crevices of the skin, in the nose, mouth, throat, intestine, and vagina. Injury to these tissues (i.e., cuts, puncture wounds, or trauma) especially at or adjacent to the mucus membranes allows anaerobes entry into otherwise sterile areas of the body and is the primary cause of anaerobic infection. A second source of anaerobic infection occurs from the introduction of spores into a normally sterile site. Spore producing anaerobes live in the soil and water and spores may be introduced via wounds especially punctures. Anaerobic infections are most likely to be found in persons who are immunosuppressed, those treated recently with broad-spectrum **antibiotics**, and persons who have a necrotic, discolored injury on or near a mucus membrane, especially if the site is foul-smelling.

Some specimens from which anaerobes are likely to be isolated are:

- blood
- bile
- bone marrow
- cerebrospinal fluid
- direct lung aspirate
- tissue biopsy from a normally sterile site
- fluid from a normally sterile site (like a joint)
- dental abscess
- abdominal or pelvic abscess
- knife, gunshot, or surgical wound
- severe burn

Some of the specimens that are not suitable for anaerobic cultures include:

- coughed throat discharge (sputum)
- rectal swab
- nasal or throat swab

- urethral swab
- voided urine

Specimen collection

The keys to effective anaerobic bacteria cultures include collecting a contamination-free specimen and protecting it from oxygen exposure. Anaerobic bacteria cultures should be obtained from an appropriate site without the health care professional contaminating the sample with bacteria from the adjacent skin, mucus membrane, or tissue. Swabs should be avoided when collecting specimens for anaerobic culture because cotton fibers may be detrimental to anaerobes. Abscesses or fluids can be aspirated using a sterile syringe that is then tightly capped to prevent entry of air. Tissue samples should be placed into a degassed bag and sealed, or into a gassed out screw top vial that may contain oxygen-free prereduced culture medium and tightly capped. The specimens should be plated as rapidly as possible onto culture media that has been prepared as prereduced anaerobically sterilized media (PRAS). Alternatively, media that contains a reducing agent such as dithiothreitol or palladium chloride and has been stored for one day in an anaerobic chamber can be used.

Culture

Broth and solid media should both be inoculated. The culture media should include anaerobic blood agar plates enriched with substances such as brain-heart infusion, yeast extract, amino acids, and **vitamin K**; a selective medium such as kanamycin-vancomycin (KV) blood agar or laked blood agar; and a broth such as **brain heart** infusion broth with thioglycolate or other reducing agent. The choice of media depends upon the type of specimen. Some commonly used media include prereduced peptone-yeast extract-glucose broth which is suitable for analysis of volatile products by gas chromatography; egg yolk agar for detection of lecithinase activity of *Clostridium spp.*; cycloserine-cefoxitin-fructose agar (CCFA) for isolation of *Clostridium difficile* from stool; and Bacteroides bile esculin agar for isolation of the *Bacteroides fragilis* group.

Cultures should be placed in an environment that is free of oxygen, at 35°C for at least 48 hours before the plates are examined for growth. In addition, blood agar plates should be cultured both aerobically and in 10% carbon dioxide. Comparison of these cultures to anaerobic cultures is needed to identify the oxygen tolerance of the organisms. An anaerobic glove box made of acrylic or plastic with sealed armholes and attached gloves is the most commonly used environment for anaerobic culture. The interior of the glove box or hood is supplied with a

mixture of 10% hydrogen, 10% carbon dioxide, and 80% nitrogen from compressed gases. Inoculation and transfers can be performed in the glove box without risk of oxygen exposure. The alternative to an anaerobic chamber is a jar such as the GasPak system. When using jars, several are needed to contain uninoculated media and subcultured plates (i.e., plates containing a colony transferred from the primary isolate). The GasPak system uses a disposable envelope containing citric acid, sodium bicarbonate, cobalt chloride, and sodium borohydride. When water is added these react to form hydrogen gas. A catalyst, palladium, located in the lid converts the hydrogen and oxygen in the jar to water. Silica gel or paper towels are used to absorb the water, and an indicator strip of methylene blue is used to indicate anaerobic conditions. Methylene blue will be oxidized when the atmosphere contains oxygen causing formation of a blue color.

Gram staining is performed on the specimen at the time of culture. While infections can be caused by aerobic or anaerobic bacteria or a mixture of both, some infections have a high probability of being caused by anaerobic bacteria. These infections include brain abscesses, lung abscesses, aspiration **pneumonia**, and dental infections. Anaerobic organisms can often be suspected because many anaerobes have characteristic microscopic morphology (appearance). For example, *Bacteroides spp.* are gram-negative rods that are pleomorphic (variable in size and shape) and exhibit irregular bipolar staining. *Fusobacterium spp.* are often pale gram-negative spindle-shaped rods having pointed ends. *Clostridium spp.* are large gram-positive rods that form spores. The location of the spore (central, subterminal, terminal, or absent) is a useful differential characteristic. The presence of growth, oxygen tolerance, and **Gram stain** results are sufficient to establish a diagnosis of an anaerobic infection and begin antibiotic treatment with a drug appropriate for most anaerobes such as clindamycin or vancomycin.

Gram-negative anaerobes and some of the infections they produce include the following genera:

- *Bacteroides* (the most commonly found anaerobes in cultures; intra-abdominal infections, rectal abscesses, soft tissue infections, **liver** infection)
- *Fusobacterium* (abscesses, wound infections, pulmonary and intracranial infections)
- *Porphyromonas* (aspiration pneumonia, periodontitis)
- *Prevotella* (intra-abdominal infections, soft tissue infections)

Gram-positive anaerobes include the following:

- *Actinomyces* (head, neck, pelvic infections; aspiration pneumonia)

KEY TERMS

Aerobic bacteria—Bacteria that can grow freely in oxygen-rich environments.

Aseptic—Free from living disease-causing organisms; sterile and without contamination.

Pathogen—An organism capable of causing disease.

Sepsis—The systemic inflammatory response due to an infectious organism circulating throughout the body. Sepsis can progress to severe sepsis and septic shock, where blood pressure drops (hypotension), the blood supply to tissues decreases, and organs fail.

Venipuncture—Puncture of a vein with a needle for the purpose of withdrawing a blood sample for analysis.

- *Bifidobacterium* (ear infections, abdominal infections)
- *Clostridium* (gas **gangrene**, **food poisoning**, tetanus, pseudomembranous colitis)
- *Peptostreptococcus* (oral, respiratory, and intra-abdominal infections)
- *Propionibacterium* (shunt infections)

Isolated organisms are always subcultured and the pure culture is tested in order to identify the organism. The identification of anaerobes is highly complex, and laboratories may use different identification systems. Partial identification is often the goal. For example, there are six species of the *Bacteroides* genus that may be identified as the *Bacteroides fragilis* group rather than identified individually. Organisms are identified by their colonial and microscopic morphology, growth on selective media, oxygen tolerance, and biochemical characteristics. These include sugar fermentation, bile solubility, esculin, starch, and gelatin hydrolysis, casein and gelatin digestion, catalase, lipase, lecithinase, and indole production, nitrate reduction, volatile fatty acids as determined by gas chromatography, and susceptibility to antibiotics. The antibiotic susceptibility profile is determined by the microtube broth dilution method. Many species of anaerobes are resistant to penicillin, and some are resistant to clindamycin and other commonly used antibiotics.

Preparation

The health care provider should take special care to collect a contamination-free specimen. All procedures

must be performed aseptically. The health care professional who collects the specimen should be prepared to take two samples, one for anaerobic culture and one for aerobic culture, since it is unknown whether the pathogen can grow with or without oxygen. In addition, health care professionals should document any antibiotics that patient is currently taking and any medical conditions that could influence growth of bacteria.

Aftercare

In the case of venipuncture for anaerobic blood cultures, direct pressure should be applied to the venipuncture site for several minutes or until the bleeding has stopped. An adhesive bandage may be applied, if appropriate. If swelling or bruising occurs, ice can be applied to the site. For collection of specimens other than blood, the patient and the collection site should be monitored for any complications after the aspiration, biopsy, etc.

Complications

Special care must be taken by the health care team obtaining, transporting, and preparing the specimen for anaerobic culture. Poor methodology may delay the identification of the bacterium, may allow the patient's condition to deteriorate, and may require the patient to provide more samples than would otherwise be required. Patients may experience bruising, discomfort, or swelling at the collection site when tissue, blood, or other fluids are obtained.

Results

Negative results will show no pathogenic growth in the sample. Positive results will show growth, the identification of each specific bacterium, and its antibiotic susceptibility profile.

Health care team roles

The physician orders the culture, and the physician, nurse, or physician assistant usually collects the specimen. A health care team member transports the specimen to the laboratory. The decision to perform anaerobic culture is determined by the type of specimen submitted to the laboratory. A clinical laboratory scientist/medical technologist performs the culture and Gram stain. The physician receives the culture report and selects the appropriate antibiotic if one is required.

Patient education

A health care team member should explain the specimen collection procedure to the patient. If the patient is

seriously ill, the team member should explain the procedure to the patient's family members. The patient and his or her family should understand that because bacteria need time to grow in the laboratory, several days may be required for bacterium identification.

Analgesia, patient-controlled see **Patient-controlled analgesia**

Analgesics

Definition

Analgesics are medicines that relieve **pain**.

Purpose

Analgesics are those drugs whose primary purpose is pain relief. The primary classes of analgesics are the narcotics, including additional agents that are chemically based on the morphine molecule but have minimal abuse potential; **nonsteroidal anti-inflammatory drugs** (NSAIDs) including the salicylates; and acetaminophen. Other drugs, notably the tricyclic antidepressants and anti-epileptic agents such as gabapentin, have been used

to relieve pain, particularly neurologic pain, but are not routinely classified as analgesics. Analgesics provide symptomatic relief, but have no effect on causation, although clearly the NSAIDs, by virtue of their dual activity, may be beneficial in both regards.

Description

Pain has been classified as "productive" pain and "non-productive" pain. While this distinction has no physiologic meaning, it may serve as a guide to treatment. "Productive" pain has been described as a warning of injury, and so may be both an indication of need for treatment and a guide to diagnosis. "Non-productive" pain by definition serves no purpose either as a warning or diagnostic tool.

Although pain syndromes may be dissimilar, the common factor is a sensory pathway from the affected organ to the **brain**. Analgesics work at the level of the nerves, either by blocking the signal from the peripheral nervous system, or by distorting the interpretation by the **central nervous system**. Selection of an appropriate analgesic is based on consideration of the risk-benefit factors of each class of drugs, based on type of pain, severity of pain, and risk of adverse effects. Traditionally, pain has been divided into two classes, acute and chronic, although severity and projected patient survival are other factors that must be considered in drug selection.

Acute pain

Acute pain is self limiting in duration, and includes post-operative pain, pain of injury, and **childbirth**. Because pain of these types is expected to be short term, the long-term side effects of analgesic therapy may routinely be ignored. Thus, these patients may safely be treated with narcotic analgesics without concern for their addictive potential, or NSAIDs with only limited concern for their ulcerogenic risks. Drugs and doses should be adjusted based on observation of healing rate, switching patients from high to low doses, and from narcotic analgesics to non-narcotics when circumstances permit.

An important consideration of **pain management** in severe pain is that patients should not be subject to the return of pain. Analgesics should be dosed adequately to assure that the pain is at least tolerable, and frequently enough to avoid the **anxiety** that accompanies the anticipated return of pain. Analgesics should never be dosed on a "prn" (as needed) basis, but should be administered often enough to assure constant **blood** levels of analgesic. This applies to both the narcotic and non-narcotic analgesics.

Opioid analgesics			
Drug	Route of administration	Onset of action (min)	Duration of action (h)
Strong agonists			
Fentanyl (Sublimaze)	IM	7–15	1–2
	IV	1–2	0.5–1
Hydromorphone (Dilaudid)	Oral	30	4
	IM	15	4
	IV	10–15	2–3
	Sub-Q	15	4
Levorphanol (Levo-Dromoran)	Oral	10–60	4–5
	IM	—	4–5
	IV	—	4–5
	Sub-Q	—	4–5
Meperidine (Demerol)	Oral	15	2–4
	IM	10–15	2–4
	IV	1	2–4
	Sub-Q	10–15	2–4
Methadone (Dolophine)	Oral	30–60	4–6
	IM	10–20	4–5
	IV	—	3–4
	Oral	—	4–5
Morphine (many trade names)	IM	10–30	4–5
	IV	—	4–5
	Sub-Q	10–30	4–5
	Epidural	15–60	up to 24
Oxymorphone (Numorphan)	IM	10–15	3–6
	IV	5–10	3–4
	Sub-Q	10–20	3–6
	Rectal	15–30	3–6
Mild-to-moderate agonists			
Codiene (many trade names)	Oral	30–40	4
	Im	10–30	4
	Sub-Q	10–30	4
Hydrocodone (Hycodan)	Oral	10–30	4–6
Oxycodone (Percodan)	Oral	—	3–4
Propoxyphene (Darvon, Dolene)	Oral	15–60	4–6
Butorphanol (Stadol)	IM	10–30	3–4
	IV	2–3	2–4
Nalbuphine (Nubian)	IM	within 15	3–6
	IV	2–3	3–4
	Sub-Q	within 15	3–6
Pentazocine (Talwin)	Oral	15–30	3
	IM	15–20	2–3
	IV	2–3	2–3
	Sub-Q	15–20	2–3

IM= intramuscular; IV = intravenous; sub-Q = subcutaneous

Chronic pain

Chronic pain, pain lasting over three months and severe enough to impair function, is more difficult to treat, since the anticipated side effects of the analgesics are more difficult to manage. In the case of narcotic analgesics this means the addiction potential, as well as respiratory depression and constipation. For the NSAIDs, the risk of gastric ulcers may be dose limiting. While some classes of drugs, such as the narcotic agonist/antagonist drugs bupronorphine, nalbuphine and pentazocine, and the selective COX-2 inhibitors celecoxib and rofe-

coxib represent advances in reduction of adverse effects, they are still not fully suitable for long-term management of severe pain. Generally, chronic pain management requires a combination of drug therapy, life-style modification, and other treatment modalities.

Narcotic analgesics

The narcotic analgesics, also termed opioids, are all derived from opium. The class includes morphine, codeine, and a number of semi-synthetics including meperidine (Demerol), propoxyphen (Darvon), and others. The narcotic analgesics vary in potency, but all are effective in treatment of visceral pain when used in adequate doses. Adverse effects are dose related. Because these drugs are all addictive, they are controlled under federal and state laws. A variety of dosage forms are available, including oral solids, liquids, intravenous and intrathecal injections, and transcutaneous patches.

NSAIDs, non-steroidal anti-inflammatory drugs, are effective analgesics even at doses too low to have any anti-inflammatory effects. There are a number of chemical classes, but all have similar therapeutic effects and side effects. Most are appropriate only for oral administration; however ketorolac (Toradol) is appropriate for injection and may be used in moderate to severe pain for short periods.

Acetaminophen is a non-narcotic analgesic with no anti-inflammatory properties. It is appropriate for mild to moderate pain. Although the drug is well tolerated in normal doses, it may have significant toxicity at high doses. Because acetaminophen is largely free of side effects at therapeutic doses, it has been considered the first choice for mild pain, including that of **osteoarthritis**.

Recommended dosage

Appropriate dosage varies by drug, and should consider the type of pain, as well as other risks associated with patient age and condition. For example, narcotic analgesics should usually be avoided in patients with a history of substance abuse, but may be fully appropriate in patients with **cancer** pain. Similarly, because narcotics are more rapidly metabolized in patients who have used these drugs for a long period, higher than normal doses may be needed to provide adequate pain management. NSAIDs, although comparatively safe in adults, represent an increased risk of gastrointestinal bleeding in patients over the age of 60.

KEY TERMS

Acute pain—Pain that is usually temporary and results from something specific, such as a surgery, an injury, or an infection.

Analgesic—Medicine used to relieve pain.

Chronic pain—Pain that lasts more than three months and threatens to disrupt daily life.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Osteoarthritis—Joint pain resulting from damage to the cartilage.

Precautions

Narcotic analgesics may be contraindicated in patients with respiratory depression. NSAIDs may be hazardous to patients with ulcers or an ulcer history. They should be used with care in patients with renal insufficiency or coagulation disorders. NSAIDs are contraindicated in patients allergic to aspirin.

Side effects

Review adverse effects of each drug individually. Drugs within a class may vary in their frequency and severity of adverse effects.

The primary adverse effects of the narcotic analgesics are addiction, constipation, and respiratory depression. Because narcotic analgesics stimulate the production of enzymes that cause the **metabolism** of these drugs, patients on narcotics for a prolonged period may require increasing doses. This is not the same thing as addiction, and is not a reason for withholding medication from patients in severe pain.

NSAIDs are ulcerogenic and may cause kidney problems. Gastrointestinal discomfort is common, although in some cases, these drugs may cause ulcers without the prior warning of gastrointestinal distress. Platelet aggregation problems may occur, although not to the same extent as if seen with aspirin.

Interactions

Interactions depend on the specific type of analgesic. See specific references.

Samuel Uretsky, PharmD

Anaphylaxis

Definition

Anaphylaxis is a rapidly progressing, life-threatening allergic reaction.

Description

Anaphylaxis is a type of allergic reaction, in which the **immune system** responds to otherwise harmless substances from the environment. Unlike other allergic reactions, however, anaphylaxis can result in death. Reaction may begin within minutes or even seconds of exposure, and rapidly progress to cause airway constriction, skin and intestinal irritation, and altered **heart** rhythms. In severe cases, it can result in complete airway obstruction, **shock**, and death.

In 2001, more cases of anaphylaxis have been reported, especially in reaction to latex and exotic food antigens. The increased use of latex gloves in hospitals, doctors' offices, dentist offices, and among forensic investigators has also increased exposure to latex allergens.

The broadening of the Western diet, with the incorporation of more exotic foods and increased food processing, also exposes more people to possible food allergens, and at earlier ages. Peanut oil, for example, is often used in fast-food restaurants, and sulfites are used in processed meats and seafood. There is still no labeling for trace amounts of foods or food additives. Unfortunately, problem food allergens can still be present in favorite foods, even if the label does not show it. In some cases, even a small amount can prove fatal in certain individuals.

Causes and symptoms

Causes

Like the majority of other allergic reactions, anaphylaxis is caused by the release of histamine and other chemicals from mast cells, which are a type of white **blood** cell found in large numbers in the tissues that regulate exchange with the environment: the airways, **digestive system**, and skin.

On their surfaces, mast cells display antibodies called immunoglobulin type E (IgE). These antibodies are designed to detect environmental substances to which the immune system is sensitive. Substances from a gen-

usually threatening source such as **bacteria** or **viruses** are called antigens. A substance that most people tolerate well, but to which others have an allergic response, is called an allergen. When IgE antibodies bind with allergens, they cause the mast cells to release histamine and other chemicals that spill out onto neighboring cells.

The interaction of these chemicals with receptors on the surface of **blood vessels** causes the vessels to leak fluid into surrounding tissues, resulting in fluid accumulation, redness, and swelling. On the smooth muscle cells of the airways and digestive system, they cause constriction. On nerve endings, they increase sensitivity and cause itching.

In anaphylaxis, the dramatic response is due both to extreme hypersensitivity to the allergen and its usually systemic distribution. Allergens are more likely to cause anaphylaxis if they are introduced directly into the circulatory system by injection. However, exposure by ingestion, inhalation, or skin contact can also cause anaphylaxis. In some cases, anaphylaxis may develop over time from less severe **allergies**.

Anaphylaxis most often results from allergens in foods, drugs, latex, and insect venom. Specific causes include, but are not limited to:

- fish, shellfish, and mollusks
- peanuts, tree nuts, and seeds
- eggs
- milk
- insulin in vegetables and processed foods
- stings of bees, wasps, and hornets
- preservatives, especially sulfites and parabens
- vaccines (e.g. flu, measles, rabies, chicken pox, and diphtheria-tetanus-pertussis) prepared with a gelatin base made from pork products
- antibiotics, including penicillin and its derivatives, cephalosporins, streptomycin, tetracycline, and sulphonamides
- gamma globulin and human serum albumin
- hormones like insulin, ACTH, and glucocorticoids
- anti-inflammatory drugs such as aspirin, ibuprofen, and other NSAIDs
- anti-venoms
- antiseptics such as mercurochrome
- allergy immunotherapy vaccines
- radiopaque dyes used in diagnostic studies (radiocontrast media)

- latex from exam gloves, catheters, tubing, condoms, etc.
- local anesthetics
- dyes (erythrosine and resorcinol, used in hair dyes)

Exposure to cold or **exercise** can also trigger anaphylaxis in some individuals.

Symptoms

Symptoms may include:

- flushing of face, head, or hands
- urticaria (hives)
- swelling and irritation of the tongue or mouth
- swelling of the sinuses
- difficulty breathing
- wheezing
- cramping, vomiting, or diarrhea
- anxiety or confusion
- strong, very rapid heartbeat (palpitations)
- drop in blood pressure
- chest pain
- loss of consciousness

Not all symptoms may be present, and some may be more severe than others. Symptoms usually occur immediately or within 20 minutes of exposure. On occasion, with food anaphylaxis, symptoms may not appear for several minutes or even hours. As a general guideline, the slower the onset of symptoms comes on, the less serious the episode. Symptoms may also reappear several hours later, sometimes in a more severe form.

Diagnosis

Anaphylaxis is diagnosed based on the rapid development of symptoms in response to a suspected allergen. Identification of the cause may be done with RAST testing, a blood test that identifies IgE reactions to specific allergens. Skin testing can also be done, but with care. Food challenges should be avoided.

Sometimes, the offending allergen is not readily apparent, and the diagnosis of anaphylaxis could be overlooked. Also, some of the symptoms resemble other conditions such as cardiac arrhythmia, **myocardial infarction**, **seizure disorder**, insulin reaction, and pulmonary embolism.

A detailed medical history taken of the patient before medical or surgical procedures may help in diagnosis if

symptoms manifest. Often, the only evidence of anaphylactic reaction is anecdotal or self-reported surveys.

Treatment

Emergency treatment of anaphylaxis involves injection of adrenaline (epinephrine), which constricts blood vessels and counteracts the effects of histamine. Oxygen may be given, as well as intravenous replacement fluids. **Antihistamines** may be used for skin rash, and aminophylline for bronchial constriction. If the upper airway is obstructed, the insertion of a breathing tube or **tracheotomy** tube may be needed.

Treatment should be administered immediately. Epinephrine injected directly into muscle tissue is quick and extremely effective. Intravenous injections require specific calculations regarding the dilution of adrenaline in order for it to be administered. Epinephrine inhalers are not as effective, as are short-acting b-agonist inhalers used by persons suffering from **asthma**. These can prove fatal because they delay effective treatment.

Self-administered epinephrine devices such as EpiPen and EpiE-Z are life-saving tools. Patients must be properly trained in their use and instructed to keep these devices updated and close at hand.

Patients should also be monitored for 24 hours after the symptoms have subsided. Symptoms have been known to return several hours later when the patient has returned home from the hospital.

Prognosis

The rapidity of symptom development is an indication of the likely severity of reaction: the faster symptoms develop, the more severe the ultimate reaction. Prompt emergency medical attention and close monitoring reduces the likelihood of death. Nonetheless, death is possible from severe anaphylaxis. For most people who receive rapid treatment, recovery is complete.

Health care team roles

All medical personnel should be trained to recognize the symptoms of anaphylaxis and to use the proper emergency procedures. Nurses and physicians assistants need to ask patients about their history of allergy when preparing them for a doctor's visit or before invasive procedures. Physicians, lab personnel, and nurses need to routinely ask whether a person is allergic to medications and latex. Inquiries about food allergies can be very helpful when preparing to administer vaccinations or medica-

KEY TERMS

Allergen—A substance that causes an allergic reaction.

Adrenocorticotrophic hormone (ACTH)—A hormone normally produced by the pituitary gland, sometimes taken as a treatment for arthritis and other disorders.

Antibody—An immune system protein that binds to a substance from the environment.

Histamine—A substance produced by the immune system in response to an allergen.

NSAIDs—Non-steroidal anti-inflammatory drugs, including aspirin and ibuprofen.

Tracheostomy tube—A tube that is inserted into an incision in the trachea (tracheotomy) to relieve upper airway obstruction.

tions. A patient's allergy history may have changed since the last doctor's visit. Even a small reaction like a rash on initial exposure to an allergen can be an indicator that a patient may have a more serious reaction on subsequent encounters with the agent.

In the case of latex allergy in the wake of a surgical procedure, medical personnel will need to strip the operating room or the procedure room of all latex items. Some patients are so sensitive to latex in any form that even inhaling a latex particle in the air could be life threatening.

Prevention

Avoidance of the allergic trigger is the only reliable method of preventing anaphylaxis. For insect allergies, this requires recognizing likely nest sites, wearing long sleeves, and using insect repellent. Preventing food allergies requires knowledge of the prepared foods or dishes in which the allergen is likely to occur, reading labels, and carefully questioning about ingredients when dining out. Use of a Medic-Alert tag detailing drug allergies is vital to prevent inadvertent administration during a medical emergency. In addition, patients with latex sensitivity need to avoid using latex products of all kinds and must notify medical and dental personnel of their latex allergy.

People prone to anaphylaxis should carry an Epi-pen or Ana-kit, which contains an adrenaline dose ready for injection. They also should be carefully trained in its use.

Anemias

Definition

Anemia is a condition characterized by abnormally low levels of healthy red **blood** cells or hemoglobin (the component of red blood cells that delivers oxygen to tissues throughout the body).

Description

The tissues of the human body need a regular supply of oxygen to stay healthy. Red blood cells, which contain hemoglobin that allows them to deliver oxygen throughout the body, live for only about 120 days. When they die, the **iron** they contain is returned to the bone marrow and used to create new red blood cells. Anemia develops when heavy bleeding causes significant iron loss or when something happens to slow down the production of red blood cells or to increase the rate at which they are destroyed.

Types of anemia

Anemia can be mild, moderate, or severe enough to lead to life-threatening complications. More than 400 different types of anemia have been identified. Many of them are rare.

IRON DEFICIENCY ANEMIA. Iron deficiency anemia is the most common form of anemia in the world. In the United States, iron deficiency anemia affects about 240,000 toddlers between one and two years of age and 3.3 million women of childbearing age. This condition is less common in older children and in adults over 50 and rarely occurs in teenage boys and young men.

The onset of iron deficiency anemia is gradual and, at first, there may be no symptoms. The deficiency begins when the body loses more iron than it derives from food. Because depleted iron stores cannot meet the body's red blood cell needs, fewer red blood cells develop. In this early stage of anemia, the red blood cells look normal, but they are reduced in number. Then the body tries to compensate for the iron deficiency by producing more red blood cells, which are characteristically smaller in size. Symptoms develop at this stage.

FOLIC ACID DEFICIENCY ANEMIA. Folic acid deficiency anemia is the most common type of megaloblastic anemia (in which red blood cells are bigger than normal). It is caused by a deficiency of folic acid, a vitamin that the body needs to produce normal cells.

Folic acid anemia is especially common in infants and teenagers. Although this condition usually results from a dietary deficiency, it is sometimes due to inability to absorb enough folic acid from such foods as:

- cheese
- eggs
- fish
- green vegetables
- meat
- milk
- mushrooms
- yeast

Smoking raises the risk of developing this condition by interfering with the absorption of **vitamin C**, which the body needs to absorb folic acid. Folic acid anemia can also be a complication of **pregnancy**, when a woman's body needs eight times as much folic acid.

VITAMIN B₁₂ DEFICIENCY ANEMIA. Less common in this country than folic acid anemia, **vitamin B₁₂** deficiency anemia is another type of megaloblastic anemia that develops when the body doesn't absorb enough of this

nutrient. Necessary for the creation of red blood cells, B₁₂ is found in meat and vegetables.

Large amounts of B₁₂ are stored in the body, so this condition may not become apparent until as much as four years after B₁₂ absorption stops or slows down. The resulting drop in red blood cell production can cause:

- loss of muscle control
- loss of sensation in the legs, hands, and feet
- soreness or burning of the tongue
- weight loss
- yellow-blue color blindness

The most common form of B₁₂ deficiency is pernicious anemia. Since most people who eat meat or eggs get enough B₁₂ in their diets, a deficiency of this vitamin usually means that the body is not absorbing it properly. This can occur among people who have had intestinal surgery or among those who do not produce adequate amounts of intrinsic factor, a chemical secreted by the **stomach** lining that combines with B₁₂ to help its absorption in the **small intestine**.

Pernicious anemia usually strikes between the ages of 50 and 60. Eating disorders or an unbalanced diet increases the risk of developing pernicious anemia. So do:

- diabetes mellitus
- **gastritis**, stomach **cancer**, or stomach surgery
- thyroid disease
- family history of pernicious anemia

VITAMIN C DEFICIENCY ANEMIA. A rare disorder that causes the bone marrow to manufacture abnormally small red blood cells, vitamin C deficiency anemia results from a severe, long-standing dietary deficiency.

HEMOLYTIC ANEMIA. Hemolytic anemia is a condition in which **infection** or antibodies destroy red blood cells more rapidly than bone marrow can replace them. Some people are born with the disease, while others acquire it later in life.

Hemolytic anemia can enlarge the spleen, accelerating the destruction of red blood cells (hemolysis). Other complications of hemolytic anemia include **pain**, **shock**, gallstones, and other serious health problems.

THALASSEMIAS. An inherited form of hemolytic anemia, thalassemia stems from the body's inability to manufacture as much normal hemoglobin as it needs. There are two categories of thalassemia, depending on which of the amino acid chains is affected. (Hemoglobin is composed of four chains of amino acids.) In alpha-thalassemia, there is an imbalance in the production of the alpha chain of amino acids; in beta-thalassemia, there is

an imbalance in the beta chain. Alpha-thalassemias most commonly affect blacks (25% have at least one gene); beta-thalassemias most commonly affect people of Mediterranean and Southeast Asian ancestry.

Characterized by production of red blood cells that are unusually small and fragile, thalassemia only affects people who inherit the gene for it from each parent (autosomal recessive inheritance).

AUTOIMMUNE HEMOLYTIC ANEMIAS. Warm antibody hemolytic anemia is the most common type of this disorder. This condition occurs when the body produces autoantibodies that coat red blood cells. The coated cells are destroyed by the spleen, **liver**, or bone marrow.

Warm antibody hemolytic anemia is more common in women than in men. About one-third of patients who have warm antibody hemolytic anemia also have lymphoma, leukemia, lupus, or connective tissue disease.

In cold antibody hemolytic anemia, the body attacks red blood cells at or below normal body temperature. The acute form of this condition frequently develops in people who have had **pneumonia**, mononucleosis, or other acute infections. It tends to be mild and short-lived, and disappears without treatment.

Chronic cold antibody hemolytic anemia is most common in women and most often affects those who are over 40 and who have arthritis. This condition usually lasts for a lifetime, generally causing few symptoms. However, exposure to cold temperatures can accelerate red blood cell destruction, causing fatigue, joint aches, and discoloration of the arms and hands.

SICKLE CELL ANEMIA. Sickle cell anemia is a chronic, incurable condition that causes the body to produce defective hemoglobin, which forces red blood cells to assume an abnormal crescent shape. Unlike normal oval cells, fragile sickle cells can't hold enough hemoglobin to nourish body tissues. The deformed shape makes it hard for sickle cells to pass through narrow **blood vessels**. When capillaries become obstructed, a life-threatening condition called sickle cell crisis is likely to occur.

Sickle cell anemia is hereditary. Its rate of incidence is highest among those of African descent, although it can occur in peoples around the world. A child who inherits the sickle cell gene from each parent will have the disease. A child who inherits the sickle cell gene from only one parent carries the sickle cell trait, but does not have the disease.

APLASTIC ANEMIA. Sometimes curable by bone marrow transplant, but potentially fatal, aplastic anemia is characterized by decreased production of red and white blood cells and platelets (disc-shaped cells that allow the

blood to clot). This disorder may be inherited or acquired as a result of recent severe illness, long-term exposure to industrial chemicals, and use of **anticancer drugs** and certain other medications.

SIDEROBLASTIC ANEMIA. Sideroblastic anemia results from an enzyme disorder in which the body has adequate iron but is unable to incorporate it into hemoglobin. In sideroblastic anemia, iron enters a developing red blood cell and builds up in mitochondria of the cell. This build-up of iron gives the cell nucleus a ringed appearance, and the cell is called a ringed sideroblast, the primary sign of sideroblastic anemia. Ringed sideroblasts develop poorly or not at all into mature red blood cells, and the red blood cells cannot properly transport oxygen to tissues throughout the body. X-linked sideroblastic anemia is the hereditary form of sideroblastic anemia, also known as iron overload anemia or sideroblastosis. Another, more common type of sideroblastic anemia is called acquired sideroblastic anemia, which can result from prolonged exposure to toxins or nutritional imbalances. Other causes may be inflammatory disease, cancerous conditions such as leukemia and lymphoma, kidney disorders causing uremia, endocrine disorders, or metabolic disorders.

ANEMIA OF CHRONIC DISEASE. Cancer, chronic infection or inflammation, and kidney and liver disease often cause mild or moderate anemia. Chronic liver failure generally produces the most severe symptoms.

Causes and symptoms

Anemia is caused by bleeding, decreased red blood cell production, or increased red blood cell destruction. Poor diet can contribute to vitamin deficiency and iron deficiency anemias in which fewer red blood cells are produced. Hereditary disorders and certain diseases can cause increased blood cell destruction. However, excessive bleeding is the most common cause of anemia, and the speed with which blood loss occurs has a significant effect on the severity of symptoms. Chronic blood loss is usually a consequence of:

- cancer
- gastrointestinal tumors
- diverticulosis
- polyposis
- heavy menstrual flow
- hemorrhoids
- nosebleeds
- stomach ulcers
- long-standing alcohol abuse

Acute blood loss is usually the result of:

- childbirth
- miscarriage of pregnancy
- injury
- a ruptured blood vessel
- surgery

When a large volume of blood is lost within a short time, **blood pressure** and the amount of oxygen in the body drop suddenly. **Heart failure** and death can follow.

Loss of even one-third of the body's blood volume in the space of several hours can be fatal. More gradual blood loss is less serious, because the body has time to create new red blood cells to replace those that have been lost.

Symptoms

Weakness, fatigue, and a run-down feeling may be signs of mild anemia. Skin that is pasty or sallow, or lack of color in the creases of the palm, gums, nail beds, or linings of the eyelids are other signs of anemia. Someone who is weak, tires easily, is often out of breath, and feels faint or dizzy may be severely anemic.

Other symptoms of anemia are:

- angina pectoris (chest pain, often accompanied by a choking sensation that provokes severe anxiety)
- cravings for ice, paint, or dirt (called pica)
- headache
- inability to concentrate, **memory** loss
- inflammation of the mouth (**stomatitis**) or tongue (glossitis)
- insomnia
- irregular heartbeat
- loss of appetite
- nails that are dry, brittle, or ridged
- rapid breathing
- sores in the mouth, throat, or rectum
- sweating
- swelling of the hands and feet
- thirst
- tinnitus (ringing in the ears)
- unexplained bleeding or bruising

In pernicious anemia, the tongue feels unusually slick. A patient with pernicious anemia may have problems with movement or balance, tingling in the hands and feet, confusion, depression, and memory loss.

Pernicious anemia can damage the **spinal cord**. A doctor should be notified whenever symptoms of this condition occur.

A doctor should also be notified if a patient who has been taking iron supplements develops **diarrhea**, cramps, or vomiting.

Diagnosis

Personal and family **health history** may suggest the presence of certain types of anemia. Laboratory tests that measure the percentage of red blood cells or the amount of hemoglobin in the blood are used to confirm diagnosis and determine which type of anemia is responsible for a patient's symptoms. X rays and examinations of bone marrow may be used to identify the source of bleeding.

Treatment

Anemia due to nutritional deficiencies can usually be treated at home with appropriate supplements, under a health professional's guidance. People with iron deficiency should take iron supplements. People with folic acid anemia should take oral folic acid replacements. Vitamin C deficiency anemia can be cured by the recommended daily allowance of vitamin C. People with pernicious anemia may be able to self-administer injections of vitamin B₁₂.

Surgery may be necessary to treat anemia caused by excessive loss of blood. Transfusions of red blood cells may be used to accelerate production of red blood cells in the body.

Medication or surgery may also be necessary to control heavy menstrual flow, repair a bleeding ulcer, or remove polyps (growths or nodules) from the bowels.

Patients with thalassemia usually do not require treatment. However, people with a severe form may require periodic hospitalization for blood transfusions or bone marrow transplantation.

Alternative therapies for iron deficiency anemia focus on adding iron-rich foods to the diet or on techniques to improve circulation and digestion. Herbal remedies to improve digestion include Gentian (*Gentiana lutea*), which is widely used in Europe to treat anemia and other nutritionally based disorders, as well as anise (*Pimpinella anisum*), caraway (*Carum carvi*), cumin (*Cuminum cyminum*), and licorice.

SICKLE CELL ANEMIA. Treatment for sickle cell anemia involves regular eye examinations, immunizations for pneumonia and infectious diseases, and prompt treatment for sickle cell crises and infections of any kind.

Psychotherapy or counseling may help patients deal with the emotional impact of this condition.

VITAMIN B₁₂ DEFICIENCY ANEMIA. A life-long regimen of B₁₂ shots is necessary to control symptoms of pernicious anemia. The patient may be advised to limit physical activity until treatment restores strength and balance.

APLASTIC ANEMIA. People who have aplastic anemia are especially susceptible to infection. Treatment for aplastic anemia may involve blood transfusions and bone marrow transplant to replace malfunctioning cells with healthy ones.

SIDEROBLASTIC ANEMIA. X-linked sideroblastic anemia often improves with pyridoxine (vitamin B₆) therapy. In cases of extreme anemia, whole red blood cell transfusion may be required.

If anemia is acquired, removal of the offending agent or treatment for the primary disorder may allow the anemia to disappear.

ANEMIA OF CHRONIC DISEASE. There is no specific treatment for anemia associated with chronic disease, but treating the underlying illness may alleviate this condition. This type of anemia rarely becomes severe. If it does, transfusions or hormone treatments to stimulate red blood cell production may be prescribed.

HEMOLYTIC ANEMIA. There is no specific treatment for cold-antibody hemolytic anemia. About one-third of patients with warm-antibody hemolytic anemia respond well to large doses of intravenous and oral **corticosteroids**, which are gradually discontinued as the patient's condition improves. Patients with this condition who don't respond to medical therapy must have the spleen surgically removed. This operation controls anemia in about half of the patients on whom it's performed. **Immune system** suppressants are prescribed for patients whose surgery is not successful.

Self-care

Anyone who has anemia caused by poor **nutrition** should modify his or her diet to include more **vitamins**, **minerals**, and iron. Vitamin C can stimulate iron absorption. The following foods are also good sources of iron:

- almonds
- broccoli
- dried beans
- dried fruits
- enriched breads and cereals
- lean red meat
- liver
- potatoes

KEY TERMS

Aplastic—Exhibiting incomplete or faulty development.

Diabetes mellitus—A disorder of carbohydrate metabolism brought on by a combination of hereditary and environmental factors.

Erythropoiesis—Erythropoiesis is the development of mature red blood cells (erythrocytes).

Hemoglobin—An iron-containing pigment of red blood cells composed of four amino acid chains (alpha, beta, gamma, delta) that delivers oxygen from the lungs to the tissues of the body.

Megaloblast—A large erythroblast (a red marrow cell that synthesizes hemoglobin).

Red blood cells—Yellowish, circular, biconcave disks found in the blood, which contain hemoglobin and carries oxygen. Also known as erythrocytes.

- poultry
- rice
- shellfish
- tomatoes

Because light and heat destroy folic acid, fruits and vegetables should be eaten raw, or cooked as little as possible.

Health care team roles

Often, anemia is not discovered until blood tests are run as part of a routine **physical examination**. Hemoglobin tests are commonly run by medical technologists or other laboratory professionals. Nurses and allied health professionals can play a critical role in the well-being and quality of life of patients at risk for anemia by understanding erythropoiesis, pathophysiology, nursing assessment (including laboratory data assessment), and nursing interventions related to anemia. In particular, nurses should be sure that patients are educated about their disease and about the treatment options available. In cases where anemia may be inherited, they may provide patients with information about **genetic testing**. They may also refer patients to professional genetic counselors.

Prognosis

Folic acid and iron deficiency anemias

It usually takes three to six weeks to correct folic acid or iron deficiency anemia. Patients should continue taking supplements for another six months to replenish iron reserves and should have periodic blood tests to make sure the bleeding has stopped and the anemia has not recurred.

Pernicious anemia

Although pernicious anemia is considered incurable, regular B₁₂ shots will alleviate symptoms and reverse complications. Some symptoms will disappear almost as soon as treatment begins.

Aplastic anemia

Aplastic anemia can sometimes be cured by bone marrow transplantation. If the condition is due to immunosuppressive drugs, symptoms may disappear after the drugs are discontinued.

Sickle cell anemia

Although sickle cell anemia cannot be cured, effective treatments enable patients with this disease to enjoy longer, more productive lives.

Thalassemia

People with mild thalassemia (alpha thalassemia trait or beta thalassemia minor) lead normal lives and do not require treatment. Those with severe thalassemia may require bone marrow transplantation. Genetic therapy is being investigated and may soon be available.

Hemolytic anemia

Acquired hemolytic anemia can generally be cured when the cause is removed.

Health care team roles

Anemia is often overlooked as a priority associated with quality patient care. Identifying the underlying causes of anemia in patients is critical to positive care outcomes and requires early assessment and intervention. The entire health care team plays a critical role in the well-being and quality of life of patients with anemia by understanding the disease and appropriate treatments, and by providing patients with any materials and education needed to understand the disease and its treatment.

Prevention

Inherited anemias cannot be prevented. **Genetic counseling** can help parents cope with questions and concerns about transmitting disease-causing genes to their children.

Avoiding excessive use of alcohol, eating a balanced diet that contains plenty of iron-rich foods, and taking a daily multivitamin can help prevent anemia.

Methods of preventing specific types of anemia include:

- Avoiding lengthy exposure to industrial chemicals and drugs known to cause aplastic anemia.
- Not taking medication that has triggered hemolytic anemia and not eating foods that have caused hemolysis (breakdown of red blood cells).
- Receiving regular B₁₂ shots to prevent pernicious anemia resulting from gastritis or stomach surgery.

Anencephaly *see* **Neural tube defect**

Anesthesia, general

Definition

General anesthesia is the induction of a balanced state of unconsciousness, accompanied by the absence of **pain** sensation and the **paralysis** of skeletal muscle over the entire body. It is induced through the administration of anesthetic drugs and is used during major and other invasive surgical procedures.

Purpose

General anesthesia is intended to bring about five distinct states during surgery:

- analgesia, or pain relief
- amnesia, or loss of **memory** of the procedure
- loss of consciousness
- motionlessness
- weakening of autonomic responses

Precautions

A complete medical history, including a history of **allergies** in family members, is an important precaution. Patients may have a potentially fatal allergic response to anesthesia known as malignant hyperthermia, even if there is no previous personal history of reaction.

General anesthetics should be administered only by board-certified medical professionals. Anesthesia providers consider many factors, including a patient's age, weight, allergies to medications, medical history, and general health when deciding which anesthetic or combination of anesthetics to use. The American Society of Anesthesiologists has compiled guidelines for classifying patients according to risk levels as follows:

- I: healthy patient
- II: patient with mild systemic disease without functional limitations
- III: patient with severe systemic disease with definite functional limitations

ANESTHETICS: HOW THEY WORK			
Type	Name(s)	Administered	Affect
General	Halothane, Enflurane Isoflurane, Ketamine, Nitrous Oxide, Thiopental	Intravenously, Inhalation	Produces total unconsciousness affecting the entire body
Regional	Mepivacaine, Chloroprocaine, Lidocaine	Intravenously	Temporarily interrupts transmission of nerve impulses (temperature, touch, pain) and motor functions in a large area to be treated; does not produce unconsciousness
Local	Procaine, Lidocaine, Tetracaine, Bupivacaine	Intravenously	Temporarily blocks transmission of nerve impulses and motor functions in a specific area; does not produce unconsciousness
Topical	Benzocaine, Lidocaine Dibucaine, Pramoxine, Butamben, Tetracaine	Dermal (Sprays, Drops, Ointments, Creams, Gels)	Temporarily blocks nerve endings in skin and mucous membranes; does not produce unconsciousness

(Illustration by Standley Publishing. Courtesy of Gale Group.)

- IV: patient with severe systemic disease that is life-threatening
- V: dying patient not expected to survive for 24 hours with or without an operation

Equipment for general anesthesia should be thoroughly checked before the operation; all items that might be needed, such as extra tubes or laryngoscope blades, should be available. Staff members should be knowledgeable about the problems that might arise with the specific anesthetic being used, and be able to recognize them and respond appropriately. General anesthetics cause a lowering of the **blood pressure** (hypotension), a hemodynamic response that requires close monitoring and special drugs to reverse it in emergency situations.

Description

General anesthetics may be gases or volatile liquids that evaporate as they are inhaled through a mask along with oxygen. Other general anesthetics are given intravenously. The amount of anesthesia produced by inhaling a general anesthetic can be adjusted rapidly, if necessary, by adjusting the anesthetic-to-oxygen ratio that is inhaled by the patient. The degree of anesthesia produced by an intravenously injected anesthetic cannot be changed as rapidly and must be reversed by administration of another drug.

The precise mechanism of general anesthesia is not yet fully understood. There are, however, several

hypotheses that have been advanced to explain why general anesthesia occurs. The first, the so-called Meyer-Overton theory, suggests that anesthesia occurs when a sufficient number of molecules of an inhalation anesthetic dissolve in the lipid cell membrane. The second theory maintains that protein receptors in the **central nervous system** are involved, in that inhalation anesthetics inhibit the enzyme activity of **proteins**. A third hypothesis, proposed by Pauling in 1961, suggests that anesthetic molecules interact with water molecules to form clathrates (hydrated microcrystals), which in turn inhibit receptor function.

Stages of anesthesia

There are four stages of general anesthesia that help providers to better predict the course of events, from anesthesia induction to emergence. Stage I begins with the induction of anesthesia and ends with the patient's loss of consciousness. The patient still feels pain in Stage I. Stage II, or REM stage, includes uninhibited and sometimes dangerous responses to stimuli, including vomiting and uncontrolled movement. This stage is typically shortened by administering a barbiturate, such as sodium pentothal, before the anesthetic agent. Stage III, or surgical anesthesia, is the stage in which the patient's pupillary gaze is central and the pupils are constricted. This is the target depth of surgical anesthesia. During this stage, the **skeletal muscles** relax, the patient's breathing becomes regular, and eye movements stop. Stage IV, or overdose, is

marked by hypotension or circulatory failure. Death may result if the patient cannot be revived quickly.

Types of anesthetic agents

There are two major types of anesthetics used for general anesthesia, inhalation and intravenous anesthetics. Inhalation anesthetics, which are sometimes called volatile anesthetics, are compounds that enter the body through the **lungs** and are carried by the **blood** to body tissues. Inhalation anesthetics are less often used alone in recent clinical practice; they are usually used together with intravenous anesthetics. A combination of inhalation and intravenous anesthetics, often with opioids added for pain relief and neuromuscular blockers for muscle paralysis, is called balanced anesthesia.

INHALATION ANESTHETICS. The following are the most commonly used inhalation anesthetics:

- Halothane causes unconsciousness but provides little pain relief; often administered with **analgesics**. It may be toxic to the **liver** in adults. Halothane, however, has a pleasant smell and is therefore often the anesthetic of choice when mask induction is used with children.
- Enflurane is less potent, but produces in a rapid onset of anesthesia and possibly a faster recovery. Enflurane is not used in patients with kidney failure.
- Isoflurane is not toxic to the liver but can induce irregular **heart** rhythms.
- Nitrous oxide (laughing gas) is used with such other drugs as thiopental to produce surgical anesthesia. It has the fastest induction and recovery time. It is regarded as the safest inhalation anesthetic because it does not slow respiration or blood flow to the **brain**.
- Sevoflurane works quickly and can be administered through a mask since it does not irritate the airway. On the other hand, one of the breakdown products of sevoflurane can cause renal damage.
- Desflurane, a second-generation version of isoflurane, is irritating to the airway and therefore cannot be used for mask (inhalation) inductions, especially not in children.

INTRAVENOUS ANESTHETICS. Commonly administered intravenous general anesthetics include ketamine, thiopental (a barbiturate), methohexital (Brevital), etomidate, and propofol (Diprivan). Ketamine produces a different set of reactions from other intravenous anesthetics. It resembles phencyclidine, which is a street drug that may cause hallucinations. Because patients who have been anesthetized with ketamine often have sensory illusions and vivid dreams during post-operative recovery, ketamine is not often given to adult patients. It

Monitoring a patient under general anesthesia is important so that his or her state of unconsciousness is maintained at a safe level. (M. English, MD/Custom Medical Stock Photo. Reproduced by permission.)

is, however, useful in anesthetizing children, patients in **shock**, and trauma casualties in war zones where anesthesia equipment may be difficult to obtain.

General anesthesia in dental procedures

The use of general anesthesia in dental and oral surgery patients differs from its use in major surgery because the patient's level of fear is usually a more important factor than the nature of the procedure. In 1985 an NIH Consensus Statement reported that high levels of preoperative **anxiety**, lengthy and complex procedures, and the need for a pain-free operative period may be indications for general anesthesia in healthy adults and in very young children. The NIH statement specified that at least three professionals are required when general anesthesia is used during dental procedures: one is the operating dentist; the second is a professional responsible for observing and monitoring the patient; the third person assists the operating dentist.

Although the United States allows general anesthesia for dental procedures to be administered outside hospitals provided that the facility has the appropriate equipment and emergency drugs, Scotland banned the use of general anesthesia outside hospitals in 2000, after a ten-year-old boy died during a procedure to have a tooth removed.

Preparation

Preparation for general anesthesia includes the taking of a complete medical history and the evaluation of all factors—especially a family history of allergic responses to anesthetics—that might influence the patient's response to specific anesthetic agents.

Patients should not eat or drink before general anesthesia because of the risk of regurgitating food and liquid or aspirating vomitus into the lungs.

Informed consent

Patients should be informed of the risks associated with general anesthesia as part of their **informed consent**. These risks include possible dental injuries from intubation as well as such serious complications as stroke, liver damage, or massive hemorrhage. If **local anesthesia** is an option for some procedures, the patient should be informed of this alternative. In all cases, patients should be given the opportunity to ask questions about the risks and benefits of the procedure requiring anesthesia as well as questions about the anesthesia itself.

Premedication

Depending on the patient's level of anxiety and the procedure to be performed, the patient may be premedicated. Most medications given before general anesthesia are either anxiolytics, usually benzodiazepines; or analgesics. Patients in severe pain prior to surgery may be given morphine or fentanyl. Anticholinergics (drugs that block impulses from the parasympathetic nervous system) may be given to patients with a known history of bronchospasm or heavy airway secretions.

Aftercare

The anesthetist and medical personnel provide supplemental oxygen and monitor patients for **vital signs** and monitor their airways. Vital signs include an EKG (unless the patient is hooked to a monitor), blood pressure, pulse rate, oxygen saturation, respiratory rate, and temperature. The staff also monitors the patient's level of consciousness as well as signs of excess bleeding from the incision.

Complications

Although the risk of serious complications from general anesthesia are low, they can include heart attack, stroke, brain damage, and death. The risk of complications depends in part on the patient's age, sex, weight, allergies, general health, and history of smoking, drinking alcohol, or drug use.

The overall risk of mortality from general anesthesia is difficult to evaluate as of 2001, because so many different factors are involved, ranging from the patient's overall health and the circumstances preceding surgery to the type of procedure and the skill of the physicians involved. The risk appears to be somewhere between 1:1,000 and 1:100,000, with infants younger than age one and patients older than 70 being at greater risk.

Awareness during surgery

One possible complication is the patient's "waking up" during the operation. It is estimated that about 30,000 patients per year in the United States "come to" during surgery. This development is in part the result of the widespread use of short-acting general anesthetics combined with blanket use of neuromuscular blockade. The patients are paralyzed with regard to motion, but otherwise "awake and aware." At present, special devices that measure brain wave activity are used to monitor the patient's state of consciousness. The bispectral index monitor was approved by the FDA in 1996 and the patient state analyzer in 1999.

Nausea and vomiting

Post-operative nausea and vomiting is a common problem during recovery from general anesthesia. In addition, patients may feel drowsy, weak, or tired for several days after the operation, a combination of symptoms sometimes called the "hangover effect." Fuzzy thinking, blurred **vision**, and coordination problems are also possible. For these reasons, anyone who has had general anesthesia should not drive, operate machinery, or perform other activities that could endanger themselves or others for at least 24 hours, or longer if necessary.

Anesthetic toxicity

Inhalation anesthetics are sometimes toxic to the liver, the kidney, or to blood cells. Halothane may cause hepatic necrosis or hepatitis. Sevoflurane may react with the carbon dioxide absorbents in anesthesia machines to form compound A, a haloalkene that is toxic to the **kidneys**. The danger to red blood cells comes from carbon monoxide formed by the breakdown products of inhalation anesthetics in the circuits of anesthesia machines.

Malignant hyperthermia

Malignant hyperthermia is a rare condition caused by an allergic response to a general anesthetic. The signs of malignant hyperthermia include rapid, irregular heart-beat; breathing problems; very high **fever**; and muscle tightness or spasms. These symptoms can occur following the administration of general anesthetics, especially halothane.

Results

General anesthesia is much safer today than it was in the past, thanks to faster-acting anesthetics; improved safety standards in the equipment used to deliver the drugs; and better devices to monitor breathing, heart rate, blood pressure, and brain activity during surgery. Unpleasant

side effects are also less common, in part because of recent developments in equipment that reduce the problems of anesthetizing patients with “difficult” airways. These developments include the laryngeal mask airway and the McCoy laryngoscope, which has a hinged tip on its blade that allows a better view of the patient’s larynx.

Health care team roles

Nurse anesthetists sometimes work with physician anesthesiologists in administering general anesthesia. Anesthesiologist assistants are other allied health professionals who assist anesthesiologists. Anesthesiologist assistants help in many areas, including preparation for the delivery of general anesthesia; performance of pre-treatment assessments; administration of maintenance and supportive drugs; **airway management**; and assistance with transferring the patient to the recovery room.

KEY TERMS

Analgesia—Relief from pain.

Anticholinergics—Drugs that interfere with impulses from the parasympathetic nervous system. They may be given before general anesthesia to reduce airway secretions or the risk of bronchospasm.

Anxiolytics—Medications given to reduce anxiety; tranquilizers. Benzodiazepines are the anxiolytics most commonly used to premedicate patients before general anesthesia.

Balanced anesthesia—The use of a combination of inhalation and intravenous anesthetics, often with opioids for pain relief and neuromuscular blockers for muscle paralysis.

Clathrates—Substances in which a molecule from one compound fills a space within the crystal lattice of another compound. One theory of general anesthesia proposes that water molecules interact with anesthetic molecules to form clathrates that decrease receptor function.

Laryngoscope—An endoscope equipped for viewing a patient’s larynx through the mouth.

Malignant hyperthermia—A type of allergic reaction (probably with a genetic basis) that can occur during general anesthesia in which the patient experiences a high fever, the muscles become rigid, and the heart rate and blood pressure fluctuate.

Volatile anesthetics—Another name for inhalation anesthetics.

NIH Consensus Statement. 1985 April 22-24. *Anesthesia and Sedation in the Dental Office*. 5(10): 1-18.

Lisette Hilton

Anesthesia, local

Definition

Local or regional anesthesia involves the injection or application of an anesthetic drug to a specific area of the body. This is in contrast to **general anesthesia**, which provides anesthesia to the entire body and **brain**.

Purpose

Local anesthetics are used to prevent patients from feeling **pain** during medical, surgical, or dental procedures. Over-the-counter local anesthetics are also available to provide temporary relief from pain, irritation, and itching caused by various conditions, such as cold sores, canker sores, sore throats, sunburn, insect bites, poison ivy, and minor cuts and scratches.

Precautions

People who feel strongly that they do not want to be awake and alert during certain procedures may not be good candidates for local or regional anesthesia. However, other medications that have systemic effects may be given in addition to an anesthetic to relieve **anxiety** and help the patient relax.

Local anesthetics should be used only for the conditions for which they are intended. For example, a topical anesthetic meant to relieve sunburn pain should not be used on cold sores. Anyone who has had an unusual reaction to any local anesthetic in the past should check with a doctor before using any type of local anesthetic again. The doctor should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

Older people may be more sensitive to the effects of local anesthetics, especially lidocaine. Children may also be especially sensitive to some local anesthetics, and certain types should not be used at all on young children. People caring for these groups need to be aware that they are at increased risk of more severe side effects. Packages should be followed carefully so that the recommended dosage is not exceeded. A doctor or pharmacist should be consulted about any concerns.

Regional anesthetics

Serious and possibly life-threatening side effects may occur when injectable or inhaled anesthetics are given to people who use street drugs. Doctors and nurses should inform patients about the dangers of mixing anesthetics with cocaine, **marijuana**, amphetamines, barbiturates, phencyclidine (PCP or angel dust), heroin, or other street drugs. Some anesthetic drugs may interact with other medicines. When this happens, the effects of one or both of the drugs may change, or the risk of side effects may be greater. In select cases, a **urinalysis** can help identify drug use.

Patients who have a personal or family history of malignant hyperthermia after receiving a general anesthetic must also be cautious when receiving regional or local anesthetics. Malignant hyperthermia is a serious reaction that involves a fast or irregular heartbeat, high

fever, breathing problems, and muscle spasms. All patients should be asked if they are aware of such a risk in their family before receiving any kind of anesthetic.

Although problems are rare, some side effects may occur when regional anesthetics are used during labor and delivery. Anesthetics can prolong labor and increase the risk of requiring a cesarean section. Doctors should discuss the risks and benefits associated with epidural or spinal anesthesia with pregnant patients.

Patients should not drive or operate machinery immediately following a procedure involving regional anesthesia because of the danger that numbness or weakness may cause impairment. Doctors and nurses should also warn patients who have had local anesthesia, especially when combined with drugs to make patients sleep or to reduce pain, about operating any type of machinery.

Injectable local anesthetics

Until the anesthetic wears off, patients should be careful not to inadvertently injure the numbed area. If the anesthetic was used in the mouth, patients should not eat or chew gum until feeling returns.

Topical anesthetics

Unless advised by a doctor, topical anesthetics should not be used on or near any part of the body with large sores, broken or scraped skin, severe injury, or **infection**. They should also not be used on large areas of skin. Some topical anesthetics contain alcohol and should not be used near an open flame or while smoking.

Patients should be careful not to get topical anesthetics in the eyes, nose, or mouth. If a spray-type anesthetic is to be used on the face, it can be applied with a cotton swab or sterile gauze pad. After using a topical anesthetic on a child, make sure the child does not get the medicine in his or her mouth or eyes.

Topical anesthetics are intended for the temporary relief of pain and itching. They should not be used for more than a few days at a time. Check with a doctor if:

- discomfort continues for more than seven days
- the problem gets worse
- the treated area becomes infected
- new signs of irritation, such as skin rash, burning, stinging, or swelling appear

Dental anesthetics

Dental anesthetics should not be used if certain kinds of infections are present. Check package directions or check with a dentist, pharmacist, or doctor if uncertain.

Dental anesthetics should be used only for temporary pain relief. Consult the dentist if problems such as toothache, mouth sores, or pain from dentures or braces continue or if signs of general illness, such as fever, rash, or vomiting develop.

Patients should not eat or chew gum while the mouth is numb from a dental anesthetic to avoid accidentally biting the tongue or the inside of the mouth. In addition, nothing should be eaten or drunk for one hour after applying a dental anesthetic to the back of the mouth or throat, because the medicine may interfere with swallowing and may cause choking. If normal feeling does not return to the mouth within a few hours after receiving a dental anesthetic or if it is difficult to open the mouth, the dentist should be consulted.

Ophthalmic anesthetics

When anesthetics are used in the eye, it is important not to rub or wipe the eye until the effect of the anesthetic has worn off and feeling has returned. Rubbing the eye while it is numb could cause injury.

Description

Medical procedures and situations that regularly make use of local or regional anesthesia include the following:

- biopsies, in which skin or tissue samples are taken for diagnostic procedures
- childbirth
- scar repair
- surgery on the face (including plastic surgery), skin, arms, hands, legs, and feet
- eye surgery
- surgery involving the urinary tract or reproductive organs

Surgery involving the chest or abdomen is usually performed under general anesthesia. **Laparoscopy** and hernia repair, however, may be performed under local or regional anesthesia.

Local and regional anesthesia have many advantages over general anesthesia. Most importantly, the risk of unusual and sometimes fatal reactions to general anesthesia is lessened. More minor but significant risks of general anesthesia include longer recovery time and the psychological discomfort of losing consciousness.

Regional anesthesia typically affects a larger area than local anesthesia. As a result, regional anesthesia is typically used for more involved or complicated proce-

A local anesthetic is administered to the foot prior to a minor operation to remove a verruca (plantar wart).

(Photograph by David Parker. Science Source/Photo Researchers. Reproduced by permission.)

dures. The duration of action of an anesthetic depends on the type and amount of anesthetic administered.

Regional anesthetics are injected. Local anesthesia involves the injection into the skin or application to the skin surface of an anesthetic directly where pain will occur. Local anesthesia can be divided into four groups: injectable, topical, dental (non-injectable), and regional blockade injection.

Local and regional anesthesia work by altering the flow of sodium molecules into nerve cells (**neurons**) through the cell membrane. The exact mechanism is not understood, since the drug apparently does not bind to any receptor on the cell surface and does not seem to affect the release of chemicals that transmit nerve impulses (neurotransmitters) from the nerve cells. Experts believe, however, that when the sodium molecules do not get into the neurons, nerve impulses are not generated and pain impulses are not transmitted to the brain.

KEY TERMS

Canker sore—A painful sore inside the mouth.

Cold sore—A small blister on the lips or face, caused by a virus. Also called a fever blister.

Epidural space—The space surrounding the spinal fluid sac.

Malignant hyperthermia—A type of reaction (probably with a genetic basis) that can occur during general anesthesia in which the patient experiences a high fever, the muscles become rigid, and the heart rate and blood pressure fluctuate.

Subarachnoid space—The space surrounding the spinal cord that is filled with cerebrospinal fluid.

Topical—Not ingested; applied to the outside of the body, for example to the skin, eye, or mouth.

Regional anesthesia

Types of regional anesthesia include:

- Spinal anesthesia, which involves the injection of a small amount of local anesthetic into the cerebrospinal fluid surrounding the **spinal cord** (the subarachnoid space). A drop in **blood pressure** is a common but easily treated side effect.
- Epidural anesthesia, which involves the injection of a large volume of local anesthetic into the space surrounding the spinal fluid sac (the epidural space), not directly into the spinal fluid. Pain relief occurs more slowly but is less likely to produce a drop in **blood pressure**. The block can be maintained for long periods, even for days if necessary.
- Nerve blockades, which involve the injection of an anesthetic into the area around a sensory or motor nerve that supplies a particular region of the body, preventing the nerve from carrying nerve impulses to and from the brain.

Local and regional anesthetics may be administered with other drugs to enhance their action. Examples include vasoconstrictors such as epinephrine (adrenaline) to decrease bleeding, or sodium bicarbonate to lower acidity, which may make a drug work faster. In addition, medications may be administered to help a patient remain calm and more comfortable or to make them sleepy.

Local anesthesia

INJECTABLE LOCAL ANESTHETICS. Injectable local anesthetics provide pain relief for some part of the body

during surgery, dental procedures or other medical procedures. They are given only by a trained health care professional and only in a doctor's office or a hospital. Some commonly used injectable local anesthetics are lidocaine (Xylocaine), bupivacaine (Marcaine), and mepivacaine (Carbocaine).

TOPICAL ANESTHETICS. Topical anesthetics, such as benzocaine, lidocaine (in smaller quantities or doses), dibucaine and tetracaine, relieve pain and itching by blocking the sensory nerve endings in the skin. They are ingredients in a variety of nonprescription products that are applied to the skin to relieve the discomfort of sunburn, insect bites or stings, poison ivy, and minor cuts, scratches, and **burns**. These products are sold as creams, ointments, sprays, lotions, and gels.

Topical dental anesthetics are intended for pain relief in the mouth or throat. They may be used to relieve throat pain, teething pain, painful canker sores, toothaches, or discomfort from dentures, braces or bridgework. Some dental anesthetics are available only with a doctor's prescription. Others may be purchased over the counter, including products such as Num-Zit, Orajel, Chloraseptic lozenges, and Xylocaine.

Ophthalmic anesthetics are designed for use in the eye. Lidocaine and tetracaine are used to numb the eye before certain eye examinations. Eye doctors may also use these medicines before measuring eye pressure or removing stitches or foreign objects from the eye. These drugs are to be given only by a trained health care professional.

The recommended dosage of a topical anesthetic depends on the type of local anesthetic and the purpose for which it is being used. When using a nonprescription local anesthetic, follow the directions on the package. Questions concerning how to use a product should be referred to a doctor, dentist or pharmacist.

Aftercare

Most patients can return home immediately after a local anesthetic, but some patients might require limited observation. The degree of aftercare needed depends on where the anesthetic was given, how much was given, and other individual circumstances. Patients who have had their eyes numbed should wear a patch after surgery or treatment until the full feeling of the eye area has returned. If the throat was anesthetized, the patient cannot drink until the gag reflex returns. If a major extremity was anesthetized, one may have to wait until function returns before the patient goes home. Some local anesthetics can cause cardiac arrhythmias and therefore require monitoring for a time with an EKG. Patients who

have had regional anesthesia or larger amounts of local anesthesia usually recover in a post-anesthesia care unit before being discharged. There, medical personnel watch for immediate postoperative problems. These patients need to be driven home after discharge.

Complications

Side effects of regional or local anesthetics vary depending on the type of anesthetic used and the way it is administered. Any unusual symptoms following the use of an anesthetic requires the immediate attention of a doctor.

Paralysis after a regional anesthetic such as an epidural, spinal or ganglionic blockade is extremely rare, but can occur. Paralysis reportedly occurs even less frequently than deaths due to general anesthesia.

There is also a small risk of developing a severe headache called a spinal headache following a spinal or epidural block. This headache is severe when the patient is upright, even when only elevated 30 degrees, and is hardly felt when the patient lies down. It is treated by increasing fluids to help clear the anesthetic and enhance the flow of spinal fluid.

Finally, blood clots or **abscess** can form at the site where an anesthetic is injected. Although they can usually be treated, antibiotic resistance is becoming increasingly common. Such infections must be regarded as potentially dangerous, particularly if they develop at the site of a spinal injection.

A physician should be notified immediately if any of the following occur:

- symptoms of an allergic reaction, such as **hives** (urticaria), which are itchy swellings on the skin, or swelling in the mouth or throat
- severe headache
- blurred or double **vision** or photophobia (sensitivity to light)
- dizziness or lightheadedness
- drowsiness
- confusion
- an irregular, too slow, or rapid heartbeat
- anxiety, excitement, nervousness, or restlessness
- convulsions (seizures)
- feeling hot, cold, or numb anywhere other than the anesthetized area
- ringing or buzzing in the ears
- shivering or trembling

- sweating
- pale skin
- breathing problems
- unusual weakness or tiredness

Results

Local and regional anesthetics help to make many conditions and procedures more comfortable and tolerable for patients.

Health care team roles

A **registered nurse** often can administer local anesthesia. For other types, including spinal and epidural anesthesia and ganglionic blockades, a health care team may include a certified registered **nurse anesthetist** (CRNA) working independently or with an anesthesiologist. Anesthesiologist assistants are other allied health professionals who assist anesthesiologists. They may prepare for the delivery of anesthesia; perform pre-treatment assessments; insert catheters; administer maintenance and supportive drugs; manage patient airways; make anesthetic adjustments; and assist with the patient transition to the recovery room.

Angiography

Definition

Angiography is the x-ray (radiographic) study of the **blood vessels**. An angiogram uses a radiopaque substance, or contrast medium, to make the **blood** vessels

visible under x ray. The key ingredient in most radiographic contrast media is iodine. Arteriography is a type of radiographic examination that involves the study of the arteries.

Purpose

Angiography is used to detect abnormalities, including narrowing (stenosis) or blockages in the blood vessels (called occlusions) throughout the circulatory system and in some organs. The procedure is commonly used to identify atherosclerosis; to diagnose **heart** disease; to evaluate kidney function and detect kidney cysts or tumors; to map renal anatomy in transplant donors; to detect an aneurysm (an abnormal bulge of an artery that can rupture leading to hemorrhage), tumor, blood clot, or arteriovenous malformations (abnormal tangles of arteries and veins) in the **brain**; and to diagnose problems with the retina of the eye. It is also used to provide surgeons with an accurate vascular “map” of the heart prior to open-heart surgery, or of the brain prior to neurosurgery. Angiography may be used after penetrating trauma, like a gunshot or knife wound, to detect blood vessel injury; it may be used to check the position of shunts and stents placed by physicians into blood vessels.

Precautions

Patients with kidney disease or injury may suffer further kidney damage from the contrast media used for angiography. Patients who have blood clotting problems, have a known allergy to contrast media, or are allergic to iodine, may also not be suitable candidates for an angiography procedure. Newer types of contrast media classified as non-ionic are less toxic and cause fewer side effects than traditional ionic agents do. Because x rays carry risks of ionizing radiation exposure to the fetus, pregnant women are also advised to avoid this procedure.

Description

Angiography requires the injection of a contrast medium that makes the blood vessels visible to x ray. The contrast medium is injected through a procedure known as arterial puncture. The puncture is usually made in the groin area, armpit, inside elbow, or neck. The site is cleaned with an antiseptic agent and injected with a local anesthetic. First, a small incision is made in the skin to help the needle pass. A needle containing a solid inner core called a stylet is inserted through the incision and into the artery. When the radiologist has punctured the artery with the needle, the stylet is removed and replaced with another long wire called a guide wire. It is normal

for blood to spurt out of the needle before the guide wire is inserted.

The guide wire is fed through the outer needle into the artery and to the area that requires angiographic study. A **fluoroscope** displays a view of the patient’s vascular system and is used to direct the guide wire to the correct location. Once it is in position, the needle is removed, and a catheter is threaded over the length of the guide wire until it reaches the area of study. The guide wire is removed, and the catheter is left in place in preparation for the injection of the contrast medium.

Depending on the type of angiographic procedure being performed, the contrast medium is either injected by hand with a syringe or is mechanically injected with an automatic injector connected to the catheter. An automatic injector is used frequently because it is able to deliver a large volume of contrast medium very quickly to the angiographic site. Usually a small test injection is made to confirm that the catheter is in the correct position. The patient is told that the injection will start, and is instructed to remain very still. The injection causes some mild to moderate discomfort. Possible side effects or reactions include headache, dizziness, irregular heart-beat, nausea, warmth, burning sensation, and chest **pain**, but they usually last only momentarily. To view the area of study from different angles or perspectives, the patient may be asked to change positions several times, and subsequent contrast medium injections may be administered. During any injection, the patient or the imaging equipment may move.

Throughout the injection procedure, radiographs (x-ray pictures) and/or fluoroscopic images will be obtained. Because of the high pressure of arterial blood flow, the contrast medium will dissipate through the patient’s system quickly and become diluted, so images must be obtained in rapid succession. One or more automatic film changers may be used to capture the required radiographic images. In many imaging departments, angiographic images are captured digitally obviating the need for film changers. The ability to capture digital images also makes it possible to manipulate the information electronically allowing for a procedure known as digital subtraction angiography (DSA). Since every image captured is comprised of tiny picture elements called pixels, computers can be used to manipulate the information in ways that enhance diagnostic information. One common approach is to electronically remove or (subtract) bony structures which otherwise would be superimposed over the vessels being studied, hence the name digital subtraction angiography.

Once the x rays are complete, the catheter is slowly and carefully removed from the patient. Manual pressure

is applied to the site with a sandbag or other weight for 10-20 minutes to allow for clotting to take place and the arterial puncture to reseal itself. A pressure bandage is then applied.

Most angiograms follow the general procedures outlined above, but vary slightly depending on the area of the vascular system being studied. A variety of common angiographic procedures are outlined below:

Cerebral angiography

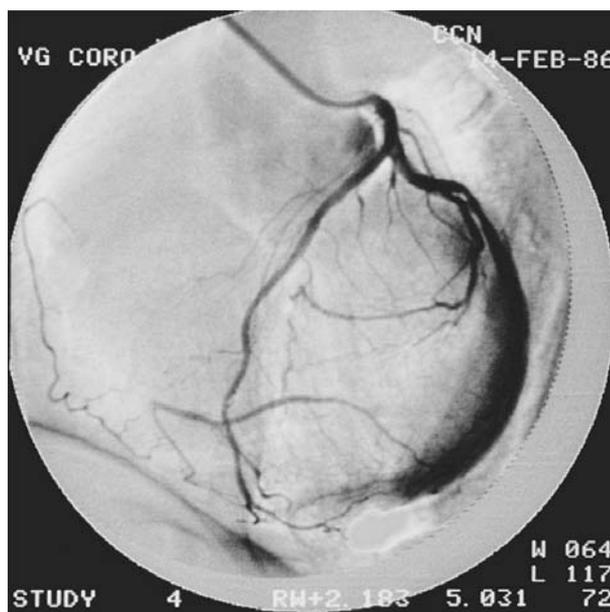

Cerebral angiography is used to detect aneurysms, stenosis, blood clots, and other vascular irregularities in the brain. The catheter is inserted into the femoral or carotid artery and the injected contrast medium travels through the blood vessels in the brain. Patients frequently experience headache, warmth, or a burning sensation in the head or neck during the injection portion of the procedure. A cerebral angiogram takes two to four hours to complete.

Coronary angiography

Coronary angiography is administered by a cardiologist with training in radiology or, occasionally, by a radiologist. The arterial puncture is typically made in the femoral artery, and the cardiologist uses a guide wire and catheter to perform a contrast injection and x-ray series on the coronary arteries. The catheter may also be placed in the left ventricle to examine the mitral and aortic valves of the heart. If the cardiologist requires a view of the right ventricle of the heart or of the tricuspid or pulmonary valves, the catheter will be inserted through a large vein and guided into the right ventricle. The catheter also serves the purpose of monitoring blood pressures in these different locations inside the heart. The angiographic procedure takes several hours, depending on the complexity of the procedure.

Pulmonary angiography

Pulmonary, or lung, angiography is performed to evaluate blood circulation to the **lungs**. It is also considered the most accurate diagnostic test for detecting a pulmonary embolism. The procedure differs from cerebral and coronary angiography in that the guide wire and catheter are inserted into a vein instead of an artery, and are guided up through the chambers of the heart and into the pulmonary artery. Throughout the procedure, the patient's **vital signs** are monitored to ensure that the catheter doesn't cause arrhythmias, or irregular heartbeats. The contrast medium is then injected into the pulmonary artery where it circulates through the lungs' capillaries. The test typically takes up to 90 minutes and carries more risk than other angiography procedures.

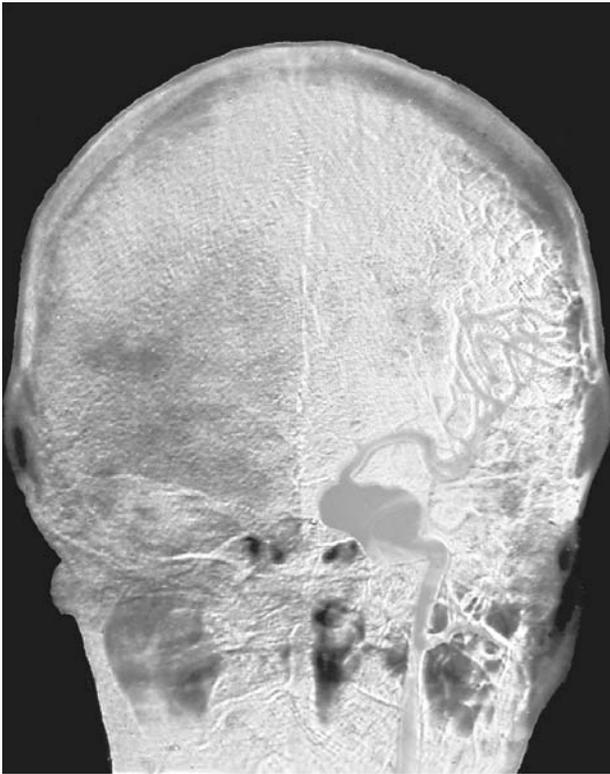

An angiogram of a coronary artery. (Phototake NYC. Reproduced by permission.)

Kidney (renal) angiography

Patients with chronic renal disease or injury can suffer further damage to their **kidneys** from the contrast medium used in a renal angiogram, yet they often require the test to evaluate kidney function. These patients should be well-hydrated with an intravenous saline drip before the procedure, and may benefit from available medications (e.g., dopamine) that help to protect the kidney from further injury associated with contrast agents. During a renal angiogram, the guide wire and catheter are inserted into the femoral artery in the groin area and advanced through the abdominal aorta, the main artery in the abdomen, and into the renal arteries. The procedure takes approximately one hour.

Fluorescein angiography

Fluorescein angiography is used to diagnose retinal problems and circulatory disorders. It is typically conducted as an outpatient procedure. The patient's pupils are dilated with eye drops and he or she rests the chin and forehead against a bracing apparatus to keep it still. Sodium fluorescein dye is then injected with a syringe into a vein in the patient's arm. The dye will travel through the patient's body and into the blood vessels of the eye. The procedure does not require x rays. Instead, a rapid series of close-up photographs of the patient's eyes are taken, one set immediately after the dye is injected, and a second set approximately 20 minutes later once the dye has moved through the patient's vascular system. The entire procedure takes up to one hour.

X ray showing brain aneurism (to the right of the midline).
(CNRI/National Audubon Society Collection/Photo
Researchers, Inc. Reproduced by permission.)

Celiac and mesenteric angiography

Celiac and mesenteric angiography involves radiographic exploration of the celiac and mesenteric arteries, arterial branches of the abdominal aorta that supply blood to the abdomen and **digestive system**. The test is commonly used to detect aneurysm, thrombosis, and signs of ischemia in the celiac and mesenteric arteries, and to locate the source of gastrointestinal bleeding. It is also used in the diagnosis of a number of conditions, including portal **hypertension**, and cirrhosis. The procedure can take up to three hours, depending on the number of blood vessels studied.

Splenoportography

A splenoportograph is a variation of an angiogram that involves the injection of contrast medium directly into the spleen to view the splenic and portal veins. It is used to diagnose blockages in the splenic vein and portal vein thrombosis and to assess the strength and location of the vascular system prior to **liver** transplantation.

Most angiographic procedures are typically paid for by major medical insurance. Patients should check

with their individual insurance plans to determine their coverage.

Computerized tomographic angiography (CTA), a new technique, is used in the evaluation of patients with intracranial aneurysms. CTA is particularly useful in delineating the relationship of vascular lesions with bony anatomy close to the **skull** base. While such lesions can be demonstrated with standard angiography, it often requires studying several projections of the two dimensional films rendered with standard angiography. CTA is ideal for more anatomically complex skull base lesions because it clearly demonstrates the exact relationship of the bony anatomy with the vascular pathology. This is not possible using standard angiographic techniques. Once the information has been captured a workstation is used to process and reconstruct images. The approach yields shaded surface displays of the actual vascular anatomy which are three dimensional and clearly show the relationship of the bony anatomy with the vascular pathology.

Angiography can also be performed using MRI (**magnetic resonance imaging**) scanners. The technique is called MRA (magnetic resonance angiography). A contrast medium is not usually used, but may be used in some body applications. The active ingredient in the contrast medium used for MRA is one of the rare earth elements, gadolinium. The contrast agent is injected into an arm vein, and images are acquired with careful attention being paid to the timing of the injection and selection of MRI specific imaging parameters. Once the information has been captured, a workstation is used to process and reconstruct the images. The post processing capabilities associated with CTA and MRA yield three dimensional representations of the vascular pathology being studied and can also be used to either enhance or subtract adjacent anatomical structures.

Preparation

Patients undergoing an angiogram are advised to stop eating and drinking eight hours prior to the procedure. They must remove all jewelry before the procedure and change into a hospital gown. If the arterial puncture is to be made in the armpit or groin area, shaving may be required. A sedative may be administered to relax the patient for the procedure. An IV line will also be inserted into a vein in the patient's arm before the procedure begins in case medication or blood products are required during the angiogram, or in case complications arise.

Prior to the angiographic procedure, patients will be briefed on the details of the test, the benefits and risks, and the possible complications involved, and asked to sign an **informed consent** form.

KEY TERMS

Arteriosclerosis—A chronic condition characterized by thickening and hardening of the arteries and the build-up of plaque on the arterial walls. Arteriosclerosis can slow or impair blood circulation.

Carotid artery—An artery located in the neck.

Catheter—A long, thin, flexible tube used in angiography to inject contrast material into the arteries.

Cirrhosis—A condition characterized by the destruction of healthy liver tissue. A cirrhotic liver is scarred and cannot break down the proteins in the bloodstream. Cirrhosis is associated with portal hypertension.

Embolism—A blood clot, air bubble, or clot of foreign material that travels and blocks the flow of blood in an artery. When blood supply to a tissue or organ is blocked by an embolism, infarction, or death of the tissue the artery feeds, occurs. Without immediate and appropriate treatment, an embolism can be fatal.

Femoral artery—An artery located in the groin area that is the most frequently accessed site for arterial puncture in angiography.

Fluorescein dye—An orange dye used to illuminate

the blood vessels of the retina in fluorescein angiography.

Fluoroscope—An imaging device which displays “moving x-rays” of the body. Fluoroscopy allows the radiologist to visualize the guide wire and catheter he is moving through the patient’s artery.

Guide wire—A wire that is inserted into an artery to guide a catheter to a certain location in the body.

Ischemia—A lack of normal blood supply to a organ or body part because of blockages or constriction of the blood vessels.

Necrosis—Cellular or tissue death; skin necrosis may be caused by multiple, consecutive doses of radiation from fluoroscopic or x-ray procedures.

Plaque—Fatty material that is deposited on the inside of the arterial wall.

Portal hypertension—A condition caused by cirrhosis of the liver. It is characterized by impaired or reversed blood flow from the portal vein to the liver, an enlarged spleen, and dilated veins in the esophagus and stomach.

Portal vein thrombosis—The development of a blood clot in the vein that brings blood into the liver. Untreated portal vein thrombosis causes portal hypertension.

Aftercare

Because life-threatening internal bleeding is a possible complication of an arterial puncture, an overnight stay in the hospital is sometimes recommended following an angiographic procedure, particularly with cerebral and coronary angiography. If the procedure is performed on an outpatient basis, the patient is typically kept under close observation for a period of at six to 12 hours before being released. If the arterial puncture was performed in the femoral artery, the patient will be instructed to keep his leg straight and relatively immobile during the observation period. The patient’s **blood pressure** and vital signs will be monitored and the puncture site observed closely. Pain medication may be prescribed if the patient is experiencing discomfort from the puncture, and a cold pack is often applied to the site to reduce swelling. It is normal for the puncture site to be sore and bruised for several weeks. The patient may also develop a hematoma, a hard mass created by the blood vessels broken during the procedure. Hematomas should be watched

carefully, as they may indicate continued bleeding of the arterial puncture site.

Angiography patients are also advised to enjoy two to three days of rest after the procedure in order to avoid placing any undue stress on the arterial puncture site. Patients who experience continued bleeding or abnormal swelling of the puncture site, sudden dizziness, or chest pain in the days following an angiographic procedure should seek medical attention immediately.

Patients undergoing a fluorescein angiography should not drive or expose their eyes to direct sunlight for 12 hours following the procedure.

Risks

Because angiography involves puncturing an artery, internal bleeding or hemorrhage are possible complications of the test. As with any invasive procedure, **infection** of the puncture site or bloodstream is also a risk, but this is rare.

A stroke or heart attack may be triggered by an angiogram if blood clots or plaque on the inside of the arterial wall are dislodged by the catheter and form a blockage in the blood vessels or artery. The heart may also become irritated by the movement of the catheter through its chambers during pulmonary and coronary angiographic procedures, and arrhythmias may develop.

Patients who develop an allergic reaction to the contrast medium used in angiography may experience a variety of symptoms, including swelling, difficulty breathing, **heart failure**, or a sudden drop in blood pressure. If the patient is aware of the allergy before the test is administered, certain medications can be administered at that time to counteract the reaction.

Angiography involves minor exposure to radiation through the x rays and fluoroscopic guidance used in the procedure. Unless the patient is pregnant, or multiple radiological or fluoroscopic studies are required, the small dose of radiation incurred during a single procedure poses little risk. However, multiple studies requiring fluoroscopic exposure that are conducted in a short time period have been known to cause skin necrosis in some individuals. This risk can be minimized by careful monitoring and documentation of cumulative radiation doses administered to these patients, particularly in those who have therapeutic procedures performed along with the diagnostic angiography.

Results

The results of an angiogram or arteriogram depend on the artery or organ system being examined. Generally, test results should display a normal and unimpeded flow of blood through the vascular system. Fluorescein angiography should result in no leakage of fluorescein dye through the retinal blood vessels.

Abnormal results of an angiogram may display a restricted blood vessel or arterial blood flow (ischemia) or an irregular placement or location of blood vessels. The results of an angiogram vary widely by the type of procedure performed, and should be interpreted by and explained to the patient, by a trained radiologist.

Health care team roles

Angiography is usually performed in a hospital-based imaging department by a trained radiologist and assisting technologist or nurse. Coronary angiography is performed by a cardiologist. It takes place in an angiographic suite, and for most types of angiograms, the patient's vital signs are monitored throughout the procedure.

Angioplasty

Definition

Angioplasty is a term describing a procedure used to widen vessels narrowed by stenoses or occlusions. There are various types of these procedures and their names are associated with the type of vessel entry and equipment used. For example, percutaneous transluminal angioplasty (PTA) describes entry through the skin (percutaneous) and navigates to the area of the vessel of interest through the same vessel or one that communicates with it (transluminal). In the case of a procedure involving the coronary arteries, the point of entry could be the femoral artery in the groin and the catheter/guidewire system is passed through the aorta to the **heart** and the origin of the coronary arteries at the base of the aorta just outside the aortic valve.

Purpose

In individuals with an occlusive vascular disease such as atherosclerosis, **blood** flow is impaired to an organ (such as the heart) or to a distal (away from the central portion of the body) body part (such as the lower leg) by the narrowing of the vessel's lumen due to fatty deposits or **calcium** accumulation. This narrowing may occur in any vessel but may occur anywhere. Once the vessel has been widened, adequate blood flow is restored.

Procedure for coronary balloon angioplasty. (Delmar Publishers, Inc. Reproduced by permission.)

The vessel may narrow again over time at the same location and the procedure may then be repeated.

Precautions

Angioplasty procedures are performed on hospital inpatients in facilities for proper monitoring and recovery. If the procedure is to be performed in a coronary artery, the patient's care is likely to be provided by specially trained physicians, nurses, and vascular specialists. Typically, patients are given anticoagulants prior to the procedure to assist in the prevention of thromboses (blood clots). Administration of anticoagulants, however, may impede the sealing of the vascular entry point. The procedure is performed using fluoroscopic guidance and contrast media. Since the decision to perform angioplasty may have been made following a diagnostic angiogram, the patient's sensitivity to iodinated contrast media is likely to be known. The procedure may then require the use of non-ionic contrast agents.

Description

Angioplasty was originally performed by dilating the vessel with the introduction of larger and larger stiff catheters through the narrowed space. Complications of this procedure caused researchers to develop means of widening the vessel using a minimally sized device. Today, catheters contain balloons that are inflated to widen the vessel and stents (devices comprised of a mesh of wire that resembles a "Chinese finger puzzle") to provide structural support for the vessel. Lasers may be used to assist in the break up of the fat or calcium plaque. Catheters may also be equipped with spinning wires or drill tips to clean out the plaque.

Angioplasty may be performed while the patient is sedated or anesthetized, depending on the vessels involved. If a percutaneous transluminal coronary angioplasty (PTCA) is to be performed, the patient is kept awake to report on discomfort and to cough if required.

KEY TERMS

Cardiac catheterization—A procedure to pass a catheter to the heart and its vessels for the purpose of diagnosing coronary artery disease, assessing injury or disease of the aorta, or evaluating cardiac function.

Contrast medium—A substance injected into the body to facilitate the radiographic imaging of internal structures.

EKG—Electrocardiogram, used to study and record the electrical activity of the heart.

Embolus—A gas or air bubble, bit of tissue, blood clot, or foreign object that circulates in the bloodstream until it lodges in a vessel.

Fluoroscopy—A radiologic technique that creates x-ray images of internal body structures for immediate projection on a fluorescent screen.

Hematoma—A collection of blood trapped in the tissues of the skin or in an organ.

Occlusion—A blockage in a vessel.

Plaque—In atherosclerosis, a swollen area in the lining of an artery formed by fatty deposits.

Stenosis—Narrowing or constriction of an opening or passageway.

PTCA procedures are performed in **cardiac catheterization** labs with sophisticated monitoring devices. If angioplasty is performed in the radiology department's angiographic suite, the patient may be sedated for the procedure and a nurse monitors the patient's **vital signs** during the procedure. If performed by a vascular surgeon, the angioplasty procedure is performed in an operating room or specially designed vascular procedure suite.

The site of the introduction of the angioplasty equipment is prepared as a sterile surgical site. Although many procedures are performed by puncturing the vessel through skin, many procedures are also performed by surgically exposing the site of entry. Direct view of the vessel's puncture site aids in monitoring damage to the vessel or excessive bleeding at the site. Once the vessel is punctured and the guidewire is introduced, fluoroscopy is used to monitor small injections of contrast media used to visualize the path through the vessel. If the fluoroscopy system has a feature called "roadmap," the amount of contrast media injected is greater in order to define the full route the guidewire will take. The fluoroscopy system then superimposes subsequent images over the roadmap

while the vessel is traversed, that is, the physician moves the guidewire along the map to the destination.

Having reached the area of stenosis, the physician inflates the balloon on the catheter that has been passed along the guidewire. Balloons are inflated in size and duration depending on the size and location of the vessel. In some cases, a stent may also be used. The vessel may be widened before, during, or after the deployment of the stent. Procedures for deploying stents are dependent on the type of stent used. In cases where the vessel is tortuous (twisted) or at intersections of vessels, the use of a graph may be necessary to provide structural strength to the vessel. Stents, graphs, and balloon dilation may all be used together or separately. Sometimes radiation is used with stents.

The procedure is verified using fluoroscopy and contrast media to produce an angiogram or by using intravascular ultrasound or both. All equipment is withdrawn from the vessel and the puncture site is repaired.

Complications

During the procedure there is a danger of puncturing the vessel with the guidewire. This is a very small risk. Patients must be monitored for hematoma or hemorrhage at the puncture site. There is also a small risk of heart attack, emboli, and, although unlikely, death. Hospitalization varies in length with the patient's overall condition, any complications, and the availability of **home care**.

Health care team roles

Physicians often have specially trained assistants for vascular procedures. These assistants may be nurses, surgical techs, or radiographers. In cardiac catheterization labs, the team also includes a member specially trained in monitoring EKG equipment and vital signs. Angioplasty is a fluoroscopy-guided procedure so a radiographer trained in vascular imaging is also required. Either a nurse, **nurse anesthetist**, or anesthesiologist will administer sedation or anesthesia for the procedure.

Antacids

Definition

Antacids are medicines that neutralize **stomach** acid.

Purpose

Antacids are used to relieve acid indigestion, upset stomach, sour stomach, and heartburn. Additional components of some formulations include dimethicone, to reduce gas pains (flatulence) and alginic acid, which, in combination with antacids, may help manage GERD (gastroesophageal reflux disease). Antacids should not be confused with gastric acid inhibitors, such as the H-2 receptor blockers (cimetidine, ranitide, and others) or the proton pump inhibitors (lansoprazole, omeprazole, and others). Although all three classes of drugs act to reduce the levels of gastric acid, their mechanisms are different,

and this affects the appropriate use of the drug. Antacids have a rapid onset and short duration of action, and are most appropriate for rapid relief of gastric discomfort for a short period of time.

Antacids may be divided into two classes: those that work by chemical neutralization of gastric acid, most notably sodium bicarbonate; and those that act by adsorption of the acid (non-absorbable antacids), such as **calcium** and magnesium salts.

The chemical antacids show the most rapid onset of action, but may cause “acid rebound,” a condition in which the gastric acid returns in greater concentration after the drug effect has stopped. Also, since these antacids may contain high concentrations of sodium, they may be inappropriate in patients with **hypertension**.

Calcium and magnesium salts act by adsorption of the acid, and are less prone to the rebound effect, but may have other significant disadvantages. These antacids are particularly prone to **drug interactions**, and patients taking other medications must often avoid simultaneous administration of the medications. These antacids are more effective in liquid formulations than in tablet or capsule form, and so may be inconvenient for routine dosing.

The non-absorbable antacids may have additional uses beyond control of hyperacidity. Calcium salts may be used as diet supplements in prevention of **osteoporosis**. Aluminum carbonate is useful for binding phosphate, and has been effective in treatment and control of hyperphosphatemia or for use with a low phosphate diet to prevent formation of phosphate urinary stones. This application is particularly valuable in patients with chronic renal failure. Antacids with aluminum and magnesium hydroxides or aluminum hydroxide alone effectively prevent significant **stress** ulcer bleeding in post-operative patients or those with severe **burns**.

Recommended dosage

The dose depends on the type of antacid. Consult specific references.

When using antacids in chewable tablet form, chew the tablet well before swallowing. Drink a glass of water after taking chewable aluminum hydroxide. Lozenges should be allowed to dissolve completely in the mouth. Liquid antacids should be shaken well before using.

Precautions

Antacids should be avoided if any signs of **appendicitis** or inflamed bowel are present. These include

KEY TERMS

Acid indigestion—Indigestion that results from too much acid in the stomach.

Chronic—A word used to describe a long-lasting condition. Chronic conditions often develop gradually and involve slow changes.

Heartburn—A burning sensation, usually in the center of the chest, near the breastbone.

Indigestion—A feeling of discomfort or illness that results from the inability to properly digest food.

Inflamed bowel—Irritation of the intestinal tract.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Pregnancy safety categories—A system for reporting the known safety issues of drugs for use during pregnancy. The ratings range from A, proven safe by well controlled studies, to X, proven harmful.

cramping, **pain**, and soreness in the lower abdomen, bloating, and nausea and vomiting.

Antacids may affect the results of some medical tests, such as those that measure how much acid the stomach produces. Health care providers and patients should keep this in mind when scheduling a medical test.

Antacids that contain magnesium may cause **diarrhea**. Other types of antacids may cause constipation.

Antacids containing sodium bicarbonate should not be taken when the stomach is uncomfortably full from eating or drinking.

Antacids should not be given to children under six years of age.

Antacids that contain calcium or sodium bicarbonate may cause side effects, such as dizziness, nausea, and vomiting, in people who consume large amounts of calcium (from dairy products or calcium supplements). In some cases, this can lead to permanent kidney damage. Before combining antacids with extra calcium, check with a physician.

Some antacids contain large amounts of sodium, particularly sodium bicarbonate (baking soda). Anyone who is on a low-sodium diet should check the list of ingredients or check with a physician or pharmacist before taking an antacid product.

Excessive use of antacids may cause or increase the severity of kidney problems. Calcium based antacids may lead to renal stone formation.

ALLERGIES. **Allergies** to antacids are extremely rare, however the inactive ingredients in some formulations may include dyes or other products with allergic potential.

PREGNANCY. Antacids are not classified under the **pregnancy** safety categories A, B, C, D, and X. Occasional use of antacids in small amounts during pregnancy is considered safe. However, pregnant women should check with their physicians before using antacids or any other medicines. Pregnant women who are consuming extra calcium should be aware that using antacids that contain sodium bicarbonate or calcium can lead to serious side effects.

BREASTFEEDING. Some antacids may pass into breast milk. However, no evidence exists that the ingestion of antacids through breast milk causes problems for nursing babies whose mothers use antacids occasionally.

DRUG INTERACTIONS. Antacids have multiple drug interactions, usually due to inhibition of absorption of other medications. In rare cases, the absorbable antacids may alter the pH of the stomach contents or urine sufficiently to alter drug absorption or excretion. Consult specific references.

Side effects

Side effects are very rare when antacids are taken as directed. They are more likely when the medicine is taken in large doses or over a long time. Minor side effects include a chalky taste, mild constipation or diarrhea, thirst, stomach cramps, and whitish or speckled stools. These symptoms do not need medical attention unless they do not go away or they interfere with normal activities.

Other uncommon side effects may occur. Anyone who has unusual symptoms after taking antacids should get in touch with his or her health care provider.

Samuel Uretsky, PharmD

Antepartum testing

Definition

Antepartum testing involves the use of **electronic fetal monitoring** (EFM) or ultrasound (US) to assess fetal well-being as determined by the fetal **heart** rate

(FHR) and other characteristics during the antepartum period (the period spanning conception and labor).

Purpose

Antepartum testing can start as early as 24 weeks but usually after 32 weeks of **pregnancy** depending on the status of the mother. It provides a means for the physician and pregnant woman to identify fetal well-being and be alert to any changes that may necessitate additional testing or interventions. The results of testing reflect the functioning of the placenta and its ability to adequately supply **blood** and, therefore, oxygen to the fetus. The testing is done for pregnancies at risk for maternal and/or fetal complications.

Some of these risks include:

- gestational (insulin requiring) diabetes
- intrauterine growth restriction
- chronic **hypertension** or pregnancy induced hypertension
- too little or too much amniotic fluid (oligohydramnios and polyhydramnios, respectively)
- history of unexplained stillbirth
- autoimmune diseases, including systemic lupus erythematosus
- multiple gestation
- placental abnormalities, i.e. partial abruption (a portion of the placenta pulls away from the wall of the uterus) or **placenta previa** (the placenta is covering the cervix and subsequent bleeding occurs)

Antepartum testing is used in low-risk pregnancies to evaluate decreased fetal activity, a lag in fundal height (the height of the fundus, measured from pubic symphysis to the highest point in the midline at the top of the uterus), and a postdate pregnancy. A normal pregnancy is 40 weeks and testing should begin at 41 weeks to assess the status of the placenta, which may be no longer capable of meeting the baby's needs. This can be indicated by the FHR pattern, amniotic fluid status, and fetal movement patterns.

Precautions

Clinicians should only prescribe these tests if they are ready to intervene when faced with ominous data. A fetus is considered viable at 24 weeks, as that is the minimum gestational age for sufficient lung development. There are no significant risks to the mother or the fetus from the nonstress test (NST) or the biophysical profile (BPP). Ultrasound waves utilized for the BPP are painless and safe because this method employs no harmful

radiation. There is no evidence that sound waves cause any harm to the mother or the baby.

Description

The spectrum of fetal assessment includes fetal movement (FM) counting, nonstress test (NST), contraction **stress test** (CST), oxytocin contraction **stress test** (OCT), biophysical profile (BPP), Doppler flow studies, **amniocentesis**, and cordocentesis. Fetal movement can be determined on a daily basis by the pregnant woman who should be instructed to monitor fetal movement between tests by selecting a consistent time of day and documenting how long it takes to feel 10 fetal movements. She should call her health care provider if there are fewer than 10 movements in 10 hours, or if there are no movements in any 10-hour period. She should also be instructed to report significant decreases in fetal activity from the baby's normal pattern. This daily monitoring of FM by the mother is the least expensive and easiest of all antepartum tests to perform.

The nonstress test (NST) is performed with an electronic fetal monitoring (EFM) that traces the fetal heart rate (FHR) and the presence of any contractions on a monitor. The mother reclines with a slight tilt and the EFM is applied to her abdomen by two straps. The NST indirectly provides information about fetal status by the observation of FHR accelerations with fetal movement. If a fetus is not receiving adequate oxygen from the placenta, the FHR will not accelerate, but if the oxygen supply is sufficient, accelerations will be observed. If it is difficult to obtain fetal movements, a vibroacoustic stimulator (VAS) may be used to provide a loud noise that will awaken the fetus and produce the desired results. The minimum amount of time required for an NST is 20 minutes, but, depending upon the conditions, it may take 60–90 minutes to obtain definitive results.

The contraction stress test (CST) is like the NST except the FHR is evaluated in response to contractions as well as for accelerations. A CST requires the presence of three uterine contractions (UCs) within a 10-minute period lasting at least 40 seconds and of moderate intensity. During a contraction, the blood flow to the baby is temporarily restricted, which provides a form of “stress” to the baby. The baby's response to this stressor reveals significant information regarding the oxygen stores available. If contractions are not present, oxytocin can be given to produce contractions or nipple stimulation may be utilized to produce contractions through the release of natural oxytocin.

The biophysical profile (BPP) is done by an ultrasound exam over a 30-minute period and the examiner looks for fetal movement, fetal tone, breathing move-

KEY TERMS

Acceleration—An increase in the fetal heart rate that can indicate normal placental blood flow to the fetus.

Amniocentesis—A procedure by which amniotic fluid is obtained for biochemical determinations, i.e. fetal lung maturity, genetic studies.

Amniotic fluid—The liquid that surrounds the baby within the amniotic sac. It is composed mostly of fetal urine, thus, a decreased amount can indicate inadequate placental blood flow to the fetus.

Cordocentesis—A method of obtaining a fetal blood sample from the umbilical cord, also called percutaneous umbilical blood sampling (PUBS).

Deceleration—A decrease in the fetal heart rate that can indicate inadequate placental blood flow to the fetus.

Doppler flow studies—A procedure for measuring blood flow that is helpful in determining abnormalities.

Oxytocin—A natural hormone that produces uterine contractions.

Ultrasound—A procedure in which high-frequency sound waves are used to create an image of a baby. It can be used alone or with other antepartum testing.

Vibroacoustic stimulation—An artificial larynx that produces a loud noise to stimulate the fetus to wake up. It should not be used more than three times in a testing period.

ments (which the mother can perceive as hiccups), and amniotic fluid volume. A score of 0 or 2 points is assigned to each observation with the NST also adding 2 points for a total possible score of 10 points. The modified BPP includes an NST and the determination of the amniotic fluid index by ultrasound, which relates to the amount of fluid present. A physician performs the Doppler flow studies, amniocentesis, and cordocentesis. The majority of health insurance companies do cover a portion, if not all, of the tests' costs.

Preparation

The health care provider gives a complete explanation to the pregnant woman about the test, what to expect, how long the test may take, what it means, and why it is

being done. It frequently helps if the pregnant woman has eaten prior to undergoing the test.

Aftercare

If the test results are acceptable, the pregnant woman is instructed to continue following her current medical regimen and return for additional testing on the dates prescribed. For NSTs/CSTs, the time period between tests should be no longer three to four days under high-risk conditions. Ultrasounds should be rescheduled as the need dictates per the physician.

Complications

There are no complications per se from the tests themselves with the exception of unfavorable test results or supine (lying horizontally on the back) hypotension secondary to a pregnant woman lying on her back for an ultrasound with resultant vena cava (one of two large veins that return blood from peripheral circulation to the heart) compression.

Results

Usually, a report of normal results for NSTs provides reassurance that the fetus is healthy and should remain so for three to four days, at which time repeat testing will be necessary. A normal NST means the FHR accelerated at least 15 beats above the baseline FHR for 15 seconds within a 20-minute period of time. A non-reactive NST is one that fails to meet this criterion within an 80–90 minute period of time. For an extremely preterm fetus, a normal NST refers to reactive for gestational age or the FHR accelerated 10 beats above the baseline for 10 seconds over a 20–30 minute period. Typically, the **central nervous system** is not completely mature until approximately 32 weeks gestational age and this report takes that into consideration. It is important to remember that a normal result does not guarantee that no problems are present. Although very rare in occurrence, false normal results can be observed.

The CST results are reported as a reactive/negative, suspicious, or positive or non-reactive/negative, suspicious, or positive. The reactive/nonreactive part of the test report refers to the presence or absence of accelerations and the negative part refers to no decelerations being present with UCs. Suspicious and positive refer to the presence of decelerations with UCs. This result requires further evaluation, i.e. prolonged EFM monitoring or a BPP. A normal BPP report is 8-10 points. Six points is suspicious and requires either a CST or a repeat BPP within 24 hours. A total of 4 points is not reassuring and requires immediate evaluation by prolonged EFM.

All results are given to the primary physician who must then make a decision as to the appropriate course of action. Abnormal CST results usually indicate the baby is not receiving sufficient oxygen and may not be able to withstand the stress of labor and vaginal delivery. If this is the case, a cesarean section may be performed. The final outcome depends on the mother's individual circumstances, i.e. severe pregnancy induced hypertension may require immediate delivery via cesarean section, and an extra large fetus of a diabetic mother may require the same. In some cases, medications may be given to the mother for her condition, and to speed up the lung maturity of the baby. If the mother's cervix is favorable for induction, labor may be induced.

Health care team roles

The physician is the head of a health team of interdisciplinary members and determines the medical regimen necessary for the pregnant woman, depending on whether the pregnancy is normal or high-risk. Nurses schedule the tests and provide the woman with the necessary information regarding the tests. Nurses must perform any tests that they conduct correctly, interpret them appropriately, and provide the necessary follow-up or interventions. They may utilize this time period with the woman for teaching, answering questions, and offering emotional support. The ultrasonographer performs the BPP and reports the results directly to the physician.

Antianxiety drugs

Definition

Antianxiety drugs are medicines that calm and relax people with excessive **anxiety**, nervousness, or tension, or for short term control of social phobia disorder or specific phobia disorder.

Purpose

Antianxiety agents, or anxiolytics, may be used to treat mild transient bouts of anxiety as well as more pronounced episodes of social phobia and specific phobia. Clinically significant anxiety is marked by several symptoms. The patient experiences marked or persistent fear of one or more social or performance situations in which he or she is exposed to unfamiliar people or possible scrutiny by others, and may react in a humiliating or embarrassing way. The exposure to the feared situation produces an anxiety attack. Fear of these episodes of anxiety leads to avoidance behavior, which impairs normal social functioning, including working or attending classes. The patient is aware that these fears are unjustified.

Description

In psychiatric practice, treatment of anxiety has largely turned from traditional antianxiety agents, anxiolytics, to antidepressant therapies. In current use, the benzodiazepines, the best known class of anxiolytics, have been largely supplanted by serotonin-specific reuptake inhibitors (SSRIs, citalopram, fluoxetine, fluvoxamine, and others) which have a milder side effect profile and less risk of dependency. However, traditional anxiolytics remain useful for patients who need a rapid onset of action, or whose frequency of exposure to anxiety provoking stimuli is low enough to eliminate the need for continued treatment. While SSRIs may require three to five weeks to show any effects, and must be taken continuously, benzodiazepines may produce a response within 30 minutes, and may be dosed on an as-needed basis.

The intermediate action benzodiazepines, alprazolam (Xanax), and lorazepam (Ativan) are the appropriate choice for treatment of mild anxiety and social phobia. Diazepam (Valium) is still widely used for anxiety, but its active metabolite, desmethyldiazepam, which has a long half-life, may make this a poorer choice than other drugs in its class. Note that there is considerable variation between individuals in **metabolism** of benzodiazepines, so patient response may not be predictable. As a class, benzodiazepines are used not only as anxiolytics, but also as sedatives, **muscle relaxants**, and in treatment of

ANTIANSXIETY DRUGS	
<i>Brand Name (Generic Name)</i>	<i>Possible Common Side Effects Include:</i>
Atarax (hydroxyzine hydrochloride)	Drowsiness, dry mouth
Ativan (lorazepam)	Dizziness, excessive calm, weakness
BuSpar, Buspirone (buspirone hydrochloride)	Dry mouth, dizziness, headache, fatigue, nausea
Centrax (prazepam)	Decreased coordination, dizziness, drowsiness, fatigue, weakness
Librium, Libritabs (chlordiazepoxide)	Constipation, drowsiness, nausea, swelling
Miltown, Equanil (meprobamate)	Diarrhea, bruising, fever, headache, nausea, rash, slurred speech
Serax (oxazepam)	Dizziness, fainting, headache, liver problems, decreased coordination, nausea, swelling, vertigo
Stelazine (trifluoperazine hydrochloride)	Abnormal glucose in urine, allergic reactions, blurred vision, constipation, eye spasms, fluid retention and swelling
Tranxene, Tranxene-SD (clorazepate dipotassium)	Drowsiness
Valium (diazepam)	Decreased coordination, drowsiness, light-headedness

(Illustration by Standley Publishing. Courtesy of Gale Group.)

epilepsy and **alcoholism**. The distinctions between these uses are largely determined by onset and duration of action, and route of administration.

Buspirone (BuSpar), which is not chemically related to other classes of **central nervous system** drugs, is also a traditional anxiolytic, although it is now considered either a third line or adjunctive agent for use after trials of SSRIs and benzodiazepines. It is appropriate for use in patients who have either failed trials of other treatments, or who should not receive benzodiazepines because of a history of substance abuse problems. Buspirone, in common with antidepressants, requires a two to three week period before there is clinical evidence of improvement, and must be continuously dosed to maintain its effects.

Benzodiazepines are controlled drugs under federal law. Buspirone is not a controlled substance and has no established abuse potential.

Recommended dosage

Benzodiazepines should be administered 30 to 60 minutes before exposure to the anticipated **stress**. Dosage should be individualized to minimize sedation. The normal dose of alprazolam is 0.25–0.5 mg. The usual dose of lorazepam is 2–3 mg. Doses may be repeated if necessary.

Buspirone is initially dosed at 5 mg t.i.d. (3 times a day.) Increase the dosage 5 mg/day, at intervals of two to three days, as needed. Do not exceed 60 mg/day. Two to three weeks may be required before a satisfactory response is seen.

Precautions

Benzodiazepines should not be used in patients with psychosis, acute narrow angle **glaucoma**, or **liver** disease. The drugs can act as respiratory depressants and should be avoided in patients with respiratory conditions. Benzodiazepines are potentially addictive and should not be administered to patients with substance abuse disorders. Because benzodiazepines are sedative, they should be avoided in patients who must remain alert. Their use for periods over four months has not been documented. These drugs should not be used during the second and third trimester of **pregnancy**, although use during the first trimester appears to be safe. They should not be taken while breastfeeding. Consult specialized references for use in children.

Buspirone is metabolized by the liver and excreted by the kidney, and should be used with care in patients with hepatic or renal disease. The drug is classified as schedule B during pregnancy, but should not be taken

KEY TERMS

Anxiety—Worry or tension in response to real or imagined stress, danger, or dreaded situations. Physical reactions, such as fast pulse, sweating, trembling, fatigue, and weakness may accompany anxiety.

Epilepsy—A brain disorder with symptoms that include seizures.

Panic disorder—An disorder in which people have sudden and intense attacks of anxiety in certain situations. Symptoms such as shortness of breath, sweating, dizziness, chest pain, and extreme fear often accompany the attacks.

Phobia—An intense, abnormal, or illogical fear of something specific, such as heights or open spaces.

Pregnancy category B—Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies.

Pregnancy category C—No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data.

Seizure—A sudden attack, spasm, or convulsion.

during breastfeeding. Its use in children under the age of 18 years has not been studied.

Drug interactions

The metabolism of alprazolam may be increased by: cimetidine, oral contraceptives, disulfiram, fluoxetine, isoniazid, ketoconazole, metoprolol, propoxyphene, propranolol and valproic acid. The absorption of all benzodiazepines is inhibited by concomitant use of **antacids**. Benzodiazepines may increase **blood** levels of digoxin, and reduce the efficacy of levodopa. Other **drug interactions** have been reported.

Buspirone levels will be increased by concomitant use of erythromycin, itraconazole, and nefazadone. Doses should be adjusted based on clinical response. Use of buspirone at the same time as mono-amine oxidase inhibitors (MAOIs, phenelzine, tranylcypromine) may cause severe **blood pressure** elevations. Use of buspirone with MAOIs should be avoided.

Valium is an antianxiety drug. (Photograph by Van Bucher. Photo Researchers, Inc. Reproduced by permission.)

Side effects

The most common side effects of benzodiazepines are secondary to their CNS effects and include sedation and sleepiness; depression; lethargy; apathy; fatigue; hypoactivity; lightheadedness; **memory** impairment; disorientation; anterograde amnesia; restlessness; confusion; crying or sobbing; delirium; headache; slurred speech; aphonia; **dysarthria**; stupor; seizures; **coma**; **syncope**; rigidity; tremor; dystonia; vertigo; dizziness; euphoria; nervousness; irritability; difficulty in concentration; agitation; inability to perform complex mental functions; akathisia; hemiparesis; hypotonia; unsteadiness; ataxia; incoordination; weakness; vivid dreams; psychomotor retardation; “glassy-eyed” appearance; extrapyramidal symptoms; paradoxical reactions. Other reactions include changes in **heart** rate and blood pressure, changes in bowel function, severe skin rash and changes in genitourinary function. Other adverse effects have been reported.

Buspirone has a low incidence of side effects. Dizziness and drowsiness are the most commonly reported adverse effects. Other CNS effects include dream disturbances; depersonalization, dysphoria, noise intolerance, euphoria, akathisia, fearfulness, loss of interest, disassociative reaction, hallucinations, suicidal ideation, seizures; feelings of claustrophobia, cold intolerance, stupor and slurred speech, psychosis. Rarely, heart problems, including congestive **heart failure** and **myocardial infarction**, have been reported. Other adverse effects have been reported.

Antibiotics

Definition

Antibiotics may be informally defined as the subgroup of anti-infectives that are derived from bacterial sources and are used to treat bacterial infections. Other classes of drugs, most notably the sulfonamides, may be effective antibacterials. Similarly, some antibiotics may have secondary uses, such as the use of demeclocycline (Declomycin, a tetracycline derivative) to treat the syndrome of inappropriate antidiuretic hormone (SIADH) secretion. Other antibiotics may be useful in treating protozoal infections.

Purpose

Antibiotics are used for treatment or prevention of bacterial **infection**.

Description

Although there are several classification schemes for antibiotics, based on bacterial spectrum (broad versus narrow) or route of administration (injectable versus oral versus topical), or type of activity (bactericidal vs. bacteriostatic), the most useful is based on chemical structure. Antibiotics within a structural class will generally show similar patterns of effectiveness, toxicity, and allergic potential.

Penicillins

The penicillins are the oldest class of antibiotics, and have a common chemical structure which they share with the cephalosporins. The two groups are classed as the beta-lactam antibiotics, and are generally bacteriocidal—that is, they kill **bacteria** rather than inhibiting growth. The penicillins can be further subdivided. The natural penicillins are based on the original penicillin G structure; penicillinase-resistant penicillins, notably methicillin and oxacillin, are active even in the presence of the bacterial enzyme that inactivates most natural penicillins. Aminopenicillins such as ampicillin and amoxicillin have an extended spectrum of action compared with the natural penicillins; extended spectrum penicillins are effective against a wider range of bacteria. These generally include coverage for *Pseudomonas aeruginosa* and may provide the penicillin in combination with a penicillinase inhibitor.

Cephalosporins

Cephalosporins and the closely related cephamycins and carbapenems, like the penicillins, contain a beta-lactam chemical structure. Consequently, there are patterns

of cross-resistance and cross-allergenicity among the drugs in these classes. The “cepha” drugs are among the most diverse classes of antibiotics, and are themselves subgrouped into 1st, 2nd and 3rd generations. Each generation has a broader spectrum of activity than the one before. In addition, ceftiofex, a cephamycin, is highly active against anaerobic bacteria, which offers utility in treatment of abdominal infections. The 3rd generation drugs, cefotaxime, ceftizoxime, ceftriaxone and others, cross the blood-brain barrier and may be used to treat **meningitis** and encephalitis. Cephalosporins are the usually preferred agents for surgical prophylaxis.

Fluoroquinolones

The fluoroquinolones are synthetic antibacterial agents, and not derived from bacteria. They are included here because they can be readily interchanged with traditional antibiotics. An earlier, related class of antibacterial agents, the quinolones, were not well absorbed, and could be used only to treat urinary tract infections. The fluoroquinolones, which are based on the older group, are broad-spectrum bacteriocidal drugs that are chemically unrelated to the penicillins or the cephalosporins. They are well distributed into bone tissue, and so well absorbed that in general they are as effective by the oral route as by intravenous infusion.

Tetracyclines

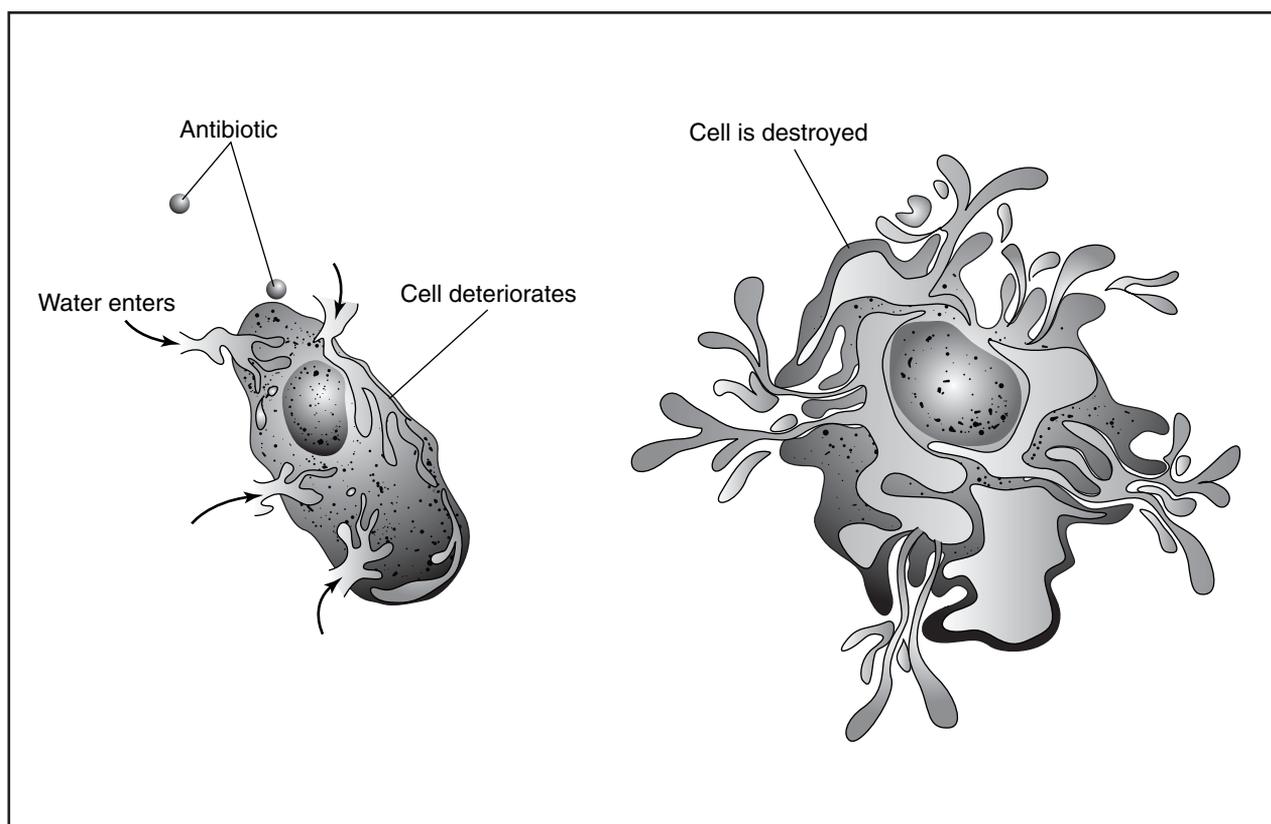

Tetracyclines got their name because they share a chemical structure which has four rings. They are derived from a species of *Streptomyces* bacteria. Broad-spectrum bacteriostatic agents, the tetracyclines may be effective against a wide variety of microorganisms, including rickettsia and amebic parasites.

Macrolides

The macrolide antibiotics are derived from *Streptomyces* bacteria, and got their name because they all have a macrocyclic lactone chemical structure. Erythromycin, the prototype of this class, has a spectrum and use similar to penicillin. Newer members of the group, azithromycin and clarithromycin, are particularly useful for their high level of lung penetration. Clarithromycin has been widely used to treat *Helicobacter pylori* infections, the cause of **stomach** ulcers.

Others

Other classes of antibiotics include the aminoglycosides, which are particularly useful for their effectiveness in treating *Pseudomonas aeruginosa* infections; the lincosamides, clindamycin and lincomycin, which are highly active against anaerobic pathogens. There are

Different antibiotics destroy bacteria in different ways. Some short-circuit the processes by which bacteria receive energy. Others disturb the structure of the bacterial cell wall, as shown in the illustration above. Still others interfere with the production of essential proteins. (Illustration by Electronic Illustrators Group.)

other, individual drugs which may have utility in specific infections.

Recommended dosage

Dosage varies with drug, route of administration, pathogen, site of infection, and severity. Additional considerations include renal function, age of patient, and other factors. Consult manufacturers' recommendations for dose and route.

Side effects

All antibiotics cause risk of overgrowth by non-susceptible bacteria. Manufacturers list other major hazards by class; however, the health care provider should review each drug individually to assess the degree of risk. Generally, breastfeeding is not recommended while taking antibiotics because of risk of alteration to infant's intestinal flora, and risk of masking infection in the infant. Excessive or inappropriate use may promote growth of resistant pathogens.

Penicillins: Hypersensitivity may be common, and cross allergenicity with cephalosporins has been reported. Penicillins are classed as category B during **pregnancy**.

Cephalosporins: Several cephalosporins and related compounds have been associated with seizures. Cefmetazole, cefoperazone, cefotetan and ceftriaxone may be associated with a fall in prothrombin activity and coagulation abnormalities. Pseudomembranous colitis has been reported with cephalosporins and other broad spectrum antibiotics. Some drugs in this class may cause renal toxicity. Pregnancy category B.

Fluroquinolones: Lomefloxacin has been associated with increased photosensitivity. All drugs in this class have been associated with convulsions. Pregnancy category C.

Tetracyclines: Demeclocycline may cause increased photosensitivity. Minocycline may cause dizziness. Do not use tetracyclines in children under the age of eight, and specifically avoid during periods of tooth development. Oral tetracyclines bind to anions such as **calcium** and **iron**. Although doxycycline and minocycline may be taken with meals, patients must be advised to take other

KEY TERMS

Bacteria—Tiny, one-celled forms of life that cause many diseases and infections.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Meningitis—Inflammation of tissues that surround the brain and spinal cord.

Microorganism—An organism that is too small to be seen with the naked eye.

Organism—A single, independent unit of life, such as a bacterium, a plant or an animal.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

tetracycline antibiotics on an empty stomach, and not to take the drugs with milk or other calcium-rich foods. Expired tetracycline should never be administered. Pregnancy category D. Use during pregnancy may cause alterations in bone development.

Macrolides: Erythromycin may aggravate the weakness of patients with myasthenia gravis. Azithromycin has, rarely, been associated with allergic reactions, including angioedema, **anaphylaxis**, and dermatologic reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Oral erythromycin may be highly irritating to the stomach and when given by injection may cause severe phlebitis. These drugs should be used with caution in patients with **liver** dysfunction. Pregnancy category B: Azithromycin, erythromycin. Pregnancy category C: Clarithromycin, dirithromycin, troleandomycin.

Aminoglycosides: This class of drugs causes kidney and ototoxicity. These problems can occur even with normal doses. Dosing should be based on renal function, with periodic testing of both kidney function and **hearing**. Pregnancy category D.

Interactions

Consult specialized references.

Recommended usage

To minimize risk of adverse reactions and development of resistant strains of bacteria, antibiotics should be restricted to use in cases where there is either known or a reasonable presumption of bacterial infection. The use of antibiotics in viral infections is to be avoided. Avoid use of fluoroquinolones for trivial infections.

In severe infections, presumptive therapy with a broad-spectrum antibiotic such as a third generation cephalosporin may be appropriate. Treatment should be changed to a narrow spectrum agent as soon as the pathogen has been identified. After 48 hours of treatment, if there is clinical improvement, an oral antibiotic should be considered.

When the pathogen is known or suspected to be *Pseudomonas*, use a suitable beta-lactam drug in combination with an aminoglycoside. Do not rely on a single agent for treatment of *Pseudomonas*. When the patient has renal insufficiency, consider azactam in place of the aminoglycoside.

In treatment of children with antibiotic suspensions, caregivers should be instructed in use of oral syringes or measuring teaspoons. Household teaspoons are not standardized and will give unreliable doses.

Anticancer drugs

Definition

Anticancer, or antineoplastic, drugs are used to treat malignancies, cancerous growths. Drug therapy may be

used alone, or in combination with other treatments such as surgery or radiation therapy.

Purpose

Anticancer drugs are used to control the growth of cancerous cells. **Cancer** is commonly defined as the uncontrolled growth of cells, with loss of differentiation and commonly, with metastasis, spread of the cancer to other tissues and organs. Cancers are malignant growths. In contrast, benign growths remain encapsulated and grow within a well-defined area. Although benign tumors may be fatal if untreated, due to pressure on essential organs, as in the case of a benign **brain tumor**, surgery or radiation are the preferred methods of treating growths which have a well defined location. Drug therapy is used when the tumor has spread, or may spread, to all areas of the body.

Description

Several classes of drugs may be used in cancer treatment, depending on the nature of the organ involved. For example, breast cancers are commonly stimulated by estrogens, and may be treated with drugs which inactive the sex hormones. Similarly, **prostate cancer** may be treated with drugs that inactivate androgens, the male sex hormone. However, the majority of antineoplastic drugs act by interfering with cell growth. Since cancerous cells grow more rapidly than other cells, the drugs target those cells which are in the process of reproducing themselves. As a result, antineoplastic drugs will commonly affect not only the cancerous cells, but others cells that commonly reproduce quickly, including hair follicles, ovaries and testis, and the blood-forming organs.

Newer approaches to antineoplastic drug therapy have taken different approaches, including angiogenesis—the inhibition of formation of **blood vessels** feeding the tumor and contributing to tumor growth. Although these approaches hold promise, they are not yet in common use.

Antineoplastic drugs may be divided into two classes: cycle specific and non-cycle specific. Cycle specific drugs act only at specific points of the cell's duplication cycle, such as anaphase or metaphase, while non-cycle specific drugs may act at any point in the cell cycle. In order to gain maximum effect, antineoplastic drugs are commonly used in combinations.

Precautions

Because antineoplastic agents do not target specific cell types, they have a number of common adverse side

effects. Hair loss is common due to the effects on hair follicles, and anemia, **immune system** impairment, and clotting problems are caused by destruction of the **blood** forming organs, leading to reduction in the number of red cells, white cells, and platelets. Because of the frequency and severity of these side effects, it is common to administer **chemotherapy** in cycles, allowing time for recovery from the drug effects before administering the next dose. Doses are often calculated, not on the basis of weight, but rather based on blood counts, in order to avoid dangerous levels of anemia (red cell depletion), neutropenia (white cell deficiency), or thrombocytopenia (platelet deficiency).

Nausea and vomiting are among the most common adverse effects of cancer chemotherapy, and in some cases may be severe enough to cause dose reduction or discontinuation of treatment. The health professional has many responsibilities in dealing with patients undergoing chemotherapy. The patient must be well informed of the risks and benefits of chemotherapy, and must be emotionally prepared for the side effects. These may be permanent, and younger patients should be aware of the high risk of sterility after chemotherapy.

The patient must also know which side effects should be reported to the practitioner, since many adverse effects do not appear until several days after a dose of chemotherapy. When chemotherapy is self-administered, the patient must be familiar with proper use of the drugs, including dose scheduling and avoidance of drug-drug and food-drug interactions.

Appropriate steps should be taken to minimize side effects. These may include administration of anti-nauseant medications to reduce nausea and vomiting, maintaining fluid levels to reduce drug toxicity, particularly to the **kidneys**, or application of a scalp tourniquet to reduce blood flow to the scalp and minimize hair loss due to drug therapy.

Patients receiving chemotherapy are also at risk of infections due to reduced white blood counts. While prophylactic **antibiotics** may be useful, the health care professional should also be sure to use standard precautions, including gowns and gloves when appropriate. Patients should be alerted to avoid risks of viral contamination, and live virus immunizations are contraindicated until the patient has fully recovered from the effects of chemotherapy. Similarly, the patient should avoid contact with other people who have recently had live virus immunizations.

Other precautions which should be emphasized are the risks to pregnant or nursing women. Because antineoplastic drugs are commonly harmful to the fetus, women of childbearing potential should be cautioned to

ANTI CANCER DRUGS		
Generic (Brand Name)	Clinical Uses	Common Side Effects To Drug
Altretamine (Hexalen)	Treatment of advanced ovarian cancer	Bone marrow depression, nausea and vomiting
Asparaginase (Elspar)	Commonly used in combination with other drugs; refractory acute lymphocytic leukemia	Liver, kidney, pancreas, CNS abnormalities,
Bleomycin (Blenoxane)	Lymphomas, Hodgkin's disease, testicular cancer	Hair loss, stomatitis, pulmonary toxicity, hyperpigmentation of skin
Busulfan (Myleran)	Chronic granulocytic leukemia	Bone marrow depression, pulmonary toxicity
Carboplatin (Paraplatin)	Palliation of ovarian cancer	Bone marrow depression, nausea and vomiting
Carmustine	Hodgkin's disease, brain tumors, multiple myeloma, malignant melanoma	Bone marrow depression, nausea and vomiting, toxic damage to liver
Chlorambucil (Leukeran)	Chronic lymphocytic leukemia, non-Hodgkin's lymphomas, breast and ovarian cancer	Bone marrow depression, excess uric acid in blood
Cisplatin (Platinol)	Treatment of bladder, ovarian, uterine, testicular, head and neck cancers	Renal toxicity and ototoxicity
Cladribine (Leustatin)	Hairy cell leukemia	Bone marrow depression, nausea and vomiting, fever
Cyclophosphamide (Cytoxan)	Hodgkin's disease, non-Hodgkin's lymphomas, neuroblastoma. Often used with other drugs for breast, ovarian, and lung cancers; acute lymphoblastic leukemia in children; multiple myeloma	Bone marrow depression, hair loss, nausea and vomiting, inflammation of the bladder
Cytarabine (Cytosar-U)	Leukemias occurring in adults and children	Bone marrow depression, nausea and vomiting, diarrhea, stomatitis
Dacarbazine (DTIC-Dome)	Hodgkin's disease, malignant melanoma	Bone marrow depression, nausea and vomiting
Diethylstilbestrol (DES) (Stilbestrol)	Breast cancer in post-menopausal women, prostate cancer	Hair loss, nausea and vomiting, edema, excess calcium in blood; feminizing effects in men
Ethinyl estradiol (Estinyl)	Advanced breast cancer in post-menopausal women, prostate cancer	Excess calcium in blood, anorexia, edema, nausea and vomiting; feminizing effects in men
Etoposide (VePesid)	Acute leukemias, lymphomas, testicular cancer	Bone marrow depression, nausea and vomiting, hair loss

(Illustration by Standley Publishing. Courtesy of Gale Group.)

ANTI CANCER DRUGS (continued)		
Generic (Brand Name)	Clinical Uses	Common Side Effects To Drug
Floxuridine (FUDR)	Cancers of the liver, pancreas, GI and biliary tract, head and neck tumors	See Cytarabine
Fludarabine (Fludara)	Chronic lymphocytic leukemia	Bone marrow depression, nausea and vomiting, fever
Fluorouracil (5-FU) (Adrucil)	Breast, colon, pancreatic cancer, cancer of the rectum and stomach	See Cytarabine
Flutamide (Eulexin)	Advanced prostate cancer	Nausea and vomiting, hot flashes, diarrhea, impotence, decreased libido, gynecomastia
Goserelin (Zoladex)	Advanced prostate cancer	Pain in bones
Hydroxyurea (Hydrea)	Chronic granulocytic leukemia, malignant melanoma	Bone marrow depression, gastrointestinal irritation
Idarubicin (Idamycin)	Used in combination with other antileukemic drugs, acute myelogenous leukemia	See Doxorubicin
Ifosfamide (Ifex)	Germ cell testicular cancer	Bone marrow depression, nausea and vomiting, inflammation of the bladder
Leuprolide (Lupron)	Advanced prostate cancer	See Goserelin
Levamisole (Ergamisol)	Used in conjunction with Fluorouracil to treat colon cancer	Diarrhea, dermatitis, nausea and vomiting
Lomustine	Brain tumors, Hodgkin's disease	Bone marrow depression, nausea and vomiting, toxic damage to liver
Mechlorethamine (Mustargen)	Lung cancer, Hodgkin's disease and non-Hodgkin's lymphomas	Bone marrow depression, nausea and vomiting
Medroxyprogesterone (Depo-Provera)	Advanced uterine cancer	May cause edema
Megestrol (Megace)	Advanced uterine cancer, breast cancer	Masculinizing effects
Melphalan (Alkeran)	Multiple myeloma	Bone marrow depression, nausea and vomiting
Mercaptopurine (Purinethol)	Acute and chronic leukemias	Bone marrow depression, nausea, excess uric acid in blood
Methotrexate (Mexate)	Acute lymphoblastic leukemias in children, bone cancer, choriocarcinoma of the testes	Bone marrow depression, diarrhea, nausea, stomatitis

(Illustration by Standley Publishing. Courtesy of Gale Group.)

ANTI CANCER DRUGS (continued)		
Generic (Brand Name)	Clinical Uses	Common Side Effects To Drug
Mitomycin (Mutamycin)	Bladder, breast, colon, lung, pancreas, rectum cancers, head and neck cancer, malignant melanoma	Bone marrow depression, nausea and vomiting, diarrhea, stomatitis, possible tissue damage
Mitotane (Lysodren)	Cancer of the adrenal cortex (inoperable)	Damage to adrenal cortex, nausea, anorexia
Mitoxantrone (Novantrone)	Acute nonlymphocytic leukemia	Cardiac arrhythmias, labored breathing, nausea and vomiting, diarrhea, fever, congestive heart failure
Paclitaxel (Taxol)	Advanced ovarian cancer	Bone marrow depression, hair loss, nausea and vomiting, hypotension, allergic reactions, slow heart action, muscle and joint pain
Pentastatin (Nipent)	Hairy cell leukemia unresponsive to alpha-interferon	Bone marrow depression, fever, skin rash, liver damage, nausea and vomiting
Pipobroman (Vercyte)	Chronic granulocytic leukemia	Bone marrow depression
Plicamycin (Mithracin)	Testicular tumors	Toxicity/damage to bone marrow, kidneys, and liver
Prednisone (Meticorten)	Used in adjunct therapy for palliation of symptoms in lymphomas, acute leukemia, Hodgkin's disease	May be toxic to all body systems
Procarbazine (Matulane)	Hodgkin's disease	Bone marrow depression, nausea and vomiting
Streptozocin (Zanosar)	Islet cell carcinoma of pancreas	Nausea and vomiting, toxicity to kidneys
Tamoxifen (Nolvadex)	Advanced breast cancer in post menopausal	Nausea and vomiting, ocular toxicity, hot flashes
Teniposide (Vumon)	Acute lymphocytic leukemia in children	See Etoposide
Vinblastine (Velban)	Breast cancer, Hodgkin's disease, metastatic testicular cancer	Bone marrow depression, neurotoxicity
Vincristine (Oncovin)	Acute leukemia, Hodgkin's disease, lymphomas	Constipation, neurotoxicity, possible tissue necrosis

(Illustration by Standley Publishing. Courtesy of Gale Group.)

use two effective methods of birth control while receiving cancer chemotherapy. This also applies if the woman's male partner is receiving chemotherapy. Breastfeeding should be avoided while the mother is being treated.

Before prescribing or administering anticancer drugs, health care providers should inquire whether the patient has any of the following conditions:

- chickenpox or recent exposure to someone with chickenpox
- shingles (herpes zoster)
- mouth sores
- current or past seizures
- head injury
- nerve or muscle disease
- hearing problems
- infection of any kind
- gout
- colitis
- intestine blockage
- stomach ulcer
- kidney stones
- kidney disease
- liver disease
- current or past alcohol abuse
- immune system disease
- **cataracts** or other eye problems
- high cholesterol

Other precautions

The anticancer drug methotrexate has additional precautions. Patients should be given advice on the effects of sun exposure and the use of alcohol and **pain** relievers.

Side effects

Tamoxifen

The anticancer drug tamoxifen (Nolvadex) increases the risk of cancer of the uterus in some women. It also causes cataracts and other eye problems. Women taking this drug may have hot flashes, menstrual changes, genital itching, vaginal discharge, and weight gain. Men who take tamoxifen may lose interest in sex or become impotent. Health care providers should keep in close contact with patients to assess the individual risks associated with taking this powerful drug.

Other anticancer drugs

These side effects are not common, but could be a sign of a serious problem. Health care providers should immediately be consulted if any of the following occur:

- black, tarry, or bloody stools
- blood in the urine
- diarrhea
- fever or chills
- cough or hoarseness
- wheezing or shortness of breath
- sores in the mouth or on the lips
- unusual bleeding or bruising
- swelling of the face
- red “pinpoint” spots on the skin
- redness, pain, or swelling at the place on the body where an injectable anticancer drug is given
- pain in the side or lower back
- problems urinating or painful urination
- dizziness or faintness
- fast or irregular heartbeat

Other side effects do not need immediate care, but should have medical attention. They are:

- joint pain
- skin rash
- hearing problems or ringing in the ears
- numbness or tingling in the fingers or toes
- trouble walking or balance problems
- swelling of the feet or lower legs
- unusual tiredness or weakness
- loss of **taste**
- seizures
- dizziness
- confusion
- agitation
- headache
- dark urine
- yellow eyes or skin
- flushing of the face

In addition, there are other possible side effects that do not need medical attention unless they persist or interfere with normal activities. These include changes in

KEY TERMS

Cataract—Clouding of the lens of the eye, leading to poor vision or blindness.

Impotent—Unable to achieve or maintain an erection of the penis.

menstrual period, itchy skin, nausea and vomiting, and loss of appetite.

Other rare side effects may occur. Anyone who has unusual symptoms after taking anticancer drugs should contact the physician who prescribed the medication.

Interactions

Anticancer drugs may interact with a number of other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. The health care provider should be aware of all other prescription or non-prescription (over-the-counter) medicines a patient is taking. The primary care provider should also be told if the patient has been treated with radiation or has taken other anticancer drugs.

Samuel Uretsky, PharmD

Anticholinergic drugs see **Antiparkinson drugs**

Antidepressant drugs

Definition

Antidepressant drugs are medicines that relieve symptoms of **depressive disorders**.

Purpose

Depressive disorders may be either unipolar (depression alone) or bipolar (depression alternating with periods of extreme excitation). The formal diagnosis requires a cluster of symptoms lasting at least two weeks. These symptoms include, but are not limited to mood changes, insomnia or hypersomnia, and diminished interest in daily activities. The symptoms are not caused by any medical condition, drug side effect, or adverse life event. The condition is severe enough to cause clinically signif-

icant distress or impairment in social, occupational, or other important areas of functioning.

Secondary depression, depression caused by unfavorable life events, is normally self limiting, and may be best treated with cognitive/behavioral therapy rather than drugs.

Description

Antidepressant agents act by increasing the levels of excitatory neurotransmitters. The main types of antidepressant drugs in use today are:

- tricyclic antidepressants, such as amitriptyline (Elavil), imipramine (Tofranil), nortriptyline (Pamelor)
- selective serotonin reuptake inhibitors (SSRIs or serotonin boosters), such as fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft)
- monoamine oxidase inhibitors (MAO inhibitors), such as phenelzine (Nardil), and tranylcypromine (Parnate)
- tetracyclic compounds and atypical antidepressants that do not fall into any of the above categories

Selective serotonin reuptake inhibitors maintain levels of the excitatory neurohormone serotonin in the **brain**. They do not alter levels of norepinephrine. These have become the drugs of choice for a variety of psychiatric disorders, primarily because of their low incidence of severe side effects as compared with other drugs in this therapeutic class. SSRIs show similar actions and side effect profiles, but may vary in duration of action.

Tricyclic compounds, identified by their chemical structure containing three carbon rings, are an older class of antidepressants. Although generally effective, they have a high incidence of anticholinergic effects, notably dry mouth and dry eyes, which can cause discomfort. They also cause cardiac arrhythmias. Because tricyclics act on both serotonin and norepinephrine, they may have some value in treatment of patients who fail to respond to SSRIs. Drugs in this class are often available at low prices, which may be significant when cost is a major factor in treatment. They have also been found useful in control of some neurologic **pain** syndromes.

Tricyclic antidepressants are similar, but may vary in severity of side effects, most notably the degree of sedation and the extent of the anticholinergic effects.

Tetracyclic compounds and atypical antidepressants are chemically distinct from both the major groups and each other. Although maprotilene (no brand name, marketed in generic form only) and mirtazepine (Remeron) are similar in chemical structures, they differ in their balance of activity on serotonin and norepinephrine levels.

ANTIDEPRESSANT DRUGS	
<i>Brand Name (Generic Name)</i>	<i>Possible Common Side Effects Include:</i>
Desyrel (trazodone hydrochloride)	Allergic skin reactions, blurred vision, decreased appetite, fluid retention, headache
Effexor (venlafaxine hydrochloride)	Diarrhea, dizziness, gas, headache, insomnia, rash, vomiting
Elavil (amitriptyline hydrochloride)	Constipation, dizziness, high blood pressure, fever, nausea, rash, weight gain or loss
Nardil (phenelzine sulfate)	Dry mouth, fatigue, headache, muscle spasms, tremors
Norpramin (desipramine hydrochloride)	Blurred vision, cramps, hallucinations, hair loss, vomiting
Pamelor (nortriptyline hydrochloride)	Diarrhea, fatigue, headache, decreased coordination
Paxil (paroxetine hydrochloride)	Cold symptoms, drowsiness, nervousness, stomach pain
Prozac (fluoxetine hydrochloride)	Bronchitis, drowsiness, fatigue, nausea, tremors
Sinequan (doxepin hydrochloride)	Bruising, constipation, fluid retention, itching, increased heartbeat
Surmontil (trimipramine maleate)	Disorientation, flushing, headache, nausea, vomiting
Tofranil (imipramine hydrochloride)	Bleeding sores, fever, hives, decreased coordination
Travil	Asthma, diarrhea, dizziness, fatigue, seizures
Wellbutrin (bupropion hydrochloride)	Agitation, dry mouth, headache, nausea, rash
Zoloft (sertraline)	Diarrhea, fainting, gas, headache, nervousness

(Illustration by Standley Publishing. Courtesy of Gale Group.)

Monoamine oxidase inhibitors (phenelzine [Nardil], tranylcypromine [Parnate]) have largely been supplanted in therapy because of their high risk of severe adverse effects, most notably severe **hypertension**. They act by inhibiting the enzyme monoamine oxidase, which is responsible for the **metabolism** of the stimulatory neurohormones norepinephrine, epinephrine, dopamine, and serotonin. The MAOIs are normally reserved for patients who are resistant to safer drugs. Two drugs, eldepryl (Carbex, used in treatment of **Parkinson's disease**) and the herb, St. John's wort, have some action against monoamine oxidase B, and have shown some value as anti-depressants. They do not share the same risks as the non-selective MAO inhibitors.

All antidepressant agents, regardless of their structure, have a slow onset of action, typically three to five weeks. Although adverse effects may be seen as early as the first dose, significant therapeutic improvement is

always delayed. Similarly, the effects of antidepressants will continue for a similar length of time after the drugs have been discontinued.

Recommended dosage

Dose varies with the specific drug and patient. Consult specialized references.

Precautions

Antidepressants have many significant cautions and adverse effects. Although a few are listed here, specific references should be consulted for more complete information.

SSRIs. The most common side effect of SSRIs is excitation and insomnia. Excitation has been reported in over 20% of patients, and insomnia in 33%. Significant weight loss has been frequently reported, but most com-

KEY TERMS

Cognitive behavioral therapy—A type of psychotherapy in which people learn to recognize and change negative and self-defeating patterns of thinking and behavior.

Depression—A mental condition in which people feel extremely sad and lose interest in life. People with depression may also have sleep problems and loss of appetite and may have trouble concentrating and carrying out everyday activities.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

monly in patients who are already underweight. SSRIs may cause some sedation, and patients should be cautioned not to perform tasks requiring alertness until they have evaluated the effects of these drugs. SSRIs are **pregnancy** category C drugs. Most SSRIs are excreted in breast milk, and there have been anecdotal reports of somnolence in infants whose mothers were taking SSRIs while breastfeeding.

Tricyclic antidepressants. Amoxepine (not marketed by brand, generic available), although a tricyclic antidepressant rather than a neuroleptic (major tranquilizer), displays some of the more serious effects of the neuroleptics, including tardive dyskinesias (drug induced involuntary movements) and neuroleptic malignant syndrome, a potentially fatal syndrome whose symptoms include high **fever**, altered mental status, irregular pulse or **blood pressure**, and changes in **heart** rate. These adverse effects have not been reported with other tricyclic antidepressants.

The most common adverse effects of tricyclic antidepressants are sedation and the anticholinergic effects, such as dry mouth, dry eyes, and difficult urination. Alterations in heartbeat are also common, and may progress to congestive **heart failure**, stroke, and sudden death.

Tricyclic antidepressants are in pregnancy categories C or D, although there have been no formal studies of the drugs on **fetal development**. There are no studies of effects on newborns, but some anecdotal reports of malformations have resulted from animal studies. The drugs are excreted in breast milk.

Monoamine oxidase inhibitors. The greatest risk associated with these drugs is a hypertensive crisis which may be fatal and most often occurs when the drugs are taken with interacting foods or drugs. More common adverse reactions may include low **blood** pressure and slowing of heartbeat. Sedation and gastrointestinal disturbances are also common. MAOIs are in pregnancy category C. Safety in breast feeding has not been established.

Tetracyclines and atypicals. Because these drugs are individual, there are no group patterns of adverse reactions. Consult specific references.

Interactions

The antidepressants have many **drug interactions**, some severe. Although a few are listed here, specific references should be consulted for more complete information.

SSRIs should not be administered with MAOIs. Allow a wash-out period of about four weeks before switching from one class of drugs to the other. Allow five weeks if switching from fluoxetine (Prozac) to an MAOI.

MAOIs have many interactions; however the best known are those with foods containing the amino acid tyramine. These include aged cheese, chianti wine, and many others. Patients and providers should review the MAOI diet restrictions before using or prescribing these drugs. Because of the severity of MAOI interactions, all additions to the patient's drug regimen should be reviewed with care.

Tricyclic compounds have many interactions, and specialized references should be consulted. Specifically avoid other drugs with anticholinergic effects. Tricyclics should not be taken with the **antibiotics** grepafloxacin and sparfloxacin, since the combination may cause serious heart arrhythmias.

Tricyclic compounds should not be taken with the gastric acid inhibitor cimetidine (Tagamet), since this increases the blood levels of the tricyclic compound. Other acid inhibiting drugs do not share this interaction.

SSRIs interact with a number of other drugs which act on the **central nervous system**. Use care in combining these drugs with major or minor tranquilizers, or with anti-epileptic agents such as phenytoin (Dilantin) or carbamazepine (Tegretol).

Antidiabetic drugs

Definition

Antidiabetic drugs are medicines that help control **blood** sugar levels in people with **diabetes mellitus** (sugar diabetes).

Purpose

Diabetes may be divided into type I and type II, formerly termed juvenile onset or insulin-dependent, and maturity onset or non insulin-dependent. Type I is caused by a deficiency of insulin production, while type II is characterized by insulin resistance.

Treatment of type I diabetes is limited to insulin replacement, while type II diabetes is treatable by a number of therapeutic approaches. Many cases of insulin resistance are asymptomatic due to normal increases in insulin secretion, and others may be controlled by diet and **exercise**. Drug therapy may be directed towards increasing insulin secretion, increasing insulin sensitivity, or increasing insulin penetration of the cells.

Description

Antidiabetic drugs may be subdivided into six groups: insulin, sulfonyleureas, alpha-glucosidase inhibitors, biguanides, meglitinides, and thiazolidinediones.

Insulin (Humulin, Novolin) is the hormone responsible for glucose utilization. It is effective in both types of diabetes, since, even in insulin resistance, some sensitivity remains and the condition can be treated with larger doses of insulin. Most insulins are now produced by recombinant DNA techniques, and are chemically identical to natural human insulin. Isophane insulin suspension, insulin **zinc** suspension, and other formulations are intended to extend the duration of action of insulin, and permit glucose control over longer periods of time.

ANTIDIABETIC DRUGS

<i>Brand Name (Generic Name)</i>	<i>Possible Common Side Effects Include:</i>
Diabinese (chlorpropamide)	Diarrhea, nausea, loss of appetite
Glucotrol (glipizide)	Dizziness, fatigue, headache, nervousness
*Insulin	Mild allergic reactions, decreased blood pressure, rash, shortness of breath
Micronase (glyburide)	Nausea, heartburn, bloating
Orinase (tolbutamide)	Nausea, heartburn, bloating
*Insulin is the generic name for several brands which may be animal-based, human-based, or synthetic.	

(Illustration by Standley Publishing. Courtesy of Gale Group.)

Sulfonylureas (chlorpropamide [Diabinese], tolazamide [Tolinase], glipizide [Glucotrol], and others) act by increasing insulin release from the beta cells of the pancreas. Glimpiride (Amaryl), a member of this class, appears to have a useful secondary action in increasing insulin sensitivity in peripheral cells.

Alpha-glucosidase inhibitors (acarbose [Precose], miglitol [Glyset]) do not enhance insulin secretion. Rather, they inhibit the conversion of disaccharides and complex **carbohydrates** to glucose. This mechanism does not prevent conversion, but only delays it, reducing the peak blood glucose levels. Alpha-glucosidase inhibitors are useful for either monotherapy or in combination therapy with sulfonylureas or other hypoglycemic agents.

Metformin (Glucophage) is the only available member of the biguanide class. Metformin decreases hepatic glucose production, decreases intestinal absorption of glucose and increases peripheral glucose uptake and utilization. Metformin may be used as monotherapy, or in combination therapy with a sulfonylurea.

There are two members of the meglitinide class: repaglinide (Prandin) and nateglitinide (Starlix). The mechanism of action of the meglitinides is to stimulate insulin production. This activity is both dose dependent and dependent on the presence of glucose, so that the drugs have reduced effectiveness in the presence of low blood glucose levels. The meglitinides may be used alone, or in combination with metformin. The manufacturer

KEY TERMS

Blood sugar—The concentration of glucose in the blood.

Glucose—A simple sugar that serves as the body's main source of energy.

Hormone—A substance that is produced in one part of the body, then travels through the bloodstream to another part of the body where it has its effect.

Metabolism—All the physical and chemical changes that occur in cells to allow growth and maintain body functions. These include processes that break down substances to yield energy and processes that build up other substances necessary for life.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Salicylates—A group of drugs that includes aspirin and related compounds. Salicylates are used to relieve pain, reduce inflammation, and lower fever.

Seizure—A sudden attack, spasm, or convulsion.

warns that nateglitinide should not be used in combination with other drugs which enhance insulin secretion.

Rosiglitazone (Avandia) and pioglitazone (Actos) and the members of the thiazolidinedione class. They act by both reducing glucose production in the **liver**, and increasing insulin dependent glucose uptake in muscle cells. They do not increase insulin production. These drugs may be used in combination with metoformin or a sulfonylurea.

Recommended dosage

Dosage must be highly individualized for all antidiabetic agents and is based on blood glucose levels which must be taken regularly. Review specific literature.

Precautions

The greatest short term risk of insulin is hypoglycemia, which may be the result of either a direct **overdose** or an imbalance between insulin injection and level of exercise and diet. This may also occur in the presence of other conditions which reduce the glucose load, such as illness with vomiting and **diarrhea**. Treatment is with glucose in the form of glucose tablets or liquid, although severe cases may require intravenous therapy. Allergic reactions and skin reactions may also occur. Insulin is classified as category **B** in **pregnancy**, and is considered the drug of choice for glucose control during pregnancy. Insulin glargine (Lantus), an insulin analog which is suitable for once-daily dosing, is classified as category **C**, because there have been reported changes in the hearts of newborns in animal studies of this drug. The reports are essentially anecdotal, and no cause and effect relationship has been determined. Insulin is not recommended during breast feeding because either low or high doses of insulin may inhibit milk production. Insulin administered orally is destroyed in the GI tract, and represents no risk to the newborn.

All sulfonylurea drugs may cause hypoglycemia. Most patients become resistant to these drugs over time, and may require either dose adjustments or a switch to insulin. The list of adverse reactions is extensive, and includes **central nervous system** problems and skin reactions, among others. Hematologic reactions, although rare, may be severe and include aplastic anemia and hemolytic anemia. The administration of oral hypoglycemic drugs has been associated with increased cardiovascular mortality as compared with treatment with diet alone or diet plus insulin. The sulfonylureas are classified as category **C** during pregnancy, based on animal studies, although glyburide has not shown any harm to the fetus and is classified as category **B**. Because there may be significant alterations in blood glucose levels during pregnancy, it is recommended that patients be switch to insulin. These drugs have not been fully studied during breast feeding, but it is recommended that because their presence in breast milk might cause hypoglycemia in the newborn, breast feeding be avoided while taking sulfonylureas.

Alpha-glucosidase inhibitors are generally well tolerated, and do not cause hypoglycemia. The most common adverse effects are gastrointestinal problems, including flatulence, diarrhea, and abdominal **pain**. These drugs are classified as category **B** in pregnancy. Although there is no evidence that the drugs are harmful to the fetus, it is important that rigid blood glucose control be maintained during pregnancy, and pregnant women should be switched to insulin. Alpha-glucosidase inhibitors may be excreted in

small amounts in breast milk, and it is recommended that the drugs not be administered to nursing mothers.

Metformin causes gastrointestinal reactions in about a third of patients. A rare, but very serious, reaction to metformin is lactic acidosis, which is fatal in about 50% of cases. Lactic acidosis occurs in patients with multiple medical problems, including renal insufficiency. The risk may be reduced with careful renal monitoring, and careful dose adjustments to metformin. Metformin is category B during pregnancy. There have been no carefully controlled studies of the drug during pregnancy, but there is no evidence of fetal harm from animal studies. It is important that rigid blood glucose control be maintained during pregnancy, and pregnant women should be switched to insulin. Animal studies show that metformin is excreted in milk. It is recommended that metformin not be administered to nursing mothers.

Meglitinides are generally well tolerated, with an adverse event profile similar to placebo. The drugs are classified as category C during pregnancy, based on fetal abnormalities in rabbits given about 40 times the normal human dose. It is important that rigid blood glucose control be maintained during pregnancy, and pregnant women should be switched to insulin. It is not known whether the meglitinides are excreted in human milk, but it is recommended that these drugs not be given to nursing mothers.

Thiazolidinediones are generally well tolerated, however they are structurally related to an earlier drug, troglitazone, which was associated with liver function problems. It is strongly recommended that all patients treated with pioglitazone or rosiglitazone have regular liver function monitoring. The drugs are classified as pregnancy category C, based on evidence of inhibition of fetal growth in rats given more than four times the normal human dose. It is important that rigid blood glucose control be maintained during pregnancy, and pregnant women should be switched to insulin. It is not known whether the thiazolidinediones are excreted in human milk, however they have been identified in the milk of lactating rats. It is recommended that these drugs not be administered to nursing mothers.

Interactions

The sulfonylureas have a particularly long list of **drug interactions**, several of which may be severe. Review specific literature for these drugs.

The actions of oral hypoglycemic agents may be strengthened by highly protein bound drugs, including NSAIDs, salicylates, sulfonamides, chloramphenicol, coumarins, probenecid, MAOIs, and beta blockers.

Review the specific literature of each drug for possible drug-drug or food-drug interactions.

Antifungal drugs, topical

Definition

Topical antifungal drugs are medicines applied to the skin to treat skin infections caused by a fungus.

Purpose

Dermatologic fungal infections are usually described by their location on the body: tinea pedis (**infection** of the foot), tinea unguium (infection of the nails), tinea capitis (infection of the scalp). Three types of fungus are involved in most skin infections: *Trichophyton*, *Epidermophyton*, and *Microsporum*. Mild infections are usually susceptible to topical therapy, however severe or resistant infections may require systemic treatment.

Description

There are a large number of drugs currently available in topical form for fungal infections. Other than the imidazoles, (miconazole [Micatin, Miconazole], clotrimazole [Lotrimin], econazole [Spectazole], ketoconazole [Nizoral], oxiconazole [Oxistat], sulconazole [Exelderm]) and the allylamine derivatives (butenafine [Mentax], naftifine [Naftin], terbinafine [Lamisil]), the drugs in this therapeutic class are chemically distinct from each other. All drugs when applied topically have a good margin of safety, and most show a high degree of effectiveness. There are no studies comparing drugs on which to base a recommendation for drugs of choice. Although some of

KEY TERMS

Cream—A spreadable substance, similar to an ointment, but not as thick. Creams may be more appropriate than ointments for application to exposed skin areas such as the face and hands.

Ointment—A thick, spreadable substance that contains medicine and is meant to be used on the skin, or if a vaginal preparation, in the vagina.

Ophthalmic—Pertaining to the eye.

Otic—Pertaining to the ear.

Topical—A term used to describe medicine that has effects only in a specific area, not throughout the body, particularly medicine that is put directly on the skin.

the topical antifungals are available over-the-counter, they may be as effective as prescription drugs for this purpose.

Traditional antifungal drugs such as undecylinic acid (Cruex, Desenex) and gentian violet (also known as crystal violet) remain available, but have a lower cure rate (complete eradication of fungus) than the newer agents and are not recommended. Tolnaftate (Tinactin) has a lower cure rate than the newer drugs, but may be used prophylactically to prevent infection.

Recommended dosage

All drugs are applied topically. Consult individual product information for specific application recommendations.

As with all topical products, selection of the dosage form may be as important as proper drug selection. Consider factors such as presence or absence of hair on the affected area, and type of skin to which the medication is to be applied. Thin liquids may be preferable for application to hairy areas, creams for the hands and face, and ointments may be preferable for the trunk and legs. Other dosage forms available include shampoos and sprays. Ciclopirox and triacetin are available in formulations for topical treatment of nail fungus as well as skin infections (ciclopirox as Penlac Nail Lacquer and triacetin as Ony-Clear Nail).

Most topical antifungal drugs require four weeks of treatment. Infections in some areas, particularly the spaces between toes, may take up to six weeks for cure.

Precautions

Most topical antifungal agents are well tolerated. The most common adverse effects are localized irritation caused by the vehicle or its components. This may include redness, itch, and a burning sensation. Some direct allergic reactions are possible.

Topical antifungal drugs should only be applied in accordance with labeled uses. They are not intended for ophthalmic (eye) or otic (ear) use. Application to mucous membranes should be limited to appropriate formulations.

The antifungal drugs have not been evaluated for safety in **pregnancy** and **lactation** on topical application under the pregnancy risk category system. Although systemic absorption is probably low, review specific references. Gentian violet is labeled with a warning against use in pregnancy.

Interactions

Topical antifungal drugs have no recognized drug-drug or food-drug interactions.

Samuel Uretsky, PharmD

Antiglobulin tests

Definition

Antiglobulin (Coombs') tests are **blood** tests that identify the causes of immune-mediated anemia or hemolysis. Antiglobulin tests utilize an antibody to human immunoglobulin in order to detect antibody coated (sensitized) cells. In addition to being a medical test that is ordered by a physician, the antiglobulin test is a procedure employed in various blood banking and immunology methods in order to detect immune complex formation. This test is also the basis for some blood typing tests.

Purpose

Antiglobulin tests are used to detect antibodies in serum or attached to cells. The test is ordered as a medical laboratory test to aid in the differential diagnosis of anemia. Anemia refers to blood with abnormally low oxygen-carrying capacity. The hemoglobin in red blood cells carries oxygen. Anemia may be caused by low numbers of red blood cells or a low level of functional hemoglobin. One of the many causes of anemia is destruction of red blood cells, a process called hemolysis (*hemo*

means blood and *lysis* means disintegration). Any anemia caused by a shortened red blood cell survival in the circulation is called a hemolytic anemia. The causes of hemolytic anemia include **septic shock**, mechanical trauma, intrinsic red blood cell membrane defects or biochemical (enzyme) defects that make the cells more fragile, and antibody induced destruction. The antiglobulin test identifies red blood cells coated (sensitized) by antibody, and therefore, hemolytic anemia caused by immune mediated destruction. The test also identifies red blood cells coated by complement. Complement is a series of **proteins** that attach to the cell following the reaction of some types of antibodies with antigens on the cell surface. Complement components undergo changes after attachment to the red cells that damage the membrane and serve as binding sites for phagocytes that remove the red cells from the blood as they pass through the spleen and **liver**.

Immune-mediated hemolytic anemia can result from a transfusion reaction in which antibodies formed by the recipient attach to and destroy the donor's red blood cells, or it can result from the production of antibodies that attach to the surface of the person's own red cells (autoimmune hemolytic anemia).

Autoimmunity is the cause of many systemic collagen-vascular diseases, including rheumatoid arthritis and systemic lupus erythematosus, and several organ-specific diseases such as type I **diabetes mellitus** and chronic lymphocytic thyroiditis (hypothyroidism). Some persons with systemic autoimmune disease produce autoantibodies to their red cells, and the antiglobulin test is used to identify these antibodies. In addition, the antiglobulin test may be employed to detect the antibodies responsible for the destruction of the target tissue in autoimmune diseases.

Causes of immune-mediated hemolytic anemia include:

- drugs such as penicillin, methyldopa (lowers **blood pressure**), and quinidine (treats **heart** rhythm disturbances)
- cancers of the lymph system, including Hodgkin's disease and lymphomas
- some viral infections
- collagen-vascular diseases
- incompatible blood transfusions
- Rh incompatibility between a mother and fetus (hemolytic disease of the newborn)

In some cases, the cause of an autoimmune hemolytic anemia cannot be identified.

Precautions

A blood sample collected by venipuncture is used for antiglobulin tests. The nurse or phlebotomist collecting the specimen should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. It is recommended that samples for the direct antiglobulin test be collected in EDTA. This chelates **calcium**, preventing the attachment of complement components to red cells during storage. Refrigeration of blood specimens that have cold agglutinins may cause a false positive test. The blood should be stored at room temperature until separation of red cells and serum or plasma.

Description

There are two forms of the antiglobulin (Coombs') test. A direct antiglobulin (Coombs') test (DAT) detects antibody bound *in vivo* to either antigen(s) or complement components on the red cell surface. The test uses a broad spectrum reagent containing antibodies that bind to human immunoglobulin and C3. Such antibodies can be made by immunizing rabbits, burros, or goats with purified human immunoglobulin or complement proteins or by gene fusion technology (hybridomas) that produces a malignant clone of antibody secreting cells containing the genes needed to make the desired antibody. Reagents typically have reactivity to human IgG (the most common class of antibody), complement components C3b and C3d, and immunoglobulin light chains to permit detection of other immunoglobulin classes (IgA and IgM). A 2-3% suspension of the cells is made using saline. The blood cells are washed three times with isotonic saline to remove the immunoglobulins and other proteins not bound to the red cells. After washing the antiglobulin (AHG) reagent is added to the cell button. The cells are suspended in the reagent and the mixture is centrifuged. The cells are resuspended and examined for visible clumping (agglutination). If the red blood cells are coated with either antibody or complement they will clump, and the button will break up into small pieces instead of resuspending in the saline. If no agglutination is observed, a drop of antibody-coated red cells is added to the mixture and it is centrifuged again and examined. The presence of agglutination verifies that the antiglobulin reagent is present and had not been neutralized by improper washing. In addition, monospecific anti-human immunoglobulins may be used to distinguish between antibody and complement binding and to identify the class of antibody that has attached to the red blood cells. The direct antiglobulin tests can be used to detect autoantibodies that have attached to other types of cells. For example, the DAT test is often used to identify the autoimmune form of a kidney disease called

KEY TERMS

Anemia—Reduced oxygen-carrying capacity of the blood, due to too little hemoglobin or too few red blood cells.

Antibody—A protein made by the immune system, that is directed against antigens, and used as a weapon against foreign invaders in the body.

Antigen—The chemical that stimulates an immune response.

Collagen-vascular disease—Various diseases inflaming and destroying connective tissue.

Hematologist—Physician who specializes in diseases of the blood.

Hemoglobin—The red pigment in blood that carries oxygen.

Hemolysis—Breaking apart red blood cells.

Rh—A blood typing group, like the ABO system. When a mother is Rh negative and her baby is Rh positive, she may develop antibodies to the baby's blood that will cause it to hemolyze.

glomerulonephritis. The anti-human immunoglobulin is conjugated to a fluorescent dye. This is added to a thin-section of the renal tissue on a **microscope** slide. The slide is washed to remove unbound antibody and then examined under a fluorescent microscope. Fluorescence of the tissue indicates a positive test for antibody-coated cells.

The second type of antiglobulin test is called the indirect antiglobulin test. This procedure is used to demonstrate the presence of specific antibodies in the serum or plasma. It is also used to detect blood group antigens of several blood group systems including the Kell, Kidd, and Duffy systems, to detect incomplete (nonagglutinating) antibodies that have attached to donor red blood cells in the compatibility test (cross-match), and to investigate the cause of a transfusion reaction. Many antibodies are able to attach to the corresponding antigens on red blood cells, but do not cause agglutination because the size of the antibodies is too small to cross link antigens on adjacent cells. These antibodies can be detected in plasma or serum by the indirect antiglobulin test. This test is performed in the same way as the direct test except that the red blood cells must be incubated with the patient's serum or plasma before washing and adding the AHG reagent. For example, in order to screen for antibodies that might be present in the

serum of a person needing a blood transfusion, the serum is incubated with reagent red blood cells. Two or three different reagents are used each consisting of a standardized suspension of group O red cells obtained from various donors so that a broad spectrum of different blood group antigens is represented. Group O red cells are used because they lack A or B antigens that would cause agglutination with anti-A or anti-B antibodies that occur naturally in persons lacking the respective antigen. Following incubation, the red cells are washed to remove unbound proteins (antibodies) and the AHG is added. The cell suspension is centrifuged and examined for agglutination as described above. The presence of agglutination indicates that at least one antibody against the reagent cells are present. The indirect antiglobulin test using a fluorescent-labeled antihuman globulin is also used to identify antibodies produced against DNA and other cellular components by persons with various autoimmune diseases.

Preparation

No preparation is needed for this test. Prior to performing the venipuncture, the nurse or other health care professional should document any medications the patient is currently taking, since many medications have been implicated in autoimmune hemolytic anemia.

Aftercare

The patient may feel discomfort when blood is drawn from a vein. Bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure should be applied to the puncture site until the bleeding stops to reduce bruising. Warm packs can also be placed over the puncture site to relieve discomfort.

Complications

The most common complication is a bruise at the site of the puncture or excessive bleeding. The patient can apply moist warm compresses if there is any discomfort.

Results

Antiglobulin tests are reported as negative or positive. If the direct antiglobulin test is positive, an elution study may be performed to identify the specificity of the antibody. In addition, the indirect antiglobulin test may be performed to determine if there is unattached circulating antibody. If the indirect antiglobulin test is positive, serial dilutions may be performed to quantify the concentration of antibody. The antibody titre is defined as the highest dilution of the serum that gives a positive test

result. If the antiglobulin tests are negative, the anemia is unlikely to be immune-mediated, and the physician will have to search elsewhere for a cause.

Health care team roles

A physician will order the tests, and will interpret the results. The blood specimen is drawn by a nurse or phlebotomist, and transported to the laboratory. AHG tests are performed by clinical laboratory scientists/medical technologists. If a direct AHG test is performed on tissue, the specimen is processed by a histologic technician and the tissue is examined under the microscope by a pathologist. The pathologist writes an interpretative report of the microscopic finding.

Antihistamines

Definition

Antihistamines are drugs that block the action of histamine (a compound released in allergic inflammatory reactions) at the H₁ receptor sites, responsible for immediate hypersensitivity reactions such as sneezing and itching. Members of this class of drugs may also be used for their side effects, including sedation and antiemesis (prevention of nausea and vomiting).

Purpose

Antihistamines provide their primary action by blocking histamine H₁ at the receptor site. They have no effect on rate of histamine release, nor do they inactivate histamine. By inhibiting the activity of histamine, they

can reduce capillary fragility, which produces the erythema, or redness, associated with allergic reactions. They will also reduce histamine-induced secretions, including excessive tears and salivation. Additional effects vary with the individual drug used. Several of the older drugs, called first-generation antihistamines, bind non-selectively to H₁ receptors in the **central nervous system** as well as to peripheral receptors, and can produce sedation, inhibition of nausea and vomiting, and reduction of motion sickness. The second-generation antihistamines bind only to peripheral H₁ receptors, and reduce allergic response with little or no sedation.

The first-generation antihistamines may be divided into several chemical classes. The side effect profile, which also determines the uses of the drugs, will vary by chemical class. The alkylamines include brompheniramine (Dimetapp) and chlorpheniramine (Chlor-Trimeton). These agents cause relatively little sedation, and are used primarily for treatment of allergic reactions. Promethazine (Phenergan), in contrast, is a phenothiazine, chemically related to the major tranquilizers, and while it is used for treatment of **allergies**, may also be used as a sedative, to relieve **anxiety** prior to surgery, as an anti-nauseant, and for control of motion sickness. Diphenhydramine (Benadryl) is chemically an ethanolamine, and in addition to its role in reducing allergic reactions, may be used as a nighttime sedative, for control of drug-induced parkinsonism, and, in liquid form, for control of coughs. Consult more detailed references for further information.

The second generation antihistamines have no central action, and are used only for treatment of allergic reactions. These are divided into two chemical classes. Cetirizine (Zyrtec) is a piperazine derivative, and has a slight sedative effect. Loratidine (Claritin) and fexofenadine (Allegra) are members of the piperadine class and are essentially non-sedating.

Recommended dosage

Dosage varies with drug, patient, and intended use. Consult more detailed references for further information.

When used for control of allergic reactions, antihistamines should be taken on a regular schedule, rather than on an as-needed basis, since they have no effect on histamine itself, nor on histamine already bound to the receptor site.

Efficacy is highly variable from patient to patient. If an antihistamine fails to provide adequate relief, switch to a drug from a different chemical class. Individual drugs may be effective in no more than 40% of patients, and provide 50% relief of allergic symptoms.

ANTIHISTAMINES	
<i>Brand Name (Generic Name)</i>	<i>Possible Common Side Effects Include:</i>
*Atarax (hydroxyzine hydrochloride)	Drowsiness, dry mouth
Benadryl (diphenhydramine hydrochloride)	Dizziness, sleepiness, upset stomach, decreased coordination
Hismanal (astemizole)	Drowsiness, dry mouth, fatigue, weight gain
PBZ-SR (tripelennamine hydrochloride)	Dizziness, drowsiness, dry mouth and throat, chest congestion, decreased coordination, upset stomach
Periactin (cyproheptadine hydrochloride)	Chest congestion, dizziness, fluttery heartbeat, loss of appetite, hives, sleepiness, vision problems
Phenergan (promethazine hydrochloride)	Changes in blood pressure, dizziness, blurred vision, nausea, rash
Polaramine (dexchlorpheniramine maleate)	Drowsiness
Seldane, Seldane-D (terfenadine)	Upset stomach, nausea, drowsiness, headache, fatigue
Tavist (clemastine fumarate)	Decreased coordination, dizziness, upset stomach
Trinalin Repetabs (azatadine maleate, pseudoephedrine sulfate)	Abdominal cramps, chest pain, dry mouth, headache
*Also used in the treatment of anxiety	

(Illustration by Standley Publishing. Courtesy of Gale Group.)

Side effects

The frequency and severity of adverse effects will vary between drugs. Not all adverse reactions will apply to every member of this class.

Central nervous system reactions include drowsiness, sedation, dizziness, faintness, disturbed coordination, lassitude, confusion, restlessness, excitation, tremor, seizures, headache, insomnia, euphoria, blurred **vision**, hallucinations, disorientation, disturbing dreams/nightmares, schizophrenic-like reactions, weakness, vertigo, hysteria, nerve **pain**, and convulsions. Overdoses may cause involuntary movements. Other problems have been reported.

Gastrointestinal problems include increased appetite, decreased appetite, nausea, vomiting, **diarrhea**, and constipation.

Hematologic reactions are rare, but may be severe. These include anemia, or breakdown of red **blood** cells; reduced platelets; reduced white cells; and bone marrow failure.

A large number of additional reactions have been reported. Not all apply to every drug, and some reactions may not be drug related. Some of the other adverse effects are chest tightness; wheezing; nasal stuffiness; dry mouth, nose and throat; **sore throat**; respiratory depression; sneezing; and a burning sensation in the nose.

When taking antihistamines during **pregnancy**, Chlorpheniramine (Chlor-Trimeton), dexchlorpheniramine (Polaramine), diphenhydramine (Benadryl), brompheniramine (Dimetapp), cetirizine (Zyrtec), cyproheptadine (Periactin), clemastine (Tavist), azatadine (Optimine), and loratadine (Claritin) are all listed as category B. Azelastine (Astelin), hydroxyzine (Atarax), and promethazine (Phenergan) are category C.

Regardless of chemical class of the drug, it is recommended that mothers not breast feed while taking antihistamines.

Contraindications

The following are absolute or relative contraindications to use of antihistamines. The significance of the contraindication will vary with the drug and dose.

KEY TERMS

Allergen—A substance that causes an allergy.

Anaphylaxis—A sudden, life-threatening allergic reaction.

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Histamine—A chemical released from cells in the immune system as part of an allergic reaction.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

- glaucoma
- hyperthyroidism (overactive thyroid)
- high **blood pressure**
- enlarged prostate
- heart disease
- ulcers or other **stomach** problems
- stomach or intestinal blockage
- liver disease
- kidney disease
- bladder obstruction
- diabetes

Interactions

Drug interactions will vary with the chemical class of antihistamine. In general, antihistamines will increase the effects of other sedatives, including alcohol.

Monoamine oxidase inhibitor antidepressants (phenelzine [Nardil], tranylcypromine [Parnate]) may prolong and increase the effects of some antihistamines. When used with promethazine (Phenergan) this may cause reduced blood pressure and involuntary movements.

Antihypertensive drugs

Definition

Antihypertensive drugs are medicines that help lower **blood pressure**.

Purpose

The overall class of antihypertensive agents lowers **blood pressure**, although the mechanisms of action vary greatly. Within this therapeutic class, there are several subgroups. There are a very large number of drugs used to control **hypertension**, and the drugs listed below are representatives, but not the only members of their classes.

The **calcium** channel blocking agents, also called slow channel blockers or calcium antagonists, inhibit the movement of ionic calcium across the cell membrane. This reduces the force of contraction of muscles of the **heart** and arteries. Although the calcium channel blockers are treated as a group, there are four different chemical classes, leading to significant variations in the activity of individual drugs. Nifedipine (Adalat, Procardia) has the greatest effect on the **blood vessels**, while verapamil (Calan, Isoptin) and diltiazem (Cardizem) have a greater effect on the heart muscle itself.

Peripheral vasodilators such as hydralazine (Apresoline), isoxuprine (Vasodilan), and minoxidil (Loniten) act by relaxing blood vessels.

There are several groups of drugs which act by reducing adrenergic nerve stimulation, the excitatory nerve stimulation that causes contraction of the muscles in the arteries, veins, and heart. These drugs include the beta-adrenergic blockers and alpha/beta adrenergic blockers. There are also non-specific adrenergic blocking agents.

Beta-adrenergic blocking agents include propranolol (Inderal), atenolol (Tenormin), and pindolol (Visken). Propranolol acts on the beta-adrenergic receptors any-

ANTIHYPERTENSIVE DRUGS	
Brand Name (Generic Name)	Possible Common Side Effects Include:
Accupril (quinapril hydrochloride)	Headache, dizziness
Aldactazide	Diarrhea, fever, headache, decreased coordination
Aldactone (spironolactone)	Cramps, drowsiness, stomach disorders
Aldomet (methyldopa)	Fluid retention, headache, weak feeling
Altace (ramipril)	Headache, cough
Calan, Calan SR (verapamil hydrochloride)	Constipation, fatigue, decreased blood pressure
Capoten (captopril)	Decreased sense of taste, decreased blood pressure itching, rash
Capozide	Decreased sense of taste, decreased blood pressure, itching, rash
Cardene (nicardipine hydrochloride)	Dizziness, headache, indigestion and nausea, increased heartbeat
Cardizem (diltiazem hydrochloride)	Dizziness, fluid retention, headache, nausea, skin rash
Cardura (doxazosin mesylate)	Dizziness, fatigue, drowsiness, headache
Catapres	Dry mouth, drowsiness, dizziness, constipation
Corgard (nadolol)	Behaviorial changes, dizziness, decreased heartbeat, tiredness
Corzide	Dizziness, decreased heartbeat, fatigue, cold hands and feet
Diuril (chlorothiazide)	Cramps, constipation or diarrhea, dizziness, fever, increased glucose level in urine
Dyazide	Blurred vision, muscle and abdominal pain, fatigue
DynaCirc (isradipine)	Chest pain, fluid retention, headache, fatigue
HydroDIURIL (hydrochlorothiazide)	Upset stomach, headache, cramps, loss of appetite
Hygroton (chlorthalidone)	Anemia, constipation or diarrhea, cramps, itching
Hytrin (terazosin hydrochloride)	Dizziness, labored breathing, nausea, swelling
Inderal (propranolol hydrochloride)	Constipation or diarrhea, tingling sensation, nausea and vomiting
Inderide	Blurred vision, cramps, fatigue, loss of appetite
Lasix (furosemide)	Back and muscle pain, indigestion, nausea
Lopressor (metoprolol tartrate)	Diarrhea, itching/rash, tiredness
Lotensin (benazepril hydrochloride)	Nausea, dizziness, fatigue, headache

(Illustration by Standley Publishing. Courtesy of Gale Group.)

ANTIHYPERTENSIVE DRUGS (continued)	
Brand Name (Generic Name)	Possible Common Side Effects Include:
Alozol (indapamide)	Anxiety, headache, loss of energy, muscle cramps
Maxzide	Cramps, labored breathing, drowsiness, irritated stomach
Minipress (prazosin hydrochloride)	Headache, nausea, weakness, dizziness
Moduretic	Diarrhea, fatigue, itching, loss of appetite
Monopril (fosinopril sodium)	Nausea and vomiting, headache, cough
Normodyne (labetalol hydrochloride)	Fatigue, nausea, stuffy nose
Norvasc (amlodipine besylate)	Fluid retention, fatigue, dizziness, headache
Plendil (felodipine)	Pain in back, chest, muscles, joints, and abdomen, itching, dry mouth, respiratory problems
Procardia, Procardia X (nifedipine)	Swelling, constipation, decreased blood pressure, nausea, fatigue
Sectral (acebutolol hydrochloride)	Constipation or diarrhea, gas, chest and joint pain
Ser-Ap-Es	Blurred vision, cramps, muscle pain, dizziness
Tenex (guanfacine hydrochloride)	Headache, constipation, dry mouth, weakness
Tenoretic	Decreased heartbeat, fatigue, nausea
Tenormin (atenolol)	Nausea, fatigue, dizziness
Veseretic	Diarrhea, muscle cramps, rash
Vasotec (enalapril maleate)	Chest pain, blurred vision, constipation or diarrhea, hives, nausea
Visken (pindolol)	Muscle cramps, labored breathing, nausea, fluid retention
Wytensin (guanabenz acetate)	Headache, drowsiness, dizziness
Zaroxolyn (metolazone)	Constipation or diarrhea, chest pain, spasms, nausea
Zestoretic (lisinopril hydrochlorothiazide)	Fatigue, headache, dizziness
Zestril (lisinopril)	Labored breathing, abdominal and chest pain, nausea, decreased blood pressure

(Illustration by Standley Publishing. Courtesy of Gale Group.)

where in the body, and has been used as a treatment for emotional **anxiety** and rapid heart beat. Atenolol and acebutolol (Sectral) act specifically on the nerves of the heart and circulation.

There are two alpha/beta adrenergic blockers, labetalol (Normodyne, Trandate) and carvedilol (Coreg). These work similarly to the beta blockers.

Angiotensin-converting enzyme inhibitors (ACE inhibitors) act by inhibiting the production of angiotensin II, a substance that both induces constriction of blood vessels and retention of sodium, which leads to water retention and increased blood volume. There are 10 ACE inhibitors currently marketed in the United States, including captopril (Capoten), benazepril (Lotensin),

KEY TERMS

Adrenergic—Activated by adrenalin (norepinephrine), loosely applied to the sympathetic nervous system responses.

Angioedema—An allergic skin disease characterized by patches of circumscribed swelling involving the skin and its subcutaneous layers, the mucous membranes, and sometimes the viscera—called also angioneurotic edema, giant urticaria, Quincke's disease, or Quincke's edema.

Arteries—Blood vessels that carry blood away from the heart to the cells, tissues, and organs of the body.

Laryngospasm—Spasmodic closure of the larynx.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Sympathetic nervous system—The part of the autonomic nervous system that is concerned especially with preparing the body to react to situations of stress or emergency; it contains chiefly adrenergic fibers and tends to depress secretion, decrease the tone and contractility of smooth muscle, and increase heart rate.

enalapril (Vasotec), and quinapril (Acupril). The primary difference between these drugs is their onset and duration of action.

The ACE II inhibitors, losartan (Cozaar), candesartan (Atacand), irbesartan (Avapro), telmisartan (Micardis), valsartan (Diovan) and eprosartan (Teveten) directly inhibit the effects of ACE II rather than blocking its production. Their actions are similar to the ACE inhibitors, but they appear to have a more favorable side effect and safety profile.

In addition to these drugs, other classes of drugs have been used to lower blood pressure, most notably the thiazide diuretics. There are 12 thiazide diuretics marketed in the United States, including hydrochlorothiazide

(Hydrodiuril, Esidrex), indapamide (Lozol), polythiazide (Renese), and hydroflumethiazide (Diucardin). The drugs in this class appear to lower blood pressure through several mechanisms. By promoting sodium loss they lower blood volume. At the same time, the pressure of the walls of blood vessels, the peripheral vascular resistance, is lowered. Thiazide diuretics are commonly used as the first choice for reduction of mild hypertension, and may be used in combination with other antihypertensive drugs.

Recommended dosage

Recommended dosage varies with patient, drug, severity of hypertension, and whether the drug is being used alone or in combination with other drugs. Consult specialized references for further information.

Precautions

Because of the large number of classes and individual drugs in this group, consult specialized references for complete information.

Peripheral vasodilators may cause dizziness and orthostatic hypotension—a rapid lowering of blood pressure when the patient stands up in the morning. Patients taking these drugs must be instructed to rise from bed slowly. **Pregnancy** risk factors for this group are generally category C. Hydralazine has been shown to cause cleft palate in animal studies, but there is no human data available. Breastfeeding is not recommended.

ACE inhibitors are generally well tolerated, but may rarely cause dangerous reactions including laryngospasm and angioedema. Persistent cough is a common side effect. ACE inhibitors should not be used in pregnancy. When used in pregnancy during the second and third trimesters, ACE inhibitors can cause injury to and even death in the developing fetus. When pregnancy is detected, discontinue the ACE inhibitor as soon as possible. Breastfeeding is not recommended.

ACE II inhibitors are generally well tolerated and do not cause cough. Pregnancy risk factor is category C during the first trimester and category D during the second and third trimesters. Drugs that act directly on the renin-angiotensin system can cause fetal and neonatal morbidity and death when administered to pregnant women. Several dozen cases have been reported in patients who were taking ACE inhibitors. When pregnancy is detected, discontinue ACE inhibitors as soon as possible. Breastfeeding is not recommended.

Thiazide diuretics commonly cause potassium depletion. Patients should have potassium supplementation either through diet, or potassium supplements. Pregnancy risk factor is category B (chlorothiazide, chlorthalidone, hydrochlorothiazide, indapamide, metolazone) or category C (bendroflumethiazide, benzthiazide, hydroflumethiazide, methyclothiazide, trichlormethiazide). Routine use during normal pregnancy is inappropriate. Thiazides are found in breast milk. Breastfeeding is not recommended.

Beta blockers may cause a large number of adverse reactions including dangerous heart rate abnormalities. Pregnancy risk factor is category B (acebutolol, pindolol, sotalol) or category C (atenolol, labetalol, esmolol, metoprolol, nadolol, timolol, propranolol, penbutolol, carteolol, bisoprolol). Breastfeeding is not recommended.

Interactions

Consult specific references for food and drug interactions.

Antiparkinson drugs

Definition

Antiparkinson drugs are medicines that relieve the symptoms of **Parkinson's disease** and other forms of parkinsonism.

Purpose

Antiparkinson drugs are used to treat symptoms of parkinsonism, a group of disorders that share four main symptoms: tremor or trembling in the hands, arms, legs, jaw, and face; stiffness or rigidity of the arms, legs, and trunk; slowness of movement (bradykinesia); and poor balance and coordination. Parkinson's disease is the most common form of parkinsonism and is seen more frequently with advancing age. Other forms of the disorder may result from viral infections, environmental toxins, **carbon monoxide poisoning**, and the effects of treatment with **antipsychotic drugs**.

ANTIPARKINSON DRUGS

<i>Brand Name (Generic Name)</i>	<i>Possible Common Side Effects Include:</i>
Artane (trihexyphenidyl hydrochloride)	Dry mouth, nervousness, blurred vision, nausea
Benadryl (diphenhydramine hydrochloride)	Dizziness, sleepiness, upset stomach, decreased coordination
Cogentin (benztropine mesylate)	Constipation, dry mouth, nausea and vomiting, rash
Eldepryl (selegiline hydrochloride)	Abdominal and back pain, drowsiness, decreased coordination
Parlodel (bromocriptine mesylate)	Constipation, decreased blood pressure, abdominal cramps
Sinemet CR	Involuntary body movements, confusion, nausea, hallucinations

(Illustration by Standley Publishing. Courtesy of Gale Group.)

The immediate cause of Parkinson's disease or parkinsonian-like syndrome is the lack of the neurotransmitter dopamine in the **brain**. Drug therapy may take several forms, including replacement of dopamine, inhibition of dopamine **metabolism** to increase the effects of the dopamine already present, or sensitization of dopamine receptors. Drugs may be used singly or in combination.

Description

Levodopa (Larodopa) is the mainstay of Parkinson's treatment. The drug crosses the blood-brain barrier, and is converted to dopamine. The drug may be administered alone, or in combination with carbidopa (Lodosyn) which inhibits the enzyme responsible for the destruction of levodopa. The limitation of levodopa or levodopa-carbidopa therapy is that after approximately two years of treatment, the drugs cease to work reliably. This has been termed the "on-off phenomenon." Additional treatment strategies have been developed to retard the progression of parkinsonism, or to find alternative approaches to treatment.

Anticholinergic drugs reduce some of the symptoms of parkinsonism, and reduce the reuptake of dopamine, thereby sustaining the activity of the natural neurohormone. They may be effective in all stages of

KEY TERMS

Anorexia—Lack or loss of appetite.

Anticholinergic—An agent that blocks the parasympathetic nerves and their actions.

Bradykinesia—Extremely slow movement.

Bruxism—Compulsive grinding or clenching of the teeth, especially at night.

Carbon monoxide—A colorless, odorless, highly poisonous gas.

Central nervous system—The brain, spinal cord and nerves throughout the body.

Chronic—A word used to describe a long-lasting condition. Chronic conditions often develop gradually and involve slow changes.

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Heat stroke—A severe condition caused by prolonged exposure to high heat. Heat stroke interferes with the body's temperature regulating abilities and can lead to collapse and coma.

Parkinsonism—A group of conditions that all have these typical symptoms in common: tremor, rigidity, slow movement, and poor balance and coordination.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Seizure—A sudden attack, spasm, or convulsion.

Spasm—Sudden, involuntary tensing of a muscle or a group of muscles.

Tremor—Shakiness or trembling.

the disease. All drugs with anticholinergic properties, the naturally occurring belladonna alkaloids (atropine, scopolamine, hyoscyamine), some **antihistamines** with anticholinergic properties, and synthetics such as benzotropin (Cogentin), procyclidine (Kemadrin) and biperiden (Akineton) are members of this group. Although the anticholinergic drugs have only limited activity against Parkinson's disease, they are useful in the early stages, and may be adjuncts to levodopa as the disease progresses.

Amantadine (Symmetrel), was developed for prevention of **influenza virus infection**, but has anti-Parkinsonian properties. Its mechanism of action is not known.

Bromocriptine (Parlodel) is a prolactin inhibitor, which is used for a variety of indications including amenorrhea/galactorrhea, female **infertility**, and acromegaly. It appears to work by direct stimulation of the dopamine receptors. Bromocriptine is used as a late adjunct to levodopa therapy, and may permit reduction in levodopa dosage. Pergolide (Permax) is similar to bromocriptine, but has not been studied as extensively in Parkinson's disease.

Entacapone (Comtan) appears to act by maintaining levels of dopamine through enzyme inhibition. It is used as an adjunct to levodopa as the patient is beginning to experience the on-off effect. Tolcapone (Tasmar) is a similar agent, but has demonstrated the potential for inducing severe **liver** failure. As such, tolcapone is reserved for cases where all other adjunctive therapies have failed or are contraindicated.

Selegeline (Carbex, Eldepryl) is a selective monoamine oxidase B (MAO-B) inhibitor, however its mechanism of action in Parkinsonism is unclear, since other drugs with MAO-B inhibition have failed to show similar anti-parkinsonian effects. Selegeline is used primarily as an adjunct to levodopa, although some studies have indicated that the drug may be useful in the early stages of Parkinsonism, and may delay the progression of the disease.

Pramipexole (Mirapex) and ropinirole (Requip) are believed to act by direct stimulation of the dopamine receptors in the brain. They may be used alone in early Parkinson's disease, or as adjuncts to levodopa in advanced stages.

Recommended dosage

Dosages of anti-parkinsonian medications must be highly individualized. All doses must be carefully titrated. Consult specific references.

Precautions

There are a large number of drugs and drug classes used to treat Parkinson's disease, and individual references should be consulted. The most common side effects are associated with the **central nervous system**, and include dizziness, lightheadedness, mood changes and hallucinations. Gastrointestinal problems, including nausea and vomiting, are also common.

The anticholinergics have a large number of adverse effects, all related to their primary mode of activity. Their cardiovascular effects include tachycardia, palpitations, hypotension, postural hypotension, and mild bradycardia. They may also cause a wide range of central nervous system effects, including disorientation, confusion, **memory** loss, hallucinations, psychoses, agitation, nervousness, delusions, delirium, paranoia, euphoria, excitement, lightheadedness, dizziness, headache, listlessness, depression, drowsiness, weakness, and giddiness. Dry mouth, dry eyes and gastrointestinal distress are common problems. Sedation has been reported with some drugs in this group, but this may be beneficial in patients who suffer from insomnia. **Pregnancy** risk factor is C. Because anticholinergic drugs may inhibit milk production, their use during breastfeeding is not recommended. Patients should be warned that anticholinergic medications will inhibit perspiration, and so **exercise** during periods of high temperature should be avoided.

Levodopa has a large number of adverse effects. Anorexia, loss of appetite, occurs in roughly half the patients using this drug. Symptoms of gastrointestinal upset, such as nausea and vomiting, have been reported in 80% of cases. Other reported effects include increased hand tremor, headache, dizziness, numbness, weakness and faintness, **bruxism**, confusion, insomnia, nightmares, hallucinations and delusions, agitation and **anxiety**, malaise, fatigue, and euphoria. Levodopa has not been listed under the pregnancy risk factor schedules, but should be used with caution. Breastfeeding is not recommended.

Amantadine is generally well tolerated, but may cause dizziness and nausea. It is classified as pregnancy schedule C. Since amantadine is excreted in breast milk, breastfeeding while taking amantadine is not recommended.

Pergolide and bromocriptine have been generally well tolerated. Orthostatic hypotension is a common

problem, and patients must be instructed to risk slowly from bed. This problem can be minimized by low initial doses with small dose increments. Hallucinations may be a problem. Bromocriptine has not been evaluated for pregnancy risk, while pergolide is category B. Since both drugs may inhibit **lactation**, breastfeeding while taking these drugs is not recommended.

Pramipexole and ropinirole cause orthostatic hypotension, hallucinations and dizziness. The two drugs are in pregnancy category C. In animals, ropinirole has been shown to have adverse effects on embryo-fetal development, including teratogenic effects, decreased fetal body weight, increased fetal death and digital malformation. Because these drugs inhibit prolactin secretion, they should not be taken while breastfeeding.

Interactions

All anti-parkinsonian regimens should be carefully reviewed for possible **drug interactions**. Note that combination therapy with anti-parkinsonian drugs is, in itself, use of additive and potentiating interactions between drugs, and so careful dose adjustment is needed whenever a drug is added or withdrawn.

Antipsychotic drugs

Definition

Antipsychotic drugs are a class of medicines used to treat psychosis and other mental and emotional conditions.

Purpose

Psychosis is defined as "a serious mental disorder (as **schizophrenia**) characterized by defective or lost contact with reality often with hallucinations or delu-

KEY TERMS

Agranulocytosis—An acute condition marked by severe depression of the bone marrow, which produces white blood cells, and by prostration, chills, swollen neck, and sore throat sometimes with local ulceration. Also called agranulocytic angina or granulocytopenia.

Anticholinergic—Blocking the action of the neurohormone acetylcholine. The most obvious effects include dry mouth and dry eyes.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies, or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies, or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

sions.” Psychosis is an end-stage condition arising from a variety of possible causes. Anti-psychotic drugs control the symptoms of psychosis, and in many cases are effective in controlling the symptoms of other disorders that may lead to psychosis, including bipolar mood disorder (formerly termed manic-depressive), in which the patient cycles from severe depression to feelings of extreme excitation. This class of drugs is primarily composed of the major tranquilizers; however, lithium carbonate, a drug that is largely specific to bipolar mood disorder, is commonly classified among the antipsychotic agents.

Description

The antipsychotic agents may be divided by chemical class. The phenothiazines are the oldest group, and include chlorpromazine (Thorazine), mesoridazine (Serentil), prochlorperazine (Compazine), and thioridazine (Mellaril). These drugs are essentially similar in action and adverse effects. They may also be used as anti-emetics, although prochlorperazine is the drug most often used for this indication.

The phenylbutylpiperadines are haloperidol (Haldol) and pimozide (Orap). They find primary use in control of Tourette’s syndrome. Haloperidol has been extremely useful in controlling aggressive behavior.

The debenzapine derivatives, clozapine (Clozaril), loxapine (Loxitane), olanzapine (Zyprexa) and quetiapine (Seroquel), have been effective in controlling psychotic symptoms that have not been responsive to other classes of drugs.

The benzisoxidil group is composed of resperidone (Resperidal) and ziprasidone (Geodon). Resperidone has been found useful for controlling bipolar mood disorder, while ziprasidone is used primarily as second-line treatment for schizophrenia.

In addition to these drugs, the class of antipsychotic agents includes lithium carbonate (Eskalith, Lithonate), which is used for control of bipolar mood disorder, and thiothixene (Navane), which is used in the treatment of psychosis.

Recommended dosage

Dose varies with the drug, condition being treated, and patient response. See specific references.

Precautions

Neuroleptic malignant syndrome (NMS) is a rare, idiosyncratic combination of extra-pyramidal symptoms (EPS), hyperthermia, and autonomic disturbance. Onset may be hours to months after drug initiation, but once started, proceeds rapidly over 24 to 72 hours. It is most commonly associated with haloperidol, long-acting fluphenazine, but has occurred with thiothixene, thioridazine, and clozapine, and may occur with other agents. NMS is potentially fatal, and requires intensive symptomatic treatment and immediate discontinuation of neuroleptic treatment. There is no established treatment. Most patients who develop NMS will have the same problem if the drug is restarted.

Tardive dyskinesia (TD) is a syndrome of involuntary movements that may appear in patients treated with neuroleptic drugs. Although prevalence of TD appears highest among the elderly, especially women, it is impossible to predict which patients are likely to develop the syndrome. Both the risk of developing TD and the likelihood that it will become irreversible are increased with higher doses and longer periods of treatment. The syndrome can develop after short treatment periods at low doses. Anticholinergic agents may worsen these effects. Clozapine has occasionally been useful in controlling the TD caused by other antipsychotic drugs.

Agranulocytosis has been associated with clozapine. This is a potentially fatal reaction, but can be prevented with careful monitoring of the white **blood** count. There are no well-established risk factors for developing agranulocytosis, and so all patients treated with this drug must

ANTIPSYCHOTIC DRUGS	
Brand Name (Generic Name)	Possible Common Side Effects Include:
Clozaril (clozapine)	Seizures, agranulocytosis, dizziness, increased blood pressure
Compazine (prochlorperazine)	Involuntary muscle spasms, dizziness, jitteriness, puckering of the mouth
Haldol (haloperidol)	Involuntary muscle spasms, blurred vision, dehydration, headache, puckering of the mouth
Mellaril (thioridazine)	Involuntary muscle spasms, constipation and diarrhea, sensitivity to light
Navane (thiothixene)	Involuntary muscle spasms, dry mouth, rash, hives
Risperdal (risperidone)	Involuntary muscle spasms, abdominal and chest pain, fever, headache
Stelazine (trifluoperazine hydrochloride)	Involuntary muscle spasms, drowsiness, fatigue
Thorazine (chlorpromazine)	Involuntary muscle spasms, labored breathing, fever, puckering of the mouth
Triavil	Involuntary muscle spasms, disorientation, excitability, lightheadedness

(Illustration by Standley Publishing. Courtesy of Gale Group.)

follow the clozapine Patient Management System. For more information, call 1-800-448-5938.

Anticholinergic effects, particularly dry mouth, have been reported with all of the phenothiazines, and can be severe enough to cause patients to discontinue their medication.

Photosensitization is a common reaction to chlorpromazine. Patients must be instructed to use precautions when exposed to sunlight.

Lithium carbonate commonly causes increased frequency of urination.

Antipsychotic drugs are **pregnancy** category C. (Clozapine is category B.) The drugs in this class appear to be generally safe for occasional use at low doses during pregnancy, but should be avoided near time of delivery. Although the drugs do not appear to be teratogenic, when used near term, they may cross the placenta and have adverse effects on the newborn infant, including causing involuntary movements. There is no information about safety in breastfeeding.

As a class, the antipsychotic drugs have a large number of potential side effects, many of them serious. Specific references should be consulted.

Drug interactions

Because the phenothiazines have anticholinergic effects, they should not be used in combination with other drugs that may have similar effects.

Because the drugs in this group may cause hypotension, or low **blood pressure**, they should be used with extreme care in combination with blood pressure-lowering drugs.

The antipsychotic drugs have a large number of **drug interactions**. Consult specific references.

Samuel D. Uretsky, PharmD

Antiretroviral drugs

Definition

Antiretroviral drugs inhibit the reproduction of retroviruses—viruses composed of RNA rather than DNA. The best known of this group is HIV, human **immunodeficiency** virus, the causative agent of **AIDS**.

Purpose

Antiretroviral agents are virustatic agents which block steps in the replication of the virus. The drugs are not curative; however continued use of drugs, particularly in multi-drug regimens, significantly slows disease progression.

Description

There are three main types of antiretroviral drugs, although only two steps in the viral replications process are blocked. Nucleoside analogs, or nucleoside reverse transcriptase inhibitors (NRTIs), such as didanosine (ddI, Videx), lamivudine (3TC, Epivir), stavudine (d4T, Zerit), zalcitabine (ddC, Hivid), and zidovudine (AZT, Retrovir), act by inhibiting the enzyme reverse transcriptase. Because a retrovirus is composed of RNA, the virus must make a DNA strand in order to replicate itself. Reverse transcriptase is an enzyme that is essential to making the DNA copy. The nucleoside reverse transcriptase inhibitors are incorporated into the DNA strand. This is a faulty DNA molecule which is incapable of reproducing.

The non-nucleoside reverse transcriptase inhibitors (NNRTIs), such as delavirdine (Rescriptor), loviride, and nevirapine (Viramune) act by binding directly to the reverse transcriptase molecule, inhibiting its activity.

Protease inhibitors, such as indinavir (Crixivan), nelfinavir (Viracept), ritonavir (Norvir), and saquinavir (Invirase) act on the enzyme protease, which is essential for the virus to break down the **proteins** in infected cells. Without this essential step, the virus produces immature copies of itself, which are non-infectious.

Because HIV mutates readily, the virus can develop resistance to single drug therapy. However, treatment with drug combinations appears to produce a durable response. Proper treatment appears to slow the progression of HIV infections and reduce the frequency of opportunistic infections.

Recommended dosage

Doses must be individualized based on the patient, and use of interacting drugs. The optimum combinations of antiretroviral drugs have not been determined, nor is there agreement on the stage of **infection** at which to start treatment.

Precautions

Although the antiretroviral drugs fall into three groups, each drug has a unique pattern of adverse effects and **drug interactions**. Since the drugs are used in vari-

KEY TERMS

Antiviral drugs—Medicines that cure or control virus infections.

Bioavailability—A measure of the amount of drug that is actually absorbed from a given dose.

Immune system—The body's natural defenses against disease and infection.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Insomnia—A sleep disorder characterized by inability to either fall asleep or to stay asleep.

Mutates—Undergoes a spontaneous change in the make-up of genes or chromosomes.

Pancreas—A gland located beneath the stomach. The pancreas produces juices that help break down food and secretes insulin that helps the body use sugar for energy.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Retrovirus—A virus composed of ribonucleic acid (RNA) instead of deoxynucleic acid (DNA).

Virus—A tiny, disease-causing particle that can reproduce only in living cells.

ous combinations, the frequency and severity of adverse effects will vary with the combination. Although most drug combinations show a higher rate of adverse events than single drug therapy, some patterns are not predictable. For example, indinavir has been reported to cause insomnia in 3% of patients, however, when used in combination with zidovudine, only 1.5% of patients complained of sleep difficulties.

The most severe adverse effects associated with the protease inhibitors are renal and hepatic toxicity. Patients have also reported a syndrome of abdominal distention and increased body odor, which may be socially limiting.

Hemophilic patients have reported increased bleeding tendencies while taking protease inhibitors. The drugs are **pregnancy** category B. There have been no controlled studies of safety in pregnancy. HIV-infected mothers are advised not to breast feed in order to prevent transmission of the virus to the newborn.

The nucleoside reverse transcriptase inhibitors have significant levels of toxicity. Lactic acidosis in the absence of hypoxemia and severe hepatomegaly with steatosis have been reported with zidovudine and zalcitabine, and are potentially fatal. Rare cases of hepatic failure, considered possibly related to underlying hepatitis B and zalcitabine monotherapy, have been reported.

Abacavir has been associated with fatal hypersensitivity reactions. Didanosine has been associated with severe **pancreatitis**. Nucleoside reverse transcriptase inhibitors are pregnancy category C. There is limited information regarding safety during pregnancy. Zidovudine has been used during pregnancy to reduce the risk of HIV infection to the infant. HIV-infected mothers are advised not to breastfeed in order to prevent transmission of the virus to the newborn.

Efavirenz has been associated with a high frequency of skin rash, 27% in adults and 40% in children. Nevirapine has been associated with severe **liver** damage and skin reactions. All of the non-nucleoside reverse transcriptase inhibitors are pregnancy category C, based on animal studies.

Because of the high risk of viral resistance development, antiretroviral agents should be used in combination. If one drug in the group must be discontinued, it is recommended that all antiretroviral therapy be discontinued until a multi-drug regimen can be resumed. The non-nucleoside reverse transcriptase inhibitors particularly should not be used alone.

Interactions

Because of the high frequency of drug interactions associated with AIDS therapy, specialized references should be consulted.

Saquinavir is marketed in both hard and soft gelatin capsules. Because saquinavir in the hard gelatin capsule formulation (Invirase) has poor bioavailability, it is recommended that this formulation only be used in combination with other drugs which interact to raise saquinavir **blood** levels. Saquinavir soft gelatin capsules (Fortovase) are the preferred dosage form of this drug.

Antiseptics

Definition

An antiseptic is a substance which inhibits the growth and development of microorganisms. For practical purposes, antiseptics are routinely thought of as topical agents, for application to skin, mucous membranes, and inanimate objects, although a formal definition includes agents which are used internally, such as the urinary tract antiseptics.

Purpose

Antiseptics are a diverse class of drugs which are applied to skin surfaces or mucous membranes for their anti-infective effects. This may be either bacteriocidal or bacteriostatic. Their uses include cleansing of skin and wound surfaces after injury, preparation of skin surfaces prior to injections or surgical procedures, and routine disinfection of the oral cavity as part of a program of **oral**

Hands shown applying ointment to baby's lower back.
(Field Mark Publications. Reproduced by permission.)

hygiene. Antiseptics are also used for disinfection of inanimate objects, including instruments and furniture surfaces.

Commonly used antiseptics for skin cleaning include benzalkonium chloride, chlorhexidine, hexachlorophene, iodine compounds, mercury compounds, alcohol, and hydrogen peroxide. Other agents which have been used for this purpose, but have largely been supplanted by more effective or safer agents, include boric acid and volatile oils such as methyl salicylate (oil of wintergreen).

Chlorhexidine shows a high margin of safety when applied to mucous membranes, and has been used in oral rinses and preoperative total body washes.

Benzalkonium chloride and hexachlorophene are used primarily as hand scrubs or face washes. Benzalkonium may also find application as a disinfecting agent for instruments, and in low concentration as a preservative for drugs including ophthalmic solutions. Benzalkonium chloride is inactivated by organic compounds, including soap, and must not be applied to areas that have not been fully rinsed.

Iodine compounds include tincture of iodine and povidone iodine compounds. Iodine compounds have the broadest spectrum of all topical anti-infectives, with action against **bacteria, fungi, viruses**, spores, protozoa, and yeasts. Iodine tincture is highly effective, but its alcoholic component is drying and extremely irritating when applied to abraded (scraped or rubbed) skin. Povidone iodine, an organic compound, is less irritating and less toxic, but not as effective. Povidone iodine has been used for hand scrubs and disinfection of surgical sites. Aqueous solutions of iodine have also been used as antiseptic agents, but are less effective than alcoholic solutions and less convenient to use than the povidone iodine compounds.

Hydrogen peroxide acts through the liberation of oxygen gas. Although the antibacterial activity of hydrogen peroxide is relatively weak, the liberation of oxygen bubbles produces an effervescent action, which may be useful for wound cleansing through removal of tissue debris. The activity of hydrogen peroxide may be reduced by the presence of **blood** and pus. The appropriate concentration of hydrogen peroxide for antiseptic use is 3%, although higher concentrations are available.

Thimerosal (Mersol) is a mercury compound with activity against bacteria and yeasts. Prolonged use may result in mercury toxicity.

Recommended dosage

Dosage varies with product and intended use. Consult individualized references.

Precautions

Precautions vary with individual product and use. Consult individualized references.

Hypersensitivity reactions should be considered with organic compounds such as chlorhexidine, benzalkonium and hexachlorophene.

Skin dryness and irritation should be considered with all products, but particularly with those containing alcohol.

Systemic toxicity may result from ingestion of iodine containing compounds or mercury compounds.

Most antiseptics have not been rated according to **pregnancy** category under the pregnancy risk factor system. Hexachlorophene is schedule C during pregnancy, and should not be used on newborns due to risk of systemic absorption with potential **central nervous system** (CNS) effects, including convulsions. Avoid application of hexachlorophene to open **wounds**, mucous membranes, or areas of thin skin, such as the genitalia, since this may promote systemic absorption.

Chlorhexidine should not be instilled into the ear. There is one anecdotal report of deafness following use of chlorhexidine in a patient with a perforated eardrum. Safety in pregnancy and breastfeeding have not been reported, however there is one anecdotal report of an infant developing slowed heartbeat apparently related to maternal use of chlorhexidine.

Iodine compounds should be used sparingly during pregnancy and **lactation** due to risk of infant absorption of iodine with alterations in thyroid function.

KEY TERMS

Antibiotic—A medicine used to treat infections.

Bacteria—Tiny, one-celled forms of life that cause many diseases and infections.

Mucous membrane—The moist lining of a body cavity or structure, such as the mouth or nose.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Residue—Traces that remain after most of the rest of the material is gone.

Interactions

Antiseptics are not known to interact with any other medicines. However, they should not be used together with any other topical cream, solution, or ointment.

Antilucer drugs

Definition

Antilucer drugs are a class of drugs, exclusive of the antibacterial agents, used to treat ulcers in the **stomach** and the upper part of the **small intestine**.

Purpose

Recurrent gastric and duodenal ulcers are caused by *Helicobacter pylori* infections, and are treated with com-

bination treatments that incorporate antibiotic therapy with gastric acid suppression. Additionally, bismuth compounds have been used. The primary class of drugs used for gastric acid suppression are the proton pump inhibitors, omeprazole, lansoprazole, pantoprazole and rabeprazole. The H₂ receptor blocking agents, cimetidine, famotidine, nizatidine, and ranitidine have been used for this purpose, but are now more widely used for maintenance therapy after treatment with the proton pump inhibitors. Sucralfate, which acts by forming a protective coating over the ulcerate lesion, is also used in ulcer treatment and may be appropriate for patients in whom other classes of drugs are not indicated, or those whose gastric ulcers are caused by non-steroidal anti-inflammatory drugs (NSAIDs) rather than *H. pylori* infections.

Description

The proton pump inhibitors block the secretion of gastric acid by the gastric parietal cells. The extent of inhibition of acid secretion is dose related. In some cases, gastric acid secretion is completely blocked for over 24 hours on a single dose. In addition to their role in treatment of gastric ulcers, the proton pump inhibitors are used to treat syndromes of excessive acid secretion (Zollinger-Ellison Syndrome) and gastroesophageal reflux disease (GERD).

Histamine H₂ receptor blockers stop the action of histamine on the gastric parietal cells, inhibiting the secretion of gastric acid. These drugs are less effective than the proton pump inhibitors, but may achieve a 75–79% reduction in acid secretion. Higher rates of acid inhibition may be achieved when the drug is administered by the intravenous route. The H₂ receptor blockers may also be used to treat heartburn and hypersecretory syndromes. When given before surgery, the H₂ receptor blockers are useful in prevention of aspiration **pneumonia**.

Sucralfate (Carafate), a substituted sugar molecule with no nutritional value, does not inhibit gastric acid, but rather, reacts with existing stomach acid to form a thick coating that covers the surface of an ulcer, protecting the open area from further damage. A secondary effect is to act as an inhibitor of the digestive enzyme pepsin. Sucralfate does not bind to the normal stomach lining. The drug has been used for prevention of **stress** ulcers, the type seen in patients exposed to physical stress such as **burns** and surgery. It has no systemic effects.

ANTIULCER DRUGS	
Brand Name (Generic Name)	Possible Common Side Effects Include:
Axid (nizatidine)	Diarrhea, headache, nausea and vomiting, sore throat
Carafate (sucralfate)	Constipation, insomnia, hives, upset stomach, vomiting
Cytotec (misoprostol)	Cramps, diarrhea, nausea, gas, headache, menstrual disorders (including heavy bleeding and severe cramping)
Pepcid (famotidine)	Constipation or diarrhea, dizziness, fatigue, fever
Prilosec (omeprazole)	Nausea and vomiting, headache, diarrhea, abdominal pain
Tagamet (cimetidine)	Headache, breast development in men, depression and disorientation
Zantac (ranitidine hydrochloride)	Headache, constipation or diarrhea, joint pain

(Illustration by Standley Publishing. Courtesy of Gale Group.)

Recommended dosage

The doses of the proton pump inhibitors and H₂ receptor blockers vary depending on the drug and condition being treated. Consult individual references.

The dose of sucralfate for acute ulcer therapy is 1 gram four times a day. After the ulcer has healed, maintenance treatment may continue at 1 gram two times daily.

Precautions

The proton pump inhibitors are generally well tolerated, and the most common adverse effects are **diarrhea**, itching, skin rash, dizziness, and headache. Muscle aches and a higher than normal rate of respiratory infections are among the other adverse reactions reported. Omeprazole is classed as **pregnancy category C** due to an increased rate of fetal deaths in animal studies. The other drugs in this group are pregnancy category B. It is not known if these drugs are excreted in human milk, but because of reported adverse effects to infants in animal studies, it is recommended that proton pump inhibitors not be used by nursing mothers.

The H₂ receptor blockers vary widely in their adverse effects. Although they are generally well tolerated, cimetidine may cause confusion in elderly patients, and has an antiandrogenic effect that may cause **sexual dysfunction** in males. Famotidine has been reported to cause headache in 4.7% of patients. Nizatidine is pregnancy category C, the others are schedule B. It is advisable that mothers not take H₂ receptor blockers while nursing.

Sucralfate is well tolerated. It is poorly absorbed, and its most common side effect is constipation in 2% of patients. Diarrhea, nausea, vomiting, gastric discomfort, indigestion, flatulence, dry mouth, rash, pruritus (itching), back **pain**, headache, dizziness, sleepiness, and vertigo have been reported, as well as rare allergic responses. Because sucralfate releases small amounts of aluminum into the system, it should be used with caution in patients with renal insufficiency. Sucralfate is category B in pregnancy. There is no information available about its safety in breastfeeding.

Interactions

Proton pump inhibitors may increase the pH of the stomach. This will inactivate some antifungal drugs that require an acid medium for effectiveness, notable itraconazole and ketoconazole.

H₂ receptor blocking agents have a large number of **drug interactions**. Consult individualized references.

Sucralfate should not be used with aluminum containing **antacids**, because of the risk of increased aluminum absorption. Sucralfate may inhibit absorption and reduce **blood** levels of anticoagulants, digoxin, quinine, ketoconazole, quinolones, and phenytoin.

ORGANIZATIONS

Digestive Disease National Coalition. 507 Capitol Court NE, Suite 200, Washington, DC 20003. (202) 544-7497.

KEY TERMS

Antibiotic—Medicine used to treat infections.

Enzyme—A type of protein, produced in the body, that brings about or speeds up chemical reactions.

Gastrointestinal tract—The stomach, small intestine and large intestine.

Hypersecretory—Excessive production of a bodily secretion. The most common hypersecretory syndrome of the stomach is Zollinger-Ellison Syndrome, a syndrome consisting of fulminating intractable peptic ulcers, gastric hypersecretion and hyperacidity, and the occurrence of gastrinomas of the pancreatic cells of the islets of Langerhans.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Mucous—Thick fluid produced by the moist membranes that line many body cavities and structures.

Nonsteroidal anti-inflammatory drug (NSAID)—A type of medicine used to relieve pain, swelling, and other symptoms of inflammation, such as ibuprofen or ketoprofen.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Antiviral drugs

Definition

Antiviral drugs are medicines that cure or control virus infections.

Purpose

Antivirals are used to treat infections caused by **viruses**. Unlike antibacterial drugs, which may cover a wide range of pathogens, antiviral agents tend to be narrow in spectrum, and have limited efficacy.

Description

Exclusive of the antiretroviral agents used in HIV (**AIDS**) therapy, there are currently only 11 antiviral drugs available, covering four types of virus. Acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex) are effective against herpesvirus, including herpes zoster and herpes genitalis. They may also be of value in either conditions caused by herpes, such as chickenpox and shingles. These drugs are not curative, but may reduce the **pain** of a herpes outbreak and shorten the period of viral shedding.

Amantadine (Symmetrel), oseltamivir (Tamiflu), rimantidine (Flumadine), and zanamivir (Relenza) are useful in treatment of **influenza** virus. Amantadine, rimantidine, and oseltamivir may be administered throughout the flu season as preventatives for patients who cannot take influenza virus vaccine.

Cidofovir (Vistide), foscarnet (Foscavir), and ganciclovir (Cytovene) have been beneficial in treatment of cytomegalovirus in immunosuppressed patients, primarily HIV-positive patients and transplant recipients. Ribavirin (Virazole) is used to treat respiratory syncytial virus. In combination with interferons, ribavirin has shown some efficacy against hepatitis C, and there have been anecdotal reports of utility against other types of viral infections.

KEY TERMS

Asthenia—Muscle weakness.

Cytomegalovirus (CMV)—A type of virus that attacks and enlarges certain cells in the body. The virus also causes a disease in infants.

Herpes simplex—A virus that causes sores on the lips (cold sores) or on the genitals (genital herpes).

HIV—Acronym for human immunodeficiency virus, the virus that causes AIDS.

Parkinsonism—A group of conditions that all have these typical symptoms in common: tremor, rigidity, slow movement, and poor balance and coordination.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies, or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies, or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Prophylactic—Guarding from or preventing the spread or occurrence of disease or infection.

Retrovirus—A group of viruses that contain RNA and the enzyme reverse transcriptase. Many viruses in this family cause tumors. The virus that causes AIDS is a retrovirus.

Shingles—An disease caused by an infection with the Herpes zoster virus, the same virus that causes chickenpox. Symptoms of shingles include pain and blisters along one nerve, usually on the face, chest, stomach, or back.

Virus—A tiny, disease-causing structure that can reproduce only in living cells and causes a variety of infectious diseases.

As a class, the antivirals are not curative, and must be used either prophylactically or early in the development of an **infection**. Their mechanism of action is typically to inactivate the enzymes needed for viral replication. This will reduce the rate of viral growth, but will not inactivate the virus already present. Antiviral therapy must normally be initiated within 48 hours of the onset of an

infection to provide any benefit. Drugs used for influenza may be used throughout the influenza season in high risk patients, or within 48 hours of exposure to a known carrier. Antiherpetic agents should be used at the first signs of an outbreak. Anti-cytomegaloviral drugs must routinely be used as part of a program of secondary prophylaxis (maintenance therapy following an initial response) in order to prevent reinfection in immunocompromised patients.

Recommended dosage

Dosage varies with the drug, patient age and condition, route of administration, and other factors. See specific references.

Precautions

Ganciclovir is available in intravenous injection, oral capsules, and intraocular inserts. The capsules should be reserved for prophylactic use in organ transplant patients, or for HIV infected patients who cannot be treated with the intravenous drug. The toxicity profile of this drug when administered systemically includes granulocytopenia, anemia, and thrombocytopenia. The drug is in **pregnancy** category C, but has caused significant fetal abnormalities in animal studies, including cleft palate and organ defects. Breastfeeding is not recommended.

Cidofovir causes renal toxicity in 53% of patients. Patients should be well hydrated, and renal function should be checked regularly. Other common adverse effects are nausea and vomiting in 65% of patients, asthenia in 46% and headache and **diarrhea**, both reported in 27% of cases. The drug is category C in pregnancy, due to fetal abnormalities in animal studies. Breastfeeding is not recommended.

Foscarnet is used in treatment of immunocompromised patients with cytomegalovirus infections and in acyclovir-resistant herpes simplex virus. The primary hazard is renal toxicity. Alterations in electrolyte levels may cause seizures. Foscarnet is category C during pregnancy. The drug has caused skeletal abnormalities in developing fetuses. It is not known whether foscarnet is excreted in breast milk, however the drug does appear in breast milk in animal studies.

Valaciclovir is metabolized to acyclovir, so that the hazards of the two drugs are very similar. They are generally well tolerated, but nausea and headache are common adverse effects. They are both pregnancy category B. Although there have been no reports of fetal abnormalities attributable to either drug, the small number of reported cases makes it impossible to draw conclusions regarding safety in pregnancy. Acyclovir is found in

breast milk, but no adverse effects have been reported in the newborn. Famciclovir is similar in actions and adverse effects.

Ribavirin is used by aerosol for treatment of hospitalized infants and young children with severe lower respiratory tract infections due to respiratory syncytial virus (RSV). When administered orally, the drug has been used in adults to treat other viral diseases including acute and chronic hepatitis, herpes genitalis, measles, and Lassa fever, however there is relatively little information about these uses. In rare cases, initiation of ribavirin therapy has led to deterioration of respiratory function in infants. Careful monitoring is essential for safe use.

The anti-influenza drugs are generally well tolerated. Amantadine, which is also used for treatment of parkinsonism, may show more frequent CNS effects, including sedation and dizziness. Rapid discontinuation of amantadine may cause an increase in parkinsonian symptoms in patients using the drug for that purpose. All are schedule C for pregnancy. In animal studies, they have caused fetal malformations in doses several times higher than the normal human dose. Use caution in breastfeeding.

Interactions

Consult specific references for information on **drug interactions**.

Use particular caution in HIV-positive patients, since these patients are commonly on multi-drug regimens with a high frequency of interactions. Ganciclovir should not be used with other drugs which cause hematologic toxicity, and cidofovir should not be used with other drugs that may cause kidney damage.

Anxiety

Definition

Anxiety is a multisystem response to a perceived threat or danger. It reflects a combination of biochemical changes in the body, the patient's personal history and **memory**, and the social situation at hand. Human anxiety

involves an ability to use memory and imagination and to move backward and forward in time; a large portion of human anxiety is produced by anticipation of future events. Without a sense of personal continuity over time, people would not have the "raw materials" of anxiety.

It is important to distinguish between anxiety as a feeling or experience, and an anxiety disorder as a psychiatric diagnosis. A person may feel anxious without having an anxiety disorder.

Short-term anxiety can be considered within the range of normal human experience. It is only when anxiety presents with great intensity or long duration that it is classified as a pathological state. Particular manifestations of anxiety, such as a flashback experience, the development of a phobia, or the sudden onset of a panic attack, are suggestive of a serious anxiety problem.

Description

Although anxiety is something that everyone experiences from time to time, it is difficult to describe concretely because it has so many different potential causes and degrees of intensity. Doctors sometimes categorize anxiety as either an emotion or an affect, depending on whether it is being described by the person having it (emotion) or by an outside observer (affect). The word "emotion" is generally used for the biochemical changes and feeling state that underlie a person's internal sense of anxiety. The term "affect" is used to describe the person's emotional state from an observer's perspective. If a doctor says that a patient has an anxious affect, he or she means that the patient appears outwardly nervous or anxious, or responds to others in an anxious manner.

Although anxiety is related to fear, it is not the same thing. Fear is a direct, focused response to a specific event or object, and the person is consciously aware of it. Anxiety, on the other hand, is often vague and unfocused. In this form it is called free-floating anxiety. Sometimes anxiety being experienced in the present may stem from an event or person that produced **pain** and fear in the past, but the anxious individual is not consciously aware of the original source of the feeling. It is anxiety's aspect of remoteness that makes it hard for people to compare their experiences of it. Whereas most people will be fearful in physically dangerous situations, and can agree that fear is an appropriate response in the presence of danger, anxiety is often triggered by objects or events that are unique and specific to an individual. An individual might be anxious because of a unique meaning or memory being stimulated by present circumstances, not because of some immediate danger. Another individual looking at the anxious person from the outside may be truly puzzled as to the reason for the person's anxiety.

Generalized anxiety disorder (GAD) is the common name for a clinically confirmed diagnosis of anxiety. GAD is defined as a state in which an individual has significant worry, fear, and anxiety for a majority of the time for a period of at least six months. The anxiety present in such an individual must produce at least three significant somatic symptoms, such as impaired concentration, sleep disturbance, muscle tension, irritability, increased fatigue, or restlessness.

GAD has been estimated to occur in 4% to 7% of the population at any given time in the United States. Females are about twice as likely as males to develop GAD. Nearly one-third of cases of GAD present before 11 years of age. Half of all cases have onset before 18 years of age.

Causes and symptoms

Anxiety can have a number of different causes. It is a multidimensional response to stimuli in the person's environment, or a response to an internal stimulus (for example, a hypochondriac's reaction to a **stomach** rumbling) resulting from a combination of general biological and individual psychological processes.

Physical

In some cases, anxiety is produced by physical responses to **stress**, or by certain disease processes or medications.

THE AUTONOMIC NERVOUS SYSTEM (ANS). The nervous system is "hard-wired" to respond to dangers or threats. These responses are not subject to conscious control and are the same in humans as in lower animals. They represent an evolutionary adaptation to the animal predators and other dangers with which all animals, including primitive humans, had to cope. The most familiar reaction of this type is the so-called "fight-or-flight" reaction. This is the human organism's automatic response to a life-threatening situation, a state of physiological and emotional hyperarousal marked by high muscle tension and strong feelings of fear or anger. When people have a fight-or-flight reaction, the level of stress hormones in their **blood** rises. They become more alert and attentive, their eyes dilate, their heartbeat increases, their breathing rate increases, and their digestion slows down, allowing more energy to be available to the muscles.

This emergency reaction is regulated by a part of the nervous system called the **autonomic nervous system**, or ANS. The ANS is controlled by the hypothalamus, a specialized part of the brainstem that is among a group of structures called the limbic system. The limbic system controls human emotions through its connections to

glands and muscles; it also connects to the ANS and "higher" **brain** centers, such as parts of the cerebral cortex. One problem with this arrangement is that the limbic system cannot tell the difference between a realistic physical threat and an anxiety-producing thought or idea. The hypothalamus may trigger the release of stress hormones by the **pituitary gland**, even when there is no external and objective danger. A second problem is caused by the biochemical side effects of too many "false alarms" in the ANS. When a person responds to a real danger, his or her body gets rid of the stress hormones by running away or by fighting. In modern life, however, people often have fight-or-flight reactions in situations in which they can neither run away nor lash out physically. As a result, their bodies have to absorb all the biochemical changes of hyperarousal rather than release them. These biochemical changes can produce anxious feelings, as well as muscle tension and other physical symptoms associated with anxiety. They may even produce permanent changes in the brain, if the process occurs repeatedly. Moreover, chronic physical disorders, such as **coronary artery disease**, may be worsened by anxiety, as chronic hyperarousal puts undue stress on the **heart**, stomach, and other organs.

Other theorists attribute some drug addiction to the desire to relieve symptoms of anxiety. Most addictions, they argue, originate in the use of mood-altering substances or behaviors to "medicate" anxious feelings.

DISEASES AND DISORDERS. Anxiety can be a symptom of certain medical conditions. Some of these diseases are disorders of the **endocrine system**, such as Cushing's syndrome (overproduction of cortisol by the adrenal cortex), and include over- or underactivity of the **thyroid gland**. Other medical conditions that can produce anxiety include **respiratory distress syndrome**, mitral valve prolapse, porphyria, and chest pain caused by inadequate blood supply to the heart (angina pectoris).

MEDICATIONS AND SUBSTANCE USE. Numerous medications may cause anxiety-like symptoms as a side effect. They include birth control pills; some thyroid or **asthma** drugs; some psychotropic agents; occasionally, local anesthetics; **corticosteroids**; **antihypertensive drugs**; and **nonsteroidal anti-inflammatory drugs** (such as flurbiprofen and ibuprofen).

Although people do not usually think of **caffeine** as a drug, it can cause anxiety-like symptoms when consumed in sufficient quantity. Patients who consume caffeine-rich foods and beverages, such as chocolate, cocoa, coffee, tea, or carbonated soft drinks (especially cola beverages) can sometimes lower their anxiety symptoms simply by reducing their intake of these substances.

Withdrawal from certain prescription drugs, primarily beta blockers and corticosteroids, can cause anxiety. Withdrawal from drugs of abuse, including LSD, cocaine, alcohol, and opiates, can also cause anxiety.

Learned associations

Some aspects of anxiety appear to be unavoidable byproducts of the human developmental process. Humans are unique among animals in that they spend an unusually long period of early life in a relatively helpless condition, and a sense of helplessness can lead to anxiety. The extended period of human dependency on adults means that people may remember, and learn to anticipate, frightening or upsetting experiences long before they are capable enough to feel a sense of mastery over their environment. In addition, the fact that anxiety disorders often run in families indicates that children can learn unhealthy attitudes and behaviors from parents. Also, recurrent disorders in families may indicate that there is a genetic or inherited component in some anxiety disorders. For example, there has been found to be a higher rate of anxiety disorders (panic) in identical twins than in fraternal twins.

CHILDHOOD DEVELOPMENT AND ANXIETY. Researchers in early childhood development regard anxiety in adult life as a residue of childhood memories of dependency. Humans learn during the first year of life that they are not self-sufficient and that their basic survival depends on the care of others. It is thought that this early experience of helplessness underlies the most common anxieties of adult life, including fear of powerlessness and fear of being unloved. Thus, adults can be made anxious by symbolic threats to their sense of competence and/or significant relationships, even though they are no longer helpless children.

SYMBOLIZATION. The psychoanalytic model gives considerable weight to the symbolic aspect of human anxiety; examples include phobic disorders, obsessions, compulsions, and other forms of anxiety that are highly individualized. The length of the human maturation process allows many opportunities for children and adolescents to connect their experiences with certain objects or events that can bring back feelings in later life. For example, a person who was frightened as a child by a tall man wearing glasses may feel panicky years later by something that reminds him of that person without consciously knowing why.

PHOBIAS. Phobias are a special type of anxiety reaction in which the person's anxiety is concentrated on a specific object or situation that the person then tries to avoid. In most cases, the person's fear is out of proportion to its "cause." Prior to the *Diagnostic and Statistical*

Manual of Mental Disorders, 4th edition (*DSM-IV*), currently the model text for diagnostic criteria, these specific phobias were called simple phobias. It is estimated that 10%-11% of the population will develop a phobia in the course of their lives. Some phobias, such as agoraphobia (fear of open spaces), claustrophobia (fear of small or confined spaces), and social phobia, are shared by large numbers of people. Others are less common or unique to the patient.

Social and environmental stressors

Anxiety often has a social dimension because humans are social creatures. People frequently report feelings of high anxiety when they anticipate—and therefore fear—the loss of social approval or love. Social phobia is a specific anxiety disorder that is marked by high levels of anxiety or fear of embarrassment in social situations.

Another social stressor is prejudice. People who belong to groups that are targets of bias are at higher risk for developing anxiety disorders. Some experts assert, for example, that the higher rates of phobias and panic disorders among women reflect their greater social and economic vulnerability.

Some controversial studies indicate that the increase in violent or upsetting pictures and stories in news reports and entertainment may raise the anxiety level of many people. Stress and anxiety management programs often suggest that patients cut down their exposure to upsetting stimuli.

Anxiety may also be caused by environmental or occupational factors. People who must live or work around sudden or loud noises, bright or flashing lights, chemical vapors, or similar nuisances that they cannot avoid or control, may develop heightened anxiety levels.

Existential anxiety

Another factor that shapes human experiences of anxiety is knowledge of personal mortality. Humans are the only animals that appear to be aware of their limited life span. Some researchers think that awareness of death influences experiences of anxiety from the time that a person is old enough to understand death.

Symptoms of anxiety

In order to understand the diagnosis and treatment of anxiety, it is helpful to have a basic understanding of its symptoms.

SOMATIC. The somatic or physical symptoms of anxiety include headaches, dizziness or lightheadedness, nausea and/or vomiting, **diarrhea**, gastrointestinal prob-

lems, tingling, pale complexion, sweating, numbness, difficulty breathing or sleeping, and sensations of tightness in the chest, neck, shoulders, or hands. These symptoms are produced by the hormonal, muscular, and cardiovascular reactions involved in the fight-or-flight reaction.

BEHAVIORAL. Behavioral symptoms of anxiety include pacing, trembling, general restlessness, hyperventilation, pressured speech, hand wringing, or finger tapping.

COGNITIVE. Cognitive symptoms of anxiety include recurrent or obsessive thoughts, feelings of doom, morbid or fear-inducing thoughts or ideas, and confusion or inability to concentrate.

EMOTIONAL. Feeling states associated with anxiety include tension or nervousness, feeling “hyper” or “keyed up,” and feelings of unreality, panic, or terror.

DEFENSE MECHANISMS. In psychoanalytic theory, the symptoms of anxiety in humans may arise from or activate a number of unconscious defense mechanisms. Because of these defenses, it is possible for a person to be anxious without being consciously aware of it or appearing anxious to others. These psychological defenses include:

- **Repression.** The person pushes anxious thoughts or ideas out of conscious awareness.
- **Displacement.** Anxiety from one source is attached to a different object or event. Phobias are an example of the mechanism of displacement in psychoanalytic theory.
- **Rationalization.** The person justifies the anxious feelings by saying that any normal person would feel anxious in their situation.
- **Somatization.** The anxiety emerges in the form of physical complaints and illnesses, such as recurrent headaches, stomach upsets, or muscle and joint pain.
- **Delusion formation.** The person converts anxious feelings into conspiracy theories or similar ideas without reality testing. Delusion formation can involve groups as well as individuals.

Diagnosis

The diagnosis of anxiety is difficult and complex because of the variety of causes and the highly personalized and individualized nature of its symptom formation. When a doctor examines an anxious patient, he or she will first rule out physical conditions and diseases that have anxiety as a symptom. Apart from these exclusions, the **physical examination** is usually inconclusive. Some anxious patients may have their **blood pressure** or pulse rate affected by anxiety, or may look pale or perspire heavily, but others may appear physically normal. The

doctor will then take the patient’s medication, dietary, and occupational history to determine if they are taking prescription drugs that may cause anxiety; if they are abusing alcohol or mood-altering drugs; if they are consuming large amounts of caffeine; or if their workplace is noisy or dangerous. In most cases, patient history is the most important source of diagnostic information. The doctor may administer a brief psychological test to help evaluate the intensity of the patient’s anxiety and some of its features. Some tests that are often performed include the Hamilton Anxiety Scale and the Anxiety Disorders Interview Schedule (ADIS). Many doctors will check a number of chemical factors in the blood, such as the level of thyroid hormone and blood sugar.

The diagnosis of GAD is made when a person experiences anxiety coupled with physical symptoms that exists a majority of the time over a six-month period. The following conditions must be ruled out to confirm the GAD diagnosis:

- cardiovascular disease
- pulmonary disease
- myasthenia gravis
- alcohol and substance abuse

Treatment

Not all patients with anxiety require treatment, but for more severe cases, treatment is recommended. Because anxiety often has more than one cause and is experienced in highly individual ways, its treatment usually requires more than one type of therapy. In addition, there is no way to predict how patients will respond to a specific drug or therapy. Sometimes, the doctor will need to try different medications or methods of treatment before finding the best combination for the particular patient. It usually takes about six to eight weeks for a doctor to evaluate the effectiveness of a treatment regimen.

Medications

Medications are often prescribed to relieve the physical and psychological symptoms of anxiety. Most agents work by counteracting the biochemical and muscular changes involved in the fight-or-flight reaction. Some work directly on the chemicals in the brain that are thought to cause the anxiety.

ANXIOLYTICS. Most anxiolytic drugs (sometimes called tranquilizers) are either benzodiazepines or barbiturates. Barbiturates, once commonly used, are now rarely involved in clinical practice. Barbiturates work by slowing down the transmission of nerve impulses from

the brain to other parts of the body. They include such drugs as phenobarbital (Luminal) and pentobarbital (Nembutal). Benzodiazepines work by relaxing the **skeletal muscles** and calming the limbic system. They include such drugs as chlordiazepoxide (Librium) and diazepam (Valium). Both barbiturates and benzodiazepines are potentially habit-forming and may cause withdrawal symptoms, but benzodiazepines are far less likely than barbiturates to cause physical dependency. Benzodiazepines are associated with a high rate of anxiety relapse if use is discontinued. Both drugs also increase the effects of alcohol and should never be taken in combination with it. Longer-acting benzodiazepines, such as flurazepam and diazepam, should generally not be used in the elderly.

Two other types of anxiolytic medications include meprobamate (Equanil), which is now rarely used, and buspirone (BuSpar), a new type of anxiolytic that appears to work by increasing the efficiency of the body's own emotion-regulating brain chemicals. Buspirone has several advantages over other anxiolytics. It is not known to cause dependency, does not interact with alcohol, and does not affect the patient's ability to drive or operate machinery. Buspirone is also associated with a lower rate of relapse when use is discontinued. Buspirone is also far less likely to lead to tolerance over time than the benzodiazepines, so it is effective for a much longer period of time. However, buspirone is not effective against certain types of anxiety, such as panic disorder.

ANTIDEPRESSANTS AND BETA-BLOCKERS. For some anxiety disorders such as obsessive-compulsive disorder and panic-type anxiety, selective serotonin reuptake inhibitors (SSRIs), such as Prozac and Paxil, are the treatment of choice. SSRIs are most commonly used to treat depression. Because anxiety often coexists with symptoms of depression, many doctors prescribe antidepressant medications for anxious/depressed patients. While SSRIs are more common, antidepressants, including tricyclic antidepressants such as imipramine (Tofranil) or monoamine oxidase inhibitors (MAO inhibitors) such as phenelzine (Nardil), are prescribed. The tricyclic antidepressants are also somewhat effective in relieving insomnia in many patients.

Beta-blockers are medications that work by blocking the body's reaction to the stress hormones that are released during the fight-or-flight reaction. These include drugs like propranolol (Inderal) or atenolol (Tenormin). Beta-blockers are sometimes given to patients with post-traumatic anxiety symptoms. More commonly, the beta-blockers are given to patients with a mild form of social phobic anxiety, such as fear of public speaking.

Psychotherapy

Most patients with anxiety will be given some form of **psychotherapy** along with medication. Many patients benefit from insight-oriented therapies, which are designed to help them uncover unconscious conflicts and defense mechanisms in order to understand how their symptoms developed. Patients who are extremely anxious may benefit from supportive psychotherapy, which aims at symptom reduction rather than personality restructuring.

Two newer approaches that work well with anxious patients are cognitive-behavioral therapy (CBT) and **relaxation** training. In CBT, the patient is taught to identify the thoughts and situations that stimulate his or her anxiety, and to view them more realistically. In the behavioral part of the program, the patient is exposed to the anxiety-provoking object, situation, or internal stimulus (like a rapid heartbeat) in gradual stages until he or she is desensitized to it. Relaxation training, which is sometimes called anxiety management training, includes breathing exercises and similar techniques intended to help the patient prevent hyperventilation and relieve the muscle tension associated with the fight-or-flight reaction. Both CBT and relaxation training can be used in group therapy as well as individual treatment. In addition to CBT, support groups are often helpful to anxious patients because they provide a social network and lessen the embarrassment that often accompanies anxiety symptoms. Biofeedback training is also used in an approach similar to relaxation training.

Psychosurgery

Surgery on the brain is very rarely recommended for patients with anxiety; however, some patients with severe cases of obsessive-compulsive disorder (OCD) have been helped by an operation on a part of the brain that is involved in OCD. Normally, this operation is attempted after all other treatments have failed.

Alternative treatment

Alternative treatments for anxiety cover a variety of approaches. **Meditation** and mindfulness training are thought to be beneficial to patients with phobias and panic disorders. **Hydrotherapy** and aromatherapy can be useful to some anxious patients by promoting general relaxation of the nervous system. **Yoga**, aikido, tai chi, and **dance therapy** can help patients work with the physical, as well as the emotional, tensions that either promote anxiety or are created by the anxiety.

Prognosis

The prognosis for resolution of anxiety depends on the specific disorder and a wide variety of factors, includ-

KEY TERMS

Affect—An observed emotional expression or response. In some situations, anxiety would be considered an inappropriate affect.

Anxiolytic—A type of medication that helps to relieve anxiety.

Autonomic nervous system (ANS)—The part of the nervous system that supplies nerve endings in the blood vessels, heart, intestines, glands, and smooth muscles, and governs their involuntary functioning. The autonomic nervous system is responsible for the biochemical changes involved in experiences of anxiety.

Endocrine gland—A ductless gland, such as the pituitary, thyroid, or adrenal gland, that secretes its products directly into the blood or lymph.

Free-floating anxiety—Anxiety that lacks a definite focus or content.

Hyperarousal—A state or condition of muscular and emotional tension produced by hormones released during the fight-or-flight reaction.

Hypothalamus—A portion of the brain that regulates the autonomic nervous system, the release of hormones from the pituitary gland, sleep cycles, and body temperature.

Limbic system—A group of structures in the brain that includes the hypothalamus, amygdala, and hippocampus. The limbic system plays an important part in regulation of human moods and emotions. Many psychiatric disorders are related to malfunctioning of the limbic system.

Phobia—In psychoanalytic theory, a psychological defense against anxiety in which the patient displaces anxious feelings onto an external object, activity, or situation.

ing the patient's age, sex, general health, living situation, belief system, social support network, and responses to different anxiolytic medications and forms of therapy. Success rates using pharmacologic therapy in patients with acute anxiety is between 50% and 70%. Success rates using antidepressants in patients with chronic or generalized anxiety are lower. Anxiety disorders typically involve a complex interaction of psychologic and physiologic factors. They are not easy to treat and do not disappear with great ease. Medications, behavioral techniques, and psychotherapy can be successful to varying degrees. The best outcomes occur when the anxiety-

panic-phobia-depression cycle that is commonly found in these patients is disrupted. Anxiety should be viewed as a chronic condition that may involve an occasional increase in the severity of symptoms.

Health care team roles

Allied health personnel may be involved in the diagnosis and treatment of persons with anxiety at a variety of stages. Nurses will likely be involved in the initial interview of patients who present with anxiety. Psychological technicians may help conduct a more in-depth interview. Radiologic technicians play an important role in the process by conducting tests that help rule out conditions such as cardiovascular disease, hyperthyroidism, and myasthenia gravis. Nurse practitioners and physician assistants will often make the diagnosis of anxiety.

Pharmacists play a large role in the proper treatment of patients with anxiety because they dispense the drugs that are so important in the therapy of these patients. They also provide essential information on how to properly use these drugs to achieve peak effectiveness. Technicians may also be involved if the patient receives biofeedback, relaxation training, or cognitive-behavioral therapy.

Prevention

Humans have significant control over thoughts, and, therefore, may learn ways of preventing anxiety by changing irrational ideas and beliefs. Humans also have some power over anxiety arising from social and environmental conditions. Other forms of anxiety, however, are built into the human organism and its life cycle, and cannot be prevented or eliminated. Some cognitive-behavioral techniques may be effective in preventing more serious anxiety when applied at an early stage.

Apgar testing

Definition

Apgar testing is the assessment of the neonate rating color, **heart** rate, stimulus response, muscle tone, and respirations on a scale of zero to two, for a maximum possible score of 10. It is performed twice, first at one minute and then again at five minutes after birth.

Purpose

Apgar scoring was originally developed in the 1950s by the anesthesiologist Virginia Apgar to assist practitioners attending a birth in deciding whether or not a newborn was in need of resuscitation. Using a scoring method fosters consistency and standardization among different practitioners.

Precautions

When the neonate needs immediate intervention or resuscitation, time is not taken away from these actions in order to perform the test. The interventions (such as suctioning to remove mucus and thereby improve breathing) are begun, while simultaneously noting the scoring of the five specific areas.

Description

The five areas are scored as follows:

- Appearance, or color: 2 if the skin is pink all over; 1 for acrocyanosis, where the trunk and head are pink, but the arms and legs are blue; and 0 if the whole body is blue. Newborns with naturally darker skin color will not be pink. However, pallor is still noticeable, especially in the soles and palms. Color is related to the neonate's ability to oxygenate its body and extremities, and is dependent on heart rate and respirations. A perfectly healthy newborn will often receive a score of 9 because of some blueness in the hands and feet.
- Pulse (heart rate): 2 for a pulse of 100+ beats per minute (bpm); 1 for a pulse below 100 bpm; 0 for no pulse. Heart rate is assessed by listening with a **stethoscope** to the newborn's heart and counting the number of beats.
- Grimace, or reflex irritability: 2 if the neonate coughs, sneezes, or vigorously cries in response to a stimulus (such as the use of nasal suctioning, stroking the back to assess for spinal abnormalities, or having the foot tapped); 1 for a slight cry or grimace in response to the stimulus; 0 for no response.

KEY TERMS

Acrocyanosis—A slight cyanosis, or blueness of the hands and feet of the neonate is considered normal. This impaired ability to fully oxygenate the extremities is due to an immature circulatory system which is still in flux.

Amniotic fluid—The protective bag of fluid that surrounds the fetus while growing in the uterus.

Neonate—A term referring to the newborn infant, from birth until one month of age.

Neonatologist—A physician who specializes in problems of newborn infants.

Pallor—Extreme paleness in the color of the skin.

- Activity, or muscle tone: 2 for vigorous movements of arms and legs; 1 for some movement; 0 for no movement, limpness.
- Respirations: 2 for visible breathing and crying; 1 for slow, weak, irregular breathing; 0 for apnea, or no breathing. A crying newborn can adequately oxygenate its **lungs**. Respirations are best assessed by watching the rise and fall of the neonate's abdomen, as infants are diaphragmatic breathers.

The combined first letters in these five areas spell Apgar.

Preparation

No preparation is needed to perform the test. However, while being born the neonate may receive nasal and oral suctioning to remove mucus and amniotic fluid. This may be done when the head of the newborn is safely out, while the mother rests before she continues to push.

Aftercare

Since the test is primarily observational in nature, no aftercare is needed. However, the test may flag the need for immediate intervention or prolonged observation.

Complications

There are no complications from the test itself, just the possible complications if intervention is required but not initiated.

Results

The maximum possible score is 10, the minimum is zero. It is rare to receive a true 10, as some acrocyanosis

APGAR SCORING SYSTEM			
Factor	0 points	1 point	2 points
Heart rate	No heartbeat	Under 100 beats per minute	Over 100 beats per minute
Respiration	Not breathing	Irregular, with weak cry	Regular with strong cry
Muscle tone	Limp, no movement	Limited movement of the limbs	Active movement of the limbs
Color	Completely blue, pale	Pink body with blue hands and feet	All pink
Reflexes	No response to being poked in the nose	Grimace when poked	Cry, cough, or sneeze when poked

(Illustration by Standley Publishing. Courtesy of Gale Group.)

in the neonate is considered normal, and therefore not a cause for concern. Most infants score between 7 and 10. These infants are expected to have an excellent outcome. A score of 4, 5, or 6 requires immediate intervention, usually in the form of oxygen and respiratory assistance, or perhaps just suctioning if breathing has been obstructed by mucus. While suctioning is being done, a source of oxygen may be placed near, but not over the newborn's nose and mouth. This form of oxygen is referred to as blow-by. A score in the 4-6 range indicates that the neonate is having some difficulty adapting to extrauterine life. This may be due to medications given to the mother during a difficult labor, or at the very end of labor, when these medications have an exaggerated effect on the neonate. With a score of 0-3 the neonate is unresponsive, apneic, pale, limp and may not have a pulse. Interventions to resuscitate will begin immediately. The test is repeated at 5 minutes after birth and both scores are documented. Should the resuscitation effort continue into the five minute time period, interventions will not stop in order to perform the test. The one-minute score indicates the need for intervention at birth. It addresses survival and prevention of birth-related complications resulting from inadequate oxygen supply. Poor oxygenation may be due to inadequate neurological and/or chemical control of respiration. The five-minute score appears to have a more predictive value for morbidity and normal development, although research studies on this are inconsistent in their conclusions.

A February 2001 study published in the *New England Journal of Medicine* investigated whether Apgar scoring continues to be relevant. Researchers concluded that "The Apgar scoring system remains as rele-

vant for the prediction of neonatal survival today as it was almost 50 years ago."

Health care team roles

In an uncomplicated delivery, the attending labor and delivery nurse, the obstetrician, or the midwife usually performs the test. If a problem birth has been anticipated, there may be a nurse from the neonatal intensive care unit or a neonatologist in attendance at the birth. One or all of these individuals may make a mental score and provide input regarding their observations, if there appears to be a discrepancy in the score to be noted on the official delivery and nursery forms.

The first question asked by new parents after the birth of their child is usually "Is s/he all right?" Reassuring the parents is an important nursing role. Explaining to new parents what is being done to their newborn keeps them informed, without interfering with the nurse's actions. The brief time spent suctioning and stimulating the neonate to take its first breath can seem like an eternity to the waiting parent, especially for the first-time parent for whom all this is a new experience. The ability to attend to the neonate's needs while simultaneously addressing the parents' needs becomes smoother as the nurse gains experience.

Aphasia

Definition

Aphasia is an impairment of spoken language understanding and expression associated with **brain** damage.

Description

Neurologic etiologies that affect the left cerebral cortex can lead to aphasia (sometimes termed dysphasia). Aphasia is a language disturbance affecting the use of words and sentences; it is not simply difficulty with speech articulation. Aphasia is usually accompanied by difficulties with reading (dyslexia/alexia) and writing (dysgraphia/agraphia) and may also co-occur with speech articulation difficulties (**apraxia** of speech and **dysarthria**). Though more common in adults, aphasia can arise in children who incur brain damage or who fail to develop language abilities related to left hemisphere neurologic dysfunction, sometimes termed developmental dysphasia.

Causes and symptoms

Stroke leads to approximately 80,000 new cases of aphasia each year. Tumor, **dementia**, trauma, anoxic events (lack of oxygen), and infections affecting the left cerebral hemisphere also may lead to aphasia.

Broca's aphasia results from damage to the frontal lobe of the language-dominant area of the brain. Individuals with Broca's aphasia may become mute or may be able to use single-word statements or full sentences, although it may require great effort. **Wernicke's aphasia** is caused by damage to the temporal lobe of the language-dominant area of the brain. People with this condition speak in long, uninterrupted sentences, but the words used are often unnecessary and unintelligible. (Illustration by Electronic Illustrators Group.)

Approximately one million people in the United States live with aphasia.

The symptoms of aphasia vary depending upon the portion of the brain that is damaged. Fluency of verbal expression in aphasia refers to the ease with which individuals initiate and fill time with words, form grammatical and melodious sentences, and articulate speech sounds. Disruption of any one of these characteristics associated with damage anterior to the left Rolandic/central sulcus parts of the brain can lead to nonfluency. Comprehension of messages can be disrupted, especially with damage affecting the left superior temporal gyrus. Repetition of spoken messages can be impaired, particularly with damage surrounding the left Sylvian/lateral fissure. The patterns of preserved or impaired abilities in fluency, comprehension, and repetition lead to different syndromes of aphasia (for example, Broca's aphasia: nonfluent, impaired repetition, relatively spared compre-

KEY TERMS

Anomia—Difficulty thinking of a specific word to express an idea; word retrieval impairment.

Apraxia of speech—Difficulty selecting and sequencing movements to pronounce speech sounds in the absence of weakness or uncoordination.

Compensatory—Treatments focused on circumventing language impairments by using alternative methods to communicate.

Comprehension—Ability to understand language messages.

Dysarthria—Speech impairment due to impaired motor (for example, weakness, uncoordination) or sensory function.

Dysgraphia—Impaired writing abilities.

Dyslexia—Impaired reading abilities.

Fluency—Ease with which an individual forms complete, correct, rhythmic sentences.

Neologism—Nonsense words misspoken for an intended word (for example, sparndle for fork).

Paraphasia—Mis-selection of a word that may relate to the intended word in meaning or sound.

Repetition—Ability to imitate words and sentences exactly as presented.

Restorative—Treatments focused on regaining normal language abilities.

hension; Wernicke's aphasia: fluent, impaired repetition and comprehension). Anomia, or difficulty thinking of specific words (for example, knife), can occur across syndromes of aphasia. Instead, individuals may provide a description (it's for cutting), a paraphasia related by meaning (fork) or sound (night or nipe), a meaningless word or neologism (sparn), or no response.

Diagnosis

Following a clinical neurological examination, patients with aphasia are referred to speech-language pathologists or neuropsychologists trained in the administration of standardized language assessments to identify the patterns of aphasia. Most aphasia assessments include subtests to evaluate fluency, comprehension, repetition, and word retrieval (for example, Boston Diagnostic Aphasia Examination). Other tests allow assessment of specific symptoms of aphasia (for exam-

ple, word retrieval: Boston Naming Test; reading: Reading Comprehension Battery for Aphasia). Assessment of aphasia, which occurs in acute through chronic stages of the disorder, takes one to three hours to complete. Trained professionals are reimbursed for assessment and treatment of aphasia at the rate consistent with **Medicare** allowances.

Treatment

Patients with aphasia participate in speech-language treatment to alleviate its consequences for communication. A number of studies have indicated the efficacy of behavioral treatments for aphasia. Some treatment methods use drills and practice with language activities to restore skills or to engage other neural regions to mediate language abilities. In other treatments, clinicians teach patients to compensate for the symptoms of aphasia using alternative modalities to communicate including writing, gesture, musical abilities, pointing boards, or speech-generation devices. Speech-language pathologists also provide consultation to patients and family members on strategies to improve communication. Pharmacologic treatments for aphasia (for example, bromocriptine, amphetamines) primarily are experimental in nature and are not used in standard clinical practice.

Prognosis

The prognosis for recovery of aphasia relates to a number of medical, neurological, behavioral, and psychosocial factors. Positive indicators include acute neurologic conditions (for example, stroke) over degenerative conditions, hemorrhagic over ischemic stroke, unilateral left hemisphere lesion sparing subcortical white matter, onset within the past six to 12 months, and mild form of aphasia at onset. Psychosocial factors such as age, gender, intelligence, emotional state, and family support may also contribute to recovery to a lesser degree. The majority of individuals demonstrate some language recovery; fewer completely regain their previous language levels.

Health care team roles

Nursing and medical staff providing medical care for individuals with aphasia implement strategies recommended by speech-language pathologists to foster communication with patients. Nursing staff monitors changes in patient communication status, often noting the need for referral to speech-language pathology services. In performing their unique roles to assist neurological recovery, the rehabilitation team (for example, physical therapist,

occupational therapist, psychiatrist, social worker), implement strategies to maximize communication skills.

Prevention

Avoiding the neurologic event that causes aphasia is the only way to prevent its occurrence. For example, since strokes are a leading cause of aphasia, reducing the chances of having a stroke by not smoking cigarettes also reduces the chances of developing aphasia.

Appendicitis

Definition

Appendicitis is an inflammation of the appendix, which is the worm-shaped pouch attached to the cecum, the beginning of the **large intestine**. The appendix has no known function in the body, but it can become diseased and inflamed. Appendicitis is a medical emergency. If it is left untreated, the appendix may rupture and cause a potentially fatal **infection**.

An extracted appendix. (Photograph by Lester V. Bergman, Corbis Images. Reproduced by permission.)

Description

Appendicitis is the most common abdominal emergency in children and young adults. One person in 15 develops appendicitis in his or her lifetime. The incidence is highest among males aged 10–14 and females aged 15–19. More males than females develop appendicitis between **puberty** and age 25. It is rare among the elderly and in children under the age of two.

The hallmark symptom of appendicitis is increasingly severe abdominal **pain**. The pain of appendicitis begins in the center of the abdomen and becomes concentrated in the lower right quadrant of the abdomen. Since many different conditions can cause abdominal pain, an accurate diagnosis of appendicitis can be difficult. A timely diagnosis is important, however, because a delay can result in perforation, or rupture, of the appendix. When this happens, infected contents of the appendix spill into the abdomen, potentially causing a serious infection of the abdomen called peritonitis.

Other conditions can have similar symptoms, especially in women. These include pelvic inflammatory disease, ruptured ovarian follicles, ruptured ovarian cysts, tubal pregnancies, and endometriosis. Various forms of **stomach** upset and bowel inflammation may also mimic appendicitis.

KEY TERMS

Appendectomy—Surgical removal of the appendix.

Appendix—The worm-shaped pouch attached to the cecum, the beginning of the large intestine.

Laparotomy—A surgical incision into the abdomen, made between the ribs and the pelvis, that offers surgeons a view inside the abdominal cavity.

Peritonitis—Inflammation of the peritoneum, membranes lining the abdominal pelvic wall.

Ulceration—An abnormal change in tissue accompanied by the death of cells.

The treatment for acute (sudden, severe) appendicitis is an appendectomy, surgery to remove the appendix. Because of the potential for a life-threatening ruptured appendix, persons suspected of having appendicitis are often taken to surgery before the diagnosis is certain.

Causes and symptoms

The causes of appendicitis are not well understood, but it is believed to occur as a result of one or more of these factors: an obstruction within the appendix, the development of an ulceration within the appendix, and the invasion of **bacteria**.

Under these conditions, bacteria may multiply within the appendix. The appendix may become swollen and filled with pus and may eventually rupture. Signs of rupture include the presence of symptoms for more than 24 hours, a **fever**, a high white **blood** cell count, and a fast **heart** rate. Very rarely, the inflammation and symptoms of appendicitis may disappear but recur again later.

The distinguishing symptom of appendicitis is pain beginning around or above the navel. The pain, which may be severe or only achy and uncomfortable, eventually moves into the right lower corner of the abdomen. There, it becomes more steady and more severe, and often increases with movement or coughing. The abdomen often becomes rigid and tender to the touch. Increasing rigidity and tenderness indicates an increased likelihood of perforation and peritonitis.

Loss of appetite is very common. Nausea and vomiting may occur in about half of the cases, and occasionally there may be constipation or **diarrhea**. The temperature may be normal or slightly elevated. The presence of a fever may indicate that the appendix has ruptured.

Diagnosis

A careful examination is the best way to diagnose appendicitis. It is often difficult, even for experienced physicians, to distinguish the symptoms of appendicitis from those of other abdominal disorders. A physician should ask questions such as where the pain is centered, whether the pain has shifted, and where the pain began. The physician should press on the abdomen to judge the location of the pain and the degree of tenderness.

The typical sequence of symptoms is present in about 50% of cases. In the other half of cases, less typical patterns may be seen, especially in pregnant women, older people, and infants. In pregnant women, appendicitis is easily masked by the frequent occurrence of mild abdominal pain and nausea from other causes. Elderly people may feel less pain and tenderness than most individuals, thereby delaying diagnosis and treatment, and leading to rupture in 30% of cases. Infants and young children often have diarrhea, vomiting, and fever in addition to pain.

While laboratory tests cannot establish the diagnosis, an increased white cell count may point to appendicitis. **Urinalysis** may help to rule out a urinary tract infection that can mimic appendicitis.

Persons with a diagnosis of appendicitis are usually taken immediately to surgery, where a laparotomy (surgical exploration of the abdomen) is done to confirm the diagnosis. In cases with a questionable diagnosis, other tests such as a computed tomography (CT) scan may be performed to avoid unnecessary surgery. An ultrasound examination of the abdomen may help to identify an inflamed appendix or other condition that would explain the symptoms. Abdominal x rays are not of much value, except when an appendix has ruptured.

Often, the diagnosis is not certain until an operation is completed. To avoid a ruptured appendix, surgery may be recommended without delay if the symptoms point clearly to appendicitis. If the symptoms are not clear, surgery may be postponed until they progress enough to confirm a diagnosis.

When appendicitis is strongly suspected in a woman of child-bearing age, a diagnostic **laparoscopy** is sometimes recommended to be sure that a gynecological problem such as a ruptured ovarian cyst is not causing the pain. In this procedure, a lighted viewing tube is inserted into the abdomen through a small incision around the navel.

A normal appendix is discovered in about 10–20% of patients who undergo laparotomy for suspected appendicitis. Sometimes the surgeon will remove a normal appendix as a safeguard against appendicitis in the future.

During the surgery, another specific cause for the pain and symptoms of appendicitis is found for about 30% of these patients.

Treatment

The treatment for appendicitis is an immediate appendectomy, which is done by opening the abdomen in the standard open appendectomy technique, or through laparoscopy. In laparoscopy, a smaller incision is made beside the navel. Both methods can successfully accomplish the removal of an appendix. It is not certain that laparoscopy holds any advantage over open appendectomy. When an appendix has ruptured, patients undergoing a laparoscopic appendectomy may have to be switched to the open appendectomy procedure for successful management of the rupture. If a ruptured appendix is left untreated, the condition is fatal.

Prognosis

Appendicitis is usually treated successfully by appendectomy. Unless there are complications, people usually recover without further problems. The mortality rate in cases without complications is less than 0.1%. When an appendix has ruptured, or a severe infection has developed, the likelihood for complications is higher, with slower recovery, or death from disease. There are higher rates of perforation and mortality among children and elderly persons.

Health care team roles

A physician, physician assistant, or nurse practitioner usually makes an initial diagnosis of appendicitis based on history, physical findings, and laboratory results. A laboratory technician may provide a test that confirms a diagnosis. A surgeon removes an appendix. Nurses assist by collecting data from the patient and family, monitoring **vital signs** and status of pain, and providing **patient education** about the diagnosis, surgery, and recovery.

Prevention

Appendicitis is probably not preventable, although there is some indication that a diet high in green vegetables and tomatoes may help prevent appendicitis.

Apraxia

Definition

Apraxia is an impairment in the use of learned skilled movements (e.g., limb movements; speech) that occurs most often with damage affecting the left hemisphere of the **brain**.

KEY TERMS

Aphasia—Impairment of spoken language understanding and expression associated with damage affecting the left hemisphere of the brain.

Apraxia of speech—Difficulty selecting and sequencing movements to pronounce speech sounds in the absence of weakness or incoordination.

Apraxic agraphia—Difficulty selecting and sequencing movements necessary for legible writing.

Buccofacial apraxia—Impaired ability to perform learned, skilled facial (nonspeech) movements.

Dysarthria—Speech impairment due to impaired motor (e.g., weakness, incoordination) or sensory function.

Dysgraphia—Impaired writing and spelling abilities.

Dyslexia—Impaired reading abilities.

Limb apraxia—Impaired ability to perform learned, skilled limb movements.

Description

Apraxia is a general term for a disturbance of learned, skilled movements that cannot be attributed to sensory loss, weakness, or other cognitive impairments. To gain a processing advantage or skill each time a person attempts to enact complex, skilled movements of the limbs, mouth, and face, individuals develop memories that allow for smooth and efficient movements. The left hemisphere of the brain is integral to the ability to perform learned, skilled movements. Neurologic etiologies that affect the left cerebral cortex can lead to apraxia. Apraxia may be observed for different types of learned skilled movements leading to limb apraxia, apraxia of speech, buccofacial apraxia, and apraxic agraphia. Apraxia often is accompanied by other impairments of left hemisphere function including **aphasia**, **dyslexia**, **dysarthria**, and **dysgraphia**. Although more common in adults, apraxia can arise in children who incur brain damage or who fail to develop abilities due to left hemisphere neurologic dysfunction, sometimes termed developmental dyspraxia.

Causes and symptoms

Stroke affecting the left cerebral hemisphere is one leading cause of apraxia. Other neurologic conditions

that affect the left hemisphere, such as tumor, **dementia**, trauma, anoxic events, and infections, may lead to apraxia. Little data exist to document the number of cases of apraxia; however, it is known that apraxia is less common than aphasia following left hemisphere damage. Although the term apraxia has been applied to other disordered movements, such as eyelid opening or dressing, it more appropriately subsumes movements related to learned skilled movements.

The patterns of apraxia vary depending upon which portion of the left cerebral hemisphere is affected:

- Limb apraxia refers to difficulty activating patterns of muscle movements when using tools and implements (e.g., unsafe use of knife or razor) and producing common pantomimes (e.g., ok, come here, drink, comb).
- Buccofacial apraxia leads to difficulty with skilled oral movements (e.g., whistle, blow out a candle).
- Apraxia of speech leads to difficulty activating the complex array of movements necessary for accurate pronunciation of sounds in words. Individuals suffering from speech apraxia struggle to utter words, mispronouncing and simplifying the sounds of speech. Some are rendered mute when the disorder is severe.
- Apraxic agraphia is impaired ability to select and sequence the series of strokes necessary for legible writing. An individual affected this way may know how to spell but cannot write.

Diagnosis

Following a clinical neurological examination, patients with apraxia are referred to rehabilitation specialists (e.g., speech-language pathologists, occupational therapists, physical therapists) trained in the examination of apraxia using standardized testing batteries for speech and limb apraxia. Specialized training is often required to recognize the error patterns in apraxia and to distinguish it from other abnormalities that may disrupt the ability to perform movements including weakness, sensory loss, or language impairments. Assessment of apraxia, which occurs in acute through chronic stages of the disorder, takes one to three hours to complete. Although some individuals may recover from apraxia, others may demonstrate chronic, significant impairments of learned skilled movements that affect communication and functioning in activities of daily living.

Treatment

Patients with apraxia may participate in rehabilitation to alleviate its consequences for communication or for safe performance of activities of daily living. A num-

ber of small group or case studies have demonstrated that behavioral treatments provided by rehabilitation professionals can be effective for improving skilled movements of the limbs or speech. Some treatment methods use drills and practice with speech or limb movements to restore skills or to engage other neural regions to mediate skilled movements. In other treatments, clinicians teach patients to compensate for the symptoms of apraxia using alternative communication modalities or methods to complete daily living activities. Patients with apraxia participate in speech-language treatment to alleviate its consequences for communication.

Prognosis

Less is known about the prognosis for recovery of apraxia than is known about other left-hemisphere cognitive disorders such as aphasia. Positive indicators may include:

- acute neurologic conditions (e.g. stroke) over degenerative conditions
- hemorrhagic over ischemic stroke
- unilateral left-hemisphere lesion
- onset within the past six to 12 months
- mild form of apraxia at onset

Health care team roles

Nursing and medical rehabilitation staff providing care for individuals with apraxia may need to implement strategies recommended by rehabilitation professionals. This will help foster communication with patients with apraxia of speech, and ensure patient safety in the hospital environment for individuals with limb apraxia. Individuals with severe limb apraxia may require close supervision when using tools and implements in daily living activities (e.g., grooming or eating).

Prevention

The way to prevent apraxia is to prevent the neurologic event that causes apraxia.

Art therapy

Definition

Art therapy, sometimes called creative arts therapy or expressive arts therapy, encourages people to express and understand emotions through artistic expression and through the creative process.

Origins

Humans have expressed themselves with symbols throughout history. Masks, ritual pottery, costumes, other objects used in rituals, cave drawings, Egyptian hieroglyphics, and Celtic art and symbols are all visual records of self-expression and communication through art. Art has also been associated spiritual power, and artistic forms such as the Hindu and Buddhist mandala and Native American sand painting are considered powerful healing tools.

In the late nineteenth century, French psychiatrists Ambrose Tardieu and Paul-Max Simon both published studies on the similar characteristics of and symbolism in the artwork of the mentally ill. Tardieu and Simon viewed art therapy as an effective diagnostic tool to identify specific types of mental illness or traumatic events. Later, psychologists would use this diagnostic aspect to develop psychological drawing tests (the Draw-A-Man test, the Draw-A-Person Questionnaire [DAP.Q]) and projective personality tests involving visual symbol recognition (e.g., the Rorschach Inkblot Test, the Thematic Apperception Test [TAT], and the Holtzman Inkblot Test [HIT]).

The growing popularity of milieu therapies at psychiatric institutions in the twentieth century was an important factor in the development of art therapy in the United States. Milieu therapies (or environmental therapy) focus on putting the patient in a controlled therapeutic social setting that provides the patient with opportuni-

Art therapist with students. (Photograph by Peter Berndt. Custom Medical Stock Photo, Inc. Reproduced by permission.)

ties to gain self-confidence and interact with peers in a positive way. Activities that encourage self-discovery and empowerment such as art, music, dance, and writing are important components of this approach.

Educator and therapist Margaret Naumburg was a follower of both Freud and Jung and incorporated art into **psychotherapy** as a means for her patients to visualize and recognize the unconscious. She founded the Walden School in 1915, where she used students' artworks in psychological counseling. She published extensively on the subject and taught seminars on the technique at New York University in the 1950s. Today, she is considered the founder of art therapy in the United States.

In the 1930s, Karl, William, and Charles Menninger introduced an art therapy program at their Kansas-based psychiatric hospital, the Menninger Clinic. The Menninger Clinic employed a number of artists in residence in the following years, and the facility was also considered a leader in the art therapy movement through the 1950s and 60s. Other noted art therapy pioneers who emerged in the 50s and 60s include Edith Kramer, Hanna Yaxa Kwiatkowska (National Institute of Mental Health), and Janie Rhyne.

Benefits

Art therapy provides the client-artist with critical insight into emotions, thoughts, and feelings. Key benefits of the art therapy process include:

- **Self-discovery.** At its most successful, art therapy triggers an emotional catharsis.
- **Personal fulfillment.** The creation of a tangible reward can build confidence and nurture feelings of self-worth. Personal fulfillment comes from both the creative and the analytical components of the artistic process.
- **Empowerment.** Art therapy can help people visually express emotions and fears that they cannot express through conventional means, and can give them some sense of control over these feelings.
- **Relaxation and stress relief.** Chronic stress can be harmful to both mind and body. Stress can weaken and damage the **immune system**, can cause insomnia and depression, and can trigger circulatory problems (like high **blood pressure** and irregular heartbeats). When used alone or in combination with other relaxation techniques such as guided imagery, art therapy can effectively relieve stress.
- **Symptom relief and physical rehabilitation.** Art therapy can also help patients cope with **pain**. This therapy can promote physiological healing when patients identify and work through anger, resentment, and other emotional stressors. It is often prescribed to accompany pain control therapy for chronically and terminally ill patients.

Description

Art therapy, sometimes called expressive art or art psychology, encourages self-discovery and emotional growth. It is a two-part process, involving both the creation of art and the discovery of its meaning. Rooted in Freud and Jung's theories of the subconscious and unconscious, art therapy is based on the assumption that visual symbols and images are the most accessible and natural form of communication to the human experience. Patients are encouraged to visualize, and then create, the thoughts and emotions that they cannot talk about. The resulting artwork is then reviewed and its meaning interpreted by the patient.

The "analysis" of the artwork produced in art therapy typically allows patients to gain some level of insight into their feelings and lets them to work through these issues in a constructive manner. Art therapy is typically practiced with individual, group, or family psychotherapy (talk therapy). While a therapist may provide critical guidance for these activities, a key feature of effective art

therapy is that the patient/artist, not the therapist, directs the interpretation of the artwork.

Art therapy can be a particularly useful treatment tool for children, who frequently have limited language skills. By drawing or using other visual means to express troublesome feelings, younger patients can begin to address these issues, even if they cannot identify or label these emotions with words. Art therapy is also valuable for adolescents and adults who are unable or unwilling to talk about thoughts and feelings.

Beyond its use in mental health treatment, art therapy is also used with traditional medicine to treat organic diseases and conditions. The connection between mental and physical health is well documented, and art therapy can promote healing by relieving stress and allowing the patient to develop coping skills.

Art therapy has traditionally centered on visual mediums, like paintings, sculptures, and drawings. Some mental healthcare providers have now broadened the definition to include music, film, dance, writing, and other types of artistic expression.

Art therapy is often one part of a psychiatric inpatient or outpatient treatment program, and can take place in individual or group therapy sessions. Group art therapy sessions often take place in hospital, clinic, shelter, and community program settings. These group therapy sessions can have the added benefits of positive social interaction, empathy, and support from peers. The client-artist can learn that others have similar concerns and issues.

Preparations

Before starting art therapy, the therapist may have an introductory session with the client-artist to discuss art therapy techniques and give the client the opportunity to ask questions about the process. The client-artist's comfort with the artistic process is critical to successful art therapy.

The therapist ensures that appropriate materials and space are available for the client-artist, as well as an adequate amount of time for the session. If the individual artist is exploring art as therapy without the guidance of a trained therapist, adequate materials, space, and time are still important factors in a successful creative experience.

The supplies used in art therapy are limited only by the artist's (and/or therapist's) imagination. Some of the materials often used include paper, canvas, poster board, assorted paints, inks, markers, pencils, charcoals, chalks, fabrics, string, adhesives, clay, wood, glazes, wire, bendable metals, and natural items (like shells, leaves, etc.). Providing artists with a variety of materials in assorted

colors and textures can enhance their interest in the process and may result in a richer, more diverse exploration of their emotions in the resulting artwork. Appropriate tools such as scissors, brushes, erasers, easels, supply trays, glue guns, smocks or aprons, and cleaning materials are also essential.

An appropriate workspace should be available for the creation of art. Ideally, this should be a bright, quiet, comfortable place, with large tables, counters, or other suitable surfaces. The space can be as simple as a kitchen or office table, or as fancy as a specialized artist's studio.

The artist should have adequate time to become comfortable with and explore the creative process. This is especially true for people who do not consider themselves "artists" and may be uncomfortable with the concept. If performed in a therapy group or one-on-one session, the art therapist should be available to answer general questions about materials and/or the creative process. However, the therapist should be careful not to influence the creation or interpretation of the work.

Precautions

Art materials and techniques should match the age and ability of the client. People with impairments, such as traumatic **brain** injury or an organic neurological condition, may have difficulties with the self-discovery portion of the art therapy process depending on their level of functioning. However, they may still benefit from art therapy through the sensory stimulation it provides and the pleasure they get from artistic creation.

While art is accessible to all (with or without a therapist to guide the process), it may be difficult to tap the full potential of the interpretive part of art therapy without a therapist to guide the process. When art therapy is chosen as a therapeutic tool to cope with a physical condition, it should be treated as a supplemental therapy and not as a substitute for conventional medical treatments.

Research and general acceptance

A wide body of literature supports the use of art therapy in a mental health capacity. And as the mind-body connection between psychological well-being and physical health is further documented by studies in the field, art therapy gains greater acceptance by mainstream medicine as a therapeutic technique for organic illness.

Training and certification

Both undergraduate and graduate art therapy programs are offered at many accredited universities across the United States. Typical art therapy programs combine

KEY TERMS

Catharsis—Therapeutic discharge of emotional tension by recalling past events.

Mandala—A design, usually circular, that appears in religion and art. In Buddhism and Hinduism, the mandala has religious ritual purposes and serves as a yantra (a geometric emblem or instrument of contemplation).

Organic illness—A physically, biologically based illness.

courses in art and psychology. The majority of these programs meets or exceeds standards set by the American Art Therapy Association (AATA).

The Art Therapy Credentials Board (ATCB), a voluntary organization, grants the designation ATR (Art Therapist Registered) to professionals who have completed an approved master's level program of study in art therapy (as described by the AATA) and have accumulated at least 1,000 hours of additional supervised clinical experience. Board certification is also available through the ATCB for art therapists who have met the ATR requirements and have passed a certification exam (ATR-BC). Art therapists with the ATR-BC designation must complete continuing education credits to maintain their certification.

Registration and/or certification is a recognition of professional expertise, not a legal qualification or requirement to practice. Professional licensing requirements for art therapists vary by state. However, if the therapy is intended as a companion treatment to psychological counseling or other mental health treatment, state licensing requirements typically apply. Where licensing is a prerequisite to practice, a combination of education and clinical experience, a written test, and continuing education are required to maintain the license.

Arthrography

Definition

Arthrography is the radiologic examination of soft tissue structures in the joints following an injection of a contrast agent with or without air. The structures demonstrated are the menisci, ligaments, tendons, articular cartilage, and bursae.

Purpose

The most commonly studied joints are the knee and shoulder, but this procedure may also be done on the hip, wrist, elbow, ankle and temporomandibular joints. Arthrography of the knee or a knee arthrogram is the most frequently performed arthrographic procedure; it is requested for patients with persistent **pain**, decrease in range of motion, or locking of the knee. Arthrography of the shoulder may be used to demonstrate partial or complete tears of the rotator cuff. A hip arthrogram is often used to detect a loose hip prosthesis or a congenital abnormality. Arthrography of the temporomandibular joints is ordered to detect abnormalities of the articular disk due to trauma or loosening of the ligaments. In many cases, however, an MRI may be obtained instead of an arthrogram.

Precautions

Patients who are or may be pregnant should not have this procedure unless the benefits of the findings outweigh the risk of radiation exposure. Patients who are known to be allergic to iodine should discuss this complication with their physician. Routine x rays of the

affected joint must be taken before starting an arthrogram to ensure that there is no fracture or dislocation.

Description

The patient is asked to change into a hospital gown for a hip, knee, or shoulder arthrogram. Since arthrography is done in a sterile field to prevent **infection**, the x-ray technologist must be trained to work with the radiologist under sterile conditions. All needles, syringes, contrast material, local anesthetic, extension tubing, and cleansing solutions are prepared in advance by the x-ray technologist depending on the part to be examined.

Routine x rays of the affected joint are done by the x-ray technologist if no recent x-rays have been taken. The films are reviewed by the radiologist to ensure that there is no fracture or dislocation in the joint.

The radiologist begins the procedure by cleansing the skin of the affected joint and applying a sterile drape. The x-ray technologist places all the required needles and syringes onto the sterile tray using proper sterile technique and assists the radiologist by drawing up the anesthetic and contrast material into the various syringes.

Once the area of skin over the joint has been numbed with a local anesthetic, the radiologist will place the needle into the joint, using x-ray images to guide placement. Additional fluid in the joint may be aspirated and sent for analysis, particularly if a joint infection is suspected. A small test injection of the contrast medium is done to confirm accurate needle placement. The contrast medium is then injected either with or without air depending on the area under investigation. The needle is removed and a small self-adhesive dressing is applied. The joint is then manipulated to properly distribute the contrast medium over the entire joint space.

Before the contrast medium can be absorbed by the joint itself, several films will be taken by the radiologist. The patient will be asked to move the joint into a series of positions, keeping still between positioning. During a knee arthrogram, the knee is manually stressed by the radiologist to open the joint space. Patients may experience some tingling or discomfort during the procedure. These are normal reactions, caused by the contrast material and air inside the joint as well as the manual positioning of the painful joint.

Following fluoroscopic tracking of the contrast medium, standard x rays of the area are taken by the x-ray technologist. An overexposed lateral x ray of the knee flexed at 90 degrees is usually done in addition to the routine AP (anteroposterior) internal and external oblique x rays in order to visualize the cruciate ligaments. An axillary view of the shoulder is usually

requested as well as an AP (anteroposterior) view of the shoulder with the arm rotated internally and externally. The procedure is usually completed within 30 minutes.

Preparation

It is important to alert the physician to any known sensitivity to local anesthetics or iodine prior to an arthrogram. Routine x rays of the affected joint should be taken before starting the arthrogram to make sure there is no fracture or dislocation, and to verify the diameter of the joint space before the needle is inserted. A small section of the knee may be shaved before starting the arthrogram.

Aftercare

The affected joint should be rested for approximately 12 hours following the procedure. Swelling may occur and can be treated with an application of ice or cold packs. A mild pain reliever may also be necessary to lessen discomfort for the first 12 hours. Noises in the joint such as cracking or clicking are normal for a few hours following an arthrogram. These noises are the result of the extra liquid (contrast) and air in the joint.

Complications

Some patients may have allergic reactions to iodine, ranging from mild nausea or a rash to severe cardiac and respiratory problems. Since the contrast material is injected directly into a joint, however, rather than the venous circulation, allergic reactions are rare. Facilities licensed to perform contrast examinations should meet requirements for emergency equipment, supplies and staff training in order to handle a possible severe reaction. Non-ionic contrast material is also available in most radiology departments.

Arthrographic studies should not be done on patients with a known joint infection, bleeding problems, or severe active arthritis.

Results

A normal arthrogram demonstrates a normal joint space with no damage to the articular cartilage, tendons, ligaments or bursae. Partial or incomplete tears of the rotator cuff are better demonstrated using MRI imaging.

Abnormal results of an arthrogram may indicate partial or complete tears of the rotator cuff, demonstrated as a leakage of contrast material out of the joint and into the bursa. In a knee arthrogram, meniscal tears are demonstrated as well as problems with the ligaments or evidence of a popliteal cyst, commonly referred to as a Baker's cyst. A Baker's cyst is demonstrated on the radi-

KEY TERMS

Aspirate—To remove fluids by suction, often through a needle.

Bursa—A closed space between two moving surfaces containing a small amount of lubricating fluid to reduce friction in the joint.

Contrast (agent, medium)—A substance injected into the body that outlines certain structures that would otherwise be hard to see on the radiograph (film).

Fluoroscope—An under-table x-ray tube used to visualize structures in real time on a television screen.

Fossa—An anatomical cavity or hollow.

Meniscus—A wedge of cartilage that separates the articulating bones in certain joints.

Popliteal—Pertaining to the area at the back of the knee.

Rotator cuff—A group of muscles lying outside the shoulder joint that allow the joint to move in many directions.

X ray—A form of electromagnetic radiation with shorter wavelengths than normal light. X-rays can penetrate most structures.

ographs as an extension of fluid into the popliteal fossa located behind the knee. Dislocations of the hip are visible as well as a loose hip prosthesis. Joint space narrowing and arthritis are also visualized on an arthrogram.

Health care team roles

Since a reaction to an iodine-based contrast medium is always a risk in arthrography, the x-ray technologist must be familiar with emergency procedures in place to deal with a cardiac arrest. The x-ray technologist works closely with the radiologist during this procedure and must be familiar with sterile techniques in order to prevent infection.

Patient education

The radiography technologist explains the procedure to the patient and inquires about any known **allergies** and the possibility of **pregnancy**. Since many patients are nervous about an injection directly into the joint, the x-ray technologist must assure the patient that the area will be numbed in advance with a local anesthetic. During a

knee arthrogram the radiologist manually positions the patient, so the patient must be encouraged to relax the knee completely. All radiography technologists must be certified and registered with the A.S.R.T. and are required to obtain continued education credits to maintain their credentials.

Following the arthrogram, the patient is also instructed to put ice on the affected joint and to take a mild pain reliever if necessary.

Arthroscopy

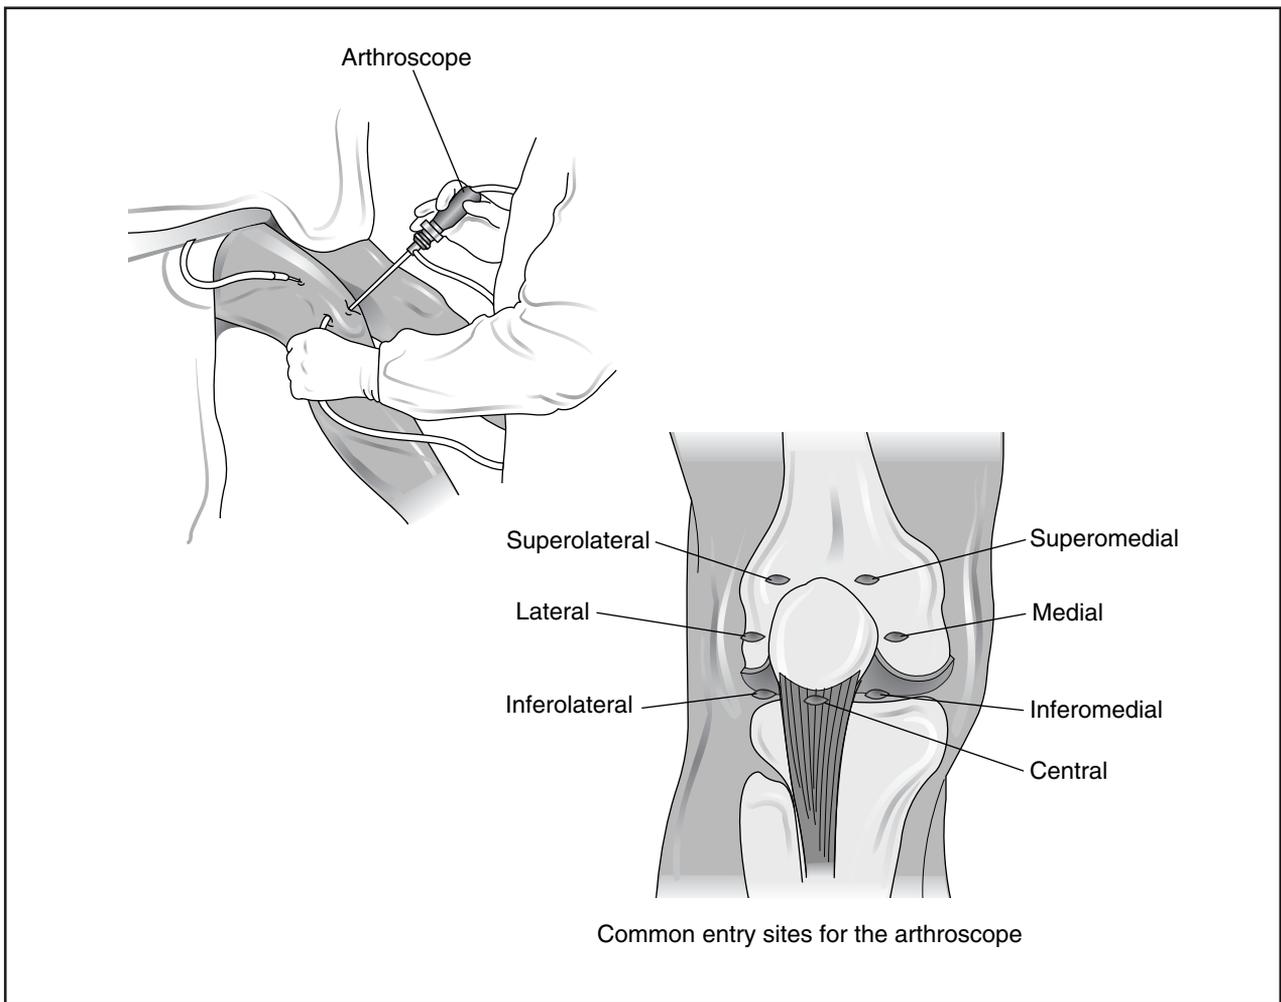

Definition

Arthroscopy is the examination of a joint, specifically, the inside structures. The procedure is performed by inserting a specifically designed illuminated device, called an arthroscope, into the joint through a small incision. Arthroscopy may be used to diagnose, as well as treat, conditions. When a repair is performed, the procedure is called arthroscopic surgery.

Purpose

Arthroscopy is used primarily by physicians who specialize in treating disorders of the bones and related structures (orthopedics) to help diagnose joint problems. Once described as essential for those who primarily care for athletic injuries, arthroscopy is now a technique commonly used by orthopedic surgeons for the treatment of patients of all ages. The six joints most frequently examined are:

- knee

Arthroscopy is primarily used to help diagnose joint problems. This procedure, most commonly associated with knee and shoulder problems, allows accurate examination and diagnosis of damaged joint ligaments, surfaces, and other related joint structures. The illustration above indicates the most common entry sites, or portals, in knee arthroscopy. (Illustration by Electronic Illustrators Group.)

- shoulder
- elbow
- ankle
- hip
- wrist

A joint is a complex system. Within a joint, ligaments attach bones to other bones, tendons attach muscles to bones, cartilage lines and helps protect the ends of bones, and a special fluid (synovial fluid) cushions and lubricates the structures. Direct visualization of the joint allows the doctor to see exactly which structures are damaged. Arthroscopy also permits earlier diagnosis of many types of joint problems, including those that had been difficult to detect in previous years.

Precautions

Arthroscopy is contraindicated for patients with ankylosis, due to the stiffness of the joint involved. Arthroscopy is also contraindicated in patients with an existing local **infection**, due to the potential for sepsis. Because of inflammation after the use of contrast dye, arthroscopy is contraindicated in patients who have recently undergone an arthrogram. Most arthroscopic procedures are performed as same-day surgery and do not require hospital admission. A few hours following the procedure, the patient is allowed to return home, although usually someone else must drive. Depending on the type of anesthesia used, the patient may need to remain NPO (nil per os, nothing by mouth) for several hours prior to the arthroscopy. Before the procedure, the anesthesiologist will ask if the patient has any known

KEY TERMS

Ankylosis—A stiff or fixed joint due to disease or surgery.

Hemarthrosis—A condition of blood within a joint.

Pulmonary embolus—Blockage of an artery of the lung by foreign matter such as fat, tumor, tissue, or a clot originating from a vein.

Sepsis—A toxic condition resulting from the spreading of bacteria due to infection.

Synovial fluid—A naturally occurring fluid that lubricates the joints.

Thrombophlebitis—Inflammation of a vein with the formation of a thrombus or clot.

Tourniquet—Something used to stop the flow of blood by pressure applied with an encircling device, such as a bandage twisted with a stick to apply pressure.

allergies to local or general anesthetics. Airway obstruction is always possible in any patient who receives a **general anesthesia**. Because of this, oxygen, suction, and monitoring equipment must be available. Cardiac status should be monitored in the event that any abnormalities arise during the procedure.

Description

The arthroscope is an instrument used to directly examine the joint. It contains magnifying lenses and glass-coated fibers that send concentrated light into the joint. A camera attached to the arthroscope allows the surgeon to view a clear image of the joint. This image is then transferred to a monitor. By attaching the arthroscope to a monitor, the surgeon is able to view the interior of the joint. This video technology is also important for documentation of the arthroscopic procedure. For example, if the surgeon decides after the arthroscopic examination that a conventional approach to surgically expose or “open” the joint (arthrotomy) must be used, a good photographic record will be useful when the surgeon returns to execute the final surgical plan.

The procedure requires the surgeon to make several small incisions (portals) through the skin’s surface into the joint. Through one or two of the portals, the pencil-sized instruments that contain a lens and lighting system to magnify and illuminate the joint structures are inserted. The joint is inflated with a sterile saline solution to

expand the joint for viewing. Often, following a recent traumatic injury to a joint, the synovial fluid may be cloudy, making interior viewing of the joint difficult. Therefore, a constant flow of the saline solution may be necessary. In other cases, a tourniquet may be applied in order to distend the joint, rather than use an infusion. The arthroscope is placed through one of the portals to view and evaluate the condition of the joint.

Preparation

The patient should be kept NPO after midnight the day of the procedure. Follow facility procedure for shaving the skin area around the joint, if needed.

Before the arthroscopy, the surgeon completes a thorough medical history and evaluation, which may reveal other disorders of the joint or body parts. Anatomical models and pictures are useful aids to explain to the patient the proposed arthroscopy and what the surgeon may be looking at specifically.

Proper draping of the body part is important to prevent contamination from instruments used in arthroscopy. Draping packs used in arthroscopy usually include disposable paper gowns and drapes with adhesive backing.

General or **local anesthesia** may be used during arthroscopy. Local anesthesia is preferred because it reduces the risk of lung and **heart** complications. The local anesthetic may be injected in small amounts in multiple locations in skin and joint tissues in a process called infiltration. In other cases, the anesthetic is injected into the **spinal cord** or a main nerve supplying the area. This process is called a “block,” as it blocks all sensation below the main trunk of the nerve. For example, a femoral block anesthetizes the leg from the thigh down. Most patients are comfortable once the skin, muscles, and other tissues around the joint are numbed by the anesthetic; however, some patients may be given a sedative if they express **anxiety** about the procedure. It is important for the patient to remain still during the arthroscopic examination.

General anesthesia may be used if the procedure is unusually complicated or painful, or extensive surgery is planned. For example, people who have relatively “tight” joints may be candidates for general anesthesia because the procedure may take longer and cause more discomfort.

Aftercare

The portals are closed by small tape strips or sutures and covered with sterile dressings and a pressure bandage. The patient spends a short amount of time in the recovery room after arthroscopy. Most patients can go

home after about an hour in the recovery room. A routine arthroscopy may take from 30 minutes to two hours.

Following the surgical procedure, the patient needs to be aware of the signs of infection, which include redness, warmth, excessive **pain**, and swelling. The risk of infection increases if the incisions become wet too early following surgery. Patients can cover the joint with plastic (for example, a plastic bag) while showering after arthroscopy. If a knee arthroscopy was performed, the patient should be instructed to elevate the knee while sitting, and to avoid twisting the joint. Ice may be applied to relieve pain and swelling.

The use of crutches is common after arthroscopy of the knee or hip, with progression to independent walking on an “as tolerated” basis by the patient. Generally, a rehabilitation program, supervised by a physical therapist, follows shortly after the arthroscopy to help the patient regain mobility and strength of the affected joint and limb.

Alternative procedures

Alternatives to arthroscopy depend upon the condition, and have limitations. X rays only examine bones, they will not show ligaments or torn cartilages. **Magnetic resonance imaging** (MRI) will reveal ligaments and cartilages but does not treat the condition. If a torn cartilage were discovered with MRI, an arthroscopy would be performed to correct the problem. Lateral ligament reconstruction for the treatment of ankle injuries is preferred over arthroscopy.

Complications

The incidence of complications is low compared to the number of arthroscopic procedures performed every year. Possible complications include infection, swelling, damage to the tissues in the joint, thrombophlebitis (**blood** clots in the leg veins), hemarthrosis (leakage of blood into the joint), pulmonary embolus (blood clots that move to the lung), and injury to the nerves around the joint. Low molecular weight heparin has been found to achieve effective prophylaxis for arthroscopy.

Results

Arthroscopy may show normal ligaments, menisci, and articular surfaces. Findings that require further treatment include spur formation, torn meniscus, and torn ligaments. Another finding that may require further treatment include adhesive capsulitis. In this condition, the joint capsule that naturally forms around the joint becomes thickened, forming adhesions, which results in

a stiff and less mobile joint. This problem may be corrected by manipulation and mobilization of the joint with the patient placed under general anesthesia.

Arthroscopic examination is often followed by arthroscopic surgery performed to repair the problem with appropriate arthroscopic tools. The optimal result is decreased pain, increased joint mobility, and improved quality of the patient’s activities of daily living (ADL).

Health care team roles

Arthroscopy is usually performed on an outpatient basis by a physician, but surgical repair may require hospitalization. In addition to providing assistance during the procedure, nurses monitor **vital signs** in the recovery room, including **blood pressure**, pulse, and respiration. They may also monitor circulation and sensation in the area that has been examined and/or operated on. Following arthroscopic surgery, a physical therapist guides the patient in rehabilitation to ensure that the patient regains full functioning in the targeted joint.

Aseptic technique

Definition

Aseptic technique is a set of specific practices and procedures performed under carefully controlled conditions with the goal of minimizing contamination by pathogens.

Purpose

Aseptic technique is employed to maximize and maintain asepsis, the absence of pathogenic organisms in the clinical setting. The goal of aseptic technique is to protect the patient from **infection**.

Description

All patients are potentially vulnerable to infection. Certain situations further increase vulnerability, such as disturbance of the body's natural defenses, such as occurs with extensive **burns** or an immune disorder. Typical situations that call for aseptic measures include surgery and the insertion of intravenous lines, urinary catheters, and drains.

The concept of asepsis can be applied in any clinical setting. Pathogens may introduce infection to the patient through contact with the environment, personnel, or equipment. The environment contains potential hazards that may spread pathogens through movement, touch, or proximity. Interventions such as controlling air flow by restricting traffic in the operating room, isolating a patient to protect airborne contamination, or using low-particle generating garb help to minimize environmental hazards.

A second element requiring careful attention is equipment or supplies. Medical equipment can be sterilized by chemical treatment, radiation, gas, or heat. Personnel can take steps to ensure sterility by assessing that sterile packages are dry and intact and checking sterility indicators such as dates or colored tape that changes color when sterile.

Besides overall attention to the clinical environment and equipment, clinicians need to be attentive to their own practices and those of their peers in order to avoid inadvertent contamination.

A key difference between the operating room and other clinical environments is that the operating area has high standards of sterility at all times, while most other settings are not designed to meet such standards. However, the principles of aseptic technique can be applied in other clinical settings. The application of aseptic technique in such settings is termed "medical asepsis" or "clean technique" rather than "surgical asepsis" or "sterile technique" required in the operating room.

Aseptic technique is most strictly applied in the operating room because of the direct and often extensive disruption of skin and underlying tissue. Aseptic technique helps to prevent or minimize postoperative infection. The patient is prepared or prepped by shaving hair from the surgical site, cleansing with a disinfectant such as iodine, and applying sterile drapes.

In all clinical settings, handwashing is an important step in asepsis. In general settings, hands are to be washed when visibly soiled, before and after contact with the patient, after contact with other potential sources of microorganisms, before invasive procedures, and after removal of gloves. Patients and visitors should also be encouraged to wash their hands. Proper handwashing for most clinical settings involves removal of jewelry, avoidance of clothing contact with the sink, and a minimum of 10-15 seconds scrubbing hands with soap, warm water, and vigorous friction.

A surgical scrub requires use of a long-acting, powerful, antimicrobial soap, careful scrubbing of the fingernails, and a longer period of time for scrubbing. Institutional policy usually designates an acceptable minimum length of time required. Thorough drying is essential, as moist surfaces invite the presence of pathogens. Contact after handwashing with the faucet or other potential contaminants should be avoided. The faucet can be turned off with a dry paper towel, or, in many cases, through use of foot pedals. Despite this careful scrub, bare hands are always considered potential sources of infection. An important principle of aseptic technique is that fluid (a potential mode of pathogen transmission) flows in the direction of gravity. With this in mind, hands are held below elbows during the surgical scrub and above elbows following the surgical scrub.

Sterile surgical clothing or protective devices such as gloves, face masks, goggles, and transparent eye/face shields serve as a barrier against microorganisms and are donned to maintain asepsis in the operating room. This practice includes covering facial hair, tucking hair out of sight, and removing jewelry or other dangling objects that may harbor unwanted organisms. This garb must be donned with deliberate care to avoid touching external, sterile surfaces with nonsterile objects including the skin.

This ensures that potentially contaminated items such as hands and clothing remain behind protective barriers, thus prohibiting inadvertent entry of microorganisms into sterile areas. Personnel assist the surgeon to don gloves and garb and arrange equipment to minimize the risk of contamination.

Donning sterile gloves requires specific technique so that the outer glove is not touched by the hand. A large cuff exposing the inner glove is created so that the glove may be grasped during donning. It is essential to avoid touching nonsterile items once sterile gloves are applied; the hands may be kept interlaced to avoid inadvertent contamination. Any break in the glove or touching the glove to a nonsterile surface requires immediate removal and application of new gloves.

Asepsis in the operating room or for other invasive procedures is also maintained by creating sterile surgical fields with drapes. Sterile drapes are sterilized linens placed on the patient or around the field to delineate sterile areas. Drapes or wrapped kits of equipment are opened in such a way that the contents do not touch nonsterile items or surfaces. Aspects of this method include opening the furthest areas of a package first, avoiding leaning over the contents, and preventing opened flaps from falling back onto contents.

Other principles that are applied to maintain asepsis include:

- All items in a sterile field must be sterile.
- Sterile packages or fields are opened or created as close as possible to time of actual use.
- Moist areas are not considered sterile.
- Contaminated items must be removed immediately from the sterile field.
- Only areas that can be seen by the clinician are considered sterile, i.e., the back of the clinician is not sterile.
- Gowns are considered sterile only in the front, from chest to waist and from the hands to slightly above the elbow.
- Tables are considered sterile only at or above the level of the table.
- Nonsterile items should not cross above a sterile field.
- There should be no talking, laughing, coughing, or sneezing across a sterile field.
- Personnel with colds should avoid working while ill or apply a double mask.
- Edges of sterile areas or fields (generally the outer inch) are not considered sterile.
- When in doubt about sterility, discard the potentially contaminated item and begin again.

Proper removal of used gloves. (Delmar Publishers, Inc. Reproduced by permission.)

- A safe space or margin of safety is maintained between sterile and nonsterile objects and areas.
- When pouring fluids, only the lip and inner cap of the pouring container is considered sterile. The pouring container should not touch the receiving container, and splashing should be avoided.
- Tears in barriers are considered breaks in sterility.

In the operating room, staff have assignments so that those who have undergone surgical scrub and donning of sterile garb are positioned closer to the patient. Other “unscrubbed” staff members are assigned to the perimeter and remain on hand to obtain supplies, acquire assistance, and facilitate communication with outside personnel. Unscrubbed personnel may relay equipment to scrubbed personnel only in a way that preserves the sterile field. For example, an unscrubbed nurse may open a package of forceps in sterile fashion so that he or she never touches the sterilized inside portion, the scrubbed staff or the sterile field. The uncontaminated item may either be picked up by a scrubbed staff member or carefully placed on to the sterile field.

Asepsis in the operating room is maintained by allowing only scrubbed personnel into the sterile field and checking all equipment and packaging for breaks in sterility, such as expired sterilization date, moisture, or torn wrappings. Clinicians observe aseptic technique by strictly avoiding practices that may introduce microorganisms. Arms of scrubbed staff are to remain within the field at all times, and reaching below the level of the patient or turning away from the sterile field are considered breaches in asepsis.

Clinical areas outside of the operating room generally do not allow for the same strict level of asepsis.

Surgeons scrubbing their hands and arms before surgery.

However, avoiding potential infection remains the goal in every clinical setting. Observation of medical aseptic practices will help to avoid nosocomial infections, or those acquired in the hospital. General habits that help to preserve a clean medical environment include:

- Safe removal of hazardous waste, i.e., prompt disposal of contaminated needles or blood-soaked bandages to containers reserved for such purposes.
- Prompt removal of wet or soiled dressings.
- Prevention of accumulation of bodily fluid drainage, i.e., regular checks and emptying of receptacles such as surgical drains or nasogastric suction containers.
- Avoidance of backward drainage flow toward patient, i.e., keeping drainage tubing below patient level at all times.
- Immediate clean-up of soiled or moist areas.
- Labeling of all fluid containers with date, time, and timely disposal per institutional policy.
- Maintaining seals on all fluids when not in use.

These general practices are important for keeping the environment as free of microorganisms as possible. In addition, specific situations outside of the operating room require a strict application of aseptic technique. Some of these situations include:

- wound care
- drain removal and drain care
- intravascular procedures
- vaginal exams during labor
- insertion of urinary catheters
- respiratory suction

For example, a surgical dressing change at the bedside, though in a much less controlled environment than

the operating room, will still involve thorough hand-washing, use of gloves and other protective garb, creation of a sterile field, opening and introducing packages and fluids in such a way as to avoid contamination, and constant avoidance of contact with nonsterile items.

The isolation unit is another clinical setting that requires a high level of attention to aseptic technique. Isolation is the use of physical separation and strict aseptic technique for a patient who either has a contagious disease or is immunocompromised. For the patient with a contagious disease, the goal of isolation is to prevent the spread of infection to others. In the case of respiratory infections (i.e., **tuberculosis**), the isolation room is especially designed with a negative pressure system that prevents airborne flow of pathogens outside the room. The severely immunocompromised patient is placed in reverse isolation, where the goal is to avoid introducing any microorganisms to the patient. In these cases, attention to aseptic technique is especially important to avoid spread of infection in the hospital or injury to the patient unprotected by sufficient immune defenses. Entry and exit from the isolation unit involves careful handwashing, use of protective barriers like gowns and gloves, and care not to introduce or remove potentially contaminated items. Institutions supply specific guidelines that direct practices for different types of isolation, i.e., respiratory versus body fluid isolation precautions.

Preparation

Novice and less-experienced clinicians require thorough training and supervision in the principles and practices of aseptic technique. Maintaining asepsis requires practice and vigilance.

Health care team roles

In a multidisciplinary setting, one role of the nurse or other allied health professional is to assist the doctor in caring for the patient while maintaining asepsis, i.e., by supplying equipment to the surgeon in a sterile fashion. Nursing staff independently practice aseptic techniques in many day-to-day procedures, such as urinary catheter insertion, dressing changes, and respiratory suction. Even personnel experienced with aseptic technique must constantly monitor their own movements and practices, those of others, and the status of the overall field to prevent inadvertent breaks in sterile or clean technique. It is expected that personnel will alert other staff when the field or objects are potentially contaminated. Health care workers can also promote asepsis by evaluating, creating, and periodically updating policies and procedures that relate to this principle.

KEY TERMS

Contamination—A breach in the preservation of a clean or sterile object or environment

Host—A living organism that harbors or potentially harbors infection.

Immunocompromised—Lacking or deficient in defenses provided by the immune system, usually due to disease state or a side effect of treatment.

Invasive—Involving entry into the body.

Nosocomial—Occurring in the hospital or clinical setting.

Pathogen—A disease-causing organism.

Resistant organisms—Organisms that are difficult to eradicate with antibiotics.

Sterile—Completely free of pathogens.

Asthma

Definition

Asthma is a chronic inflammatory disease of the airways in which periods of relatively free breathing are

punctuated by episodes in which breathing becomes difficult. During an attack, inflammation causes the airways to fill with mucus secretions and become obstructed. Asthmatics cough, gasp for air, wheeze, gag, and feel choking sensations as they struggle to breathe. Obstruction to airflow usually responds to a wide range of treatments.

Depending on the type of asthma, attacks may be triggered by environmental factors such as cold temperatures, air pollution, smoke, pollen, dust, mildew, mold, and animal hair or dander. **Exercise**, allergic reactions, respiratory infections, and emotional **stress** may also trigger attacks. Like other chronic diseases, asthma can be controlled, but not cured.

According to the American Lung Association, in 1998 there were 26 million Americans asthmatics, 10.6 of whom had had an attack during the past year. About a third of all asthmatics are children under 18. Since asthma is often undiagnosed, these statistics probably underestimate the true prevalence of the disease.

Description

The **lungs** of asthmatics are hypersensitive to stimuli that do not affect healthy lungs. Many patients with asthma react to allergens such as pollen, dust mites, or animal dander, but colds, **viruses**, and environmental irritants such as dust and pollution can also be triggers.

During an asthma attack, cells in the bronchial walls called mast cells release chemicals that force the bronchial muscle to contract in spasms. These chemicals, which include histamine, acetylcholine, and a group of substances called leukotrienes, also bring white **blood** cells into the area, which is a key part of the inflammatory response. This process also stimulates mucus formation. The entire process creates bronchoconstriction, making it difficult for the asthmatic person to breathe.

Asthma usually begins in childhood or adolescence, but it also may first appear in adulthood. While the symptoms may be similar, certain important aspects of asthma are different in children and adults.

Child-onset asthma

When asthma begins in childhood, it often does so in an atopic child, one who is genetically predisposed to become sensitized to allergens in the environment. Atopy is present in at least one-third and as many as half of the general population. When these children are exposed to dust mites, animal **proteins**, **fungi**, or other potential allergens, they produce a type of antibody intended to engulf and destroy the foreign materials. This sensitizes the airway cells to particular allergens. Further exposure can lead rapidly to an asthmatic response.

This patient is using a nebulizer for breathing treatment in the emergency room. (Photograph by Larry Mulvehill. Science Source/Photo Researchers. Reproduced by permission.)

Adult-onset asthma

Allergies may also play a role in adult-onset asthma, which can start at any age and in a wide variety of situations. Adults may begin to react to allergens such as pollen, dust mites, and pet dander; they may find themselves allergic to aspirin and other drugs; and can even trigger an asthma attack with exercise. Another major cause of adult asthma is occupational exposure (and sensitization) to animal products, certain forms of plastic, wood dust, or metals. In addition, many people have such conditions as sinusitis or nasal polyps that also make them prone to asthma attacks.

Causes and symptoms

In most cases, asthma is caused by inhaling an allergen that sets off the biochemical chain reaction, causing the tissue changes that lead to airway inflammation, bronchoconstriction, and wheezing. Since avoiding, or at least minimizing, exposure is the most effective way to treat asthma, it is vital to identify which allergen or irritant is causing symptoms in each patient. Once asthma is present, symptoms can be triggered or made worse if the patient also has rhinitis (a cold or cold-like symptoms

caused by allergies), sinusitis (inflammation or **infection** of the sinuses), or a viral infection of the respiratory tract (such as **influenza**). Gastroesophageal reflux disease (GERD), commonly referred to as acid reflux or heartburn, can also make asthma worse. Some asthmatics are free of symptoms most of the time but may occasionally be short of breath. Others spend their days (and nights) coughing and wheezing, until properly treated.

Allergens and irritants most likely to cause asthma attacks are: smoke, animal dander, dust mites, fungi and molds, cockroach allergens, pollen, and industrial chemicals, fumes, or pollution. In addition, there are three conditions that can also provoke attacks in certain asthmatic patients: inhaling cold air, breathing hard during exercise, and stress or a high **anxiety** level.

During moderate to severe asthma attacks wheezing may be obvious, but mild attacks can be confirmed by listening to the patient's chest with a **stethoscope**. Wheezing is often loudest during exhalation, when the patient tries to expel air through narrowed airways. Besides wheezing and shortness of breath, the patient may also cough and report a feeling of tightness in the chest. Children may experience itching on their back or

neck. Crying or even laughing may bring on an attack. Severe episodes often occur when patients contract viral respiratory tract infections or are exposed to heavy loads of an allergen or irritant. Asthma attacks may last only a few minutes or can persist for hours or even days (a condition called status asthmaticus).

Shortness of breath may cause a patient to become very anxious, sit upright, lean forward, and use the accessory muscles of respiration to help breathe. The patient may be able to say only a few words at a time before stopping to take a breath. Confusion and a bluish tint to the skin indicate that the patient's oxygen supply is very low and emergency treatment is needed. If a severe attack lasts for some time, air sacs in the lung may rupture, trapping air within the chest. This makes it even harder to breathe in enough air. Fortunately, even patients with the most severe attacks usually recover completely.

Diagnosis

Physical examination

Apart from listening to the patient's chest, the examiner should look for maximum chest expansion while taking in air. Hunched shoulders and contracting neck muscles are other signs of narrowed airways. Nasal polyps or increased amounts of nasal secretions are often noted in asthmatic patients. Skin problems like atopic dermatitis or eczema indicate that the patient has allergic problems. A family history of asthma or allergies can be a valuable indicator. The diagnosis may be strongly suggested when typical symptoms and signs are present.

Spirometry and chest x ray

Spirometry can confirm a diagnosis of asthma by measuring lung function: how much air the lungs can hold and how much they can expel. Asthma patients typically have normal lung volumes with diminished flow rates. Repeating the test after the patient inhales a bronchodilator will show whether the airway narrowing is reversible, a finding that distinguishes asthma from other obstructive diseases like **emphysema**.

Often patients use a related instrument, called a peak flow meter, to monitor asthma severity at home. Because this device measures the strength with which air is exhaled, it can detect narrowed airways at the earliest stage, before an attack becomes full blown. This allows the patient to take the appropriate medication and diminish or avoid the episode.

Determining what triggers asthma attacks can be difficult. Skin testing may be helpful, although an allergic skin response does not necessarily mean that the allergen being tested is causing the asthma. Once a specific aller-

gen is suspected, a blood test can be run to check for IgE antibodies, since the **immune system** always produces an antibody in response to an allergen. This will show if the patient is sensitive to a particular allergen. If the diagnosis is still in doubt, the patient can inhale a suspect allergen while using a spirometer to detect airway narrowing, a test called "allergen challenge." Spirometry may also be repeated after a bout of exercise to confirm or refute the diagnosis of exercise-induced asthma. A **chest x ray** may help to rule out other pulmonary disorders, or confirm findings particular to asthma.

Treatment

Patients should be examined periodically and have their pulmonary function measured by spirometry to ensure that treatment goals are being maintained. The goal is to prevent troublesome symptoms, maintain lung function as close to normal as possible, and allow patients to pursue their normal activities, including those requiring exertion. The best drug therapy is that which controls asthmatic symptoms while causing few or no side-effects.

Drugs

METHYDXANTHINES. The chief methylxanthine is theophylline. It may exert some anti-inflammatory effect, and is especially helpful in controlling nighttime asthma. When, for some reason, a patient cannot use an inhaler to maintain long-term control, sustained-release oral theophylline is a good alternative. The blood levels of the drug must be measured periodically, as too high a dose can cause an abnormal **heart** rhythm or convulsions.

BETA-RECEPTOR AGONISTS. These bronchodilators, such as albuterol, are the best choice for relieving sudden attacks of asthma and for preventing attacks triggered by exercise because they relax the smooth muscles in the lungs. This prevents bronchospasm but doesn't help the swelling that often accompanies an asthma attack. These drugs are effective within about 30 minutes, and are maximally effective for three or four hours. They may be taken by mouth, inhaled, or injected, although the oral forms often produce such side effects as jitters and sleeplessness.

STEROIDS. Steroids and **corticosteroids** block inflammation and are extremely effective in relieving asthma symptoms. When taken by inhalation for a long period, they reduce the airways' sensitivity to allergens, and asthma attacks become less frequent. This is the strongest medicine for asthma, and can control even severe cases over the long term. Oral or intravenous steroids taken over long periods, however, can cause numerous side effects, including gastric bleeding, loss of

calcium from bones, **cataracts**, and diabetes. Patients on long-term steroid therapy may also have problems with wound healing and weight gain, and may develop mental problems as well. In children, growth may be slowed. Besides being inhaled, steroids may be taken by mouth or injected to control severe asthma rapidly.

LEUKOTRIENE MODIFIERS. Leukotriene modifiers, such as montelukast (Singulair), zileuton (Zyflo), and zafirlukast (Accolate) are drugs that work by counteracting leukotrienes, substances released by white blood cells in the lungs that constrict air passages and promote mucus secretion. They may reduce the need for short-acting inhalers, and may replace inhaled steroid treatment for patients with mild forms of asthma. Leukotriene modifiers may also help asthma patients recover from severe attacks more quickly, and can even help alleviate the allergic rhinitis that often accompanies allergies.

OTHER DRUGS AND TREATMENTS. Cromolyn sodium (Intal) and nedocromil (Tilade) are anti-inflammatory agents that stabilize the airways and help prevent the swelling and inflammation that trigger asthma attacks. They can also prevent flareups when given before exercise or when exposure to an allergen cannot be avoided. Like most asthma medication, these drugs must be taken regularly even if there are no symptoms, and require weeks or months of use before they reach their optimum effectiveness.

Anti-cholinergic drugs, such as ipratropium bromide (Atrovent), are useful in controlling severe attacks when added to an inhaled beta-receptor agonist. They help widen the airways and suppress mucus production. The effects of anti-cholinergics usually last longer than beta-agonists, and are often given in combination with bronchodilators to improve breathing.

If a patient's asthma is caused by an allergen that cannot be avoided and has become difficult to control through drug therapy alone, immunotherapy (allergy shots) may be beneficial. In this treatment, increasing amounts of the allergen are injected over a period of three to five years, so the body can build up an effective **immune response**. There is a risk that this treatment may itself trigger an asthma attack or even **anaphylaxis**. Immunotherapy has been used since the early twentieth century to treat allergies and hayfever. New studies have indicated that it also reduces asthma symptoms caused by exposure to such allergens as dust mites, ragweed pollen, and cats.

Managing asthmatic attacks

A severe asthma attack can be a medical emergency and should be treated as quickly as possible. It is most important for a patient suffering an acute attack to be

given oxygen. Rarely, it may be necessary to use a mechanical ventilator to help the patient breathe. Under a doctor's care, a beta-receptor agonist is inhaled repeatedly or continuously. If the patient does not respond promptly and completely, a steroid is given. An additional course of steroid therapy, given after the attack is over, will make a recurrence less likely.

Once asthma has been controlled for several weeks or months, the dose may be gradually tapered. The last drug added to the regimen should be the first to be reduced. Patients should be evaluated every one to six months, depending on the frequency of attacks.

Long-term treatment

Long-term asthma treatment is based on inhaled medications that are a combination of beta-receptor agonists and steroids. The drugs are delivered to the lungs via special inhalers that meter each dose. While this regimen is usually quite successful in diminishing or preventing attacks, all patients should be taught how to monitor their symptoms so they will know when an attack is starting. Those with moderate or severe asthma can use a peak flow meter to determine if inflammation is increasing.

Asthmatics should also have a written action plan to follow if symptoms suddenly worsen, including how to adjust their medication and when to seek medical care. When deciding whether a patient should be hospitalized, the past history of acute attacks, severity of symptoms, current medication, and whether good support is available at home all must be taken into account.

Referral to an asthma specialist should be considered if:

- There has been a life-threatening asthma attack or severe, persistent asthma.
- Treatment for three to six months has been ineffective.
- Another condition, such as nasal polyps or chronic lung disease, is complicating asthma.
- Special tests, such as allergy skin testing or an allergen challenge are needed.
- Intensive steroid therapy has been necessary.

Special populations

INFANTS AND YOUNG CHILDREN. It is especially important to monitor the course of asthma in young patients so that treatment may be diminished or increased as necessary. The health care provider should write out an asthma treatment plan for the child's school. Although asthmatic children often need medication at school to control acute symptoms or to prevent exercise-induced attacks, proper management usually enables a child to

take part in physical activities. Only as a last resort should activities be limited.

OLDER ADULTS. Side effects from beta-receptor agonist drugs (including rapid heart rate and tremor) may be more common in older patients. These patients may benefit from receiving an anti-cholinergic drug along with the beta-receptor agonist. If theophylline is given, the dose should be carefully monitored, as older patients may be less able to metabolize this drug. Asthma in older patients may also be complicated by other obstructive lung diseases such as chronic bronchitis or emphysema. It is important to know the extent the symptoms caused by the asthma. A two- to three-week course of steroids can help determine which symptoms are attributable to asthma.

Prognosis

Once the best drug or combination of drugs is found, most patients with asthma respond well and are able to lead relatively normal lives. More than half of affected children stop having attacks by the time they reach twenty-one. Many others have less frequent and less severe attacks as they grow older. In either case ongoing treatment to prevent attacks and urgent measures to control them if they occur are equally important. A small minority of patients will have progressive difficulties breathing. These patients are at risk for **respiratory failure** and must receive intensive treatment.

Health care team roles

Diagnosis and effective asthma management involve cooperation and collaboration between the patient, family, and an interdisciplinary team of health care professionals. These include the patient's primary health care provider, allergy and immunology specialists, nurses, laboratory technologists, respiratory therapists, pharmacists, pharmacy assistants, and health educators are involved in helping patients and families gain an understanding of how to manage this chronic disease.

Patient education

Nurses, respiratory therapists, and health educators teach patients and families how to prevent, recognize, and manage asthma attacks, including the distinction between mild episodes and those requiring immediate medical attention. They can also train them in stress management techniques that reduce anxiety to help them gain control of this chronic condition.

USING AN INHALER. Perhaps most importantly, these professionals show patients the proper technique for using inhalers and other medications, and stress the importance of compliance. Using a respiratory inhaler properly is a

KEY TERMS

Allergen—A foreign substance, such as mites in dust or animal dander which, when inhaled, causes the airways to narrow and produces asthma symptoms.

Allergen challenge—“Provocation” testing in which a patient is exposed to a suspected allergen under controlled conditions.

Atopy—An allergy (probably hereditary) that makes people react immediately to allergens they encounter. Atopic individuals are more likely to develop allergic reactions of any type, including the inflammation and airway narrowing typical of asthma.

Hypersensitivity—The state where even a tiny amount of allergen can cause the airways to constrict and bring on an asthmatic attack.

Spirometry—A test using an instrument called a spirometer that shows how well an asthmatic is breathing, the severity of the asthma, and how well it is responding to treatment.

critical skill in asthma management and it's vitally important that patients be instructed in its proper use:

- Remove the inhaler's cap.
- Holding the inhaler upright, shake it thoroughly for several seconds.
- Exhale as much air as possible, while tilting the head back slightly.
- Hold the inhaler in the position required by the manufacturer. Some should be held an inch or two away from the mouth, others should be placed directly in the mouth.
- Press the inhaler to dispense the medication.
- Inhale slowly and deeply *through the mouth only* for several seconds.
- Hold the breath for at least 10 seconds; this allows the medication to penetrate into the lungs. Take only one breath for each puff.
- Exhale.
- Wait a minute or so between puffs. This delay allows the second dose to get even farther into the airways.

Successful use of metered-dose inhalers requires a close degree of coordination between dispensing the drug and inhaling it. Because this is usually difficult for young

children, they are often told to attach “spacers” to their inhalers. These are chambers into which the drug is sprayed before it is inhaled, allowing the medication to be ingested in one or more breaths. For the tiniest patients, masks are attached to the spacers. Many doctors recommend spacers for adult patients as well, since they decrease the chances of using the inhaler improperly, and increase the amount of medication that reaches the lungs. During a severe asthma attack, when patients may not have the ability to inhale a full dose, spacers can literally save lives by allowing patients in distress to take their medication in shorter breaths. Spacers are also usually attached to corticosteroid inhalers.

When using powder inhalers (Rotacaps), patients should close their lips around the inhaler’s mouthpiece and inhale quickly. After using a corticosteroid inhaler patients should gargle or rinse their mouths with water to avoid thrush, an overgrowth of yeast in the mouth.

Pharmacists and pharmacy assistants may offer additional instruction about medication use and reiterate the importance of adhering to prescribed treatment.

Prevention

Minimizing exposure to allergens

There are a number of ways patients can reduce exposure to allergens and irritants that provoke asthmatic attacks, or to avoid them altogether:

- If the patient is sensitive to the family pet, remove the animal or at least keep it out of the bedroom. Keep the pet away from carpets and upholstered furniture. Remove all feathers.
- To reduce exposure to dust mites, remove wall-to-wall carpeting, keep the humidity down, and use special pillow and mattress covers. Wash bedding in hot water once a week.
- Reduce the number of stuffed toys, and wash them each week in hot water as well.
- Eliminate cockroaches using poison, traps, or boric acid rather than chemical pesticides.
- Keep indoor air clean by vacuuming carpets once or twice a week (with the patient absent), avoid using humidifiers, and use air conditioning during warm weather so windows can remain closed.
- Avoid exposure to tobacco smoke.
- Do not exercise outside when air pollution levels are high.
- To reduce occupational exposure, wear a mask when working with or around irritants. Some patients may find it necessary to find work in a safer environment.

Astigmatism

Definition

Astigmatism results from an inability of the cornea to properly focus an image as a single point onto the retina, instead focusing the image on two different locations. The result is a blurred image.

Description

The cornea is a transparent layer that bends light and helps to focus it onto the retina, where light is detected. Any incorrect shaping of the cornea results in an incorrect focusing of the light that passes through it. Usually the cornea is spherically shaped, like a baseball. However, in astigmatism the cornea is elliptically shaped with a long meridian and a short meridian. These two meridians generally have a constant curvature and are generally perpendicular to each other (regular astigmatism). Irregular astigmatism may have more than two meridians of focus and they may not be 90° apart. A point of light, therefore, will have two points of focus instead of one. This causes blurry **vision**.

Some astigmatism is caused by problems in the eye’s lens. Minor variations in the curvature of the lens can produce minor degrees of astigmatism (lenticular astigmatism). Infants generally have the least amount of astig-

matism. Astigmatism may increase during childhood as the eye develops.

Causes and symptoms

The main symptom of astigmatism is blurred vision. Patients may also experience headaches and eyestrain. Astigmatism is suspected when the child can see some part of a pattern or picture more clearly than others. For example, lines going across may seem clearer than lines going up and down.

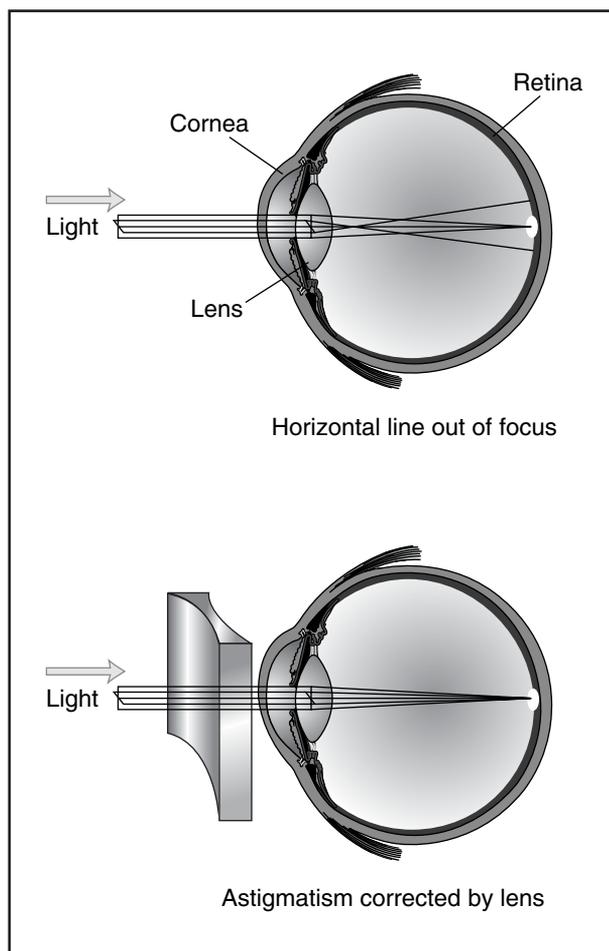

Regular astigmatism can be caused by the weight of the upper eyelid upon the eyeball, creating distortion; surgical incisions in the cornea; trauma or scarring to the cornea; tumors of the eyelid; or a developmental anomaly. Irregular astigmatism can be caused by scarring or keratoconus, a condition in which the cornea thins and becomes cone shaped. Although the etiology of keratoconus is unknown, it may be hereditary and may be worsened by chronic eye rubbing. Diabetes can also play a role in astigmatism. High **blood** sugar levels can cause shape changes in the intraocular lens. This usually occurs slowly and is often noticed only when the diabetic starts treatment. The return to a more normal blood sugar allows the lens to return to normal; this is sometimes manifested as farsightedness. Diabetics should wait until their blood sugar is under control for at least one month before being refracted for eyeglasses.

Diagnosis

Patients seek treatment because of blurred vision. Ophthalmologists and optometrists use a variety of tests to detect astigmatism. The patient may be asked to describe the astigmatic dial, a series of lines that radiate outward from a center. People with astigmatism will see some of the lines more clearly than others. Another diagnostic instrument is the keratometer, which measures the curvature of the central cornea. A computerized corneal topographer can measure a larger area encompassing the center and mid-periphery of the cornea. A keratoscope projects a series of concentric light rings onto the cornea. Misshapen locations of the cornea are revealed by noting areas of the light pattern on the cornea that do not appear concentric. It is also important to perform a refraction to determine if the lens is also contributing to the astigmatism. A refraction is when different lenses are placed in front of the eyes of the patient, who is asked which one permits better vision.

Treatment

Astigmatism is treated with cylindrical lenses. These can be eyeglasses or **contact lenses**. Lenses are shaped

Astigmatism can be treated by the use of cylindrical lenses. The lenses are shaped to counteract the shape of the sections of the cornea that are causing the difficulty.

(Illustration by Electronic Illustrators Group.)

to counteract the abnormalities of the cornea that are causing the difficulty.

Generally, if visual acuity is good and the patient experiences no overt symptoms, treatment is not considered necessary. Larger amounts of astigmatism, or astigmatism treated for the first time, may not be totally corrected. The cylindrical correction in the eyeglasses may be initially difficult. It may take a week or so to adapt to the corrective lenses. Patients experiencing ongoing problems should be referred back to their eye doctor, who might want to recheck the prescription.

Contact lenses used to correct astigmatism are called toric lenses. When a person blinks, a contact lens rotates. In toric lenses, it is important for the lens to return to the same position each time. Lenses have a prism to weight the lenses, thin zones, cut-off areas (truncations), or other methods of stabilization.

KEY TERMS

Meridian—A section of a sphere, for example, longitude or latitude on the globe. Or, on a clock, a section going through 12:00-6:00 or 3:00-9:00, etc.

Ophthalmologist—A medical doctor who specializes in eye surgery.

Optometrist—A primary eye care doctor who examines, diagnoses, treats, and manages diseases and disorders of the visual system, the eye, and associated structures as well as diagnoses related systemic conditions. An optometrist prescribes glasses, contact lenses, low vision rehabilitation, vision therapy, and medications, as well as performs certain surgical procedures.

In 1997, the Food and Drug Administration (FDA) approved laser treatment of astigmatism. Patients considering this should verify the surgeon's experience with the procedure and should discuss the possible risks or side effects. The most common **laser surgery** technique is known as LASIK (laser in situ keratomileusis). Another widely used technique is PRK (photorefractive keratectomy).

In the case of keratoconus, a corneal transplant can be performed if hard contact lenses do not provide adequate vision. Approximately 10–20% of keratoconus patients will require corneal transplantation. Early in 2001, the FDA approved an initial feasibility study of a keratoconus treatment involving prescription inserts instead of transplantation. The researchers hoped to also obtain approval to utilize the inserts to treat complications arising in some LASIK patients.

Prognosis

Astigmatism may be present at birth. It may also be acquired if something is distorting the cornea. It may worsen with time. Vision can generally be corrected with eyeglasses, contact lenses, or refractive surgery. The major risks of surgery (aside from surgical risks such as **infection**, night-vision problems, and reduced contrast sensitivity) are over- and under-correction of the astigmatism. Some lasers are able to treat over-correction, and under-correction can be solved by repeating the operation.

Health care team roles

Diagnosis is made by an ophthalmologist or optometrist; nurses, because of their roles in vision

screening programs in schools, day care institutions, and other settings, are often front-line workers in initial detection of astigmatism.

Prevention

At present, there are no known ways to prevent astigmatism, although early detection can prevent the condition from worsening.

Audiology

Definition

Audiology is the study of **hearing**. An audiologist is a health care professional who diagnoses and treats disorders of the auditory (hearing) and vestibular (balance) systems.

Description

Audiologists are concerned with hearing and balance problems. According to the Auditory Foundation of America (AFA), **hearing loss** is the third most common chronic health problem affecting Americans. Approximately 28 million individuals in the United States are affected by some form of hearing loss, ranging from mild impairment (loss of sensitivity) to total deafness. Balance problems (caused by a defect in the structures of the inner ear) affect approximately two million Americans.

Audiologists provide diagnostic, rehabilitative, and preventative services for individuals suffering from hearing and balance problems. They dispense assistive devices

An audiologist uses tympanometry to detect fluid in the middle ear, perforation of the eardrum, and any disorders of the hammer, anvil, and stirrup bones of the inner ear. (William Gage/Custom Medical Stock Photo. Reproduced by permission.)

such as **hearing aids**, cochlear implants, and telecommunication systems according to the needs of each patient. They educate consumers on the importance of hearing protection in industry, military, music, and other workplace and recreational settings. Audiologists may also conduct research into the assessment, management, and prevention of hearing loss and balance disorders.

Work settings

An audiologist may choose to work in a variety of settings, including a private office, hospital, medical clinic, non-profit or community center, nursing home, primary or secondary school, college or university, long-term care facility, or industry clinic.

Education and training

The minimum level of education required to become an audiologist is a master's degree from an accredited university or professional school. As of 2001, approximately 115 colleges and universities offer graduate programs in the field of audiology. After completing a nine-month post-graduate clinical fellowship and passing a

national standardized examination, an audiologist may earn a Certificate of Clinical Competency in Audiology (CCC-A) from the American Speech-Language-Hearing Association (ASHA). Most states require that the audiologist become licensed by the state in which they will practice.

Advanced education and training

In the early 1990s, the first Doctor of Audiology (Au.D.) degree programs were instituted to address the need for increased clinical training and expanded consumer services. The Au.D. is a post-baccalaureate four-year program that includes a Clinical Fellowship Year (CFY), a 12-month supervised clinical experience, so that students are eligible for state licensure upon graduation. The Au.D. curriculum includes classes in the areas of anatomy and physiology, acoustics and amplification, math, genetics, diagnostic techniques, patient care, sign language, and business management.

The Au.D. was designed to replace the master's as the entry-level degree into the field of audiology. The CFY will become a requirement for national certification after December 31, 2006; by the end of 2011, the doctor-

KEY TERMS

Vestibular—Relating to one's sense of balance.

al degree will become an additional requirement. Audiologists with a master's degree may bypass the conventional four-year program by enrolling in a distance learning program offered at a number of universities.

The median starting income for an audiologist with a master's degree in 1999 was \$33,600, and \$61,300 for an audiologist with an Au.D. degree.

Future outlook

Employment growth in the field of audiology is projected to remain strong, in part due to the increasing population of persons over the age of 55 and improvements in hearing and assistive technologies and also due to recommendations by the National Institutes of Health in its "Healthy People 2000" program mandating newborn or infant hearing screening.

Audiometry

Definition

Audiometry is performed to test a person's ability to hear the sound frequencies necessary for speech. The test is carried out by a trained specialist called an audiologist with an instrument called an audiometer.

Purpose

Audiometry tests are used to identify and diagnose **hearing** problems. Audiometry is routinely performed within the framework of general health screening programs, for example in primary schools to detect hearing problems in children or in a work setting to test employees. It is also used at the doctor's office or in hospital **audiology** departments as a diagnostic tool to screen for hearing problems in children, adults, and the elderly. A complete audiometric evaluation consists of two main tests. First, the audiologist records the softest sound that a person can hear under earphones at several different frequencies. This is called testing via air conduction. Then a bone vibrator is placed behind the patient's ear to determine the softest level that the patient can hear when the inner ear is directly stimulated, thus bypassing the outer and middle ear. This is called testing via bone conduction. An ear test with an **otoscope** will be performed by a health care provider to evaluate the patient's ear canal and ensure a clear path to the ear drum. A device will then be inserted in the ear that will change the pressure, produce a pure tone, and measure the patient's response to the sound and different pressures. This test is called *tympanometry*. The proper diagnosis of a patient's specific pattern of hearing impairment allows the selection of the appropriate treatment, which may include **hearing aids**, corrective surgery, or speech therapy.

KEY TERMS

Audiogram—A chart or graph of the results of a hearing test conducted with audiographic equipment. An audiogram typically shows hearing loss as a function of frequency, as measured by an audiometer. The chart reflects the softest (lowest volume) sounds that can be heard at various frequencies or pitches.

Audiologist—A specialist trained in detecting hearing loss.

Audiometer—An instrument for measuring hearing sensitivity.

Audiometry—The measurement of hearing ability, usually with the an audiometer.

Deafness—The complete inability to hear, often present at birth.

Decibel—A unit of measure for expressing the loudness of a sound. Normal speech is typically spoken in the range of about 20-50 decibels.

Frequency—The rate of repetition of the cycles of a periodic quantity, such as a sound wave.

Hearing loss—Decreased auditory perceptive ability. Hearing loss is always acquired.

Intensity level—The measurement of the intensity of a sound in comparison to another sound or to a fixed level, expressed in decibels.

Otology—The branch of medicine concerned with the ear.

Otoscope—A hand-held instrument with a tiny light and a funnel-shaped attachment called an ear speculum, which is used to examine the ear canal and eardrum.

Pitch—The subjective impression of the frequency of a tone. Pitch is thus a psychoacoustic variable, and people have variable degrees of sensitivity to it.

Pure tone—A tone having a single pitch, or frequency, such as a flute note. It is also called a pure tone.

Sound—Any vibration in the air liable to cause a sensation of hearing.

Sound wave—Alternations of sound pressure displacement following one another in cycles of compression through a medium such as air. On striking the ear, sound waves are heard as sound.

Threshold of hearing—The intensity level at which a sound becomes barely audible. For a continuous tone of between 2000 and 4000 Hertz, heard by a person with normal hearing, this is 0.0002 dyne/cm² sound pressure and is given the reference level of 0 dB.

Tone—A single sound of definite, recognizable pitch.

Tympanometry—A test where air pressure in the ear canal is varied to test the condition and movement of the ear drum. This test is useful in detecting disorders of the middle ear.

Precautions

Audiometry tests are performed with safe equipment and are simple and painless. They do not require any special precautions.

Description

Audiometry tests are carried out in a soundproof testing room equipped with audiometry equipment such as an audiometer, earphones, special headband, and a small listening booth for the audiologist. Audiometry equipment consists of devices emitting sounds or tones, like musical notes, at various frequencies, or pitches, and at various levels of loudness. In pure tone audiometry, pure tones, meaning tones that have a single frequency, are always channeled to each ear separately. For example, in a typical procedure, beginning with either ear of the patient, a 1kHz-tone is sent through the earphones. The volume of

the tone is set to a level that can be easily heard by a person with normal hearing. The patient is instructed to press a button or activate a switch when the tone is heard. The duration of the test tone is usually kept constant at some 1.5 seconds. The volume is then decreased by 10dB-increments until the patient can no longer hear it. At the first level at which the tone becomes inaudible, the volume is increased in 5dB-increments until the patient responds to the tone. The audiologist may need to decrease and increase the loudness of the tone a few times to establish the patient's hearing threshold. By definition, this threshold is the loudness level at which a person responds to the tone 50% of the time. After the threshold for the 1 kHz-tone has been recorded by the audiologist, the entire procedure is repeated with a 1.5 kHz tone, and further increasing the tone's frequency to 2, 3, 4, and 8 kHz. After the high-frequency range has been tested, the same procedure is performed for the lower frequencies,

starting again with a 1kHz-tone, but decreasing to 0.5, 0.25, and 0.125 kHz. The test results are plotted by the audiologist, and they show **hearing loss** as a function of frequency. Such a plot is called an audiogram and it usually shows the low frequencies or tones at one end and the high frequencies at the other end. A typical audiogram also reports results for both the left and right ears, since it is not unusual for levels of sensitivity to sound to differ from one ear to the other. The audiogram also plots the volume of the tones used for the test: from soft, quiet sounds at the top of the plot to loud sounds at the bottom. Hearing is measured in decibels, the unit of a logarithmic scale of sound intensity. Most of the sounds associated with normal speech patterns are usually found in the range of 20-50 decibels. An adult with normal hearing can detect tones between 0-20 decibels. Other tests that may have been performed with the pure-tone audiometry are also reported on the audiogram.

Another audiometry procedure is performed with a headband rather than earphones. The headband is fitted with small plastic rectangles that are placed behind the ears so as to channel the tones through the bones of the **skull**. The patient feels the vibrations of the tones as they are transmitted through the bones to the inner ear. As with the earphones, the tones are repeated at various frequencies and volumes.

Speech audiometry is another type of hearing test that uses a series of simple recorded words spoken at various volumes directly into earphones worn by the patient. The patient repeats the words heard to the audiologist as they are being heard. An adult with normal hearing will be able to recognize and repeat at least 90-100% of the words.

Speech reception threshold testing (SRT) is used to determine the lowest volume or intensity when speech can be understood and is reported in decibels (dB).

Preparation

The ears are first examined with an otoscope before audiometry testing to determine if there are any blockages in the ear canal. If excessive wax is present, the patient is sent to a doctor for removal of the wax.

Results

A person with normal hearing should be able to recognize and respond to all of the tone frequencies and the different volumes used during the audiometry test in both ears. Normal hearing detects a range of low and high-pitched sounds between 0-20 decibels, and normal speech is generally spoken in the range of 20-50 decibels.

Audiometry test results are considered abnormal if there is a significant variation between the levels of

sound recognized by the two ears, or if the patient is unable to hear within the normal range for test frequencies. Failure to pick out any tone of 20 dB or louder indicates a degree of hearing loss. The pattern of responses displayed on the audiogram are used by the audiologist to determine if a significant hearing loss has occurred and if the patient might benefit from further testing for differential diagnosis, hearing aids, or corrective surgery. An unexplained difference between the two ears in the tone test or the speech test may warrant another test, called an auditory **brain** stem response (ABR) to look for a possible acoustic tumor. Or, a difference in hearing between the two ears may be explained by case history information, such as noise exposure.

Health care team roles

Audiometry is performed by an audiologist. Any hearing problems found may be investigated by physicians and treated by physicians or speech-language pathologists, depending on the nature of the problem. If necessary, imaging studies, such as a CT scan, will be ordered by physicians and performed by radiologic technologists.

Auditory integration training

Definition

Auditory integration training, or AIT, is one specific type of music/auditory therapy based upon the work of French otolaryngologists Dr. Alfred Tomatis and Dr. Guy Berard.

Origins

The premise upon which most auditory integration programs are based is that distortion in how things are heard contributes to commonly seen behavioral or learning disorders in children. Some of these disorders include attention deficit/hyperactive disorder (ADHD), autism, dyslexia, and central auditory processing disorders (CAPD). Training the patient to listen can stimulate central and cortical organization.

Auditory integration is one facet of what audiologists call central auditory processing. The simplest definition of central auditory processing, or CAP, is University of Buffalo Professor of Audiology Jack Katz's, which is: "What we do with what we hear." Central auditory integration is actually the perception of sound, including the ability to attend to sound, to remember it, retaining it in both the long- and short-term **memory**, to be able to listen to sound selectively, and to localize it.

Guy Berard developed one of the programs commonly used. Berard's auditory integration training consists of twenty half-hour sessions spent listening to musical sounds via a stereophonic system. The music is random, with filtered frequencies, and the person listens through earphones. These sound waves vibrate and **exercise** structures in the middle ear. This is normally done in sessions twice a day for 10 days.

Alfred Tomatis is also the inventor of the Electronic Ear. This device operates through a series of filters, and reestablishes the dominance of the right ear in **hearing**. The basis of Tomatis' work is a series of principles that follow:

- The most important purpose of the ear is to adapt sound waves into signals that charge the **brain**.

- Sound is conducted via both air and bone. It can be considered something that nourishes the nervous system, either stimulating or destimulating it.
- Just as seeing is not the same as looking, hearing is not the same as listening. Hearing is passive. Listening is active.
- A person's ability to listen affects all language development for that person. This process influences every aspect of self-image and social development.
- The capacity to listen can be changed or improved through auditory stimulation using musical and vocal sounds at high frequencies.
- Communication begins in the womb. As early as the beginning of the second trimester, fetuses can hear sounds. These sounds literally cause the brain and nervous system of the baby to develop.

Description

A quartet of CAP defects have been identified that can unfavorably alter how each person processes sound. Among these are:

- Phonetic decoding, a problem that occurs when the brain incorrectly decodes what is being heard. Sounds are unrecognizable, often because the person speaking talks too fast.
- Tolerance-fading memory, a condition with little or poor tolerance for background sounds.
- Auditory integration involves a person's ability to put together things heard with things seen. Characteristically there are long response delays and trouble with phonics, or recognizing the symbols for sounds.
- The fourth problem area, often called auditory organization, overlaps the previous three. It is characterized by disorganization in handling auditory and other information.

Certain audiological tests are carried out to see if the person has a CAP problem, and if so, how severe it is. Other tests give more specific information regarding the nature of the CAP problem. They include:

- Puretone air-conduction threshold testing, which measures peripheral **hearing loss**. If loss is found, then bone-conduction testing, or evaluation of the vibration of small bones in the inner ear, is also carried out.
- Word discrimination scores (WDS) determines a person's clarity in hearing ideal speech. This is done by presenting 25–50 words at 40 decibels above the person's average sound threshold in each ear. Test scores equal the percentage of words heard correctly.

- Immittance testing is made up of two parts, assessing the status of, and the protective mechanisms of the middle ear.
- Staggered sporadic word (SSW) testing delivers 40 compound words in an overlapping way at 50 decibels above threshold to each ear of the person being tested. This test provides expanded information that makes it possible to break down CAP problems into the four basic types.
- Speech in noise discrimination (SN) testing is similar to staggered sporadic word testing except that other noise is also added and the percentage correct in quiet is compared with that correct when there is added noise.
- Phonemic synthesis (PS) determines serious learning problems. The types of errors made in sounding out written words or associating written letters with the sounds they represent help in determining the type and severity of CAP problems.

Benefits

Upon completion of an auditory integration training program, the person's hearing should be capable of perceiving all frequencies at, or near, the same level. Total improvement from this therapy, in both hearing and behavior, can take up to one year.

Research and general acceptance

Auditory integration training is based upon newly learned information about the brain. Though brain structures and connections are predetermined, probably by heredity, another factor called plasticity also comes into play. Learning, we now know, continues from birth to death. Plasticity is the ability of the brain to actually change its structuring and connections through the process of learning.

Problems with auditory processing are now viewed as having a wide-reaching ripple effect on our society. It is estimated that 30–40% of children starting school have language-learning skills that can be described as poor. CAP difficulties are a factor in several different learning disabilities. They affect not only academic success, but also nearly every aspect of societal difficulties. One example to illustrate this is a 1989 University of Buffalo study where CAP problems were found to be present in a surprising 97% of youth inmates in an upstate New York corrections facility.

Training and certification

Both Tomatis and Berard have certification programs in their therapies.

Autoimmune disease tests

Definition

Autoimmune disease tests are screening procedures used in the diagnosis of **immune system** disorders and other disease states to detect autoantibodies, which are antibodies produced against the body's own tissues.

Purpose

Hundreds of different autoantibodies have been described, not all of which are involved in disease. Autoantibodies are classified into two broad categories, organ-specific, in which the targeted antigen is located in a single organ or cell type, and organ-nonspecific, in which the targeted antigen is widely distributed, usually a ubiquitous component of all cell types. Autoantibodies may be further classified as primary pathogenic antibodies, which directly cause a disorder by blocking a normal

cellular function or by damaging tissue, or secondary antibodies, which are not pathogenic in themselves but are produced as a result of the disease and thus may be used as diagnostic markers.

Autoimmune diseases are illnesses in which the immune system produces autoantibodies that attack the body's own cells or tissues as though they are foreign substances. Autoimmune diseases are generally difficult to diagnose, as individuals exhibiting very different symptoms can have the same underlying disease. Like the causative autoantibodies, the diseases are classified as organ-specific and organ-nonspecific (or systemic). In organ-specific autoimmunity, the autoantibodies are produced against a specific target antigen in a specialized cell, tissue, or organ in response to injury, inflammation, or other stimulus. Examples include autoimmune hemolytic anemia, in which anti-erythrocyte antibodies are produced, insulin-dependent or type I diabetes, characterized by T cells and antibodies against beta-cells in the **pancreas**, and myasthenia gravis, involving antibodies against the acetylcholine receptor. In systemic autoimmune diseases, the tissue injury and inflammation is generally initiated by vascular leakage and deposition in multiple sites of circulating autoimmune complexes formed against ubiquitous soluble cellular antigens, usually nuclear in origin. Systemic lupus erythematosus (SLE), characterized by the production of multiple anti-nuclear and anti-DNA autoantibodies, is the classical example of a systemic autoimmune disease. Autoimmune disease tests can help to identify the causative autoantibody in the **blood**.

Precautions

For all autoimmune disease tests, a blood sample is required, usually taken from a vein on the back of the hand or the inside of the elbow. The nurse or phlebotomist collecting the sample should observe **universal precautions** for the prevention of transmission of blood-borne pathogens. Generally, blood samples that are grossly hemolyzed or lipemic are unacceptable.

The diagnosis of autoimmune diseases is very challenging; it can take months or even years for the health care team to put together the symptoms and laboratory findings to make an accurate diagnosis. New symptoms may appear over time to aid the process of reaching a diagnosis. Knowledge and awareness on the part of the doctor and effective communication between doctor and patient, including a complete and accurate medical history, together with a thorough **physical examination** and carefully chosen laboratory tests, are essential to the process.

Conditions other than autoimmune diseases can give rise to autoantibodies. In many cases, the tests performed on healthy individuals, especially the elderly, give positive results. It should be kept in mind that transient appearance of autoantibodies is a common feature of some infections, especially Epstein-Barr virus, adenovirus, and mycoplasmal **pneumonia**. Ideally, in the end, each positive result is interpreted in the context of the patient's symptoms and history, and all other diagnostic findings.

Access to a medical laboratory that specializes in autoantibody analysis is an advantage. Clinical immunology is a rapidly changing field: new, more convenient, and more specific test protocols are evolving, and a specialized laboratory is likely to have access to the most modern diagnostic tools.

In immunofluorescence-based tests, the tissues used in the assays must be carefully chosen and handled. It is important to use serum and not plasma, since the fibrinogen in the plasma can give rise to stray fluorescence and false-positive reports. The serum must be adequately diluted to avoid non-specific interactions with the target antigens. The ratio of FTIC-bound to unlabeled immunoglobulin must be sufficiently high to allow detection but not so high as to give rise to non-specific fluorescence. It is essential that control assays—a negative control that contains no antibody, as well as positive controls that contain known amounts of autoantibody at high and low levels—be included to ensure the accuracy of the test results.

In the tests for cryoglobulins and cold agglutinins, it is essential that the syringe used to draw blood and the container used to transport it to the laboratory be pre-warmed and maintained at 37°C. The sample in these tests must be brought to the laboratory immediately for processing, and the procedure should be scheduled with the laboratory in advance.

Description

Detection techniques

INDIRECT IMMUNOFLUORESCENCE. The standard detection technique for identification of many serum autoantibodies is immunofluorescence. In indirect immunofluorescence testing for the widest range of antibodies, a “multiblock” of commercial test tissues (for example, rat **liver**, kidney, and **stomach**) or a single tissue such as mouse kidney with both muscle and blood vessel cells can be used. The tissues are frozen and cut with a cryostat into sections about 4 micrometers thick, and the sections are mounted onto sections (wells) of a glass slide and frozen. Alternatively, other cells or tissues

may be used to demonstrate specific types of autoantibodies. For antinuclear antibody testing, commercially prepared monolayers of HEp-2 cells (human epithelioma cells) grown in wells on glass slides and frozen are used. For detection of antibodies to double stranded DNA, slides with *Crithidia luciliae* (a protozoan with a kinetoplast rich in DNA) are used. The tissue or cell samples are incubated for a specific time with an initial dilution of the patient's serum. Positive and negative control slides (treated with known reactive and nonreactive standard solutions, respectively) are also prepared. The slides are then washed and incubated with the anti-human immunoglobulin that is covalently bound to a fluorescent reporter molecule, usually fluorescein isothiocyanate (FITC). The cells are then visualized under the **microscope** by shining ultraviolet light on the slide, which causes the reporter molecule to fluoresce (in the case of FITC, this is the emission of apple-green light). The presence of fluorescent cells indicates a positive test. When a positive test result occurs, the serum is serially diluted, or titered, and the test is repeated to determine the highest dilution at which the test is positive. The reciprocal of the highest dilution showing fluorescence is reported as the titre. The pattern of fluorescent staining of discrete part(s) of the cell or nucleus, which gives clues to the type of disease, is also reported.

As an alternative to the fluorescence detection method, instead of FITC, the anti-human immunoglobulin antibody is bound to an enzyme, such as horseradish peroxidase, that produces a colored product when treated with the appropriate substrate. The advantage of enzyme-based test is that an ordinary high quality light microscope may be used for detection; however, extra wash and incubation steps are necessary to produce the color change.

In a related technique, direct immunofluorescence, the tissue to be tested is obtained from the patient, frozen, and thin-sectioned using a cryostat. The sections of tissue are mounted onto microscope slides and treated directly with the FITC-linked antibody. This method detects autoantibodies that have attached *in vivo* to the specific tissue.

ENZYME-LINKED IMMUNOASSAY (EIA), ALSO CALLED ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA). This detection procedure is similar to immunofluorescence, except that, instead of cells, a specific antigen covalently bound to a solid surface (usually a commercially available microwell plate) is allowed to react with the test serum. The plate is then washed and reacted with an enzyme-labeled antihuman immunoglobulin, then washed and allowed to react with a substrate that gives a quantifiable color change. This technique is generally costlier and less information-rich than immunofluorescence on multiblock tissues, but it is often used to confirm

a diagnosis based on the immunofluorescence result. Commercial EIA test kits are available for a wide variety of autoantibodies including anticardiolipin (antiphospholipid), and thyroid antibodies such as anti-thyroglobulin and anti-thyroid peroxidase.

PARTICLE AGGLUTINATION. Detection of antibodies by particle agglutination is an old—but reliable and relatively inexpensive—technique. The target antigen is coated onto an inert gelatin or latex particle and treated with the test serum. Agglutination or clumping of the particles indicates a positive response, and the serum is then titered as in the immunofluorescence assay.

IMMUNOPRECIPITATION. The Ouchterlony double diffusion test is the prototype immunoprecipitation technique. The serum to be tested for the presence of an antibody and the antigen are added to separated wells cut into an agar gel slab and allowed to diffuse towards one another. A positive test is indicated when a precipitation line forms in the zone of the gel where the antibody comes into contact with the antigen. The process, which may require up to 72 hours, can be accelerated by using agarose gels with an electrolyte and applying a current, in a technique called immunoelectrophoresis. In a related method called nephelometry, the immunoprecipitation, carried out in a solution containing the antigen, gives rise to turbidity that can be quantified by an instrument that measures light scattering.

Representative tests

ANTINUCLEAR ANTIBODY TEST (ANA), ALSO CALLED FLUORESCENT ANTINUCLEAR ANTIBODY TEST (FANA) AND ANTINUCLEAR ANTIBODY PANEL. The antinuclear antibody (ANA) test, which screens for antibodies to components of the nuclei of all cells, is generally performed first in the evaluation of a person for autoimmune diseases, particularly when systemic lupus erythematosus (SLE) is suspected. Usually HEp-2 cells are tested with 5–10 microliters of the patient's serum. HEp-2 cells are preferred because of their very large nuclei. Recognition of the patterns of immunofluorescence staining of the nucleus is critical in the interpretation of the ANA test. EIA kits for testing ANA IgG and IgM antibodies are also commercially available, but give only titre results without staining pattern information.

ANTIMITOCHONDRIAL ANTIBODY TEST. This test is primarily used when there are symptoms of liver or other organ damage, to confirm a diagnosis, or help to identify possible causes of tissue damage. Antimitochondrial antibodies are helpful in distinguishing primary biliary cirrhosis (PBC) from other extrahepatic obstruction, hepatitis, and alcoholic cirrhosis. Nine discrete subtypes of antimitochondrial antibodies, designated M1–M9, have been described and are associated with different disease

states: M1 antibodies are found in **syphilis**, M2 and M9 in PBC, M3 in lupus, M5 in connective tissue disorders, M6 in iproniazid-induced hepatitis. Specific M2 antigens are available for confirmation of a diagnosis of PBC by EIA detection.

ANTIPHOSPHOLIPID ANTIBODY TEST, ALSO CALLED CARDIOLIPIN ANTIBODY TEST. Antiphospholipid antibodies are detected in combination with circulation disorders (livedo reticularis and Sneddon's syndrome), in SLE, in Sjögren's syndrome, and in women suffering recurrent spontaneous abortions. In these conditions, collectively called antiphospholipid syndrome, the antibodies detected are of the IgG and IgM classes. In more than 75% of the patients with spontaneous abortions, only IgG antibodies are found. EIA detection is generally used to test for antiphospholipid antibodies, and antigens to detect each of the IgG-, IgM-, and IgA-type antibodies are commercially available.

CRYOGLOBULIN TEST. Cryoglobulins are tested in the presence of symptoms induced by cold, such as purpura and Raynaud's phenomenon, and when immune-complex-mediated disease is suspected. Cryoglobulins, often confused with cold agglutinins, are abnormal immunoglobulins that precipitate to varying degrees at temperatures below 37°C and become resolubilized upon rewarming; the precipitates formed can block small **blood vessels**. Cryoglobulins have been purified and immunochemically characterized, and three major types having distinct clinical features have been described. Type I cryoglobulins are associated with single monoclonal immunoglobulins (IgM, IgG, or IgA), Type II with mixed monoclonal immunoglobulins, and Type III with mixed polyclonal immunoglobulins. Cryofibrinogen and C-reactive protein-albumin complexes are non-immunoglobulin cryoprecipitable plasma **proteins** with similar clinical manifestations.

For the test, 10mL of blood is collected with a syringe warmed to 37°C, and 6mL is transferred to a specifically designed glass cryoglobulin tube, also prewarmed to 37°C. The sample should be hand carried to the laboratory and must be kept at 37°C until the blood has clotted and the serum is collected by centrifugation. The serum sample is then stored at 4°C for 24–72 hours and observed for formation of a white precipitate (cryoglobulins). An aliquot of the serum is rewarmed at 37°C for 24 hours to test for reversibility of cryoprecipitation. The amount of cryoglobulin is quantified by measuring the serum protein concentration before and after cryoprecipitation, or by collecting the precipitate from an aliquot of serum, dissolving it in an acidic buffer, and measuring the cryoglobulin protein level. The individual cryoglobulin components may be identified from the isolated cryoprecipitate by immunoelectrophoresis, per-

formed at 37°C to prevent precipitation of the cryoglobulin during the procedure.

COLD AGGLUTININS. Cold agglutinin disease is an acquired autoimmune hemolytic anemia. Cold agglutinins, which are frequently confused with cryoglobulins, are an IgM-type autoantibody directed against an antigen (I or i) on the surface of red blood cells and react only at temperatures lower than 37°C. The antibody reaction occurs in the extremities, which are generally cooler, causing red blood cells to briefly stick together, leading to obstruction of the small blood vessels; Raynaud's syndrome is commonly associated with cold agglutinins, and hemolytic anemia may result when red blood cells undergo lysis upon rewarming. As with the cryoglobulin test, blood for the cold agglutinins test must be collected with a warm syringe and kept at 37°C during transport to the laboratory for analysis. The test is performed by mixing serial dilutions of the patient's serum with group O red blood cells and incubating at 2–8°C overnight. The tubes are examined for clumping (agglutination) and the highest dilution giving agglutination is noted. Following this, the tubes must be incubated at 37°C for 30 minutes to reverse the agglutination that occurred in the cold. The test is positive only when the agglutination is reversed by 37°C incubation.

RHEUMATOID FACTOR TEST, ALSO CALLED RF OR RHF TEST. Rheumatoid factors are associated with many different conditions, including viral and chronic bacterial infections, lymphomas and myelomas, and connective tissue diseases. Standard tests are non-specific, detecting all classes of immunoglobulins that react with the Fc region of other immunoglobulins. Commercially available EIA kits have recently become available that allow testing of individual immunoglobulin classes. The test is used mainly in the diagnosis of rheumatoid arthritis, although it is not very specific unless the disease is progressive with vasculitis. Elevated rheumatoid factor is also found with other rheumatologic diseases, such as SLE. Rheumatoid factors are detected by particle agglutination, nephelometry, or by EIA.

Preparation

Certain drugs, including **antibiotics**, oral contraceptives, procainamide, tranquilizers, steroids, thiazide diuretics, and some **antihypertensive drugs** give a false positive result in the ANA test, and the patient should be advised to stop taking these before the test. For the antimitochondrial antibody and cryoglobulin tests, fasting for six hours or overnight before the test may be required.

No special preparations or diet changes are required for the antiphospholipid, cold agglutinin, or rheumatoid factor tests.

KEY TERMS

Agglutination—Antibody-induced clumping of cells.

Antibody—Y-shaped protein molecule produced by B cells as part of the primary immune defense; each molecule and its clones have a unique binding site that combines with a complementary site of an antigen, to disable the antigen and signal other immune defenses.

Autoantibody—An antibody produced by an organism against any of its own tissues, cells, or cell components.

Autoimmune disease—Any of a variety of diseases in which the body's immune system attacks its own tissues.

Capillary—A small-bored tube used to collect, store, or test fluid samples.

Cold agglutinins—An autoantibody found on the surface of red blood cells in certain diseases that can cause the cells to clump at temperatures below 37°C and cause red blood cell lysis.

Cryoglobulin—A plasma immunoglobulin that is insoluble when cold and dissolved at body temperature.

Cryoprecipitation—Cold-induced precipitation of a substance from solution.

Deoxyribonucleoproteins—A class of proteins associated with DNA, found in the nucleus of the cell.

Enzyme—A protein that produces specific chemical changes in an organic target molecule by catalytic action.

Fluorescein isothiocyanate (FITC)—An organic molecule that can be covalently bound to other

molecules, and that emits visible light when exposed to ultraviolet radiation.

Hemolytic anemia—Anemic condition characterized by the destruction of red blood cells.

Histone—Any of a group of five small alkaline proteins that occur in the nucleus of eukaryotic cells and form molecular complexes with DNA, around which the DNA is wound in the nucleosomes.

Immunofluorescence—Any of various techniques to detect an antigen or antibody in a sample by coupling its target antibody or antigen to a fluorescent compound and observing its reaction with the sample under an ultraviolet-light.

Immunoglobulin (Ig)—Any of several classes of structurally related proteins that function as antibodies and are found in plasma and other body fluids and in the membrane of certain cells; classes include IgA, IgD, IgE, IgG, and IgM.

Microwell plate—A rectangular disposable culture dish constructed with an array of small depressions used to carry out reactions.

Mitochondrion—An organelle in the cytoplasm of cells that functions in energy production.

Monoclonal—Pertaining to cells or cellular products that are derived from a single cell; a monoclonal antibody is an immunoglobulin directed against a specific epitope of an antigen, and isolated from a culture of identical cells grown from a single clone.

Aftercare

After the blood sample is drawn, pressure should be applied to the puncture site until the bleeding stops to reduce bruising, and a bandage may be applied to the site. A warm pack may be applied to the site to relieve discomfort.

Complications

Complications associated with blood drawing may be anticipated, but are minimal when the procedure is performed correctly. Multiple punctures to locate suitable veins may be necessary to obtain a blood sample from some patients. The patient may faint or feel dizzy while the blood sample is being drawn. Discomfort or

bruising may occur at the puncture site, and there is a slight risk of **infection**.

Results

With immunofluorescence detection, lower than reference level titers that produce a fluorescent pattern in the test cells is interpreted as a negative result. In EIA, a lower than reference level titer that produces a color change, or a level of color change less than or equal to that found for a reference negative control, is interpreted as a negative result. With particle agglutination, absence of particle clumping, and in immunoprecipitation the lack of a precipitation line or solution turbidity, at titers lower than reference levels is negative.

KEY TERMS CONTINUED

Mycoplasma pneumonia—Also called Eaton-agent pneumonia, primary atypical pneumonia, or walking pneumonia, a contagious lung infection caused by the bacterium *Mycoplasma pneumoniae*.

Nephelometry—A method for studying the density of suspended particles in a liquid sample by measuring the amount of light scattered by the particles.

Nucleolus—One or more densely staining bodies, composed mainly of RNA, within the nucleus of a cell.

Nucleus—A specialized spherical structure, present in most living eukaryotic cells and enclosed in a membrane, that is the center for metabolism of DNA and RNA.

Phospholipid—Any of a group of fatty biomolecules composed of phosphoric esters.

Polyclonal—Pertaining to cells or cellular products that are derived from several lines of clones; a polyclonal antibody is a mixture of immunoglobulins isolated from antisera that is directed against all epitopes of a single antigen.

Primary biliary cirrhosis (PBC)—A liver disease of unknown origin, found mainly in women 40 – 60 years old, with swelling of the liver and characterized by intense itching, malabsorption, and jaundice.

Raynaud's phenomenon—Sporadic attacks of blood flow interruption to the fingers, toes, ears, or nose caused by exposure to cold or by emotional stimulation, in which the affected area becomes

bluish white and numb, then red, warm, and tingly, before returning to normal.

Rheumatoid factor—An autoantibody found in the blood, often associated with rheumatoid arthritis.

Ribonucleoprotein—A class of protein found in the nucleus associated with RNA.

Scleroderma—An autoimmune disease in which the connective tissue becomes hardened and rigid.

Sjögren's disease—An autoimmune disease characterized by fatigue and malaise, dry gritty eyes and dry mouth, and recurrent gingivitis and respiratory infection.

Smith's (Sm) antibodies—A nuclear autoantibody specific for SLE, named for the patient in which first described.

Systemic lupus erythematosus (SLE)—An autoimmune inflammatory disease of the connective tissue that occurs mainly among middle-aged women, characterized by skin eruptions, joint pain, recurrent pleurisy, and kidney disease.

Titer—The concentration of substance in a solution described in terms of the degree of dilution required to achieve a threshold effect.

Vacutainer—A glass tube fitted with a rubber stopper from which air is evacuated to produce a slight vacuum, used for blood specimen collection.

Venipuncture—The puncture of a vein for therapeutic purpose or to collect a specimen.

Several factors should be considered as part of interpreting a positive test, and additional tests are often indicated to aid in identification of the individual causative autoantibodies.

Antinuclear antibodies test

Normal titer ranges for antinuclear antibodies is age-dependent:

- 18 years and younger: < 1:20
- 18–65: < 1:40
- older than 65: < 1:80

The pattern of immunofluorescent staining should be reported along with the titer. Homogeneous staining indicates antibodies to histones and deoxyribonucleopro-

teins. A speckled pattern is found with antibodies against ENA, a group of saline-soluble antigens that include non-histone proteins and nuclear ribonucleoprotein (RNP). Peripheral staining indicates double-stranded (ds) DNA, rheumatoid factor, and antiphospholipid. Nucleolar staining is positive for anti-nucleolar RNP, a result specific for the autoimmune skin disorder scleroderma. Specific staining of centromeres is indicative of a systemic sclerosis variant known as CREST syndrome. More than 95% of people with SLE have a positive ANA test. Scleroderma has a 60–71% positive rate; Sjögren's disease, 50–60%, and rheumatoid arthritis, 25–30%. Serum that tests positive for ANA can be further tested by EIA with specific antigens to confirm a diagnosis. Positive tests for anti-double-stranded (ds) DNA or anti-Sm

(Smith's) antibodies are definitive for SLE. Identification of anti-RNPs is positive for mixed connective tissue disease (MCTD) as well as SLE.

Antimitochondrial antibody test

The titer in a normal sample is < 1:40. A positive result is typified by granular staining in the cytoplasm of all tissue types in the commercial multiblock. Antimitochondrial antibody tests are positive in about 94% of patients with primary biliary cirrhosis (PBC), with typical titers of > 1:160, and in 25% of patients with chronic hepatic cirrhosis. Positive samples should be screened by EIA for antibodies specific to the M2 antigen to confirm the diagnosis of PBC.

Antiphospholipid antibody test

Reference levels will be dependent on the type of commercial EIA kit used and should be independently established in each laboratory. Antiphospholipid antibodies occur with a prevalence of 40% in patients with SLE. Over 75% of patients presenting with spontaneous abortions were positive for only IgG antibodies, while patients with thromboses had mainly IgM antibodies. IgG and IgM antibodies were found simultaneously in 31% of patients with Sjögren's syndrome.

Cryoglobulin test

The percent cryoprecipitation is reported (cryocrit). Although there is considerable overlap, Type I and Type II cryoglobulins, positive in Waldenström's macroglobulinaemia and in chronic lymphocytic leukemia, are often present in relatively high concentrations, with cryocrits usually > 5%, sometimes as high as 20–40%, especially with Type I cryoglobulins. Type III cryoglobulins generally give a cryocrit of < 1% and are associated with autoimmune diseases, including systemic lupus erythematosus (SLE), rheumatoid arthritis, scleroderma, and Sjögren's syndrome.

Cold agglutinins test

A normal titre for cold agglutinins is less than 1:64. Cold agglutinin disease associated with autoimmune hemolytic anemia usually produces titres between 1,000–100,000. Higher titers are also seen in about 60% of persons with *Mycoplasma pneumoniae* infections and other acute infectious diseases such as infectious mononucleosis. In cold autoimmune hemolytic anemia, the peripheral blood smear may show red blood cells present in clumps caused by their reaction with cold agglutinins. Some cases of chronic cold agglutinin disease occur in association with Waldenström's macroglobulinemia.

Rheumatoid factor test

Normal rheumatoid factor titer for adults is < 1:80 (by particle agglutination) or 60 U/ml (by nephelometry). A positive test may result with chronic hepatitis, chronic viral infection, dermatomyositis, infectious mononucleosis, leukemia, rheumatoid arthritis, scleroderma, or SLE. Adult Still's disease, chronic infection, juvenile rheumatoid arthritis, nephrotic syndrome, and Sjögren's syndrome may also give positive results. Reference levels with commercial EIA kits will be dependent on the type of kit used and should be independently established in each laboratory. IgM-type rheumatoid factors are present in 75% of patients with chronic polyarthritis (CP), in 50–65% of patients with interstitial pulmonary fibrosis, in only 30% of patients with mixed connective tissue disease (SLE, Sjögren's syndrome), and with a prevalence of 10–20% in viral hepatitis, liver cirrhosis, sarcoidosis, and **tuberculosis**. IgA-class rheumatoid factors can be an early finding in severe rheumatic disease and are also found in SLE patients. Specific determination of IgG class rheumatoid factors, mainly present as immune complexes, have been described in both juvenile and chronic polyarthritis.

Health care team roles

A nurse or phlebotomist usually collects the blood sample by venipuncture and sees to the timely and appropriate transport to the laboratory for analysis. A member of the health care team should observe the patient to ensure that bleeding from the puncture site is stopped.

Autoimmunity tests are performed by a clinical laboratory scientist/medical technologist. For immunofluorescence assays the technologist will usually have advanced training in fluorescent microscopy and the interpretation of immunofluorescence patterns.

A physician interprets the autoantibody test results and uses them in combination with a complete medical history and thorough physical examination to reach a diagnosis.

The physicians, nurses, and other caregivers should instruct the patient that diagnosis of an autoimmune disorder is a difficult process that may take considerable time and strive to allay the patient's feelings of frustration and **anxiety**.

Autoimmune disorders

Definition

Autoimmune disorders are conditions in which a person's **immune system** attacks the body's own cells, causing tissue destruction.

Description

Autoimmunity is accepted as the cause of a wide range of disorders and suspected to be responsible for many more. Autoimmune diseases are classified as either general (the autoimmune reaction takes place simultaneously in a number of tissues) or organ specific (the autoimmune reaction targets a single organ).

Autoimmune disorders include the following:

- Systemic lupus erythematosus. A general autoimmune disease in which antibodies attack a number of differ-

ent tissues. The disease recurs periodically and is seen mainly in young and middle-aged women.

- Rheumatoid arthritis. Occurs when the immune system attacks and destroys the tissues that line bone joints and cartilage. The disease occurs throughout the body, although some joints may be more affected than others.
- Goodpasture's syndrome. Occurs when antibodies are deposited in the membranes of both the lung and **kidneys**, causing both inflammation of kidney glomerulus (glomerulonephritis) and lung bleeding. It is typically a disease of young males.
- Grave's disease. Triggered by an antibody that binds to specific cells in the **thyroid gland**, causing them to make excessive amounts of thyroid hormone.
- Hashimoto's thyroiditis. Also referred to as autoimmune thyroiditis and chronic lymphocytic thyroiditis; a chronic inflammatory glandular autoimmune disease. It is caused by an antibody that binds to cells in the thyroid gland. Unlike in Grave's disease, however, this antibody's action results in less thyroid hormone being made.
- Pemphigus vulgaris. A group of autoimmune disorders that affect the skin.
- Myasthenia gravis. A condition in which the immune system attacks a receptor on the surface of muscle cells, preventing the muscle from receiving nerve impulses and resulting in severe muscle weakness.
- Scleroderma. Also called CREST syndrome or progressive systemic sclerosis, scleroderma affects the connective tissue.
- Autoimmune hemolytic anemia. Occurs when the body produces antibodies that coat red **blood** cells.
- Autoimmune thrombocytopenic purpura. Disorder in which the immune system targets and destroys blood platelets.
- Polymyositis and dermatomyositis. Immune disorders that affect the neuromuscular system.
- Pernicious anemia. Disorder in which the immune system attacks the lining of the **stomach** in such a way that the body cannot metabolize **vitamin B₁₂**.
- Sjögren's syndrome. Occurs when the exocrine glands are attacked by the immune system, resulting in excessive dryness.
- Ankylosing spondylitis. Immune-system induced degeneration of the joints and soft tissue of the spine.
- Vasculitis. A group of autoimmune disorders in which the immune system attacks and destroys **blood vessels**.

- Type I **diabetes mellitus**. May be caused by an antibody that attacks and destroys the islet cells of the **pancreas** that produce insulin.

Causes and symptoms

The symptoms of the above disorders include:

- Systemic lupus erythematosus. Symptoms include **fever**, chills, fatigue, weight loss, skin rashes (particularly the classic “butterfly” rash on the face), vasculitis, polyarthralgia, patchy hair loss, sores in the mouth or nose, lymph-node enlargement, gastric problems, and, in women, irregular periods. About half of those who suffer from lupus develop cardiopulmonary problems, and some may also develop urinary problems. Lupus can also effect the **central nervous system**, causing seizures, depression, and psychosis.
- Rheumatoid arthritis. Initially may be characterized by a low-grade fever, loss of appetite, weight loss, and a generalized **pain** in the joints. The joint pain then becomes more specific, usually beginning in the fingers, then spreading to other areas, such as the wrists, elbows, knees, and ankles. As the disease progresses, joint function diminishes sharply and deformities occur, particularly the characteristic “swan’s neck” curling of the fingers.
- Goodpasture’s syndrome. Symptoms are similar to that of **iron deficiency anemia**, including fatigue and pallor. Symptoms involving the **lungs** may range from a cough that produces bloody sputum to outright hemorrhaging. Symptoms involving the **urinary system** include blood in the urine and/or swelling.
- Grave’s disease. This disease is characterized by an enlarged thyroid gland, weight loss without loss of appetite, sweating, **heart** palpitations, nervousness, and an inability to tolerate heat.
- Hashimoto’s thyroiditis. This disorder generally displays no symptoms. If symptoms do occur, it is most often weight gain, intolerance to cold, fatigue, enlarged neck or goiter, and constipation. About 25% of patients may be subject for developing pernicious anemia, diabetes, adrenal insufficiency, or other autoimmune diseases.
- Pemphigus vulgaris. This disease is characterized by blisters and deep lesions on the skin. It is associated with other autoimmune diseases, such as systemic lupus and myasthenia gravis.
- Myasthenia gravis. Characterized by fatigue and muscle weakness that at first may be confined to certain muscle groups, but then may progress to the point of **paralysis**. Myasthenia gravis patients often have expressionless faces as well as difficulty chewing and swallowing. If the disease progresses to the **respiratory system**, artificial respiration may be required.
- Scleroderma. Disorder is usually preceded by Raynaud’s phenomenon. Symptoms that follow include pain, swelling, and stiffness of the joints, and the skin takes on a tight, shiny appearance. The **digestive system** also becomes involved, resulting in weight loss, appetite loss, **diarrhea**, constipation, and distention of the abdomen. As the disease progresses the heart, lungs, and kidneys become involved, and malignant **hypertension** causes death in approximately 30% of cases.
- Autoimmune hemolytic anemia. May be acute or chronic. Symptoms include fatigue and abdominal tenderness due to an enlarged spleen.
- Autoimmune thrombocytopenic purpura. Characterized by pinhead-size red dots on the skin, unexplained bruises, bleeding from the nose and gums, and blood in the stool.
- Polymyositis and dermatomyositis. In polymyositis, symptoms include muscle weakness, particularly in the shoulders or pelvis, that prevents the patient from performing everyday activities. In dermatomyositis, the same muscle weakness is accompanied by a rash that appears on the upper body, arms, and fingertips. A rash may also appear on the eyelids, and the area around the eyes may become swollen.
- Pernicious anemia. Signs of pernicious anemia include weakness, sore tongue, bleeding gums, and tingling in the extremities. Because the disease causes a decrease in stomach acid, nausea, vomiting, loss of appetite, weight loss, diarrhea, and constipation are possible. Also, because vitamin B₁₂ is essential for the nervous system function, the deficiency of it brought on by the disease can result in a host of neurological problems, including weakness, lack of coordination, blurred **vision**, loss of **fine motor skills**, loss of the sense of **taste**, ringing in the ears, and loss of bladder control.
- Sjögren’s syndrome. Characterized by excessive dryness and itching of the eyes and dry mouth. Difficulty swallowing, hoarseness, loss of taste, and severe **dental caries** may also occur. Other symptoms are fatigue, joint pain, and swelling of the glands.
- Ankylosing spondylitis. Generally begins with lower back pain that progresses up the spine. The pain may eventually become crippling.
- Vasculitis. Symptoms depend upon the group of veins affected and can range greatly. Some forms of vasculitis may be caused by allergy or hypersensitivity to medications such as sulfa or penicillin, other drugs, toxins, and other inhaled environmental irritants. Other forms

may be due to **infection**, parasites, or viral infections. These causes need to be ruled out before considering an underlying autoimmune disorder.

- Type I diabetes mellitus. Characterized by fatigue and an abnormally high level of glucose in the blood (hyperglycemia).

To further understand autoimmune disorders, it is helpful to understand the workings of the immune system. The purpose of the immune system is to defend the body against attack by infectious microbes (germs) and foreign objects. When the immune system attacks an invader, it is very specific—a particular immune system cell will only recognize and target one type of invader. To function properly, the immune system must not only develop this specialized knowledge of individual invaders, but it must also learn how to recognize and not destroy cells that belong to the body itself. Every cell carries protein markers on its surface that identifies it in one of two ways: what kind of cell it is (i.e., nerve cell, muscle cell, blood cell, etc.) and to whom that cell belongs. These markers are called major histocompatibility complexes (MHCs). When functioning properly, cells of the immune system will not attack any other cell with markers identifying it as belonging to the body. Conversely, if the immune system cells do not recognize the cell as “self,” they attach themselves to it and put out a signal that the body has been invaded, that in turn stimulates the production of substances such as antibodies that engulf and destroy the foreign particles. In case of autoimmune disorders, the immune system cannot distinguish between “self” cells and invader cells. As a result, the same destructive operation is carried out on the body’s own cells that would normally be carried out on **bacteria**, **viruses**, and other such harmful entities.

The reasons why the immune systems become dysfunctional in this way is not well understood. However, most researchers agree that a combination of genetic, environmental, and hormonal factors play into autoimmunity. Researchers also speculate that certain mechanisms may trigger autoimmunity. First, a substance that is normally restricted to one part of the body, and therefore not usually exposed to the immune system, is released into other areas where it is attacked. Second, the immune system may mistake a component of the body for a similar foreign component. Third, cells of the body may be altered in some way, either by drugs, infection, or some other environmental factor, so that they are no longer recognizable as “self” to the immune system. Fourth, the immune system itself may be damaged, such as by a genetic mutation, and therefore cannot function properly.

KEY TERMS

Autoantibody—An antibody made by a person that reacts with their own tissues.

Autoimmune disease—A broad category of related diseases in which the person’s immune system attacks his or her own tissue.

Diagnosis

A number of tests that can help diagnose autoimmune diseases; however the principle tool used by doctors is antibody testing. Such tests involve measuring the level of antibodies found in the blood and determining if they react with specific antigens that would give rise to an autoimmune reaction. An elevated amount of antibodies indicates that a humoral immune reaction is occurring. Elevated antibody levels are also seen in common infections. These must be ruled out as the cause for the increased antibody levels. The antibodies can also be typed by class. There are five classes of antibodies and they can be separated in the laboratory. The class IgG is usually associated with autoimmune diseases. Unfortunately, IgG class antibodies are also the main class of antibody seen in normal immune responses. The most useful antibody tests involve introducing the patient’s antibodies to samples of his or her own tissue—if antibodies bind to the tissue it is diagnostic for an autoimmune disorder. Antibodies from a person without an autoimmune disorder would not reacting to “self” tissue. The tissues used most frequently in this type of testing are thyroid, stomach, **liver**, and kidney.

Treatment

Treatment of autoimmune diseases is specific to the disease, and usually concentrates on correction of any major deficiencies. For example, if a gland involved in an autoimmune reaction is not producing a hormone such as insulin, administration of that hormone is required. Administration of a hormone, however, will not restore the function of the gland damaged by the autoimmune disease. The other aspect of treatment is controlling the inflammatory and proliferative nature of the **immune response**. This is generally accomplished with two types of drugs. Steroid compounds are used to control inflammation. There are many different steroids, each having side effects. The proliferative nature of the immune response is controlled with immunosuppressive drugs. These drugs work by inhibiting the replication of cells

and, therefore, also suppress non-immune cells leading to side effects such as anemia.

Prognosis

Prognosis depends upon the pathology of each autoimmune disease, as well as early detection and the ability to put the disease process into remission.

Health care team roles

Health care teams should help patients to understand their illness and treatment plan. With any autoimmune disorder, communication between the patient and doctor is critical, so health care teams should be available to answer questions about the patient's particular condition, especially what changes and symptoms to expect.

Prevention

To date, prevention of many autoimmune disorders is unavailable since the exact causes of the disease are not understood in many cases. Genetic screening of an unborn fetus may be the only method of preventing some autoimmune disorders.

Autopsy

Definition

An autopsy is a postmortem assessment or examination of a body to determine the cause of death. An autopsy is performed by a physician educated in pathology. Often this physician also has forensic training.

Purpose

Most autopsies advance medical knowledge or provide evidence for legal action. Medically, autopsies may determine the exact cause and circumstances of death, discover the pathway of a disease, and/or provide valuable information to be used in the care of the living. When foul play is suspected, a government coroner or medical examiner performs an autopsy to collect data for legal investigation. This branch of medical study is called forensic medicine. Forensic specialists investigate deaths resulting from violence or occurring under suspicious circumstances.

Benefits of research from autopsies include the discovery of new medical information on diseases such as toxic shock syndrome, acquired **immunodeficiency syndrome (AIDS)**, and **Alzheimer's disease**.

Precautions

When performed for medical reasons, autopsies require formal permission (written consent), from family members or a legal guardian. Autopsies required for legal reasons when foul play is suspected require authorization from a coroner or medical examiner. Such autopsies do not need the consent of next of kin. During the autopsy, very concise notes and documentation must be made for both medical and legal reasons. Some religious groups prohibit autopsies, although special waivers apply where suspicious death occurs.

Description

An autopsy is the examination of a deceased human body with a detailed investigation of the person's remains. This procedure dates back to the Roman era when few human dissections were performed. Autopsies were utilized, however, to determine the cause of death in criminal cases.

A pathologist fills out an autopsy report during an autopsy. (Photograph by Glauber. Science Source/Photo Researchers. Reproduced by permission.)

At the beginning of the procedure, the exterior body is examined and the internal organs are removed and studied. Some pathologists argue that more autopsies are performed than necessary. However, recent studies show that autopsies can detect major findings about a person's condition which were not suspected when the person was alive. The growing awareness of the influence of genetic factors in disease has also emphasized the importance of autopsies.

Despite the usefulness of autopsies, fewer autopsies have been performed in the United States during the past 10 to 20 years. A possible reason for this decline is concern about **malpractice** suits on the part of the attending physician, although there are other reasons. Hospitals are performing fewer autopsies because of the expense. Modern technology, such as **CT scans** and **magnetic resonance imaging** (MRI), can often provide sufficient diagnostic information. Nonetheless, federal regulators and pathology groups have begun to establish new guidelines designed to increase the number and quality of autopsies being performed.

Many experts are concerned that if the number of autopsies increases, hospitals may be forced to charge families a fee for the procedure as autopsies are not normally covered by insurance companies or **Medicare**. However,

according to several pathologists, the benefits of the procedure for families and doctors justify the cost. In medical autopsies, physicians remain cautious, examining only as much of the body as necessary, taking into account the wishes of the family. It is important to note that in certain circumstances, autopsies can provide peace of mind for a bereaved family.

Preparation

If a medical autopsy is being performed, written permission is secured from the family member of record of the deceased.

Aftercare

After an autopsy has been completed, the body is prepared for final arrangements according to the family's wishes, or the funeral director's instructions.

Complications

There is some risk of **disease transmission** from the deceased. In fact, some physicians may refuse to do autopsies on specific persons because of a fear of contracting diseases such as AIDS, hepatitis, or Creutzfeld-Jakob disease.

KEY TERMS

Acquired immunodeficiency syndrome (AIDS)—

A group of diseases resulting from infection with the human immunodeficiency virus (HIV). A person infected with HIV gradually loses immune function, becoming less able to resist immune-related diseases and cancers, resulting in death.

Computed tomography scan (CT scan)—

The technique used in diagnostic studies of internal bodily structures in the detection of tumors or dysfunction. This diagnostic test consists of a computer analysis of a series of cross-sectional scans made along a single axis of a bodily structure or tissue that is used to construct a three-dimensional digital image of that structure.

Creutzfeld-Jakob disease—

A rare, often fatal disease of the brain, characterized by gradual dementia and loss of muscle control that occurs most often in middle age and is caused by a slow-acting virus.

Hepatitis—Inflammation of the liver, caused by infectious or toxic agents and characterized by jaundice, fever, liver enlargement, and abdominal pain, with abnormal blood chemistry readings.

Magnetic resonance imaging (MRI)—A diagnostic tool that utilizes nuclear magnetic energy in the production of digital images of specific atoms and molecular structures in solids, especially human cells, tissues, and organs.

Postmortem—After death.

Results

In most situations, the cause of death is determined from the autopsy without any transmission of disease. Results of tests performed on samples of tissue and bodily fluids provide information about the cause and mechanism of death.

Abnormal results include inconclusive results from the autopsy and transmission of infectious disease during the autopsy. By following proper procedures, these are both highly unusual.

Health care team roles

Bodies of persons dying in a hospital are taken to the morgue by hospital attendants. Bodies of persons from any other location are transported by funeral home personnel, coroners, or their assistants. An autopsy is conducted by a physician, usually by one trained in pathol-

ogy or forensic science. In some states, a coroner can legally carry out an autopsy. Laboratory personnel process any specimens or samples obtained during an autopsy. Once completed, funeral home personnel transport the remains to another location for burial preparation.

Back and neck pain, physical therapy for

Definition

Physical therapy for back and neck **pain** is the treatment of this pain using professionally accepted techniques and procedures carried out by a physical therapist.

Purpose

The ultimate purpose of physical therapy is to restore normal function to the patient. Such a goal may not be possible, since the persons most likely to experience back pain in the future are those patients who have experienced back pain in the past. Regardless, the physical therapist will seek to ameliorate pain and improve musculoskeletal function to the best of their ability. To reach this goal, the physical therapist may apply various types of therapy to assist in the healing process, ranging from education to electrostimulation therapy to physical manipulation of the spine. Due to the less invasive nature of physical therapy, it may be indicated as an alternative to surgery on the back or neck. Physical therapy may also be prescribed after surgery, either because the surgery did not completely ameliorate the pain, or to ensure the patient achieves maximum benefit from the surgery.

Precautions

There are a number of symptoms in patients with low back pain that may require immediate medical attention. These symptoms may indicate that back or neck pain is related to potentially serious non-mechanical or mechanical disease. Non-mechanical disorders that are neurological or organic in nature can cause symptoms of

back pain, but in these cases treatment needs to be directed at the disease, not merely the associated pain. Bowel, bladder, kidney, or gall bladder diseases, some types of **cancer**, cauda equina syndrome, and other neurological disorders are among the serious conditions that should be screened for and treated directly.

If a patient has numbness in the area roughly corresponding to where a person would sit in a saddle (basically, the buttocks) with or without problems urinating, that patient should seek immediate medical attention (these symptoms may be an indication of cauda equina syndrome). **Fever**, confusion, back pain that occurs mostly at nighttime or when lying down, or problems with urination, bowel movements, or sexual function are other symptoms implicating non-mechanical disease that may also require immediate medical attention.

Although the following symptoms may or may not be caused by mechanical disease, patients with sudden severe or increasing weakness, numbness, or tingling should seek immediate medical attention. Other symptoms in conjunction with back pain may also require immediate attention. If any unusual symptoms arise, even should they seem unrelated to back pain, a physician should be consulted. Regardless of the severity of these symptoms, all of them should at the very least be brought to the attention of a physician.

Other precautions and contraindications will vary according to the cause of pain, the therapy used, and the presence of other diseases or conditions. Some conditions either related to or coexisting with the pain, such as severe cardiac disturbances or bone weakness due to **osteoporosis** or other conditions, may contraindicate **exercise**.

Modalities, such as electrical stimulation techniques and thermal modalities, have their own sets of precautions. Conditions that may contraindicate the use of electrical stimuli include thrombophlebitis, cardiac demand pacemaker, disturbances in cardiac rhythm, local inflammation or **infection**, and cancer. The use of heat may not

be indicated immediately after an injury, and should always be used with special caution to prevent **burns**. Electrical, heat, and cold therapies may all be contraindicated for use on sensory-impaired areas. Ultrasound should not be used on tissues with metal implants, because of its deep heating properties. Manipulation techniques can aggravate disk problems, or cause compression **fractures** in patients with osteoporosis. The physical therapist needs to be familiar with any risks involved with each condition and modality. A doctor's diagnosis is often recommended prior to beginning treatment, and the physical therapist needs to make a careful diagnosis in order to make appropriate treatment choices.

Description

Physical therapy treatment, also called physiotherapy, is performed by, or under the supervision of, a physical therapist. A physical therapist may have a baccalaureate, masters, or doctoral degree in physical therapy, and is required to pass a national licensure exam. Physical therapy treatment includes a wide range of exercises, procedures and modalities. However, **patient education** is also an extremely important part of the practice of physical therapy.

According to an American Physical Therapy Association (APTA) patient education brochure on back pain, "the patient is the most important participant in the healing and prevention process." The physical therapist can instruct correct posture and safe ways of performing activities of daily living (ADLs) and other tasks. Additionally the physical therapist can show the patient various kinds of exercise that promote **relaxation**, relieve pain, and improve the condition of the muscles and other tissues surrounding the spine. Patient education may extend the benefits of treatment by helping the patient to self-manage pain and avoid re-injury or recurrence of acute pain and injury. Avoiding re-injury is a goal of special importance, since most people who have one episode of back pain are likely to have another.

Before treatment begins, the patient's problem must be evaluated. Very often, a physician will have referred a patient to physical therapy. Physical therapy may be the lone method of treatment, or may be used in combination with medication, surgery, or other types of treatments. After the role of physical therapy is determined, the patient will be evaluated by the physical therapist. Evaluation includes an interview with the patient to assess the patient's medical history, and activities that affect the condition. After the interview, the therapist will proceed with a musculoskeletal exam to assess the patient's spinal movements, posture, muscular strength, and response to repeated movements. Any additional

tests considered necessary for a diagnosis will be performed. The physical therapist will then provide a diagnosis of the condition and a prognosis.

The prognosis includes the predicted level of improvement, goals, and the time needed to achieve them. Then an individualized treatment plan will be designed and implemented. Treatment plans may vary widely from physical therapist to physical therapist for the same patient. Patients may wish to seek advice from a different therapist if their condition does not improve under the first therapist's care.

Back and neck pain can have many causes, such as: injury caused by accident or misuse, disease, general strain, postural problems, or just simple wrong movement. Specific causes of back or neck pain can include sprained ligaments, muscle strain, disk problems, joint irritation, arthritis, congenital disorders, psychological **stress**, spinal stenosis, osteoporosis, compression fractures, and various other conditions (non-mechanical causes of back pain have been discussed briefly in "Precautions"). Due to the large number of causes for back pain, it should not come as a surprise that there are a large number of therapies that address back and neck pain.

Exercise is generally considered an essential part of the physical therapy regime. Different kinds of exercise are used according to the condition and the stage of recovery. Some controversy surrounds what types of exercise to use, perhaps depending on the cause of the back pain as well as other factors. Individual exercises may seek to increase one or more of the following: flexibility, range of motion, overall aerobic conditioning, and muscle strength.

According to recent guidelines suggested by Malanga and Nadler, tolerable exercise is superior to bed rest for back pain. Bed rest and inactivity have been shown to weaken muscles and bones (a phenomenon known as deconditioning), and may prolong or interfere with recovery. Exercise, in general, increases strength and flexibility of the muscles and aids in healing by increasing **blood** flow to the affected area.

Aquatic therapy is among the exercise options available to physical therapy patients. This form of exercise has the benefits of being low-impact and gentle on joints. As a supplement to whatever forms of guided exercise are chosen by the therapist and patient, the patient is also likely to be given a home exercise program to perform independently.

Another type of treatment the physical therapist may use is manual therapy. Manual therapy is defined in the APTA's *Guide to Physical Therapist Practice, Second Edition* as "skilled hand movements intended to improve tissue extensibility; increase range of motion; induce

relaxation; mobilize or manipulate soft tissue and joints; modulate pain; and reduce soft tissue swelling, inflammation, or restriction.” Manual therapy techniques include various forms of massage, manual traction, mobilization and manipulation of the soft tissues and joints, and passive range of motion movements. Manual therapy has a long and storied history. The first mention of manual therapy in Western culture can be traced to Hippocrates, who wrote several treatises on joint manipulation and traction (traction, in the context of back and neck physical therapy, is the extension of the spine using force).

Although mobilization and manipulation have changed from the time of Hippocrates (460–355BC), they remain important techniques today (along with other forms of manual therapy). There are a large number of manipulation and mobilization techniques available to physical therapists, based on a number of different “schools of thought.” Many of these therapies have scientific evidence supporting their efficacy, and many do not. In part because there are so many different types of manipulation, the techniques, and the level of familiarity with different techniques, can vary widely from one physical therapist to the next.

The most well-known forms of manipulation are those performed by chiropractors. Although physical therapists can be trained to perform the same manipulations as chiropractors, historically, physical therapists sought to use terminology such as mobilization to differentiate themselves from the chiropractic community. Part of this impetus was based on the bias against chiropractors found in allopathic physicians. However, the APTA has recently moved toward reclaiming the term manipulation as part of the physical therapy lexicon.

Traction has also advanced since the time of Hippocrates. In the modern era, traction to the neck or low back may be applied as steady traction, or as intermittent motorized traction (IMT). The goal of traction in both cases is to correct physical deformities of the spine. Some modern traction practitioners speculate the benefit from traction is derived from pulling the intervertebral disk back into the intervertebral space (due to the force exerted on the spine).

In steady traction (for the low back) weights are applied to the ankles and patients are required to remain in bed, flat on their backs, for a significant period of time (weeks). The constant nature of the traction, and the way in which it was applied, led to a number of important disadvantages. First, bed rest is not recommended for general back health (as previously discussed). Second, the patient’s muscles might spasm, which would cause less force to be applied to the spine, the structure of interest. Third, the apparatus and the position of the patient means

that much of the force being applied to the patient would be absorbed by non-spinal structures (e.g. the hips). Most importantly, patients who receive this kind of traction do not improve compared to those who do not receive this kind of therapy.

IMT seeks to avoid these complications by applying intermittent (occasional) force a few times a week directly to the area of interest. A hip belt or a neck harness, and the immobilization of the upper body allow force to be applied more directly. The intermittent nature of the force prevents excessive muscle spasm, and the patient is spared the potentially harmful effects of bed rest.

Modalities, or passive physical therapies, do not require the patient to participate. These methods usually employ some special equipment that can apply heat, cold, electricity, or other elements or forms of stimulation to the patient. One such modality would be applications of cold using ice packs or a cryo-stimulation device. Heat can be applied using diathermy (for dry heat), hydrocollator packs (for moist heat) or a heating pad. Ultrasound uses sound waves to create a deep heating effect. Electrical muscle stimulation (EMS) is used to exercise and strengthen specific muscle groups, while TENS (transcutaneous electrical nerve stimulation) units provide therapeutic nerve stimulation to reduce pain.

Physical therapy services are often covered by medical insurance. The patient may want to ask the physical therapist to check with the insurance company to see what services and how many treatments are covered. Physical therapy is generally a cost-effective form of treatment, and if can be used to avoid surgery, then the expense of surgery and a hospital stay is also avoided.

Preparation

The patient should provide all appropriate **medical records** for the physical therapist to review. The patient may also wish to keep a journal before attending physical therapy, detailing times and activities that cause pain.

Aftercare

Since physical therapy focuses on patient education, the patient may be better equipped after the physical therapy program to pursue self-care through proper posture and performance of activities, and by continuing a home exercise program. According to an APTA patient education guide, the goal of physical therapy is to help the patient return to normal activities as soon as possible and to teach the skills needed to avoid re-injury. The patient will not necessarily require additional episodes of therapeutic care.

KEY TERMS

Co-morbidity—A disease or condition that coexists with the disease or condition for which the patient is being primarily treated.

Disk (disc)—Soft, flexible, shock-absorbing material between each vertebra.

Modalities—Passive physical therapies that are done to the patient rather than requiring their active involvement. These may not require constant attendance by the physical therapist.

Soft tissue/joint mobilization—Application of specific stretching techniques to the body's soft tissues and joints.

Spinal stenosis—A condition caused by the narrowing of the spinal canal leading to compression of nerves in the back.

Ultrasound—A treatment modality that uses high frequency sound waves to effect deep heating of soft tissue.

Complications

Possible complications related to physical therapy treatments for back and neck pain depend on the cause of pain, other conditions present, and the type of interventions used. In general, physical therapy is a safe, gentle treatment option designed to work in harmony with the body's natural structure and movement mechanisms. Severe complications are not common, as long as the diagnosis and plan of care are accurate and carefully made. The therapist should be aware of possible complications related to exercise in general, as well as those involved with various primary and co-existing conditions, and with any of the modalities used. Some forms of manipulation can lead to injury in the case of bone weakness or other pathological conditions. Patients whose conditions cause excessive fatigue should be monitored closely during exercise.

If the precautions or contraindications relating to the patient's condition, evaluation, medical history, and diagnosis are properly attended to and procedures used are observed, the risk of complications will be minimized. The patient may feel some additional pain or soreness when beginning exercise, but this should be mild and temporary. In rare cases, the patient may have an allergic reaction to gels and creams used in ultrasound or massage.

Results

Results vary widely based on the cause of the dysfunction, the therapy used, and the skill of the therapist. The goal of returning patients to their original level of function may not occur. However, since physical therapy focuses on patient education, the patient may be better equipped after the physical therapy program to pursue self-care through proper posture and performance of activities, and by continuing a home exercise program.

Health care team roles

Physical therapists may work together with physical therapist assistants and aides, physicians, nurses, social workers, occupational therapists, or other health care professionals. Doctors may provide a diagnosis and prescription for physical therapy and recommend duration or types of therapy. The physical therapist assistant, under the physical therapist's direction and supervision, may undertake various aspects of the patient's treatment. Occupational therapists and social workers may also work with the patient to supplement physical therapy's role in the patient's return to normal life and work or adaptation to disability.

Bacteria

Definition

Bacteria are prokaryotes (unicellular organisms with no membrane-enclosed nucleus) with simple structures that typically range in size from about 0.5 to 20 micrometers.

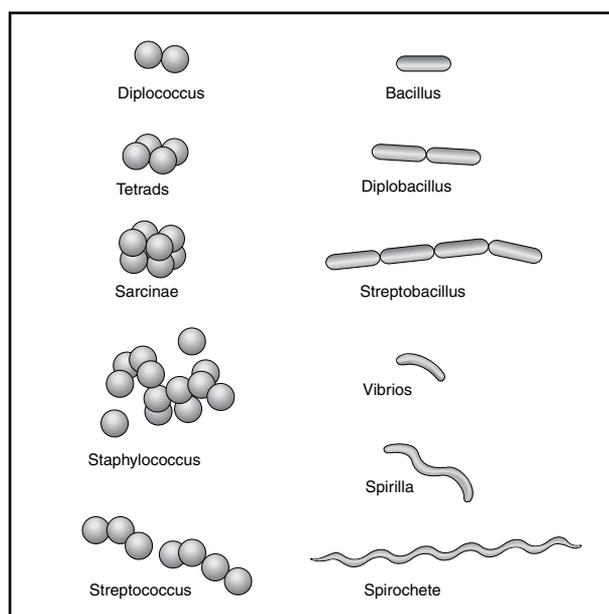

Description

Classification

Bacteria are named according to the binomial (two-name) system of nomenclature first used by Swedish botanist Carolus Linnaeus in the eighteenth century. The first name, or generic name, indicates the genus of the bacteria (a group of closely related species). The second name, or specific name, indicates the species (a group of bacteria that share a number of characteristics). Examples of generic names include *Staphylococcus* and *Esherichia*; *aureus* and *coli* are examples of specific names.

The genus and species names of bacteria often reflect their shape; for example, the *Bacillus* family of bacteria are bacilli- or rod-shaped. Others are named for their founders (e.g. *Yersinia pestis*, the causative agent of bubonic plague, is named for Alexandre Yersin) or for their preferred habitat (e.g., *Thermoplasma* prefer temperatures up to 149°F, or 65°C).

Under a **microscope**, different families of bacteria have different shapes. Typical cell shapes are straight rods (bacilli), spheres (cocci), bent or curved rods (vibrios), spirals (spirochetes), or thin filaments. Some bacteria exist as single cells, while others form clusters of

Morphology and arrangement of bacterial cells. (Delmar Publishers, Inc. Reproduced by permission.)

various shape and complexity. *Acetobacter aceti*, for example, excretes a substance called cellulose that surrounds the cells to form a skinlike layer. *Staphylococcus aureus* forms grapelike clusters of cells.

Many groups of bacteria have a cell wall, a structure surrounding the cell. Peptidoglycan (a chemical composed of **carbohydrates** and **proteins**) is a major component of the cell wall, although the exact composition of peptidoglycan varies according to bacteria group. Gram-positive organisms have a relatively thick layer of peptidoglycan and stain violet when applied with certain dyes; gram-negative organisms have a thin layer of peptidoglycan covered by an outer membrane and stain red under the same application of dyes. Gram staining is therefore an important method for identifying bacteria.

Bacteria may be classified by their biochemical composition, and analysis of the protein and lipid content of an organism is often a means of identification. Growth requirements are often used as a means of classification: *Mycobacterium tuberculosis*, for example, is an obligate aerobe and therefore requires oxygen for growth, while the presence of oxygen is toxic to the anaerobe *Clostridium tetani*.

The most precise method of classification, however, is genetic analysis. Each species of bacteria has a unique genetic makeup, and therefore a unique sequence of deoxyribonucleic acid (DNA) bases. Some sequences remain constant by genus or species, while others vary

considerably. These distinguishing factors are used to trace genetic relatedness and are often used for identification of unknown organisms.

Bacterial structure

Although prokaryotic organisms such as bacteria are considered to be “simple” in structure, each cell is equipped with all of the structures and macromolecules necessary for growth and survival. Complex functions such as energy production, synthesis of biomolecules, and assembly of new structures take place in a highly organized manner.

The genetic material of bacteria is carried on double-stranded molecules of DNA (deoxyribonucleic acid), which is arranged into a circular structure called the chromosome. The region of the cytoplasm where the chromosome is located is called the nucleoid and is not enclosed by a membrane, as in eukaryotic cells. Many bacteria carry additional genetic information (often required for survival in specific environments) on structures called plasmids, smaller circular strands of DNA that are independent of the chromosome. Also found in the cytoplasm are ribosomes, small cellular components important in the process of translating genetic information into proteins. The total collection of genes is called the bacterial genome.

Directly bordering the cytoplasm of the bacteria is the cytoplasmic membrane, which is important for various functions such as energy production and transport of materials in and out of the cell. The cell wall surrounds the cytoplasmic membrane of most bacteria. In gram-negative organisms, the cell wall is composed of a thin layer of peptidoglycan enclosed by an outer membrane. Lipopolysaccharide (LPS; also called endotoxin) is a major constituent of the outer membrane. The cell wall of gram-positive bacteria is distinctly different. Multiple peptidoglycan layers envelop the cytoplasmic membrane, and no outer membrane is present. The peptidoglycan layers form a meshlike shell around the cell that is important for maintaining structure, for replication, and for protection in extreme or toxic conditions. Proteins, **lipids**, and polysaccharides may also be found in the cell wall.

Many bacteria have additional means of protection in hostile conditions. Some have the ability to form a capsule, layers of polysaccharides and proteins attached to the cell wall, that provides protection against toxic substances and helps inhibit host **immune response**. Spores are made by some gram-positive bacteria. Under favorable conditions, the cells exist in a vegetative state; but when introduced to a hostile environment, the cells convert to a spore state and become dormant, awaiting conditions in which they may once again prosper.

The flagellum is a filamentous structure attached to many prokaryotes that provides motility. With flagella, bacteria may move toward food and away from toxins, a process called chemotaxis. Pili are hairlike structures shorter than flagella found on many bacteria; they are used for adherence to other bacteria and surfaces such as host cells.

Function

Energy requirements for growth

All living organisms must find in their environment a source of energy to fuel cellular processes. Bacteria are no different. Phototrophs are organisms that use light as an energy source; those that require organic carbon are called heterotrophs. Autotrophs use carbon dioxide. Lithotrophs oxidize inorganic compounds such as hydrogen or ammonia for energy.

Many bacteria have structures and processes that allow them to adapt to hostile environments, and they can exist under an enormous range of conditions. Those that require oxygen for growth are called obligate aerobes. In contrast, obligate anaerobes will not grow in the presence of oxygen. Acidophiles are bacteria that grow optimally under acidic conditions (pH of less than 7.0), while alkaphiles prefer alkaline or basic conditions (pH of greater than 7.0). Organisms that require a temperature near 99°F (37°C) (the body temperature of warm-blooded animals) for growth are called mesophiles; those that grow at temperatures above 113°F (45°C) are called thermophiles; and psychrophiles are able to grow at temperatures near 32°F (0°C). Halophiles require sodium chloride (salt) for growth; osmophiles are able to grow in environments high in sugar; and xerophiles grow under dry conditions.

Binary fission and the growth curve

Bacteria grow and replicate in a process known as binary fission. In this process, one parent cell divides to produce two daughter cells. The process begins with the growth of the parent cell; the chromosome unwinds and replicates, each copy moving to opposite ends of the cell. The cell is then partitioned in half by the production of a dividing wall (called the septum). The cell is cleaved at the septum, and the two daughter cells are freed. The daughter cells then go on to reproduce as parent cells (i.e., if necessary nutrients and energy sources are present).

The dynamics of a population of bacteria change during binary fission. The doubling time, or time required for one parent cell to produce two daughter cells, varies by bacteria species and strain and also by the

environmental conditions. All bacteria exhibit a characteristic pattern of growth when introduced to a new medium; this is known as the growth curve. There are four phases of the growth curve:

- During the lag phase, bacteria are adapting to the medium and begin to produce the cellular components necessary for **cell division**. There is no increase in cell population during the lag phase.
- Cell division occurs at a maximal rate during the log or exponential phase. The doubling time remains constant, so the number of cells increases exponentially.
- Cells stop growing exponentially and therefore remain constant during the stationary phase. This occurs when the medium begins to run out of the nutrients necessary for growth or when toxic products accumulate.
- The number of cells begins to decrease during the death phase as cells begin to die, usually due to toxic conditions or lack of nutrients.

Role in human health

Normal flora

Only a small percentage of the vast population of bacteria is pathogenic (disease-causing) to humans. Many species of bacteria colonize the human body and are called the normal flora. Organisms of the normal flora are normally found on surface tissues (i.e., the skin, mucous membranes, and the gastrointestinal system). It is when bacteria enter normally sterile areas of the body (e.g., the **brain, blood, muscle**, etc.) that disease may result.

Some organisms of the normal flora neither harm nor provide benefit to the human body; this relationship is called commensalism. Normal commensals are bacteria that can always be found on or in healthy individuals and rarely cause disease. Bacteria that occasionally colonize the human body without causing disease are called occasional commensals. Although a human fetus is sterile *in utero*, colonization with normal flora bacteria begins with birth when the baby comes into contact with the mother's vaginal bacteria; this continues with breastfeeding and subsequent contact with the environment.

Many other types of bacteria interact with the human body in a relationship called mutualism, from which both organisms benefit. There are a number of ways that bacteria benefit the human host:

- Normal flora bacteria on the skin such as *Staphylococcus epidermidis* protect against colonization by pathogenic bacteria, through a process called microbial competition.

Transmission electron micrograph (TEM) of a Group A *Streptococcus* bacterium. (Custom Medical Stock Photo, Inc. Reproduced by permission.)

- Bacteria in the vagina (e.g., *Lactobacillus acidophilus*) help to establish an acidic environment that inhibits colonization of pathogenic bacteria and yeast.
- The normal flora in the gastrointestinal (GI) tract (e.g., *Escherichia coli*) secrete **vitamins** such as K and B₁₂ that are essential for humans. The development of some GI tissues is stimulated by normal flora bacteria.
- Ruminants (animals with a four-chambered **stomach**) rely on enzymes secreted by bacteria such as *Ruminococcus albus* to digest cellulose (a major component of plant cell walls).

Pathogenic bacteria

Although normal flora bacteria are not normally pathogenic, disease may result from invasion of normal flora into normally sterile areas or if the host **immune system** is deficient. When bacteria that normally reside in the GI tract (such as *E. coli*) are introduced to the urinary tract, for example, a urinary-tract **infection** may result. This is considered an endogenous infection.

Exogenous infections result from invasion of non-commensal organisms (i.e., those not normally found on the human body). Transmission of exogenous bacteria may occur by various routes, including inhalation of aerosolized organisms, ingestion (e.g., contaminated food or utensils), or direct contact of a wound or mucous membrane with organisms.

When bacteria first enter the body, local inflammation may be the first sign of infection. Physical symptoms such as **pain**, erythema (redness), **edema** (swelling), or pus formation result from the response of the immune system against the invading bacteria. If the bacteria spread to the bloodstream (bacteremia), they may disseminate to and colonize at various sites in the body.

KEY TERMS

Antibiotics—Chemicals produced by microorganisms that inhibit bacterial growth or kill bacterial cells.

Binary fission—The process by which a single parent cell divides to produce two identical daughter cells.

Flagellum—A filamentous structure attached to some bacteria that provides motility.

Gram-negative—A class of bacteria that have a cell wall composed of a thin layer of peptidoglycan surrounded by an outer membrane made of polysaccharides and proteins.

Gram-positive—A class of bacteria that have a cell wall composed of a thick layer of peptidoglycan.

Growth curve—A characteristic growth pattern of bacteria when introduced into a new medium; it includes four phases (lag, log, stationary, and death).

Normal flora—Species of bacteria that colonize the human body and do not normally cause disease.

Nucleoid—Cytosolic region of a bacterial cell in which the chromosome is located.

Pathogen—A disease-causing microbe.

Peptidoglycan—A chemical composed of carbohydrates and proteins that is a major component of the bacterial cell wall.

Prokaryote—A unicellular organism lacking a membrane-enclosed nucleus.

Ribosome—A cytosolic structure important in the translating of genetic information into proteins.

Toxins—Proteins produced by bacteria that are toxic to host cells. Endotoxin is a component of the cell wall of gram-negative bacteria; exotoxin is secreted by both gram-negative and gram-positive bacteria.

VIRULENCE FACTORS. Bacteria have developed numerous mechanisms that allow them to invade a host and colonize an otherwise inhospitable site to cause disease. Many of these mechanisms enhance their ability to cause disease in humans; such traits are called virulence factors. Some common virulence factors include:

- **Bacterial growth.** The byproducts of normal bacterial growth may cause tissue destruction if colonization has occurred in a normally sterile site. For example, *Clostridium perfringens* is a normal flora bacteria of the GI tract but may cause gas **gangrene** if it infects a wound or trauma site.
- **Release of toxins.** Some pathogenic bacteria produce proteins (toxins) that are inevitably toxic to the host. An endotoxin is composed of lipopolysaccharides found in the outer membrane of gram-negative bacteria. Exotoxins are proteins produced intracellularly and secreted by either gram-negative or gram-positive bacteria.
- **Capsule formation.** The polysaccharide layers of a capsule form a protective shield around a bacteria and help the cell to evade immune response.
- **Internalization.** Some bacteria are able to escape intracellular killing when internalized by phagosomes and go on to survive in the cytoplasm (e.g., *Mycobacterium tuberculosis*). In this way they are protected from antibody-mediated immune responses.
- **Granuloma formation.** A granuloma is a lesion formed in response to infection by some intracellular pathogens. Viable bacteria are walled off in the granuloma and thus prevented from further colonization.
- **Antigenic mimicry.** A bacterial cell may be able to trick the immune system by presenting antigens (molecules recognized by antibodies) that are similar to host antigens. Immunological cells therefore have difficulty distinguishing between the bacterium and a host cell.

Antibiotic resistance

The emergence of bacterial strains that are resistant to treatment by current **antibiotics** is an important public-health concern. Antibiotics are chemical substances produced by microorganisms that inhibit bacterial growth or kill bacterial cells. Narrow-spectrum antibiotics target only a limited variety of bacteria, while broad-spectrum antibiotics have the ability to inhibit or kill a wide variety of bacteria.

Bacteria can resist the action of antibiotics using one or more of four basic mechanisms:

- inactivation or modification of the drug
- modifying the drug's target binding site
- decreasing uptake of the drug into the cell
- altering the biochemical pathway that the drug is targeting

In many developing countries, antibiotics are freely distributed as over-the-counter drugs, leading to their

widespread use for viral or noninfectious illnesses. This practice, coupled with the overuse of antibiotics in veterinary medicine, farming, and plant culture, has contributed to the spread of antibiotic-resistant bacteria.

Common diseases and disorders

The following list describes some of the most common bacteria that are pathogenic to humans.

- *Staphylococcus*. Staphylococci are gram-positive bacteria found as part of the normal flora of most individuals. *S. aureus* is the causative agent of many infections, including toxic shock syndrome (TSS), staphylococcal **food poisoning**, impetigo, and furuncles (**boils**). *S. saprophyticus* causes urinary-tract infections in sexually active women. *S. epidermidis* may infect damaged or artificial **heart** valves and cause a condition called endocarditis.
- *Streptococcus*. Streptococci are gram-positive bacteria that commonly colonize the oropharynx (the area of the throat at the back of the mouth). Example syndromes include pharyngitis (**sore throat**), scarlet **fever**, necrotizing fasciitis (streptococci are popularly known as the “flesh-eating bacteria”), and rheumatic fever. *S. pneumoniae* is a common cause of bacterial **pneumonia** and meningitis.
- *Neisseria*. *N. gonorrhoeae* is the causative agent of gonorrhea, a leading sexually transmitted disease (STD). *N. meningitidis* is a leading cause of adult meningitis.
- *Escherichia*. *E. coli* is the most commonly encountered species of this genus. The bacteria is a common cause of gastroenteritis (inflammation of the lining of the stomach and intestines) but also causes urinary-tract infections and neonatal meningitis.
- *Salmonella*. Most *Salmonella* infections result from ingestion of contaminated food and lead to enteritis. The febrile (fever-inducing) illness typhoid fever is caused by *S. typhi*.
- *Vibrio*. The most commonly known *Vibrio* infection is cholera, caused by *V. cholerae*. Spread by ingestion of contaminated food or water, cholera infection is an important cause of diarrheal disease in developing countries.
- *Clostridium*. *C. perfringens* causes a variety of human diseases, including myonecrosis (gas gangrene), clostridial food **poisoning**, and soft-tissue infections (cellulitis and fasciitis). Tetanus (also known as lock-jaw) is caused by *C. tetani*; *C. botulinum* causes food-borne botulism.

- *Mycobacterium*. **Tuberculosis**, caused by infection with *M. tuberculosis*, is a highly prevalent pulmonary disease. Hansen’s disease (also known as leprosy) is caused by *M. leprae*.
- *Chlamydia*. Chlamydiae, once thought to be **viruses** because of their small size, cause numerous human diseases. *C. trachomatis* is the causative agent of conjunctivitis (inflammation of the outer surface of the eye), infant pneumonia, and urogenital chlamydia. Bronchitis, pneumonia, and sinusitis are often caused by *C. pneumoniae*.

Balance and coordination tests

Definition

Balance is the ability to maintain the center of gravity over the base of support, usually while in an upright position. Coordination is the capacity to move through a complex set of movements that requires rhythm, muscle tension, posture, and equilibrium. Balance and coordination depend on the interaction of multiple body organs and

A patient sits on a ball, working on his balance. He wears a belt so that the physical therapist can catch him if he loses balance. (Custom Medical Stock Photo. Reproduced by permission.)

systems including the eyes, ears, **brain** and nervous system, **cardiovascular system**, and muscles. Tests or examination of any or all of these organs or systems may be necessary to determine the causes of loss of balance, dizziness, or the inability to coordinate movement or activities.

Purpose

Tests of balance and coordination, and the examination of the organs and systems that influence balance and coordination, can help to identify causes of dizziness, fainting, falling, or incoordination.

Precautions

Tests for balance and coordination should be conducted in a safe and controlled area where patients will not experience injury if they become dizzy or fall. The

practitioner should first evaluate the patient's static and dynamic balance before leaving the patient unattended.

Description

Assessment of balance and coordination can include discussion of the patient's medical history and a complete **physical examination** including evaluation of the **heart**, head, eyes, and ears. A slow pulse or heart rate, or very low **blood pressure** may indicate a circulatory system problem, which can cause dizziness or fainting. During the examination, the patient may be asked to rotate the head from side to side while sitting up or while lying down with the head and neck extended over the edge of the examination table. If these tests produce dizziness or a rapid twitching of the eyeballs (nystagmus), the patient may have a disorder of the inner ear, which is responsible for maintaining balance.

An examination of the eyes and ears may also provide clues to episodes of dizziness or incoordination. The patient may be asked to focus on a light or on a distant point or object, and to look up, down, left, and right moving only the eyes while the eyes are examined. Problems with **vision** may, in themselves, contribute to balance and coordination disturbances, or may indicate more serious problems of the nervous system or brain function. **Hearing loss**, fluid in the inner ear, or ear **infection** might indicate the cause of balance and coordination problems.

Various physical tests may also be used. A patient may be asked to walk a straight line, stand on one foot, or touch a finger to the nose to help assess balance. The patient may be asked to squeeze or push against the doctor's hands, to squat down, to bend over, or stand on tiptoes or heels. Important aspects of these tests include holding positions for a certain number of seconds, successfully repeating movements a certain number of times, and repeating the test accurately with eyes closed. The patient's **reflexes** may also be tested. For example, the doctor may tap on the knees, ankles, and elbows with a small rubber mallet to test nervous system functioning. These tests may reveal muscle weakness or nervous system problems that could contribute to incoordination.

As ergonomics becomes a major emerging practice area in **occupational therapy**, balance and coordination is increasingly analyzed in workplace evaluations. Good balance and coordination, such as finger dexterity, may be needed for a worker to properly complete a specific task in his or her job. Assessments used to determine coordination include the Crawford Small Parts Dexterity Test, Bennett Hand-Tool Dexterity Test, Purdue Pegboard, and the Minnesota Rate of Manipulation Test.

Coordination tests	
Test	Description
Alternate heel to knee and heel to toe	While lying down, the patient is asked to touch his or her knee and big toe alternately with the heel of the opposite extremity.
Alternate nose to finger	The patient alternately touches the tip of his or her nose and the tip of the therapist's finger with the index finger. The therapist may move his or her finger during testing to assess ability to change distance, direction, and force of movement.
Drawing a circle	While sitting, standing, or lying down, the patient alternately draws an imaginary circle in the air, or on a table or floor, with either upper or lower extremity. Instead of a circle, a figure-eight pattern may be used.
Finger to finger	With both shoulders abducted to 90° and the elbows extended, the patient is asked to bring both hands toward the midline and approximate the index fingers from opposing hands.
Finger to nose	With the shoulder abducted to 90° and the elbow extended, the patient is asked to bring the tip of the index finger to the tip of the nose. The initial starting position may be changed to assess performance from different planes of motion.
Finger opposition	The patient touches the tip of the thumb to the tip of each finger in sequence. Speed may be gradually increased.
Finger to therapist's finger	The patient and therapist sit opposite each other. The therapist holds his or her index finger in front of the patient, and the patient is asked to touch the tip of the index finger to the therapist's index finger. The position of the therapist's finger may be altered during testing to assess ability to change distance, direction, and force of movement.
Fixation or position holding	Upper extremity: The patient holds arms horizontally in front. Lower extremity: The patient holds the knee in an extended position.
Mass grasp	The patient alternately opens and closes the fist (finger flexion to full extension). Speed may be gradually increased.
Pronation/supination	With elbows flexed to 90° and held close to body, the patient alternately turns his or her palms up and down. This test also may be performed with shoulders flexed to 90° and elbows extended. Speed may be gradually increased. The ability to reverse movements between opposing muscle groups can be assessed at many joints, including the knee, ankle, elbow, fingers, etc.
Rebound test	The patient is positioned with the elbow flexed. The therapist applies sufficient manual resistance to produce contraction of biceps. Normally when resistance is suddenly released, the opposing muscle group (triceps) will contract and "check" movement of the limb. Many other muscle groups can be tested for this phenomenon, such as the shoulder abductors or flexors, and elbow extensors.
Tapping	Foot: The patient is asked to "tap" the ball of one foot on the floor without raising the knee; heel maintains contact with floor. Hand: With the elbow flexed and the forearm pronated, the patient is asked to "tap" his or her hand on the knee.

SOURCE: O'Sullivan, S.B. and T.J. Schmitz. *Physical Rehabilitation: Assessment and Treatment*. 3rd ed. Philadelphia: F.A. Davis Co., 1994.

Standardized tests that evaluate gross motor coordination include the Bruinlinks-Oseretsky Test of Motor Proficiency, which evaluates gross and fine motor coordination, muscle strength, balance, and visual motor control; the Devereux Test of Extremity Coordination, which assesses static balance, motor attention span, and sequential motor activity; the Lincoln-Oseretsky Motor Development Scale, which assesses motor tasks such as walking backwards and one-foot standing; and the Miller Assessment for Preschoolers, which assesses gross motor function in young children.

Balance testing instruments

The Berg Balance Scale. This widely-used instrument identifies balance impairment. Functional activities such as reaching, bending, transferring, and standing are used as items on the test to measure balance. The test items are graded on a five-point scale to determine extent of impairment.

Clinical Test of Sensory Interaction and Balance (CTSIB). This test, also known as the Sensory Organization Test, assesses static balance under six combinations of sensory conditions. For example, visual conditions vary by testing while the eyes are closed, open,

and also when peripheral vision is restricted. The test also includes having the subject balance while standing on a hard floor and while standing on foam. The effect on posture and balance is graded and scored.

Functional Reach Test. This test measures a person's stability while leaning forward and reaching as far as possible with arm outstretched and parallel to the floor in front of the body. A normal reach is at least six inches, measured from the distance the fist has traveled during the reach.

The Tinetti Balance Test of the Performance-Oriented Assessment of Mobility Problems. This test measures balance and gait while performing typical daily activities. The activities are graded as normal, adaptive, or abnormal to determine the severity of balance impairment.

The Timed Up and Go Test. This test measures the time it takes a person to rise from a standard armchair and stand, walk three meters, turn around, and walk back to the chair and sit down.

The Physical Performance Test. This test evaluates a person's physical functional capabilities. The person performs nine separate activities, such as feeding and writ-

KEY TERMS

Incoordination—Uneven, inaccurate movement.

Meniere's disease—An abnormality of the inner ear that causes dizziness, ringing in the ears, and hearing loss.

ing, and is scored on each of the activities based on speed from 0-4.

Preparation

No special preparation is required prior to administration of balance and coordination tests. The patient may be asked to disrobe and put on an examination gown to make it easier for the doctor to observe muscles and reflex responses.

Aftercare

No special aftercare is generally required. However, some of the tests may cause episodes of dizziness or incoordination. Patients may need to use caution in returning to normal activities if they are experiencing any symptoms of dizziness, lightheadedness, or weakness.

Risks

These simple tests of balance and coordination are generally harmless.

Results

These tests do not normally cause dizziness, loss of balance, or incoordination.

The presence of dizziness, lightheadedness, loss of coordination, unusual eye movements, muscle weakness, or impaired reflexes are abnormal results and may indicate the problem causing the loss of balance or incoordination. In some cases, additional testing may be needed to diagnose the cause of balance or coordination problems.

Ball and socket joint

Definition

Ball and socket joints are multiaxial, synovial joints. They are lubricated by a clear, sticky fluid called synovia.

Description

Also called spheroidal joints, the ball and socket joints are formed by the rounded or “ball-shaped” head of one bone fitting into the cup-like cavity of another bone. The articulating bone fits into the cavity and allows the distal bone to move around. The hip and shoulder joints are examples of the ball and socket joint.

Function

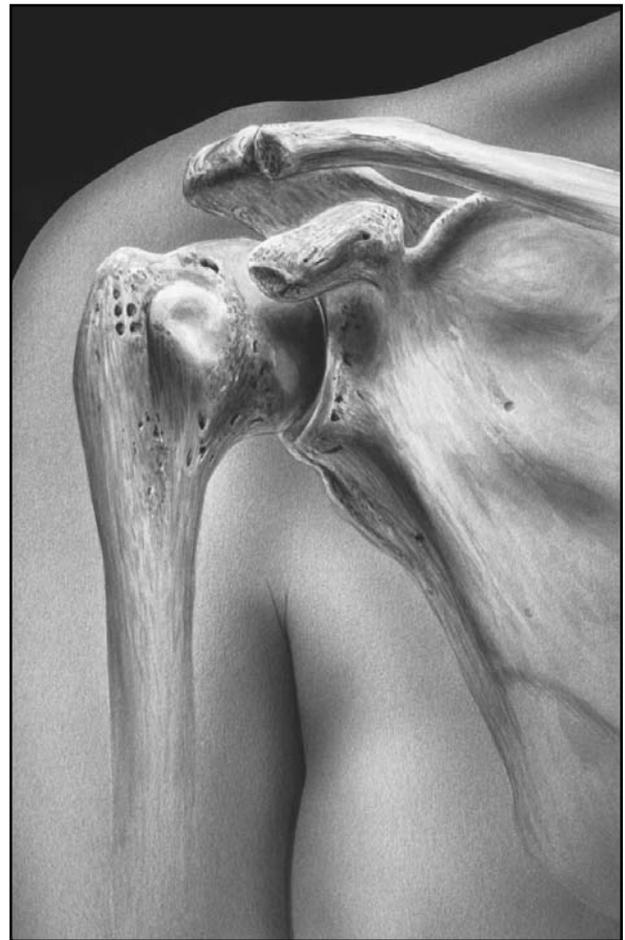

The purpose of joints is to provide movement for the body. Different types of joints move in different ways. The ball and socket joint is fully mobile under the control of muscles, ligaments, and tendons. The ends of the bones are covered with tough cartilage and are lined with the synovial membrane.

Each joint contains a small amount of synovial fluid which lubricates it. Synovial fluid provides protection for the ball and socket joint and allows for stress-free movement.

The ball and socket joint provides swinging and rotating movements. The articulating bone is received into the cavity of another bone, allowing the distal bone to move around three main axes with a common center. The joint has stabilizing ligaments that limit the directions and extent to which the bones can be moved. However, the ball and socket joint is the most mobile in the body.

Role in human health

Ball and socket joints are the most mobile and intricate of all the joints. They are also the most prone to disease and prone to require medical intervention. Hip or shoulder replacements are common forms of surgical intervention that restore a patient’s quality of life by replacing worn ball and socket joints with prosthetic ones.

The shoulder joint is supported by the scapula (shoulder blade) and the clavicle (collar bone). The humerus (upper arm bone) articulates with the glenoid cavity in a ball and socket type joint. (David Gifford. Science Source/Photo Researchers. Reproduced by permission.)

Common diseases and disorders

There are many disorders and diseases that can afflict the synovial joints, making the ball and socket joint vulnerable to **pain** and discomfort. Degenerative or inflammatory diseases, conditions involving the membranes around the joints, generalized and congenital disorders, and dislocations and **fractures** can all cause damage to ball and socket joints.

Arthritis is one of the conditions that causes pain and dysfunction in the ball and socket joint. There are several types of arthritis, but **osteoarthritis** and rheumatoid arthritis are the most common.

Osteoarthritis is a degenerative disease that affects the cartilage in the joints, and it can cause inflammation in the tissues surrounding the affected joint or joints. Degeneration is commonly thought to be caused by stress

KEY TERMS

Axis/axes—A central or principal structure about which something turns or is arranged. The cup-like structure of the ball and socket joint is the axis where the distal bone rotates.

Dysplasia—Dislocation of a bone from its proper place. Hip or shoulder displacement are two of the best-known types of dysplasia.

Multiaxial—Having more than one axis. The ball and socket joint has at least three axes on which it rotates.

Synovial fluid—A transparent, viscous fluid found in the synovial joints. It lubricates the ball and socket joint for easier movement.

on the joints or by injury to the joint lining. Osteoarthritis can affect all joints, but it is usually found in the fingers, feet, hips, spine, and knees. It causes joint stiffness and pain. Symptoms of osteoarthritis can be treated, but the disease is irreversible.

Rheumatoid arthritis is an inflammatory disease that involves the muscles and the membrane linings of cartilage and joints. The areas commonly affected are the hands, hips, knees, legs, and joints. The symptoms include low-grade **fever**, stiffness in the morning, and redness, pain, warmth, and tenderness in the affected joints. Rheumatoid arthritis can cause crippling pain and deformities of the hands and causes painful swelling of the joints.

Hip dysplasia is a dislocation of the hip joint that can be caused either by a congenital condition or by an accident. Dysplasia occurs when the thighbone (femur) does not fit correctly into or pops out of the cup-shaped socket at the hipbone (acetabulum). If hip dysplasia is caused by a congenital condition, the acetabulum is too shallow to hold the head of the femur. **Physical therapy** can help remedy the problem by deepening the cavity of the socket. Accidental hip dislocation is usually caused by a hip fracture.

Balloon angioplasty *see* **Angioplasty**

Balloon valvuloplasty

Definition

Balloon valvuloplasty is a minimally invasive procedure performed by an interventional radiologist and/or an interventional cardiologist in which a stenotic (narrowed) **heart** valve is stretched open using a special catheter with an inflatable balloon at its tip. The procedure is much less invasive than open heart surgery.

Purpose

There are four valves in the heart: the aortic valve, pulmonary valve, mitral valve, and tricuspid valve. The valves open and close to regulate the **blood** flow from one chamber to the next. They are vital to the efficient functioning of the heart.

Balloon valvuloplasty is performed on children and adults with stenosis (narrowing of the valves) to improve valve function and blood flow. The balloon stretches the thin muscular leaves of flaps of the valve, enlarging the valve opening. It is a treatment for aortic, mitral, and pulmonary stenosis. Balloon valvuloplasty is effective treatment for narrowed pulmonary valves, and results with mitral valve stenosis are generally good. For stenosis of the aortic valve, the procedure is more difficult to perform and less successful as a treatment.

Description

During balloon valvuloplasty, a contrast medium (dye) is administered to the patient to make the process visible. Then a catheter (thin tube) with a small deflated balloon at the tip is inserted in the groin area. It is then threaded back up to the heart, passing through the vessels leading to the chamber adjacent to the stenotic valve. The balloon is then inflated, which stretches the leaves of the valve open. The procedure repairs some valve obstructions quite successfully.

The procedure is performed in the **cardiac catheterization** laboratory and may take as long as four hours. About an hour before the procedure, the patient is given an oral sedative such as diazepam (Valium). The patient is also sedated intravenously, but is usually awake, and **local anesthesia** is administered to block **pain** sensation at the area of catheter insertion. After the insertion site is prepared and anesthetized, the cardiologist inserts a catheter, then passes a balloon-tipped catheter through the lumen (opening) of the first catheter. Guided by a video monitor and fluoroscopy, the physician slowly threads the catheter into the heart. The deflated balloon is positioned in the valve opening, and inflated repeatedly. The inflated balloon widens the valve's opening by splitting the valve leaflets apart. Once the valve is widened, the balloon is deflated, and the balloon-tipped catheter is removed by sliding it back out the entry route. The other catheter remains in place for six to 12 hours because in some cases the procedure must be repeated.

Preparation

For at least six hours before balloon valvuloplasty, the patient is instructed to take nothing by mouth. An intravenous line is inserted in the arm as a medication administration route. The patient's groin area is shaved and scrubbed with an antiseptic solution.

Aftercare

After balloon valvuloplasty, the patient is sent to the recovery room for several hours, where **vital signs** and heart rhythms are monitored. A 12-lead ECG (electrocardiogram) is performed. The leg in which the catheter is inserted is temporarily immobilized, and the catheter itself is secured so that it cannot come out. The insertion site is covered by a sterile dressing, on top of which is a sandbag to maintain pressure. The site is observed for bleeding until the catheter is removed. Intravenous fluids are administered to help eliminate (flush) the contrast medium; intravenous anticoagulants (blood thinners) or other medications to dilate the coronary arteries may be given. Pain medication is available.

For at least 30 minutes after removal of the catheter, direct pressure (in the form of a sand bag) is applied to the dressing at the groin where the catheter was inserted; after this, a pressure dressing is applied. Following discharge from the hospital, the patient can usually resume normal activities. After balloon valvuloplasty, lifelong followup monitoring is necessary because valve leaflets sometimes degenerate or stenosis recurs, requiring more invasive surgery.

KEY TERMS

Aortic valve—One of several valves in the heart that regulate blood flow.

Cardiac catheterization—The process of running a catheter—a long, thin, hollow tube—into the area of the heart for a variety of medical treatments.

Hematoma—Blood that has escaped from blood vessels and collected below the surface of the skin or under the surface of an organ. Also known as a blood blister or bruise.

Pulmonary valve—Any of several valves regulating blood flow to the lungs.

Stenosis—The narrowing of any valve, especially one of the heart valves or the opening into the pulmonary artery from the right ventricle.

Valve—Tissue in the passageways between the heart's upper and lower chambers that controls passage of blood and prevents regurgitation.

Valve leaflets—The tissues that form the moveable parts of a valve.

Valvuloplasty—Widening or forcing open the valves of the circulatory system, usually with a catheter equipped with a balloon.

Complications

Balloon valvuloplasty may have serious complications, such as cerebral or pulmonary embolism, in which pieces of the valve break off and travel to the **brain** or the **lungs**. Another complication is the potential for the valve opening to become distended so that it does not close completely. This condition is known as valvular incompetence. This condition permits blood backflow (regurgitation) and reduces the amount of blood pumped by the chamber through the valve, into the circulation. If the procedure causes severe damage to the valve leaflets, immediate surgery is required. Less frequent complications are bleeding and hematoma (a "bruise," or local collection of clotted blood) at the catheter insertion site, abnormal heart rhythms, reduced blood flow, **myocardial infarction**, cardiac rupture, **infection**, and circulatory problems.

Health care team roles

Balloon valvuloplasty is performed by interventional cardiologists in the cardiac catheterization laboratory. Clinical specialist nurses, radiology and laboratory tech-

nologists, and technicians assist during the procedures and provide pre- and postoperative education, monitoring, and supportive care.

Balneology see **Hydrotherapy**

Bandages and dressings

Definition

Bandages and dressings are both used in wound management. A bandage is a piece of cloth or other mate-

rial used to bind or wrap a diseased or injured part of the body. Usually shaped as a strip or pad, bandages are either placed directly against the wound or used to bind a dressing to the wound. A dressing can consist of a wide range of materials, sometimes containing medication, placed against the wound.

Purpose

The purposes served by dressings include protecting **wounds**; promoting healing; and providing, retaining, or removing moisture. Bandages can be used to hold dressings in place, and also to relieve **pain** and generally make the patient comfortable. Elastic bandages are useful to provide ongoing pressure on **varicose veins**, fractured ribs, swollen joints, etc.

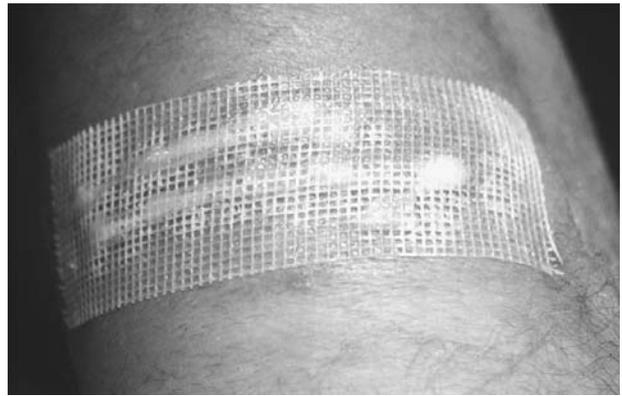

Description

There have been tremendous advances made in the design and composition of dressings and bandages in recent years. The field is becoming increasingly complex, and there are numerous reports of health care workers applying inappropriate products. Wound-care materials come in a wide variety of product classes, including the following:

- Alginate dressings. These are derived from brown seaweed, and contain **calcium** alginate, which turns into a sodium alginate gel when it comes in contact with wound fluid. Alginate dressings are available as pads or ropes.
- Biosynthetic dressings. Composites of biological (often animal-derived) and synthetic materials such as polymers.
- Collagen dressings. Made from collagen, a protein obtained from cowhide, cattle tendons, or birds. They are available as particles or gels.
- Composite dressings. These look like Band-Aids, and include an adhesive border, a nonadhesive or semiadhesive surface that is applied to the wound, an absorbent layer, and a bacterial barrier.
- Contact layers. A low-adherent layer of perforated or woven polymer material, designed to stop a secondary absorbent dressing from sticking to the wound surface.
- Gauze. This woven fabric of absorbent cotton is available in a number of formats and materials, including cotton or synthetic, nonimpregnated, and impregnated with water, saline, or other substances. Gauze is sold as surgical swabs, sheets, rolls, pads, sponges, and ribbon.
- Growth factors. These short-chain **proteins** affect specific target cells. They exist naturally in humans. They

can be transplanted from one part of the body to another, or manufactured outside the body.

- **Hydrocolloid dressings.** Used for leg ulcers, minor **burns**, pressure sores, and traumatic injuries, these self-adhesive dressings form a gel as they absorb fluid from the wound. They consist of materials such as sodium carboxymethylcellulose (an absorbent), pectin, and gelatin, attached to a foam sheet or a thin polyurethane film.
- **Hydrofibers.** Similar in appearance to cotton, carboxymethylcellulose fibers turn into a gel when they are brought into contact with wound fluid. They are available as ribbons or pads, and are highly absorbent.
- **Hydrogels.** These are sold as sheets and in gel form, and are primarily used to supply moisture to wounds. Depending on the state of the tissue, they can either absorb fluid or moisten the wound. An electrically conductive aloe vera gel is available to provide **electrotherapy** to wounds.
- **Hydropolymers.** These foamed-gel products consist of multiple layers. The surface layer is designed to expand to fill the wound's contours, at the same time drawing away fluids.
- **Leg compression/wrapping products.** Designed to apply external pressure to improve **blood** flow and resolve chronic **edema** in the feet and legs. Available in a broad range of formats including stockings, compression bandages, or pneumatic pump.
- **Polyurethane foam dressings.** These are sheets of foamed polymer solutions with small open chambers that draw fluids away from the wound. Some, but not all, of these foam products offer adhesive surfaces. They are available as sheets and rolls, as well as in various other formats suitable for packing wounds.
- **Skin substitutes.** Also known as allografts or skin equivalents, these are obtained from human cells cultured and expanded *in vitro* from neonatal foreskins.
- **Superabsorbents.** These are particles, hydropolymers, or foams that act like the material inside diapers, with a high capacity for rapid absorption.
- **Transparent films.** These consist of a thin, clear polyurethane sheet that, on one side, has a special adhesive that does not stick to moist surfaces like those found on a wound. They prevent **bacteria** and fluids from entering the wound through the dressing, but allow limited circulation of oxygen.
- **Wound fillers.** These can be bought as powders or pastes, or in strands or beads. They are used to fill wounds and also absorb wound fluid.

Dressings are used to protect wounds and promote healing. They are often held to the wound with bandages.
(Custom Medical Stock Photo. Reproduced by permission.)

- **Wound pouches.** Equipped with a special collection system for wounds that have a high flow of secretion. Designed to contain odors, and to be easily drained.
- **Other assorted wound-care products.** These include adhesive bandages, surgical tapes, adhesive skin closures, surgical swabs, paste bandages, specialty absorptive dressings, support bandages, retention bandages, elasticized tubular bandages, lightweight elasticized tubular bandages, foam-padded elasticized tubular bandages, and plain stockinettes.

Operation

Just as there is a large selection of bandage and dressing products to choose from, there is also a broad range of applications for these products:

- **Alginate dressings** are used on wounds that exude moderate to heavy amounts of fluid. They are useful for packing wounds, although strip-packing gauze may be preferable for deeper wounds because it is easier to retrieve. Common applications of alginate dressings include treatment of acute surgical wounds, leg ulcers, sinuses, and pressure sores. These dressings should not be used on third-degree burns. Neither are they advisable for wounds that are dry or are secreting only small amounts of fluid, because their powerful absorbing capability may dry out the wound. These are primary dressings that need to be covered by a secondary dressing.
- **Biosynthetic dressings** are used on burns and other wounds. Another application is as a temporary dressing for skin autograft sites. Some patients may be allergic to these dressing materials.
- **Collagen dressings** are believed to hasten wound repair and are often used on stubborn wounds. They are most effective on wounds that contain no dead tissue.

KEY TERMS

Edema—Swelling of body tissues, caused by collection of excess fluid.

Electrotherapy—The treatment of body tissues by passing electrical currents through them, stimulating the nerves and muscles.

Sinus—In the context of wound management, a narrow hollow in the body extending from an infected area to the skin's surface.

Stockinette—A soft elastic material used for bandages and clothing for infants.

Collagen dressings should not be used in dry wounds, third-degree burns, or on any patient who is sensitive to bovine (cow) products.

- Composite dressings are sometimes used alone, sometimes in combination with other dressings. Deep wounds should first be packed with wound filler material. These dressings should not be cut, and are not recommended for use of third-degree burns.
- Contact layers are designed for use in clean wounds that contain no dead tissue. They are not recommended for infected, shallow, dry, or infected wounds, or on third-degree burns.
- Gauze is used to pack wounds, and also for debridement and wicking. It is especially desirable for packing deep wounds. When using gauze to pack wounds, a loose packing technique is preferred.
- Growth factors. These have highly specific applications against such conditions as diabetic foot ulcers involving disease of the peripheral nerves. Growth factors are heat sensitive and often require refrigeration. Not recommended for patients with tumors, either benign or malignant.
- Hydrocolloid dressings are used for leg ulcers, minor burns, pressure sores, and traumatic injuries. Because they are not painful to remove, hydrocolloid dressings are often employed in pediatric wound management. Because of their absorbent capabilities, they are used on wounds that are secreting light to moderate amounts of fluid.
- Hydrofibers are highly absorbent, so they are particularly useful for wounds that are draining heavily. For this reason, they are not recommended for dry wounds or wounds with little secretion, because they may result in **dehydration**. Hydrofibers should not be used as surgical sponges or on third-degree burns.
- Hydrogels are often used on wounds that contain dead tissue, infected surgical wounds, and on painful wounds. They should not be used on wounds with moderate to heavy secretions. As with all dressings, it is important to check the manufacturer's directions. In the case of hydrogels, directions on some products indicate they are not to be used on third-degree burns.
- Hydropolymers are typically used on wounds with minimal to moderate drainage. They are not indicated for dry wounds or third-degree burns.
- Leg compression/wrapping products are used to increase blood flow and reduce edema in the lower extremities of the body. A medical doctor should be consulted before using these products on patients with edema. In many cases, topical dressings are used underneath these products.
- Polyurethane foam dressings are very absorbent and are typically used on wounds with moderate to heavy secretions. They should not be used on third-degree burns, or wounds that are not draining or have sinuses or tunneling.
- Skin substitutes are a relatively new product category, approved for treating venous leg ulcers. It is often advisable to cut slits in the artificial skin, so that wound secretions underneath do not lift the newly applied skin.
- Superabsorbents are employed on wounds that are secreting heavily, or in applications requiring extended wear. A packing material is commonly employed under this product. Superabsorbents should not be used on third-degree burns or wounds that are either dry or have minimal secretions.
- Transparent films are often employed as a secondary cover for another, primary dressing. They are used on superficial wounds, and on intact skin at risk of **infection**. It is important to remove transparent films very carefully, to avoid damaging fragile skin.
- Wound fillers are primary dressings that are usually used in conjunction with other, secondary dressings. Wound fillers are considered appropriate for shallow wounds with little or moderate secretions. They are not appropriate for use in third-degree burns, or in dry wounds. They are similarly not recommended for wounds with tunnels or sinuses.
- Wound pouches are useful in treating wounds with high volumes of secretion. They are not suitable for dry wounds.

Maintenance

Recommended intervals between dressing changes varies widely between product classes. Some dressings

are designed to be changed several times a day. Others can remain in place for one week. The manufacturer's directions should be consulted and followed.

Health care team roles

Wound-care nursing is a demanding field that can require its practitioners to also be administrators, educators, clinical experts, and researchers. Nurses are the front-line workers in **wound care**, often working as part of a multidisciplinary team of colleagues from other professions and disciplines. This approach is considered necessary because of the multifaceted nature of wounds. Its importance is especially noticeable in acute care, where 5.4% of hospital patients develop a stage one ulcer. Across the United States, such ulcers in acute care cost more than \$839 million a year. Other members of the wound-care team may come from **home care**, administration, **nutrition**, geriatrics, vascular surgery, plastic surgery, biomedical, general nursing, pharmacy, materials management, **infection control**, purchasing, quality assurance, and physical and **occupational therapy**. Numerous ad hoc members and consultants may also be involved, including representatives from dermatology, trauma, podiatry, risk management, staff development, orthotic specialists, rehabilitation, diabetology, and social services. To be successful, multidisciplinary wound-care teams must establish ongoing communication with primary-care physicians. Nurses are intensively involved in the initial assessment of tissue damage, a responsibility that demands both accuracy and consistency. Other responsibilities may include cleansing and dressing wounds, removal of non-viable tissue, **pain management**, **patient education**, nutritional counseling, statistical analysis, and helping the patient cope with the psychological effects of serious or disfiguring wounds. Determining the cause of wounds is often very important, especially the cause of chronic wounds such as skin ulcers. A physician should be advised of any signs of infection or other changes in the wound.

Training

Wound-care nursing is a rapidly advancing field that requires considerable training, clinical experience, and judgment, causing some observers to predict that it will eventually develop into advanced practice nursing or a specialty-based practice. Increasingly, the demands on wound-care nurses are expected to require that they undertake graduate studies. For all nurses working in the field, ongoing education is a must, to keep up with new knowledge, technologies, and techniques. Numerous organizations and institutions offer continuing education courses in wound care management. The Wound,

Ostomy and Continence Nurses Society is one such organization. It offers a variety of resident programs at several U.S. centers and also has distance-learning options.

Barium enema

Definition

A barium enema (or BE), also known as a lower GI (gastrointestinal) series, is a radiographic exam used to view the **large intestine**. There are two types of barium **enemas**: the single-contrast technique where just barium sulfate is injected into the rectum to outline the large intestine; and the double-contrast (or "air contrast") technique in which barium and air are injected into the rectum.

Purpose

The purpose of a barium enema is to demonstrate the anatomy and morphology of the large intestine. The large intestine frames the abdomen and is divided into six sections. These include the rectum, sigmoid colon, descending colon, transverse colon, ascending colon, and cecum.

A barium enema may be performed for a variety of reasons, including abdominal **pain** or a change in bowel habits such as **diarrhea** or constipation, as well as a change in the caliber (size) of the stools. This exam is also requested when parasites, **blood**, mucus, or pus are found in the stools. Occult (hidden) blood found in the stools and anemia may be an indication of intestinal bleeding due to ulcers, inflammatory disease, or a cancerous lesion. Doctors may also order this exam as a screening tool for patients with a history of polyps (pre-cancerous growths extending outward from a mucous membrane) or a family history of **colorectal cancer**.

A barium enema may also be requested when the large intestine was not completely visualized during a

A barium enema exam allows any obstructions or tumors to be seen on a monitor. (Photo Researchers, Inc. Reproduced by permission.)

colonoscopy (examination of the large intestine with a fiber-optic tube) or when a **sigmoidoscopy** is done, which only partially visualizes the colon. Sometimes a barium enema may be used as a treatment for intussusception (telescoping of one section of the bowel into another causing obstruction). This is a rare disorder occurring most often in young children, but when it occurs immediate action must be taken.

A barium enema may also be done to evaluate the remaining colon on **colostomy** patients. The barium is injected into the stoma (external drainage opening in the abdominal wall) instead of the rectum. A barium enema may be done if obstruction, perforation, or fistula formation is suspected.

Precautions

As with any radiographic procedure there is the risk of radiation. The x-ray technologist must always make sure there is no risk of **pregnancy** and that the least amount of films as possible are done. No lead shielding can be used since all the abdominal area must be visualized on the films.

Description

All patients must be changed into a hospital gown. All clothing is removed, including shoes and socks, since some leakage of the barium mixture can occur. In some departments disposable slippers are supplied. The x-ray

technologist may take one preliminary view of the abdomen to determine how well the patient's bowel has been cleansed. Any retained fecal material can create false filling defects and mucosal abnormalities on the films. A single-contrast enema would usually be done on patients with a poor bowel preparation. After the films are taken and the patient has evacuated as much of the barium as possible air may be introduced into the large intestine and further films taken. This method takes longer and gives more radiation to the patient.

The patient will be instructed to lie on the left side on the x-ray table, and the radiography technologist will insert a lubricated enema tip into the rectum. The enema tips contain a small balloon which may be inflated to help the patient retain the barium. The patient may remain on their left side or turned prone (face-down) depending on the procedure and routine of the radiologist.

For a single-contrast barium enema, the barium sulphate solution is a thinner consistency but a larger amount is needed to completely fill the large intestine. High kilovoltage (100-125kvp) is used to get a good penetration of the barium filled colon, and it is important to take the films as quickly as possible since the patients are very uncomfortable when the bowel is completely distended. Routine films for a single contrast study include a supine and prone abdomen film as well as both obliques to see the hepatic and splenic flexures of the large bowel. The patient will completely evacuate the bowel and one more film, the post-evacuation film (PE) usually done AP (anteroposterior, or front-to-back) supine, will be taken.

In a double-contrast barium enema, a fine coating of thick barium is needed to outline the mucosal lining of the bowel. The patient will be placed prone so that gravity can assist the air in distributing the liquid around the large bowel. The patient is asked to turn over 360 degrees a few times during the exam to aid in the coating of the bowel. The patient is then placed upright, and more air is injected into the bowel so gravity again can assist in visualizing the large intestine. Patients may develop spasms of the bowel during this exam, so the radiologist may give the patient a glucagon injection to relax the large bowel. This injection should not be given to patients with a history of **glaucoma** and can cause temporary double-vision in these patients.

The radiologist will take spot-films under fluoroscopy of each segment of the bowel but most of the films will be made following the procedure by the x-ray technologist. Since less barium is used along with some air, less kilovoltage (90-100kvp) is needed to achieve a high contrast x-ray of the large intestine. The usual AP and PA (posteroanterior) abdomen films will be done as well as the two oblique views of the abdomen. An

upright film may be done as well depending on the routine of the radiologist. The most important films for the double-contrast exam are the two lateral decubitus films. The patient is placed on a large cushion or sponge and turned completely onto one side. A stationary grid is placed next to the patient and the x-ray tube is turned 90 degrees. This film allows the air to rise to the upper surface of the abdomen so that the air along with the thin coating of barium creates a detailed visualization of the intestinal lining. This is extremely important when looking for small polyps, cancers, and ulcerations of the bowel. Films of both sides are always taken.

Preparation

In order to conduct the most accurate barium enema test, the patient must follow a prescribed diet and bowel preparation prior to the test. This includes a diet of tea, coffee (black), clear soups, and gelatin 24-48 hours before the barium enema. **Laxatives** and cathartics such as magnesium citrate (X-Prep) or Dulcolax tablets may also be required as part of the bowel preparation. Each radiology department has their own specific requirements. A rectal suppository or cleansing enema may also be necessary on the morning before the exam. Patients must drink as much fluids as possible to prevent **dehydration**. Patients with **heart** disease, diabetes, or kidney disorders should consult their physician for an alternate bowel preparation. Children are usually placed on a clear liquid diet on the day before their examination.

A barium enema may be done in a hospital or a certified x-ray clinic and will take 30 minutes to one hour depending on what type of exam has been ordered and the physical ability of the patient.

Aftercare

Patients should follow several steps immediately after undergoing a barium enema, including:

- Drinking plenty of fluids to help counteract the dehydrating effects of the bowel preparation.
- Taking time to rest. A barium enema and the bowel preparation taken before it can be exhausting.
- A cleansing enema or laxative may be given to eliminate any remaining barium. White stools containing barium are normal for two or three days following a barium enema.

Complications

While a barium enema is considered a safe screening test used on a routine basis, it can cause complica-

tions in certain patients. The following contraindications should be kept in mind before a barium enema is performed:

- Those who have a rapid heart rate, severe ulcerative colitis, toxic megacolon, or a presumed perforation in the intestine should not undergo a barium enema.
- The test can be cautiously performed if the patient has a blocked intestine. Gastrograffin, an iodine-based contrast, will be used instead of the barium in case emergency surgery is needed following the barium enema.

Results

A normal result indicates no structural or filling defects of the large intestine. Radiologists look for any enlargement or narrowing of the large bowel as well as variations in the mucosal lining. The walls of the intestine should collapse normally after the post-evacuation film, and the bowel should have normal haustral markings (undulations of the colon wall).

Abnormal results may include colorectal polyps, diverticulosis (multiple abnormal sacs bulging through the intestinal wall), ulcerative colitis, abscesses, or tumors visualized on the walls or adjacent to the large intestine. Further evaluation such as a biopsy or CT scan may be necessary to determine the extent of any positive findings.

Health care team roles

It is the responsibility of the radiography technologist to prepare the barium, insert the enema tip, and take the overhead films after the radiologist has filled the entire colon with either the barium or a combination of barium and air. In some departments an interventional radiology technologist will perform the complete exam. He or she will have had additional education and training by the radiologists to complete this duty.

The x-ray technologist must work closely with the nurses to make sure all hospital patients follow the bowel preparation. Since the preparation is physically exhausting for the patient, care is taken to complete the exam as soon as possible so the patient may resume a normal diet.

Patient education

Since a good preparation is the most important step in a barium enema, all patients should receive detailed information on the reasons and requirements for the cleansing treatment. The x-ray technologist must explain the procedure in detail before starting the exam. The patient must be informed that the barium enema can sometimes cause cramps and that the urge to have a

KEY TERMS

Barium sulfate—A barium compound used during a barium enema to block the passage of x rays during the exam, allowing visualization of the intestinal lining.

Colonoscopy—An examination of the large colon performed with a colonoscope.

Diverticula (plural of diverticulum)—A sac or pouch in the colon walls which is usually asymptomatic (without symptoms) but may cause difficulty if it becomes inflamed.

Diverticulitis—A condition of the diverticula of the intestinal tract, especially in the colon, where inflammation may cause and pain.

Diverticulosis—A condition of the colon characterized by the presence of diverticula.

Glaucoma—A disease of the eye characterized by increased ocular pressure resulting in damage to the retina and optic nerve if not treated.

Sigmoidoscopy—A visual examination of the rectum and sigmoid colon using a fiberoptic sigmoidoscope.

Ulcerative colitis—An ulceration or erosion of the mucosa of the colon.

bowel movement is completely normal. Some leakage of the barium may occur and the patient should not feel embarrassed if this happens because it occurs fairly often, especially in elderly patients. Care should be taken when inserting the enema tip because the rectum is already irritated, due to the multiple bowel movements during the preparation. The x-ray technologist must take note of any history of glaucoma in case an injection of glucagon is needed. Patients should be completely covered at all times and care taken when placing the patient in the upright position since many patients are weak after undergoing the bowel preparation.

The x-ray technologist should also explain to the patient the need to drink plenty of fluids after the barium enema and that white stools following a barium enema are normal.

All radiography technologists must be certified, having completed a two to four year program depending on where the course was completed. All x-ray technologists must be registered with the A.S.R.T. and earn continuing education credits to remain registered.

Beds and bed preparation techniques

Definition

A hospital bed is the piece of equipment most frequently used by the hospitalized patient. Hospital beds are also found in long-term-care facilities, as well as patients' homes. The ideal hospital bed should be selected for its impact on patients' comfort, safety, medical condition, and ability to change positions.

Purpose

The purpose of a well-made hospital bed, as well as an appropriately chosen mattress, is to provide a safe, comfortable place for the patient, where repositioning is more easily achieved, and pressure ulcers are prevented.

Precautions

When selecting a bed, the nurse should consider the patient's mobility, overall medical condition, and risk for **pressure ulcer** development. Safety factors should also be considered. Unless a patient is accompanied by a

health care professional or other caregiver, the bed should always be placed in its lowest position to reduce the risk of injury from a possible fall.

Another precaution to take, especially for weak or bed-bound patients, or for those with altered mental status, is to elevate the side rails. However, health care professionals should be aware of a safety alert issued by the Food and Drug Administration (FDA) in 1995 concerning the use of hospital beds' side rails. Because of a number of injuries and deaths related to side rail entrapment, the FDA recommends the following actions to prevent potential deaths and injuries related to side rail entrapment:

- All hospital bed frames, side rails, and mattresses should be inspected regularly to identify potential areas of entrapment. The alignment of the bed frame, side rail, and mattress should leave no gap that is wide enough to entrap a patient's head or any other part of the body.
- Be alert for side rails or mattresses that have been replaced. Not all of these are interchangeable, and may increase the potential for entrapment.
- Check side rails for proper installation.
- Consider additional safety measures for those patients at high risk for entrapment. Side rail protective barriers may be used to close off open spaces.
- Do not use side rails as a substitute for patient protective restraints.

Description

The usual hospital bed consists of a mattress on a metal frame that can be raised or lowered horizontally. The frame is separated into three sections so the head and foot of the bed can be raised and lowered, in addition to inclining the entire bed with the headboard up or down. The majority of hospital beds are powered by electrical motors, but some are run manually (using a crank) or by hydraulic methods.

The bed's position is typically changed by using electrical controls that may be located on the side or foot of the bed, in a bedside table, or on a pendant. The electrical controls enable patients to reposition the bed with very little effort. Patients should be instructed how to use the bed controls. They should also be cautioned against raising the bed to a position that may contribute to injuries or **falls**. At its lowest level, a hospital bed is usually about 26–28 inches (65–70 cm) above the floor.

Two nurses change bedsheets with the patient in the bed.

(Photograph by Cliff Moore. Science Source/Photo Researchers. Reproduced by permission.)

Various safety features are present on hospital beds. These features include:

- **Wheel locks:** These should be used whenever the bed is stationary.
- **Side rails:** They help to protect patients from accidentally falling out of bed, as well as provide support to the upper extremities as the patient gets out of bed.
- **Removable headboard:** This feature is important during emergency situations, especially during cardiopulmonary resuscitation.

Most hospital beds have water-repellent mattresses. However, a number of specially designed beds, frames, and mattresses have been created to aid in caring for bed-bound patients. Some of these beds help to turn the immobile patient, and may make it easier for nurses to lift or reposition the patient. The major categories of specialized beds are:

- **Air-fluidized beds:** These are also known as bead beds, sand beds, and high-air-loss beds. Air is circulated via silicone microspheres, creating a fluid-like state.
- **Low-air-loss beds.** These beds have interconnected air cells with a minimum depth of five inches (12–13 cm). They allow air to escape from the surface of the bed.

There are also a variety of support surfaces that can be placed on top of the existing mattress, or specialized mattresses that can reduce the risk of pressure ulcer formation. These surfaces and mattresses include:

- static air-filled overlays
- alternating air-filled mattress overlays
- gel- or water-filled mattress overlays
- foam mattresses
- low-air-loss replacement mattresses

KEY TERMS

Draw sheet—A sheet placed over the bottom sheet to help lift or move a patient and to protect the bottom sheet from soiling.

Fowler's position—A bed position where the head of the bed is raised to an angle of 45° or more; a semisitting position.

Trendelenburg—A bed position where the entire frame of the bed is tilted with the head of the bed down.

The rotokinetic bed is used primarily for severely immobilized patients or patients with **spinal cord** injuries. The bed can rotate a patient up to 270°. Bariatric beds are available for especially obese patients.

Preparation

The nurse normally makes the bed in the morning after a patient's bath, or when the patient is out of the room for tests. The nurse should straighten the linens throughout the day, making certain they are neither loose nor wrinkled. Any sheets that become wet or soiled should be changed promptly.

When changing bed linen, the nurse should keep the soiled linen away from the uniform, and place it in the appropriate linen bag or other designated container. Never fan or shake linens, which can spread microorganisms and, if any of the sheets touch the floor, they should be replaced.

The bed can be made in a variety of ways, depending on the particular patient situation. The categories of unoccupied bed making include:

- **Open unoccupied:** In an open bed, the top covers are folded back so the patient can easily get back into the bed.
- **Closed unoccupied:** In a closed bed, the top sheet, blanket, and bedspread are pulled up to the head of the mattress and beneath the pillows. A closed bed is done in a hospital bed prior to the admission of a new patient.
- **Surgical, recovery, or postoperative:** These techniques are similar to the open unoccupied bed. The top bed linens are placed so that the surgical patient can transfer easily from the stretcher to the bed. The top sheets and bedspread are folded lengthwise or crosswise at the foot of the bed.

The other method of making a hospital bed is an occupied bed, where the patient is in the bed while the

linens are being changed. The nurse should perform the following when making the occupied bed:

- Raise the bed to a comfortable working height. Loosen the top linens, and help the patient assume a side-lying position.
- Roll the bottom linens toward the patient.
- Place the bottom sheet on the mattress, seam side down, and cover the mattress. Miter the corners of any non-fitted sheets.
- Place waterproof pads and/or a draw sheet on the bed.
- Tuck in the remaining half of the clean sheets as close to the patient as possible.
- Assist the patient to roll over the linen. Raise the side rail, and go to the other side of the bed.
- Remove the dirty linen and dispose of appropriately.
- Slide the clean sheets over and secure. Pull all sheets straight and taut.
- Place the clean top sheets over the patient and remove the used top sheet and blanket. Miter the corners of the top linens at the foot of the bed. Loosen the linens at the foot of the bed for the patient's comfort.
- Change the pillowcase.
- Return the patient's bed to the appropriate position, at its lowest level.

The nurse also needs to place the bed into one of the following positions, considering the particular needs of each patient:

- **Fowler's:** The head of the bed is raised to an angle of 45° or more; a semisitting position. This position is appropriate when the patient is eating. It is also used during nasotracheal suctioning or during nasogastric tube placement.
- **Semi-Fowler's:** In this position, the head of the bed is raised about 30°. This position helps to promote adequate lung expansion.
- **Trendelenburg:** The entire bed frame is tilted with the head of the bed down. This helps to promote postural drainage or to promote venous return in patients with poor peripheral circulation.
- **Reverse Trendelenburg:** The entire bedframe is tilted with the foot of the bed down. This position is not frequently used, though it may help to prevent esophageal reflux.
- **Flat:** Keeping the bed flat is appropriate for some patients with spinal injuries, and for those in cervical traction. It may also be used for patients with hypotension. It is a position preferred by many for sleeping.

Aftercare

After preparing the hospital bed, the patient should be assessed for comfort and safety.

Health care team roles

Selecting and preparing a bed for the patient are important responsibilities for the nurse. The nurse or nursing assistant normally makes up the bed, but it is important that all health care professionals be aware of the positive impact an appropriate, well-made bed has on a patient's care, safety, and sense of comfort.

Behavioral optometry

Definition

Behavioral **optometry** is a system of eye care that emphasizes visual training as a way to improve the way a patient uses his or her eyes. Rather than simply prescribe lenses to compensate for eyesight weaknesses, behavioral optometrists attempt to train the patient to see better across a range of different circumstances.

Origins

Behavioral optometry traces its roots to the writings of Dr. William H. Bates, a New York City ophthalmologist. Bates began writing in the 1920s about alternatives to the use of corrective lenses. He believed that many physical and emotional stresses caused **vision** problems, and that alleviating these stresses could improve vision. He noted that modern humans spend an inordinate

amount of time doing close work such as reading, while the human eye may have been originally adapted for distance vision. Bates devised a program of eye training that allowed patients to gradually improve their vision without glasses. The English novelist Aldous Huxley recovered from near-blindness using Bates's system, and wrote a book about his experience. Other optometrists built on Bates's insights, supplementing his research and ideas. Some researchers focused on the fact that the need for corrective lenses rises in proportion to a person's level of education. They concluded that the stress of reading was probably responsible for poor eyesight. Others noted that vision problems increase as cultures become increasingly industrialized and developed. Practitioners of behavioral optometry who built on and extended Bates's ideas include Dr. Raymond L. Gottlieb and Dr. Jacob Liberman, both influential authors and teachers. Behavioral optometrists are distinctly a minority in the field of optometry, but they can be found across the United States and worldwide.

Benefits

Behavioral optometrists promise many benefits from this way of treating vision problems. Perhaps the foremost is that people can learn to live without the discomfort and bother of wearing eyeglasses or **contact lenses**. Behavioral optometry also focuses on children, particularly those with learning difficulties. These children can benefit from learning to train their eyes and so overcome reading problems due to inability to concentrate or inability to keep the eyes in place on the page. Behavioral optometry also tries to help patients deal with stress, so that vision training can lead to a more relaxed and healthy lifestyle. In addition, behavioral optometry has been used to develop the special visual acuity that is needed for sports, and some practitioners are trained to treat patients who have suffered vision trauma such as stroke, or to work with autistic or disabled children.

Description

Behavioral optometry aims to treat the whole patient, not just correct his or her vision. The first step in an examination may be a wide-ranging series of tests and questions, geared to determine the patient's overall visual abilities. This term means not just how well the eyes read letters on a chart, but such broader areas of visual perception as hand-eye coordination and color perception. Behavioral optometrists will prescribe corrective lenses, but these are usually somewhat different from traditional glasses. The lenses are designed to relieve the stress caused by such close-focus work as reading or working at a computer. But for distance seeing, the lens-

KEY TERMS

Ophthalmologist—A physician who specializes in treating diseases and disorders of the eye.

Optometrist—A professional who examines the eyes for vision defects in order to fit the patient with corrective lenses or prescribe other appropriate treatment.

es may not be as accurate as traditional lenses, since the behavioral optometrist seeks to teach the eyes to relearn distance vision skills that have atrophied. Many behavioral optometrists prescribe lenses that include a series of small prisms, which are supposed to help the eyes develop better vision patterns. Behavioral optometrists also practice vision therapy, in which the optometrist works closely with the patient in step-by-step exercises to help the eyes relax and relearn lost skills. These are not merely eye exercises, because exercising the muscles around the eye can fatigue them instead of strengthen them. The therapy might involve learning new skills such as juggling, drawing, dancing, or ball games, as well as **relaxation** techniques. The optometrist may also work with the patient to alter diet, sleep patterns, and lifestyle stress.

Research and general acceptance

Though behavioral optometrists are definitely a minority within the field of optometry, a body of research supports their methods. This can be found in professional journals such as *Journal of Behavioral Optometry* and *Journal of Optometric Vision Development*. Bates's method has been in use since the 1920s, and much anecdotal evidence attests to its efficacy, including the dramatic case of writer Aldous Huxley. Other patients and practitioners have written of their ability to function without glasses and overcome learning disabilities through behavioral optometry. And one of the major contentions of behavioral optometry is that conventional optometry does not cure the eye conditions it treats. Myopic patients are given glasses, and then a stronger pair of glasses, and then a stronger, as vision gradually worsens. Behavioral optometrists use this development as evidence that conventional optometry fails its patients.

Training and certification

In the United States, there are three major training institutions for behavioral optometry. The College of Optometrists and Vision Development offers courses and examinations leading to an international certificate in

behavioral optometry. Clinical education workshops are offered by the Optometric Extension Program Foundation in Santa Ana, California. The Baltimore Academy of Behavioral Optometry offers in-depth coursework in behavioral optometry to qualified optometrists. Only people who already have a degree in optometry can take these courses. Technicians also work with behavioral optometrists. These technicians need have no specific educational background, but to become certified, they must work for 2,000 hours under a certified behavioral optometrist and pass a written and oral examination.

Bioelectricity

Definition

Bioelectricity refers to electrical potentials and currents occurring within or produced by living organisms. It results from the conversion of chemical energy into electrical energy. Bioelectric potentials are generated by a number of different biological processes, and are used by cells to govern **metabolism**, to conduct impulses along nerve fibers, and to regulate muscular contraction. In most organisms bioelectric potentials vary in strength from one to several hundred millivolts. The most impor-

tant difference between bioelectric currents in living organisms and the type of electric current used to produce light, heat, or power is that a bioelectrical current is a flow of ions (atoms or molecules carrying an electric charge), while standard electricity is a movement of electrons.

Description

Historical background

Prior to the eighteenth century, European physicians and philosophers generally believed that nervous impulses were conducted to the **brain** via an organic fluid of some kind. The experiments of two Italians, the physician Luigi Galvani and the physicist Alessandro Volta, demonstrated that the true explanation of nervous conduction is bioelectricity. Impulses within the nervous system are carried by electricity generated directly by organic tissue.

In the nineteenth century, such researchers as Emil du Bois-Reymond invented and refined instruments that were capable of measuring the very small electrical potentials and currents generated by living tissue. One of du Bois-Reymond's students, a German scientist named Julius Bernstein, is generally credited with the hypothesis that nerve and muscle fibers are normally polarized, with positive ions on the outside and negative ions on the inside; and that the current that can be measured results from the reversal of this polarization. In the early part of the twentieth century, several British scientists identified the chemical substances involved in the transfer of information between the nerves and muscles.

Cell membrane potential

Bioelectricity begins with the fact that all animal cells have electrical properties derived from the ability of the cell membrane to maintain unequal charges inside and outside the cell. The cell membrane is semipermeable, which means that it forms a selective barrier to ions, which are electrically charged atoms or atom groups. The semipermeability of the cell membrane allows the cell to maintain concentrations of ions in the cytosol (the fluid portion of cell cytoplasm) that differ from those in the fluid outside the cell. Potassium and chloride ions can diffuse through the membrane relatively easily, while sodium ions cannot diffuse into the cell at all.

Because of the semipermeability of the cell membrane, the concentration of sodium in the fluid outside the cell is higher than in the cytosol; the concentration of potassium is higher inside the cell than outside, and the concentration of chloride is higher outside the cell than

inside. There are thus two forms of energy stored across the cell membrane—a chemical force (the differences in ion concentration) and an electrical force. This bioelectric potential across the cell membrane is called the resting potential. In most cells the resting potential is about 50 millivolts.

Diffusion

The most important ions in bioelectrical phenomena are sodium (Na^+), potassium (K^+), **calcium** (Ca_2^+), and chloride (Cl^-). The first three types of ions carry a positive charge while the chloride ion carries a negative charge.

Ions can move across the cell membrane in two ways. First, they can move through pores called ion channels. Most ion channels are specific to a particular ion or group of ions. In addition, most ion channels are gated, which means that they require a stimulus to open them. Because ions move passively through the channels, the only direction they can travel via channels is from areas of high concentration to areas of low concentration. This movement from areas of higher to areas of lower concentration is called diffusion.

Active transport

A second kind of transport, which moves ions across the cell membrane *against* the electrochemical gradient is called active transport. Active transport involves an ion pump, which is sometimes called a sodium/potassium pump. Ion pumps differ from ion channels in that the pumps require energy to move the ions. The energy is derived from adenosine triphosphate, or ATP, which is a nucleotide that is the primary source of energy in all living cells. The sodium/potassium pump controls the volume of the cell and creates the electrical potential across the cell membrane. For example, the concentration of Na^+ is approximately 10 times higher outside the cell compared to the inside, and the concentration of K^+ is about 20 times higher on the inside of the cell. This difference is maintained by the action of the cell's ion pumps, which pump three sodium ions outside the cell for every two potassium ions that are pumped inside, consuming one molecule of ATP in the process. Because ions are charged molecules, a difference in chemical concentration establishes a difference in electrical charge as well. The ion channels and the ion pump work together to maintain this charge difference across the cellular membrane.

Bioelectrical functions

Synapses and synaptic transmission

A neuron, or nerve cell, consists of dendrites (receiving portions), a cell body, an axon, and the axon terminal.

KEY TERMS

Acetylcholine—A short-acting neurotransmitter involved in the process of muscle contraction.

Action potential—The change in electrical potential that occurs between the inside and outside of a nerve or muscle fiber when it is stimulated.

Active transport—The movement of ions across the cellular membrane against the electrochemical gradient by means of the sodium/potassium pump.

Adenosine triphosphate (ATP)—A nucleotide that is the primary source of energy in living tissue. It fuels the sodium/potassium pump.

Axon—The appendage of a neuron that transmits impulses away from the cell body.

Cytosol—The fluid portion of cell protoplasm.

Depolarization—Movement of the resting potential of a cell membrane back toward zero.

Diffusion—The movement of ions across the cell membrane from areas of higher concentration to areas of lower concentration.

Ion—An atom or atom group that acquires an electrical charge by the loss or gain of electrons.

Ion channel—A passive means of moving ions from one side of the cell membrane to another by diffusion.

Myosin—A protein found in muscle tissue that interacts with another protein called actin during muscle contraction.

Neurotransmitter—A chemical released by nerve endings that helps to transmit information from one nerve cell to another nerve cell, or from a nerve to a muscle.

Resting potential—A steady-state condition with no net flow of ions across the cell membrane. The resting potential can be observed on unstimulated nerve or muscle tissue.

Sodium/potassium pump—The mechanism of active transport that moves potassium ions into the cell and sodium ions out, consuming ATP in the process.

Synapse—A region in which nerve impulses are transmitted across a gap from an axon terminal to another axon or the end plate of a muscle.

The axon is a long appendage that conducts information in the form of action potentials away from the cell body. The site of contact between two **neurons** is called a synapse. The presynaptic neuron releases a chemical called a neurotransmitter into the synaptic cleft between the two neurons. The neurotransmitter passes on information to the postsynaptic neuron. Although most forms of communication between neurons are mediated by chemicals, some neurons also transmit information by direct electrical communication. Neurons may connect to other neurons, to muscles, or to receptor cells in the skin and other sensory organs.

Chemical or electrochemical stimulation of a neuron results in a temporary change in the permeability of the cell membrane. The membrane becomes more permeable to sodium and potassium ions. The sodium ions enter the cell because of their concentration and electrical gradient, while the potassium ions leave the cell because of their chemical gradient. The result is a depolarization (loss of electrical charge) of the cell. The nerve impulse, or action potential, can be defined as a localized region of depolarization that travels down the nerve fiber with the membrane potential being immediately restored behind it.

Transmission of nerve impulses to muscle

Muscle contraction is the end result of a process similar to the transmission of action potentials from one neuron to another. The neurotransmitter that is released from the presynaptic neuron is a chemical called acetylcholine. The postsynaptic cells on the muscle cell membrane receive the acetylcholine, which increases the permeability of the muscle cell membrane to sodium and potassium ions. As the sodium ions enter the cell, the potassium ions leave, producing a net depolarization of the cell membrane. This electrical signal travels along the muscle fibers. The muscle action potential is conveyed through the movement of calcium ions into actual muscle contraction through the interaction of two types of **proteins**, actin and myosin.

Role in human health

Bioelectricity is one of the fundamental forms of energy in the human body. In the form of moving action potentials, it is the basis for such central bodily functions as conduction of motor, autonomic, or sensory messages along the nerves; muscle contraction; and brain function. Specifically, motor nerve signals result in muscle contractions. Autonomic nervous signals control such basic functions of the body as breathing and heartbeat. Sensory nerve signals collect input from the outside world, including warnings of damage to the body in the form of **pain**.

Bioelectrical signals in humans

There are three types of electrical signals in human beings, two of which are routinely monitored or analyzed for diagnostic purposes. The first is the electroencephalogram, which is a relatively weak, fluctuating signal that originates in the brain. The second is the electrocardiogram, which is about 100 times stronger than the electroencephalogram, and is produced by the contractions of the **heart** muscle. The third type of electrical signal in humans, the surface electrical potential, is about as strong as the electrocardiogram but changes more slowly over time. The origin and significance of the surface electrical potential in humans are not yet known.

Common diseases and disorders

A large number of diseases and disorders are related to disturbances of the bioelectrical system. These conditions can be classified according to the component of the nerve cell/muscle cell group, or motor unit, that is affected. The motor unit can be divided into the motor neuron, the nerve root (paired bundles of nerves coming from the **spinal cord**), the nerve plexus (bundles of nerves further removed from the spinal cord), the peripheral nerve, the neuro-muscular junction, and the muscle fiber. Defects in any of these components may disrupt bioelectrical signals.

Defects in the motor neuron can be inherited, such as spinal muscular atrophies; or acquired, such as poliomyelitis or amyotrophic lateral sclerosis (Lou Gehrig's disease). Nerve root problems may result from herniated disks in the spine, metastatic **cancer**, neurofibroma, or trauma. Diseases of the plexus include acute brachial neuritis (inflammation of the nerves of the arm), damage caused by **diabetes mellitus**, **blood** clots, metastatic cancer, and trauma.

The peripheral nerves may be damaged through hereditary, infectious, inflammatory, and metabolic causes. Examples of some hereditary conditions include hereditary motor and sensory neuropathy (HMSN) and some autonomic neuropathies. **Infection** with diphtheria, herpes, HIV, leprosy, and Lyme disease can all cause types of peripheral neuropathies. Some inflammatory causes of peripheral neuropathy include chronic inflammatory demyelinating polyneuropathy (CIDP), Guillain-Barré syndrome, and vasculitis. Metabolic causes of peripheral nerve damage include amyloidosis, diabetes mellitus, dysproteinemic neuropathy, excessive ethanol intake (alcoholic neuropathy), and renal failure.

Disorders of the neuromuscular junction can result from botulism (severe **food poisoning** caused by ingesting the neurotoxin made by *Clostridium botulinum*), congenital myasthenic syndrome, Eaton-Lambert syn-

drome, myasthenia gravis, and toxic neuromuscular junction disorders.

Muscle fiber problems can be divided into dystrophies, channelopathies, and congenital, endocrine, and metabolic defects. Dystrophies are diseases characterized by progressive muscular weakness. Channelopathies are diseases caused by defects in the ion channels that control the membrane conduction system. These include familial periodic **paralysis** and Thomsen's disease. Central core disease, centronuclear myopathy, and nemaline myopathy are three examples of congenital muscle fiber damage. Endocrine disorders that may disrupt electrical signals to muscle tissue include acromegaly, Cushing's syndrome, hypothyroidism, and thyrotoxic myopathy. Metabolic causes of muscle fiber damage include glycogen storage disease and lipid storage disease.

Bioethics

Definition

Bioethics is the study of moral issues in the fields of biology and health.

KEY TERMS

Cloning—The production of an organism that is genetically identical to its parent.

Deoxyribonucleic acid (DNA)—The genetic material of all cellular organisms and most viruses. DNA carries the information needed to direct proteins. Each molecule of DNA consists of two twisted strands, called a double helix.

Embryo—The initial developmental stage of human offspring following conception. After the eighth week an embryo is classified as a fetus.

Gene—The basic unit of heredity found in the cells of all living organisms, from bacteria to humans. Genes determine the physical characteristics that an organism inherits, such as hair and eye color.

Genetic engineering—Altering the genetic structure of an organism to provide it with traits deemed useful or desirable.

Hippocratic Oath—An oath taken by physicians to observe the ethical standards of their profession.

Human Genome Project—An international scientific collaboration that seeks to understand the entire human genetic blueprint.

In vitro fertilization—Fertilization of an ovum by sperm outside the body, and subsequent implantation in the womb.

Patent—A grant issued in the name of the United States under the seal of the Patent and Trademark Office, that gives the applicant exclusive rights related to ownership.

Stem cell—An undifferentiated cell from which specialized cells develop.

Description

Always complex and controversial, the field of bioethics has grown even more so with the advent of advanced technologies and treatments. The mechanical respirator and the heart-lung machine have blurred the line between life and death. The legalization of morning-after pills and the abortion drug RU-486, approved for use in the United States in 2000, have intensified the already volatile abortion debate. In vitro fertilization techniques to help infertile couples conceive raise a host of ethical issues including how couples should choose sperm or egg

donors, and what to do with fertilized eggs not implanted. Ethicists are also concerned with how scarce and expensive advanced treatments, such as in vitro fertilization, organ transplants, and the antiretroviral **AIDS** treatments should be distributed throughout society.

The rapidly evolving field of **genetic engineering** in particular, is introducing some of the greatest challenges ever faced in bioethics, as humans develop the ability to affect changes to living matter that were beyond imagining in the past decade or two. Current areas in experimental genetics of interest to bioethicists include:

- **Cloning.** The year 1997 marked the birth of the first clone, a sheep named Dolly produced from a cell of an adult female sheep. Since then hundreds of animals have been cloned, including bulls, cows, mice, monkeys, and pigs. Even clones of clones have been produced. The cloning controversy is multifaceted, with much of the controversy centered on the potential technical feasibility of cloning humans, although animal rights activists and others are also concerned that a substantial majority of cloned animals surviving to birth have significant birth defects. Humans should never be exposed to such risks, argue opponents of human cloning research. Some opponents fear a future in which cloning technology is used by narcissistic parents to custom design their offspring, while proponents see human cloning as a potentially useful technique to treat **infertility** or avoid known hereditary traits for disease. Several U.S. states have banned human cloning.
- **Stem cell research.** Stem cells, which are undifferentiated cells that give rise to specialized cells throughout the body, are considered one of science's best tools for finding cures for many diseases, as well as for developing bioartificial **blood**, skin, and organs that will not be rejected by the body. Stem cell research is currently hampered by the controversy surrounding the source of the cells, which are sometimes culled from aborted fetuses or from embryos left behind after **fertility treatments**, or are produced using cloning technology. Some religious groups such as the Roman Catholic Church condemn the use of human embryos for research, and Congress has passed restrictions on federal funding of embryonic stem cell research.
- **Gene patenting.** Advances in genome research wrought by the Human Genome Project and others have led many individuals and institutions, public and private, to apply for patents on genes and gene combinations. Many fear the patenting of genes may make **genetic testing** of patients prohibitively expensive. Although it will be technically possible in the not-too-distant future to analyze patients' genomes in the primary care en-

vironment and provide them with information about their future disease risk, this technology will not be economically feasible if it requires payment of multiple license fees.

- **Genetic testing.** Controversial genetic tests in use for several decades allow parents to learn about genetic diseases like sickle-cell anemia prior to birth. An experimental technique known as preimplantation genetic diagnosis gives couples even more control, enabling genetic analysis of embryos created through in vitro fertilization before they are implanted in the uterus. Many fear this technique may one day be used not just to pinpoint genetic diseases, but also to choose embryos with more desirable attributes. Other genetics tests that pinpoint flawed genes, and predict one's drug responses and vulnerability to disease offer numerous potential benefits, but ethicists are concerned about how this information will be used. Employers or insurers may use such information to discriminate, for example.

Viewpoints

A multitude of viewpoints exist regarding every area of health care influenced by bioethics. While some individuals believe bioethics results in legislation that unnecessarily impedes the progress of science (for example, it is costly and time consuming for researchers to comply with **informed consent** laws), most recognize the need for at least some bioethical guidelines (the costs of compliance pales in comparison to the safeguard of informed consent on human subjects). Some individuals believe the field of bioethics is increasingly important as research technologies develop with the potential to strip away human privacy, and even to alter the definition of human life. Private and public healthcare organizations have attempted to present ethical guidelines for practitioners. For example, the American Medical Association's Council on Ethical and Judicial Affairs sets ethics policy for the American Medical Association (AMA), and AMA's Institute for Ethics investigates how professional ethics can be integrated into health care. Other organizations such as the American Association of the Advancement of Science, take formal positions on various bioethical issues to guide health care practitioners and the general public. Also, the U.S. Department of Energy and the National Institutes of Health devoted 3% to 5% of their annual Human Genome Project budgets toward study of the bioethics of genetic information, making theirs the world's largest bioethics program.

Professional implications

Because many of the current technologic advances in health care, including the advances in genetics, offer

tremendous risks in addition to potent opportunities to predict and treat human diseases, there is a need for practitioners to main a bioethical framework in their use of these technologies, if they are to adhere to their professional oaths.

Biological rhythms

Definition

A biological rhythm is one or more biological events or functions that reoccur in time in a repeated order and with a repeated interval between occurrences.

Description

Biological rhythms are the ways that organisms adapt and live with the environmental rhythms around them, such as the spin of the earth, the movement of the earth around the sun, and movement of the moon around the earth. Often generated by “biological clocks” (the term for the internal physiological systems that track the environmental rhythms), biological rhythms allow an organism to harmonize successfully with its environment. Although biological rhythms have not been studied in every living thing, they have been found in every organism in which experiments were performed. Accordingly, scientists believe biological rhythms are ubiquitous.

Generally, there are two types of biological rhythms, exogenous and endogenous. Exogenous biological rhythms are driven directly by the environment or another external influence. Another term for this type of biological rhythm is a direct effect. An example of an exogenous biological rhythm is the hopping of sparrows on a perch when a light is turned on. Such rhythms are said to have a geophysical counterpart; in this case, the presence of light.

In contrast, endogenous biological rhythms are driven by internal biological clocks and are maintained even when environmental cues are removed. Some examples of endogenous biological rhythms are the wake-sleep cycle and the daily body temperature cycles. Sometimes it is difficult to determine whether the activity of an animal is due to a direct effect or that of an endogenous biological clock, because the two types of rhythms can mask each other.

True biological clocks have four important characteristics. First, the clock is endogenous, meaning it gives the organism an innate ability to maintain periods of a particular length between biological functions. Experiments in space, with animals completely isolated from earthbound geophysical input, have supported the innate nature of the clocks. Second, the clock is temperature independent—a very unusual situation in biology but an essential characteristic to avoid biological rhythms being governed by the weather. Third, biological clocks have the ability to be reset in order to maintain a relationship with environmental cues. Finally, biological clocks are an internal continuous monitor of the passage of time, allowing the organism to keep track of duration biologically.

Chronobiology, the study of biological rhythms, categorizes rhythms by the length of the cycle. The most studied type of biological rhythm are circadian rhythms, which fluctuate on a daily basis. Alertness, body temperature, and the circulating concentrations of growth hor-

mone, cortisol, and postassium are all examples of physiological functions that run on a circadian basis. Infradian cycles last about a month or longer. Menstruation in the human adult female is an example of an infradian biological rhythm. Circannual cycles last about a year; over-winter hibernation as a common example. The shortest cycles are ultradian, where the cycles are less than 24 hours. **Heart** rate and breathing are two examples of ultradian biological rhythms.

Function

The function of biological clocks and the resulting biological rhythms involves two factors: the capacity of the biological clock to freerun (operate without external cues), and the ability of timing signals, known as *Zeitgeber* (German for “time-giver”), to synchronize the cycles to the environmental signals. Some common Zeitgebers include light, temperature, and social cues such as clocks, sound, or physical contact. A biological clock is said to be freerunning when these external cues are removed. Based on multi-day isolation experiments, the average freerun period for circadian rhythms in humans is 25 hours. Thus, if isolated from outside input, people tend to go to sleep one hour later each day, quickly becoming out of sync with the rest of the 24 hour-based human world.

Entrainment is the process of aligning a biological rhythm with an environmental stimulus. There are limits to the time periods that biological rhythms can be entrained. For circadian rhythms in most animals, 18 hours is the shortest period tolerated, with an upper limit of about 28-30 hours. If Zeitgebers are provided for shorter or longer intervals, the organism reverts back to freerunning. A good example of entrainment is the acquisition of the 24-hour wake-sleep schedule by human infants after birth. Newborn circadian rhythms freerun, significantly disrupting the sleeping patterns of their parents. However, as they mature and become responsive to Zeitgebers such as light and dark, infants gradually adopt the 24-hour schedule of adults.

Physiology of biological clocks

The physiological location of biological clocks has been studied in a number of animal systems, including humans. In most vertebrates other than mammals—sparrows, for example—the primary biological clock has been located in the pineal gland. This gland is located at the base of the **brain** and is responsible for the production of melatonin, a hormone produced in high levels at night and low levels during the day.

In mammals, additional cells responsible for biological clock functions were located in the hypothalamus, in

two clusters of nerve cells called the suprachiasmatic nuclei (SCN). Light receptors in the retina are connected by nerves to the SCN. The SCN and the mammalian pineal gland are linked, by both nervous connections and by the presence of melatonin receptors on SCN cells. Thus, light is detected by the eye, which passes this information on to the SCN, which in turn passes the information on to the pineal gland, controlling melatonin production.

The exact function of melatonin in mammals is not completely understood. Scientists believe this hormone is likely involved in many aspects of biology, including the wake-sleep cycle, body temperature control, and (particularly with mammals that have seasonal mating) sexual maturity and reproduction.

Genetic control of biological clocks

The molecular basis for the control of circadian rhythms has been studied extensively in the fruit fly insect model, where the first genetic mutants that affected circadian rhythms were discovered. Because homologs to the fruit fly genes (genes which have a similar structure, and therefore likely have a similar function) have been discovered in mammals, including mice and humans, scientists strongly suspect that similar control mechanisms have been conserved in mammals.

In fruit flies, five genes are believed responsible for the baseline oscillation of the circadian rhythms: period (*per*), timeless (*tim*), clock (*clk*), cycle (*cyc*), and doubletime (*dbt*). The protein products of these genes work together to produce a negative feedback loop that allows the concentration of the period and timeless **proteins** to build in concentration slowly over the 12-hour day. Both clock and cycle are positive transcription elements. These proteins work together to result in the production of the period and timeless proteins.

When the period protein is produced, the doubletime protein modifies it, marking it with a phosphate molecule for quick destruction by the cell if not paired with the timeless protein. Thus, the period protein will be degraded until the concentration of timeless protein is high enough so that period and timeless dimers form. The destruction resulting from the phosphate modification delays the formation of the dimers, stretching out the process over the 12-hour evening.

Eventually, dimers of period and timeless are present in high enough concentrations to interact with clock and cycle proteins to turn off production of both period and timeless proteins, closing the feedback loop. At dawn, the highly light-sensitive timeless protein is degraded, leaving the phosphorylated period protein unpaired and vulnerable to degradation as well. In this way, light resets

KEY TERMS

Chronobiology—The study of biological rhythms.

Circadian—A biological rhythm that happens about once a day.

Dimer—A pair of proteins that noncovalently bond to each other during function.

Entrainment—The synchronization of a biological rhythm and an environmental cue.

Freerun—The length of the period of a biological rhythm in the absence of environmental cues.

Homolog—A gene found in a particular species that is similar in sequence and often in function to another gene from another species.

Zeitgeber—A cue from outside the body that resets the biological clock.

the feedback loop to start again, making it the Zeitgeber for this biological clock.

In early 2001, studies of the molecular basis of biological rhythms were extended to humans, with the report of the first known human gene homologous to the fruit fly genes. The gene is called hPer2 and is homologous to the period gene. A mutation in this gene is present in a Utah family and results in an advanced sleep phase syndrome. The mutation maps to the location where the period gene is marked with a phosphate, suggesting that the mutant protein would be not be phosphorylated. The details of the mutation fit the proposed function of the protein and the problems seen by those having the mutation. Lack of phosphorylation would cause the mutant protein to be degraded more slowly, speeding up the circadian rhythms of the person having the mutation.

Role in human health

The exact role of biological rhythms and biological clocks in human health is not fully understood. However, it is clear that humans are subject to biological clocks in a number of physiological areas, most notably hormone secretion and wake-sleep cycles. A well-functioning biological clock is important for falling asleep and getting enough of the various stages of normal sleep. This affects, in turn, alertness, job performance, interpersonal relationships, and day-to-day safety issues. Well-functioning circadian rhythms may also play a role in psychological health, particularly for persons living in areas with decreased light in the winter months.

Common diseases and disorders

The most common human disorders related to biological rhythms are due to disassociations of the endogenous biological clock and the external environmental cue. These displacements are called phase shifts and occur with rapid travel across time zones and shift work. The resulting disorientation produces the symptoms known as jet lag—sleep disturbances, fatigue, indigestion, and nausea. When occurring in the workplace these symptoms can have serious consequences. The *Exxon Valdez*, Chernobyl, and *Challenger* shuttle disasters all occurred on the night shift. Research is ongoing to develop methods of using melatonin and bright light exposure to help compensate.

The role of biological rhythms in seasonal affective disorder (SAD), a form of depression with symptoms more severe in the winter months, is much less clear. Studies have been unable to find other evidence of circadian disorder in persons diagnosed with SAD. However, treatment with light therapy does bring significant improvement in the majority of patients.

Biomedical engineering

Definition

Biomedical engineering, also known as bioengineering, is the application of engineering principles to the study of medical and biological problems. The goal of biomedical engineering is to use electrical, chemical, and mechanical engineering principles to conduct studies and develop tools that can aid in the biomedical care of patients.

In 1997, the National Institutes of Health issued the following expansive definition of biomedical engineering/bioengineering: "Bioengineering integrates physical, chemical, or mathematical sciences and engineering principles for the study of biology, medicine, behavior, or health. It advances fundamental concepts, creates knowledge from the molecular to the organ systems levels, and develops innovative biologics, materials, implants, devices, and informatics approaches for the prevention, diagnosis, and treatment of disease, for patient rehabilitation, and for improving health."

Description

Biomedical engineering can trace its history to as far back as a hundred years ago, when the first x-ray machines and electrocardiographs dramatically illustrated how technology could be applied towards the diagnosis of disease. Today, the field of biomedical engineering is in full flower, propelled by the momentum of the post-World War II technology boom and the latest molecular, genetic, and computational developments. Having gone beyond its roots in imaging and instrumentation, biomedical engineering now encompasses at least 13 specialties, according to the 2000 edition of *The Biomedical Engineering Handbook*.

These specialties include

- biomechanics
- prosthetic devices and artificial organs
- transport phenomena
- biomaterials
- biomedical instrumentation
- biosensors
- medical and biologic analysis
- medical imaging
- physiologic modeling, simulation, and control
- biotechnology
- rehabilitation engineering

- clinical engineering
- medical informatics

Biomechanics, prosthetic devices and artificial organs, and transport phenomena

Biomechanics is the application of classical mechanics (the study of how objects move in response to forces placed on them) to biomedical problems. Classical mechanics provides general principles for understanding (for example) how fluids move, how objects become deformed under various forces, and how levers and forces move objects. Biomechanics uses these principles to understand how **blood** moves throughout the body, how injuries affect the shape and mechanics of body parts, and the mechanics of body movement (e.g. how an arm is lifted, or how a person walks). Biomechanics has contributed to an understanding of the mechanical function of the bones, cartilage, and soft tissue in the musculoskeletal system, as well as an understanding of other major organ systems, such as the **heart, lungs, and blood vessels**. Some of the technologies coming from biomechanics include artificial hearts and heart valves, and artificial joints such as prosthetic hip and knee replacements. These types of technologies have spawned another specialty in biomedical engineering, prosthetic devices and artificial organs. Another closely affiliated specialty is transport phenomena. This subfield concerns itself with the processes of fluid flow and heat transfer in biological systems.

Biomaterials

Biomaterials are living and artificial materials that can be used in implantation. Whereas biomechanics focuses on the mechanical design of an implant, biomaterials science focuses on the body's biochemical interactions with the material from which an implant is made. A biomaterial for an implant should be chemically inert, non-toxic, and non-carcinogenic. It should also be resilient enough to endure a lifetime of chemical and mechanical forces. Biomedical engineers in the specialty of biomaterials test and study materials possibly suited for implantation. Biomaterials science has contributed to the use and understanding of currently used implant materials, such as ceramics, polymers, metal alloys, and composite materials. Biomaterials science is also leading research into the use of living tissue as implant material with the goal of minimizing implant rejection and simulating the body's original biomechanical environment.

Biomedical instrumentation, biosensors, medical and biologic analysis

Biomedical instrumentation, or bioinstrumentation, uses mechanical, electrical, and optical principles and

systems to monitor the body's physiologic status. Many of the physiologic changes that occur in the body are mediated by electrical signals. Different ions (charged elements or molecules) are allowed to flow into and out of cells at different times, depending on cellular and systemic demands. Biomedical instrumentation attempts to infer aspects of the body's physiologic state by measuring and interpreting these electrical signals. Optical systems are used to measure the variable of interest indirectly; for example, because hemoglobin—the molecule that carries oxygen in the blood—changes its light absorptiveness according to whether it is attached to oxygen, changes in the oxygenation of blood can be inferred from the optical properties of blood and tissue.

The specialty of biosensors focuses on the development and instrumentation of measurement systems. Technologies emerging from biomedical instrumentation generally, and biosensors specifically, include electrocardiographs (ECGs) and pulse oximeters that measure blood oxygenation. The associated specialty of medical and biologic analysis seeks to refine current understanding of the biomedical signals received by the instruments. It attempts to discern and amplify the signals of interest while diminishing noise and unrelated signals. In addition to biomedical measurement, the specialty of biomedical instrumentation includes the development of devices to control and guide biomedical processes through mechanical or electrical means, e.g., cardiac **pacemakers** and respirators.

Medical imaging

Medical imaging uses energy phenomena and physics principles, in conjunction with high-speed data processing, to produce images of the body that reflect its anatomic structure and physiologic function. Developments in medical imaging include x-ray applications (**mammography, angiography**), ultrasound, computer tomography (CT), **magnetic resonance imaging** (MRI), single-photon emission computed tomography (SPECT), and **positron emission tomography** (PET). Each of these technologies is based on exploiting an understanding of electromagnetic or sound energy patterns to provide images of not readily observable aspects of body structure and function.

Physiologic modeling, simulation, and control

Physiologic modeling, simulation, and control—also known as systems physiology—attempts to provide formal quantitative models of the various systems of the body, from micro-level systems (at the level of the cell) to macro-level systems (at the level of large organ systems and full-body interactions). Using experimental

data and mathematical models, system physiology relies on computer simulation to describe and understand human physiology. These models provide a basis for thinking about how the body functions in an integrated way. Systems physiology is the source of such models as cardiovascular models, respiratory models, neural network models, and biochemical metabolic models.

Biotechnology

Biotechnology, also known as cellular, tissue, and **genetic engineering**, is the study of how biological materials can be modified at a micro-level for useful ends. Biotechnology studies the biochemistry and physics of cells to develop beneficial interventions and biomedical research and diagnostic tools. A sprawling specialty, biotechnology developments have included the development of new diagnostic tests for diseases, the invention of miniature devices that can deliver therapeutic drugs to specific sites, and the production of synthetic vaccines and therapeutic **proteins**.

Rehabilitation engineering

Rehabilitation engineering focuses on developing tools for cognitive and physical rehabilitation. Specifically, rehabilitation engineering is concerned with designing technologies that assist mobility and communication. These include the development of rehabilitation **prosthetics**, the design of living space modifications, the development of transportation alternatives, and the design of hardware and software to aid in communication and cognitive rehabilitation.

Clinical engineering

Clinical engineering focuses on how the latest biomedical technologies are used in a clinical setting. Aspects of this specialty include the adaptation of biomedical technologies to the needs of the hospital and clinicians, the management of medical instrumentation and equipment, and the purchase and use of current biomedical technologies. An important aspect of clinical engineering is the interface between the medical instrumentation and the clinical software that records data of interest to the hospital. Patient safety and progress are also important aspects of clinical engineering.

Medical informatics

Medical informatics is the study of how information is used and disseminated in health care settings. Medical informatics includes the study of health information systems, computer networks in clinical settings, and clinical decision systems. Tools used in medical informatics

include neural network models, artificial intelligence models, expert systems, and patient records and archives.

Work settings

Biomedical engineers and biomedical engineering technologists work in a variety of private and public sector settings. In the private sector, biomedical engineers and technologists find employment in industry, such as at biomedical device firms and pharmaceutical companies, and in hospitals. In the public sector, biomedical engineers and technologists are employed at research facilities, universities, and government agencies. Depending on the specialty, biomedical engineers may work in a laboratory setting, a clinical setting, a software development setting, or a managerial/administrative environment. Because of their multidisciplinary training, biomedical engineers often serve in a liaison or coordinating role, interacting with both engineering and medical professionals.

Education and training

A four-year university degree in a biomedical engineering or bioengineering program is the minimum required for a biomedical engineer. The undergraduate program gives training in both biological and engineering aspects of the field, and specialization in a subfield may be required. The undergraduate degree program should be accredited by ABET, or the Accreditation Board for Engineering and Technology, Inc., which imposes strict requirements on curriculum design and quality.

If a biomedical engineer wants to offer his/her services to the public, she or he must be registered as a Professional Engineer. To qualify for a license, an individual must (1) have graduated from a degree program approved by ABET, (2) have had a minimum of four years of engineering experience, and (3) pass the Professional Engineer exam offered by the National Council of Engineering Examiners. After a Professional Engineer license is issued, the license can be renewed every two years, contingent on satisfying the continuing education requirements.

To become a biomedical engineering technologist (BMET), a two-year (associate) degree in **biomedical equipment technology** or electronics technology is the minimum education typically required. In this program, the BMET learns the basic biomedical principles and the instrumentation skills required to operate and maintain biomedical equipment.

Certification for BMETs is given through the International Certification Commission (ICC) for Clinical Engineering and Biomedical Technology. To be eligible

for certification, an individual must have either the appropriate associate's degree and two years of full-time BMET work experience, or four years of full-time BMET work experience. The individual must also pass the biomedical equipment technician test given by the ICC.

Advanced education and training

To conduct research and develop designs in biomedical engineering, a PhD degree in biomedical engineering is required; in some cases, depending on the specialty, a master's degree may be sufficient. Some biomedical engineers also have advanced degrees in other fields such as clinical medicine.

BMETs are typically offered many opportunities for on-the-job training. In addition, continuing education is a requirement for the renewal of BMET certification.

Future outlook

The occupational outlook for biomedical engineering is good, particularly for those engineers who elect to work in industry. According to the University of Cincinnati Center for Economic Education, the medical instruments and supplies industry grew by 27% during the period from 1987 to 1994. The biotechnology industry has been expanding at an even faster rate. Although the recent economic downturn has slowed the expansion in the biotechnology sector somewhat, the health care industry and allied industries are expected to maintain strong growth.

The American Society for Engineering Education reports that, among biomedical engineering Ph.D. graduates who received their degrees during the academic year 1996–97, the average starting salary for those working in industry was \$62,000. About 50% of Ph.D. biomedical engineering graduates surveyed chose to work at universities, and the average salary of this group of graduates was \$48,000. The average salary of clinical engineers (who do not have PhDs) was also \$48,000.

For biomedical engineering technologists, particularly those who work at hospitals, the outlook is very bright. According to the Association for the Advancement of Medical Instrumentation, the high demand for and relative shortage of BMETs mean higher salaries and greater benefits for job candidates. According to the 2000 salary survey reported in the *Journal of Clinical Engineering*, the average salary for a BMET I position in 1999 was \$31,600, while that of a BMET III position was \$48,000.

Overall, the occupational outlook for biomedical engineers and biomedical engineering technologists is very good, especially in hospitals and private industry.

Because of the continuing interest in biomedical technology developments, demand for biomedical engineers in government and at research institutes will remain moderately strong.

Biomedical equipment technology

Definition

Biomedical equipment technology professionals are employed at jobs involving the repair, sale, calibration, installation, troubleshooting, and management of biomedical instrumentation and electronics technology in the health industry.

Description

Biomedical equipment technology is a profession that requires broad knowledge of biomedical system instrumentation. Necessary knowledge includes system usage, maintenance responsibilities, and ways to obtain data on an extensive range of monitoring, diagnostic, therapeutic, and surgical instrumentation. Solutions to issues encountered while interacting with doctors, nurs-

es, and other technicians who use biomedical instrumentation are often studied and realized by those in the profession. A biomedical equipment technologist must study electronics, electronics management, medical physiology, and computer applications. After graduating, he or she may opt to specialize in particular types of equipment used, generally in nuclear medicine, surgery, radiology, clinical laboratory, dialysis, or intensive care.

Work settings

Graduates of biomedical equipment technology programs usually work

- in hospitals
- in medical clinics
- at medical colleges
- at medical research facilities
- at computer and electronic instrumentation manufacturers
- at companies as sales representatives or distributors
- in United States government agencies
- in the U.S. Armed Forces
- in **public health** services
- as field service technicians

On the job, a biomedical equipment technologist may work with machines used to diagnose and treat diseases or disorders, or those used to assist in the role of vital organs (e.g. a respirator). They often work under the supervision of biomedical engineers, performing such tasks as the evaluation, inspection, repair, maintenance, and installation of diverse instrumentation, including electrosurgical equipment; ultrasound devices; chemical analyzers; defibrillators; centrifuges; x-ray instrumentation; spectrophotometers; infusion pumps; **heart**, lung, and **kidney dialysis** machines; **pacemakers**; infant incubators; respirators; **blood pressure** and heart rate monitors; and **magnetic resonance imaging** (MRI or NMR) machines.

Education and training

Biomedical equipment technologists may be trained at vocational schools (which may lead to a job involving on-the-job training), technical colleges, community colleges, military training schools, or at various universities as part of a standard Bachelor of Science program. Education includes instruction in electronics, circuit theory, computer applications, bio-instrumentation, health and safety, and general knowledge of **human anatomy**, physiology, and terminology. Background knowledge of

physics and mathematics is essential and is expanded during coursework, especially involving applications of biomedical electronics. The technologist should possess solid communication skills, manual dexterity, and hand-eye coordination for labor on machine parts and electronic circuits. Education generally culminates in an associate's degree (two years) or a bachelor's degree (four years). Many programs associated with either degree sponsor extensive co-op or internship opportunities that provide ample occasion to sample some aspects of the field. Specialties are not commonly available during educational training, but one may choose to specialize upon graduation in a relevant type of instrumentation technology; it is possible to specialize in a specific instrument if the demand is great enough, or to specialize in education, repair, calibration, etc.

Upon graduation from an associate degree program, a graduate will be capable of performing a range of tasks. Erie Community College of western New York and the University of Florida (which adds the final four items) provide lists of what is expected of a typical graduate, reproduced below:

- Be able to use the resistor color code and component recognition.
- Be proficient at electronic soldering and terminating wire connections using solderless-type connectors.
- Use a curve tracer to check all types of diodes, bipolar transistors, and field effect transistors.
- Demonstrate proficiency in using electronic test instrumentation dual trace scopes, frequency counters, and function generators.
- Be proficient at troubleshooting half-wave, full-wave, and bridge power supplies. In addition, students should be able to troubleshoot and repair voltage doublers.
- Demonstrate proficiency in using electronic instrumentation.
- Prototype multi-stage analog and digital circuits.
- Interact with computer systems.
- Isolate data communications systems faults.
- Isolate and repair computerized process devices.
- Analyze system malfunctions by relating program execution to specific groups of circuits.
- Perform routine safety checks on equipment including ground and leakage current tests.
- Read and interpret instructions and maintenance manuals as well as blueprints, mechanical drawings, and schematic diagrams related to equipment serviced.
- Install equipment and provide instruction on its use to physicians, nurses, physical therapists, and others.

- Inspect and calibrate equipment such as radiation monitors, **blood** gas analyzers, electrocardiographs, dialysis machines, and many others to insure safety and accuracy.
- Modify components to meet specific therapeutic or diagnostic requirements.
- Maintain an inventory of parts and tools used in repair work.

Advanced education and training

Technicians with an associate's degree have advancement opportunities including progressing to senior technician or shop supervisor and becoming certified within five years (normally two years); graduation results in eligibility to take the certification exam to become a certified biomedical equipment technician (CBET). With more advanced education, technicians may become instructors, administrators, or research assistants in medical research facilities. One may also advance through specializing, becoming an expert, in a particular type of equipment.

Technicians with a bachelor's degree have all the options open to associate's degree holders with additional alternatives. Qualified students may further their education in biomedical equipment technology with a masters or doctoral degree, usually in a field such as electrical engineering or **biomedical engineering**; however, these graduates are then not generally classified as biomedical equipment technologists, but as biomedical engineers or an equivalent.

The International Certification Commission for Clinical Engineering and Biomedical Technology (ICC) is the group responsible for formally recognizing qualified biomedical equipment technicians (BMETs) through administration of written examinations. Certification is achieved by exhibiting high aptitude in both the theoretical aspects and practical applications of the central tenets of biomedical equipment technology. The exam board, which is overseen by the ICC and the United States Certification Commission (USCC), governs not only the CBET certification program, but also the programs of two specialties: radiology equipment specialists (CRES) and clinical laboratory equipment specialists (CLES). Each program requires a separate examination for certification and is entirely independent of the others. It is also possible to become certified by the Association for the Advancement of Medical Instrumentation (AAMI).

Future outlook

Biomedical equipment technologists are employed throughout the world, and there is always a need for professionals who can understand, operate, and instruct other health professionals in the increasingly complex, rarefied business of biomedical instrumentation. The outlook for biomedical equipment technologists is better than average in the near future (as of 2001), through at least the year 2005.

The field of biomedical equipment technology is still considered relatively new, so job opportunities abound as new types of jobs are found for professionals with a biomedical equipment technology education and related experience. The plethora of biomedical devices on the market and waiting to reach the market is still accelerating, and as such, requires the assistance of biomedical equipment technicians to install, calibrate, test, maintain, evaluate, assist with usage of, instruct doctors and other health professionals about, and to repair. As might be expected, however, jobs for biomedical equipment technicians tend to be significantly greater in larger cities that include more hospitals and comparable medical facilities.

Biotin

Description

Biotin is a member of the B complex family, but is not actually a vitamin. It is a coenzyme that works with them. Also known as vitamin H and coenzyme R, it was first isolated and described in 1936. It is water soluble and very unstable; it can be destroyed by heat, cooking, exposure to light, soaking, and prolonged contact with water, baking soda, or any other alkaline element. The body obtains biotin from food and can also synthesize this nutrient from **bacteria** in the digestive tract.

General use

Biotin is utilized by every cell in the body and contributes to the health of skin, hair, nerves, bone marrow, sex glands, and sebaceous glands. Apart from being a vital cofactor to several enzymes, biotin is essential in carbohydrate **metabolism** and the synthesis of fatty acids. It is also involved in the transformation of amino acids into protein. Biotin plays a role in cell growth and division through its role in the manufacture of DNA and RNA, the genetic components of cells.

Adequate biotin is required for healthy nails and hair, and biotin deficiency is known to be a factor in balding and the premature graying of hair. It has been claimed that, as part of an orthomolecular regime, it can reverse the graying of hair. When PABA and biotin are taken together in adequate amounts they can restore hair color. Biotin supplements will also effectively treat weak, splitting nails.

Biotin can be a valuable tool to combat yeast infections, which are notoriously difficult to eradicate. In their book *The Yeast Syndrome*, John Parks Trowbridge and Morton Walker describe how adequate levels of biotin can prevent *Candida albicans* from developing from its yeast-like state into fungal form, in which it sends out mycelium that further invade body organs.

Seborrheic dermatitis, or Leiner's disease, which is a non-itchy, red scaling rash affecting infants during the first three months of life, is also treated with biotin and other B complex **vitamins**.

Biotin has been used in conjunction with other nutrients as part of weight loss programs, as it aids in the digestion and breakdown of **fats**.

High doses of biotin are sometimes used by the allopathic medical profession to treat diabetes since it enhances sensitivity to insulin and effectively increases levels of enzymes involved in glucose metabolism. Biotin is also used to treat peripheral neuropathy, a com-

plication of diabetes, and those with Duchenne **muscular dystrophy**, who suffer from metabolic deficiencies.

Biotin can be found in beans, breads, brewer's yeast, cauliflower, chocolate, egg yolks, fish, kidney, legumes, **liver**, meat, molasses, dairy products, nuts, oatmeal, oysters, peanut butter, poultry, wheat germ, and whole grains.

Preparations

The recommended daily allowance for adults in the United States is 30 mcg. Daily requirements are estimated at 30 mcg for adults and 35 mcg for women who are nursing. Supplementation ranges from 100–600 mcg per day, and can be obtained in the form of brewer's yeast, which contains biotin as part of the B complex, or as an individual biotin supplement.

Precautions

The body needs biotin on a daily basis since it is not stored to any great extent. Biotin requirements increase during **pregnancy** and **lactation**, and should be supplemented in anyone who is taking **antibiotics**. Certain individuals are at risk for biotin deficiency, including infants fed biotin-deficient formula or with inherited deficiency disorders, patients who are fed intravenously, and anyone who habitually eats a lot of raw egg whites, because they contain a protein called avidin, which prevents the absorption of biotin.

Mild deficiency

Because it is synthesized in the digestive tract, deficiency symptoms of biotin are rare. However, they may include weakness, lethargy, grayish skin color, eczema (which may include a scaly red rash around the nose, mouth and other orifices), hair loss, cradle cap in infants, muscle aches, impaired ability to digest fats, nausea, depression, loss of appetite, insomnia, high cholesterol levels, eye inflammations, sensitivity to touch, anemia, and tingling in the hands and feet.

Extreme deficiency

Symptoms of extreme biotin deficiency include elevation of cholesterol levels, **heart** problems, and **paralysis**. When extreme deficiency is a problem, the liver may not be able to detoxify the body efficiently, and depression may develop into hallucinations. Infants may exhibit developmental delay and lack of muscle tone.

Biotin deficiency could result in a loss of immune function, since animal experiments have shown that biotin deficiency resulted in a decrease in white blood-

KEY TERMS

Coenzyme—A non-protein organic compound that plays an essential role in the action of particular enzymes.

Lactobacillus—A bacteria present in the digestive tract of healthy people.

Mycelium—Fine thread-like tendrils sent out by a fungus to seek nutrition, capable of invading body organs.

Peripheral neuropathy—Weakness and numbness of the nerves in the fingers and toes, which may progress up the limb—often a complication of diabetes.

cell function. Because biotin is essential to the body's metabolic functions, any deficiency could result in impaired metabolism as well.

Overdose

There have been no reports of effects of **overdose** of biotin, even at very high doses, primarily because any excess is excreted in the urine.

Side effects

There are no side effects associated with biotin supplementation.

Interactions

Biotin works in conjunction with all the B vitamins, which are synergistic, meaning they work best when all are available in adequate amounts.

Raw egg white contains the protein avidin, which prevents absorption of biotin.

Sulfa drugs, estrogen, and alcohol all increase the amount of biotin needed in the body. In addition, anti-convulsant drugs may lead to biotin deficiency. Long term use of antibiotics may prevent the synthesis of biotin in the digestive tract by killing off the bacteria which help the body produce biotin. Supplements of lactobacillus may help the body make sufficient amounts of biotin after long term antibiotic use.

Bipolar disorder

Definition

Bipolar, or manic-depressive disorder, is a mood disorder that causes radical emotional changes and mood swings, from manic highs to depressive lows. The majority of bipolar individuals experience alternating episodes of mania and depression. The switch between highs and lows often comes without warning. For instance, a “high” mood can quickly deteriorate into a “low,” which causes the sufferer exceptional **stress**.

Description

An estimate by the National Institute of Mental Health states that more than two million American adults—about 1% of the population age 18 and over in any given year—have bipolar disorder. Bipolar disorder typically develops in late adolescence or early adulthood. However, some people have their first symptoms during childhood, while others develop them late in life. Very often, bipolar disorder is not recognized as an illness. Many people suffer for years before it is properly diagnosed and treated. Like diabetes or **heart** disease, bipolar disorder is a long-term illness that must be carefully managed throughout a person's life.

An even grimmer survey by the National Depressive and Manic Depressive Association (NDMDA) estimates that over 17.4 million adults in the United States suffer with an affective disorder each year (one in seven people). Women are twice as likely as men to experience major depression, while manic depression occurs on an even percentage between the sexes. Onset of major or manic depression can occur at any age, however it most commonly develops between the ages of 25 and 44.

The problem is compounded by inaccurate or no diagnoses in the early stages. A survey taken by the NDMDA reports that half of respondents reported visiting three or more professionals before receiving a correct

diagnosis, and over one-third reported a wait of 10 years or more before they were correctly diagnosed.

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR), the diagnostic standard for mental health professionals in the United States, defines four separate categories of bipolar disorder: bipolar I, bipolar II, cyclothymia, and bipolar not-otherwise-specified (NOS).

Bipolar I disorder is characterized by manic episodes, the “high” of the manic-depressive cycle. A bipolar patient experiencing mania often has feelings of self-importance, elation, talkativeness, increased sociability, and a desire to embark on goal-oriented activities, coupled with the characteristics of irritability, impatience, impulsiveness, hyperactivity, and a decreased need for sleep. Usually this manic period is followed by a period of depression, although a few bipolar I individuals may not experience a major depressive episode. However, these individuals are usually characterized as mild, moderate, or severe without psychotic features. Mixed states, where both manic or hypomanic symptoms and depressive symptoms occur at the same time, also occur frequently with bipolar I patients (for example, depression with the racing thoughts of mania). Also, dysphoric mania is common (mania characterized by anger and irritability). Catatonic features occasionally occur. Two of the following must be present for the bipolar I diagnosis to move into bipolar I with catatonic features: 1. motor immobility; 2. excessive, purposeless motor activity that is not caused by external stimuli; 3. extreme negativity or mutism; 4. inappropriate or bizarre postures, movements, mannerisms, or grimaces; 5. repetitive or echoing speech patterns.

Bipolar II disorder is characterized by major depressive episodes alternating with episodes of hypomania, a milder form of mania. At least one hypomanic instance must occur before the bipolar II criteria are met. Bipolar depression may be difficult to distinguish from a unipolar major depressive episode. Patients with bipolar depression tend to have extremely low energy, retarded mental and physical processes, and more profound fatigue (for example, hypersomnia; a sleep disorder marked by a need for excessive sleep or sleepiness when awake) than unipolar depressives. Catatonic features may also be present in bipolar II disorder.

Cyclothymia refers to the cycling of hypomanic episodes with depression that does not reach major depressive proportions. For this diagnosis, symptoms must be present for at least two years for adults and one year for children and adolescents. During the one and two year diagnosis-gathering period, patients may not be symptom-free for more than a two-month consecutive period. After

the initial diagnostic periods, there may be superimposed mixed or manic episodes. In these instances, bipolar I and cyclothymic disorder may be diagnosed simultaneously. A third of patients with cyclothymia will develop bipolar I or II disorder later in life.

A phenomenon known as rapid cycling occurs in up to 20% of bipolar I and II patients. In rapid cycling, manic and depressive episodes must alternate frequently—at least four times in 12 months—to meet the diagnostic definition. In some cases of “ultra-rapid cycling,” the patient may bounce between manic and depressive states several times within a 24-hour period. This condition is very hard to distinguish from mixed states.

Bipolar NOS is a category for bipolar states that do not clearly fit into the bipolar I, II, or cyclothymia diagnoses. Examples include:

- Very rapid transitions (a matter of days) between manic and depressed symptoms;
- Recurrent hypomanic episodes without depressive symptoms;
- Manic or mixed episodes that are superimposed on delusional disorder, residual **schizophrenia**, or psychotic disorder NOS;
- Hypomanic episodes that alternate with depression, but are not frequent enough to qualify for a diagnosis of cyclothymia;
- Situations where it has been assumed that a bipolar condition exists, but a determination cannot be made as to whether it is the primary diagnosis, is substance-induced, or comes from another medical condition.

Causes and symptoms

The source of bipolar disorder has not been clearly defined. Because two-thirds of bipolar patients have a family history of affective or emotional disorders, researchers have searched for a genetic link to the disorder. Studies have uncovered a number of possible genetic connections to the predisposition for bipolar disorder. Another possible biological cause under investigation is the presence of an excessive **calcium** build-up in the cells of bipolar patients. Also, dopamine and other neurochemical transmitters appear to be implicated in bipolar disorder and these are under intense investigation.

Over half of patients diagnosed with bipolar disorder have a history of substance abuse. There is a high rate of association between cocaine abuse and bipolar disorder. Some studies have shown that up to 30% of abusers meet the criteria for bipolar disorder. The emotional and physical highs and lows of cocaine use correspond to the

manic depression of the bipolar patient, making the disorder difficult to diagnose.

For some bipolar patients, manic and depressive episodes coincide with seasonal changes. Depressive episodes are typical during winter and fall, and manic episodes are more probable in the spring and summer months.

Symptoms of bipolar depressive episodes include low energy levels, feelings of despair, difficulty concentrating, extreme fatigue, and psychomotor retardation (slowed mental and physical capabilities). Manic episodes are characterized by feelings of euphoria, lack of inhibitions, racing thoughts, diminished need for sleep, talkativeness, risk taking, and irritability. In extreme cases, mania can induce hallucinations and other psychotic symptoms such as grandiose illusions.

Diagnosis

Bipolar disorder is usually diagnosed and treated by a psychiatrist and/or a psychologist with medical assistance. In addition to an interview, several clinical inventories or scales may be used to assess the patient's mental status and determine the presence of bipolar symptoms. These include the Millon Clinical Multiaxial Inventory III (MCMI-III), Minnesota Multiphasic Personality Inventory II (MMPI-2), the Internal State Scale (ISS), the Self-Report Manic Inventory (SRMI), and the Young Mania Rating Scale (YMRS). The tests are verbal and/or written and are administered in both hospital and outpatient settings.

Psychologists and psychiatrists typically use the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) as a guideline for diagnosing this disorder and other mental illnesses. DSM-IV-TR describes a manic episode as an abnormally elevated or irritable mood lasting a period of at least one week that is distinguished by at least three of the mania symptoms: inflated self-esteem, decreased need for sleep, talkativeness, racing thoughts, distractibility, increase in goal-directed activity, or excessive involvement in pleasurable activities that have a high potential for painful consequences. If the mood of the patient is irritable and not elevated, four of the symptoms are required.

Although many clinicians find the criteria too rigid, a hypomanic diagnosis requires a duration of at least four days with at least three of the symptoms indicated for manic episodes (four if mood is irritable and not elevated). DSM-IV-TR notes that unlike manic episodes, hypomanic episodes do not cause a marked impairment in social or occupational functioning, do not require hospi-

talization, and do not have psychotic features. In addition, because hypomanic episodes are characterized by high energy and goal directed activities and often result in a positive outcome, or are perceived in a positive manner by the patient, bipolar II disorder can go undiagnosed.

Bipolar symptoms often present differently in children and adolescents. Manic episodes in these age groups are typically characterized by more psychotic features than in adults, which may lead to a misdiagnosis of schizophrenia. Children and adolescents also tend toward irritability and aggressiveness instead of elation. Further, symptoms tend to be chronic, or ongoing, rather than acute, or episodic. Bipolar children are easily distracted, impulsive, and hyperactive, which can lead to a misdiagnosis of attention deficit hyperactivity disorder (ADHD). Furthermore, their aggression often leads to violence, which may be misdiagnosed as a conduct disorder.

Substance abuse, thyroid disease, and use of prescription or over-the-counter medication can mask or mimic the presence of bipolar disorder. In cases of substance abuse, the patient must ordinarily undergo a period of detoxification and abstinence before a mood disorder is diagnosed and treatment begins.

Treatment

Treatment of bipolar disorder is usually involves medication. A combination of mood stabilizing agents with antidepressants, antipsychotics, and anticonvulsants is used to regulate manic and depressive episodes.

Mood stabilizing agents such as lithium, carbamazepine, and valproate are prescribed to regulate the manic highs and lows of bipolar disorder. Lithium (Cibalith-S, Eskalith, Lithane, Lithobid, Lithonate, Lithotabs) is one of the oldest and most frequently prescribed drugs available for the treatment of bipolar mania and depression. Because the drug takes 4–10 days to reach a therapeutic level in the bloodstream, it is sometimes prescribed in conjunction with neuroleptics and/or benzodiazepines to provide more immediate relief of a manic episode. Lithium has also been shown to be effective in regulating bipolar depression, but is not recommended for mixed mania. Lithium may not be an effective long-term treatment option for rapid cyclers, who typically develop a tolerance for it, or may not respond to it. Possible side effects of the drug include weight gain, thirst, nausea, and hand tremors. Prolonged lithium use may also cause hyperthyroidism (a disease of the thyroid that is marked by heart palpitations, nervousness, the presence of goiter, sweating, and a wide array of other symptoms.)

Carbamazepine (Tegretol, Atretol) is an anticonvulsant drug usually prescribed in conjunction with other mood stabilizing agents. The drug is often used to treat bipolar patients who have not responded well to lithium therapy. Blurred **vision** and abnormal eye movement are two possible side effects of carbamazepine therapy. As of early 1998, carbamazepine did not have an FDA-approved indication for mania.

Valproate (divalproex sodium or Depakote; valproic acid or Depakene) is one of the few drugs available that has been proven effective in treating rapid cycling bipolar and mixed states patients. Valproate is prescribed alone or in combination with carbamazepine and/or lithium. **Stomach** cramps, indigestion, **diarrhea**, hair loss, appetite loss, nausea, and unusual weight loss or gain are some of the common side effects of valproate. Note: valproate is also approved for the treatment of mania.

Because antidepressants may stimulate manic episodes in some bipolar patients, their use is typically short-term. Selective serotonin reuptake inhibitors (SSRIs) or, less often, monoamine oxidase inhibitors (MAO inhibitors) are prescribed for episodes of bipolar depression. Tricyclic antidepressants used to treat unipolar depression may trigger rapid cycling in bipolar patients and are, therefore, not a preferred treatment option for bipolar depression.

SSRIs, such as fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil), treat depression by regulating levels of serotonin, a neurotransmitter. **Anxiety**, diarrhea, drowsiness, headache, sweating, nausea, sexual problems, and insomnia are all possible side effects of SSRIs.

MAOIs, such as tranylcypromine (Parnate) and phenelzine (Nardil), block the action of monoamine oxidase (MAO), an enzyme in the **central nervous system**. Patients taking MAOIs must cut foods high in tyramine (found in aged cheeses and meats) out of their diet to avoid hypotensive side effects.

Bupropion (Wellbutrin) is a heterocyclic antidepressant. The exact neurochemical mechanism of the drug is not known, but it has been effective in regulating bipolar depression in some patients. Side effects of bupropion include agitation, anxiety, confusion, tremor, dry mouth, fast or irregular heartbeat, headache, and insomnia.

ECT, or electroconvulsive therapy, has a high success rate for treating both unipolar and bipolar depression, and mania. However, because of the convenience of drug treatment and the stigma sometimes attached to ECT therapy, ECT is usually employed after all pharmaceutical treatment options have been explored. ECT is given under anesthesia and patients are given a muscle

relaxant medication to prevent convulsions. The treatment consists of a series of electrical pulses that move into the **brain** through electrodes on the patient's head. Although the exact mechanisms behind the success of ECT therapy are not known, it is believed that this electrical current alters the electrochemical processes of the brain, consequently relieving depression. Headaches, muscle soreness, nausea, and confusion are possible side effects immediately following an ECT procedure. Temporary **memory** loss has also been reported in ECT patients. In bipolar patients, ECT is often used in conjunction with drug therapy.

Adjunct treatments are used in conjunction with a long-term pharmaceutical treatment plan. Long-acting benzodiazepines such as clonazepam (Klonopin) and alprazolam (Xanax) are used for rapid treatment of manic symptoms to calm and sedate patients until mania or hypomania have waned and mood stabilizing agents can take effect. Sedation is a common effect, and clumsiness, lightheadedness, and slurred speech are other possible side effects of benzodiazepines.

Neuroleptics such as chlorpromazine (Thorazine) and haloperidol (Haldol) are also used to control mania while a mood stabilizer such as lithium or valproate takes effect. Because neuroleptic side effects can be severe (difficulty in speaking or swallowing, **paralysis** of the eyes, loss of balance control, muscle spasms, severe restlessness, stiffness of arms and legs, tremors in fingers and hands, twisting movements of body, and weakness of arms and legs), benzodiazepines are generally preferred over neuroleptics.

Because bipolar disorder is thought to be biological in nature, therapy is recommended as a companion to, but not a substitute for, pharmaceutical treatment of the disease. **Psychotherapy**, such as cognitive-behavioral therapy, can be a useful tool in helping patients and their families adjust to the disorder, in encouraging compliance to a medication regimen, and in reducing the risk of suicide. Also, educative counseling is recommended for the patient and family.

Calcium channel blockers (nimodipine or Nimotop), typically used to treat angina and hypotension, have been found effective in a few small studies for treating rapid cyclers. Calcium channel blockers stop the excess calcium build up in cells that is thought to be a cause of bipolar disorder. They are usually used in conjunction with other drug therapies such as carbamazepine or lithium.

Clozapine (Clozaril) is an atypical antipsychotic medication used to control manic episodes in patients who have not responded to typical mood stabilizing agents. The drug has also been a useful prophylactic, or preventative treatment, in some bipolar patients.

Common side effects of clozapine include tachycardia (rapid heart rate), hypotension, constipation, and weight gain. Agranulocytosis, a potentially serious but reversible condition in which the white **blood** cells that typically fight **infection** in the body are destroyed, is a possible side effect of clozapine. Patients treated with the drug should undergo weekly blood tests to monitor white blood cell counts.

Risperidone (Risperdal) is another atypical antipsychotic medication that has been successful in controlling mania in several clinical trials when low doses were administered. The side effects of risperidone are mild compared to many other antipsychotics (constipation, coughing, diarrhea, dry mouth, headache, heartburn, increased length of sleep and dream activity, nausea, runny nose, **sore throat**, fatigue, and weight gain).

Lamotrigine (Lamictal, or LTG), an anticonvulsant medication, was found to alleviate manic symptoms in a 1997 trial of 75 bipolar patients. The drug was used in conjunction with divalproex (divalproate) and/or lithium. Possible side effects of lamotrigine include skin rash, dizziness, drowsiness, headache, nausea, and vomiting.

rTMS, or repeated transcranial magnetic stimulation is a new and still experimental treatment for the depressive phase of bipolar disorder. In rTMS, a large magnet is placed on the patient's head and magnetic fields of different frequency are generated to stimulate the left front cortex of the brain. Unlike ECT, rTMS requires no anesthesia and does not induce seizures.

Alternative treatment

General recommendations include maintaining a calm environment, avoiding overstimulation, getting plenty of rest, regular **exercise**, and proper diet. Chinese herbs may soften mood swings. Biofeedback is effective in helping some patients control symptoms such as irritability, poor self-control, racing thoughts, and sleep problems. A diet low in vanadium (a mineral found in meats and other foods) and high in **vitamin C** may be helpful in reducing depression.

Prognosis

While most patients will show some positive response to treatment, response varies widely, from full recovery to a complete lack of response to all drug and/or ECT therapy. Drug therapies frequently need adjustment to achieve the maximum benefit for the patient. Bipolar disorder is a chronic recurrent illness in over 90% of those afflicted, and one that requires lifelong observation and treatment after diagnosis. Patients with untreated or

KEY TERMS

Affective disorder—An emotional disorder involving abnormal highs and/or lows in mood. Now termed mood disorder.

Anticonvulsant medication—A drug used to prevent convulsions or seizures; often prescribed in the treatment of epilepsy. Several anticonvulsant medications have been found effective in the treatment of bipolar disorder.

Antipsychotic medication—A drug used to treat psychotic symptoms, such as delusions or hallucinations, in which patients are unable to distinguish fantasy from reality.

Benzodiazepines—A group of tranquilizers having sedative, hypnotic, antianxiety, amnesic, anticonvulsant, and muscle relaxant effects.

DSM-IV—*Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*. This reference book, published by the American Psychiatric Association, is the diagnostic standard for most mental health professionals in the United States.

ECT—Electroconvulsive therapy is sometimes used to treat depression or mania when pharmaceutical treatment fails.

Hypomania—A milder form of mania which is characteristic of bipolar II disorder.

Mixed mania/mixed state—A mental state in which symptoms of both depression and mania occur simultaneously.

Mania—An elevated or euphoric mood, or irritable state that is characteristic of bipolar I disorder.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells. Changes in the levels of certain neurotransmitters, such as serotonin, norepinephrine, and dopamine, are thought to be related to bipolar disorder.

Psychomotor retardation—Slowed mental and physical processes characteristic of a bipolar depressive episode.

inadequately treated bipolar disorder have a suicide rate of 15–25% and a nine-year decrease in life expectancy. With proper treatment, the life expectancy of the bipolar patient will increase by nearly seven years, with work productivity increasing by ten years.

Prevention

The ongoing medical management of bipolar disorder is critical in preventing relapse or recurrence of manic episodes. Even in carefully controlled treatment programs, bipolar patients may experience recurring episodes of the disorder. **Patient education** in the form of psychotherapy or self-help groups is crucial for training bipolar patients to recognize signs of mania and depression and to take an active part in their treatment program.

Health care team roles

The health care team roles are crucial to the proper treatment of bipolar disorder. Bipolar disorder requires lifelong care, and regular monitoring is essential so that the optimum treatment goals are achieved. A treatment team comprised of family members and caregivers, as well as professional staff, is advised to meet regularly to discuss progress and assess new needs. The treatment plan is based on input from a psychological or psychiatric evaluation, as well as input from the caregivers and the patient. This plan of care should be regularly updated and personalized to fit the patient's individual needs. Periodic assessment will track the patient's progress/regression and will make use of current research.

Birth control *see* **Contraception**

Birth injuries

Definition

A birth injury is defined by the Centers for Disease Control and Prevention (CDC) as an impairment of the neonate's (a newborn; usually less than one-month old) body function or structure caused by adverse influences occurring at birth.

Description

Birth injuries can occur during any birth. In the CDC's April 1999 report on vital statistics, birth injuries were highest when mothers were 25 to 29 years of age and lowest when mothers were 40 to 54 years old. Birth injuries include:

- asphyxia
- shoulder dystocia
- brachial plexus injury
- fractures of the clavicle and humerus
- fractures of the long bones
- cerebral injury
- cephalhematoma
- facial nerve palsy

Causes and symptoms

Infants of diabetic mothers are particularly at risk for birth injuries due to macrosomia (large body size). Macrosomia is a problem in about 33% of diabetic pregnancies, even with efforts for strong glycemic control. However, when glycemic control approximates normal **blood** glucose levels, injury rates are reduced. Macrosomia is also a problem associated with multipari-

ty (at least two births of a large infant by the same woman) because, with each **pregnancy**, the developing infant tends to be larger than its predecessor. A post-due date infant can also result in a large infant. When gestational age fetuses are large, they stretch the uterus, which can result in dysfunction during labor or delivery and increase the risk for postpartum hemorrhage. Larger infants have a 15% perinatal mortality rate versus the 4% mortality rate of appropriately sized neonates. Large infants born vaginally also have a higher than normal risk of shoulder dystocia, resulting in nerve injuries or fractured clavicle. In general, birth injuries are more likely to occur during a difficult vaginal birth, with prolonged labor, use of instrumentation such as forceps or vacuum extractor, with cephalopelvic disproportion, with fetal malpresentation, or during a Caesarian delivery. The injury may occur during labor, delivery, or neonatal resuscitation. Infants born preterm are especially at risk for birth injuries. One reason for this is the relationship between prenatal infections and preterm birth. Prenatal **infection** appears to play a significant role in premature delivery.

Diagnosis

Asphyxia is defined as the presence of hypoxia and acidosis. Hypoxia is a decreased level of oxygen in the tissues. Acidosis is the increased concentration of hydrogen ions in the tissues, a metabolic imbalance. Asphyxia may occur *in utero*, due to umbilical cord compression, **placenta previa**, or **placental abruption** (a tearing away or detachment). It can also occur during birth and postpartum. Preterm infants are especially at risk for respiratory problems. Difficulty breathing can result in prolonged fetal circulation after birth because the ductus arteriosus fails to close.

Meconium aspiration (inhalation by the newborn of its first intestinal discharges during labor and/or delivery) can also lead to impaired breathing. Deep suctioning may be required to rid the **lungs** of meconium. Meconium aspiration syndrome (MAS) is a serious condition in which the airway can become obstructed leading to respiratory distress, **pneumonia**, and even death. MAS is associated with hypoxia, pulmonary **hypertension**, and persistent fetal circulation. MAS occurs in only a small percentage of infants who aspirate meconium. Postdates infants (born later than the estimated date of delivery) are especially at risk for meconium aspiration, as are infants who suffered hypoxia *in utero*. Hypoxia leads to a relaxation of the anal sphincter muscles, allowing leakage of meconium into the amniotic (pertaining to the membrane around the fetus) fluid. MAS is eight times more likely to

occur in the postdates infant than in the term infant. Meconium release is also more likely with a breech delivery because of the pressure against the buttocks. Small for gestational age infants and preterm infants are a risk for asphyxia because of the increased risk of hypoxia and because their underdeveloped chest muscles lead to ineffective respiration. Infants born by cesarian section are also at risk for respiratory distress. This is because they avoid delivery through the birth canal which causes thoracic compression and its accompanying expulsion of lung fluid.

The incidence of shoulder dystocia is increasing along with the rise in birth weight, although 40-50% of infants with shoulder dystocia have a birth weight under 4,000 grams. A large infant or cephalopelvic (size of the fetal head compared to the mother's pelvis) disproportion may not be diagnosed prior to birth. During delivery, the head can be born, but the shoulders become stuck. Danger to the mother arises with prolonged labor and delivery, the risk of cervical or vaginal tears, and postpartal hemorrhage. Fetal risks include cord compression, fractured clavicle, and brachial plexus (spinal nerve network in neck-shoulder region) injury. Shoulder dystocia should be suspected with prolonged labor and in a condition called *turtle sign*. In turtle sign the fetal head is born then partially retracts, looking like a turtle with its head partially pulled back into its shell. Brachial plexus injury is the most common of the nerve injuries seen in neonates. Injury can arise from traction to the head and neck during a vertex (crown of the head) vaginal delivery, or during shoulder traction in a breech delivery. In Erb's palsy (**paralysis** of the upper arm) the C5 and C6 nerves are affected, and the arm on the affected side is limp with the affected shoulder drawn toward or past the body's median axis. The arm is internally rotated, with the elbow extended. The forearm is pronated (palms facing backwards), with wrist flexion. When eliciting the Moro reflex (primitive reflex that disappears a few months after birth), an asymmetrical response is noted. The grasp reflex should remain intact. Klumpke's palsy results from an injury to the C8 and T1 nerves. Diagnosis is suspected if the hand appears paralyzed, with a limp wrist and absence of the grasp reflex. Diaphragmatic paralysis or respiratory compromise can occur with injury to other cervical nerves. Not all brachial plexus injuries occur during birth. They may have occurred earlier during the pregnancy. Care should be taken during immobilization of the affected area to avoid contractures. Treatment may be followed by **physical therapy**. Full recovery is seen four months for 88% of cases, with 93% resolving within two years. Periodic neurologic evaluation can help avoid long-term impairment.

KEY TERMS

Adduction—The limb is drawn in towards the body.

Apgar score—The results of an evaluation of a newborn's physical status, including heart rate, respiratory effort, muscle tone, response to stimulation, and color of skin.

Macrosomia—A condition in which the neonate is large for gestational age with a high body weight. The condition is particularly associated with infants of diabetic mothers, especially if the diabetes is not well controlled. The circulating hyperglycemia encourages rapid growth and weight gain.

Meconium aspiration—When a newborn inhales its first fecal discharges during labor or delivery.

Pronation—The palm of the hand faces backwards.

A fractured clavicle may result from a difficult **breech birth** and also from shoulder dystocia. The clavicle should be straight, but if fractured a lump may be felt. At the time of the fracture, a cracking sound may be heard. A fracture should be suspected with decreased or lack of movement of the affected arm, swelling, skin discoloration, localized **pain** or tenderness, and lack of symmetry of the Moro reflex. The condition may also be asymptomatic. Injury can be confirmed by imaging. Treatment usually involves immobilizing the affected arm and shoulder for seven to ten days.

Fractured long bones are usually caused by arm or leg rotation during a breech birth. It should be suspected with pain, swelling, and lack of movement on the affected side. The affected side may appear shorter. Imaging can confirm the diagnosis. Treatment usually involves casting the affected limb, with complete healing taking place in a month.

Cephalhematoma is subcutaneous swelling caused by accumulation of blood from ruptured **blood vessels** located in the back of the neonatal **skull** underneath the scalp. It starts forming after trauma, perhaps as a result of the use of forceps or vacuum extractor, and increases in size over the next few days after birth. The swollen area may be black and blue due to the pooled coagulated blood. Cephalhematoma may resolve in a few days or take several months. The cephalhematoma is located on one or both sides and does not cross the suture lines. It

may be associated with anemia or **jaundice**. Usually no treatment is undertaken unless it appears infected.

Facial nerve palsy is the paralysis of a facial nerve following injury. It can occur as a result of the use of forceps, or because of pressure on the nerve due to fetal position against the mother's pelvic bones during birth or during the pregnancy. Lack of symmetry is most obvious when the infant cries. The affected side of the face looks smooth and the corner of the mouth droops. If the affected eye stays open it is necessary to use ophthalmic drops to avoid injury to the cornea. It usually resolves in a few days to weeks.

Treatment

Treatment of asphyxia involves rapid recognition of a neonate in respiratory distress. A rapid respiratory may be the first warning sign of distress. Other signs include **cyanosis**, sternal retractions, and lack of respiratory effort. The Apgar evaluation (a physical assessment of newborns) scores respiratory rate at one and five minutes after birth. Should the infant appear in immediate distress, intervention and/or resuscitation is begun before the one-minute time period. Some infants have periods of apnea, or temporary stoppage of breathing. For some, stimulation of the soles of the feet may be enough to *remind* them to continue breathing. Others may need swift intervention. **Cerebral palsy** (CP) is associated with lack of oxygenation in utero, during birth, or shortly afterwards. However, some studies indicate that only 9% of cerebral palsy cases are directly caused by birth asphyxia. CP is also associated with maternal infection, a significant cause of preterm birth, and low birth weight and small for gestational age infants. Newborn infections such as **meningitis** or encephalitis can also result in cerebral palsy. Kernicterus (a severe form of jaundice) resulting from hyperbilirubinemia (a large amount of red bile pigment, or bilirubin, in the blood) can also lead to cerebral palsy. CP is also associated with premature rupture of membranes (PROM) due to the increased risk of infection and cord compression associated with PROM.

Damage to the neonate can occur with the traction and rotation that accompanies delivery of the infant with shoulder dystocia. Asking the mother to perform the McRobert's maneuver, or the sharp flexing of her thighs against her abdomen, can widen the pelvic outlet and facilitate delivery. Cesarean delivery does not avoid all cases of brachial plexus injuries because compression can occur *in utero*, not just with birth.

Prognosis

The prognosis for birth injuries depends on many factors. Most of the injuries related to shoulder dystocia or fractured bones tend to heal completely, although some may require physical therapy or surgical intervention. About 10% of nerve injuries are permanent. Complications resulting from compromised oxygenation have a poorer outcome the longer the oxygen deficit has occurred. Cephalhematoma rarely requires intervention, but may when associated with anemia or hyperbilirubinemia. Degree of organ development at the time of birth is a significant factor in prognosis.

Health care team roles

Physicians, nurses, and respiratory therapists all play an important role in neonatal resuscitation. Physical therapists and nurses may have ongoing interactions with infants with cerebral palsy, or who need rehabilitation after injury from shoulder dystocia. Radiology technicians play an important role in gestational dating with ultrasound. Accurate dating and identification of small or large for gestational age infants can facilitate appropriate interventions.

Prevention

Many birth injuries cannot be prevented, as they occur *in utero*. Although having a member of a neonatal resuscitation team at every birth can facilitate swift intervention by specially trained individuals, it would be difficult to provide such services for all births, especially in small rural hospitals. The earlier intervention occurs, the better the prognosis. Respiratory distress is decreased with proper thermal regulation of the neonate. Drying the newborn under a radiant heater, changing the wet blankets for heated dry ones, and using a cap facilitates neonatal **thermoregulation**. Poor temperature control of the newborn increases respiratory effort. This is especially true in the preterm infant who has a decreased amount of brown fat. Ultrasonography assists in the diagnosis of placental problems, as well as in measuring fetal size. However, even with such technology, not all potential problems will be diagnosed prior to birth. Careful fetal monitoring during labor can often recognize fetal distress before permanent damage takes place. Close monitoring of the postdates fetus can decrease risk of placental insufficiency and cord compression due to insufficient amniotic fluid volume. The use of **corticosteroids** given to the mother before the delivery of a preterm infant can also decrease the risk of cerebral palsy.

Bites and stings

Definition

People can be injured by the bites or stings of many animals, including mammals such as dogs, cats, and fellow humans; arthropods such as spiders, bees, and wasps; snakes; and marine animals such as jellyfish and stingrays.

Description

Mammals

DOGS. In the United States, where the dog population exceeds 50 million, dogs surpass all other mammals in the number of bites inflicted on humans. Most come from family pets or other dogs known to the victim. Fortunately, most dog-bite injuries are minor. A 1994 telephone survey of American households indicated that there were 3,737,000 dog bites that did not require medical attention in the United States during that year, and 757,000 that did. Men and boys are more likely to be bitten than girls or women; not surprisingly, children face a greater risk than adults. Each year, about 10–20 Americans, mostly children under 10 years of age, are killed by dogs.

In the United States, dog bites send an estimated 340,000 people to the emergency room each year. Children under 10 are more likely than older people to need immediate medical treatment; this is especially true for boys between five and nine. Children under ten were also much more likely to be bitten on the face, neck, and head. Few of the injuries suffered by people seeking emergency treatment were serious; most patients were

treated and released without being admitted or referred to another facility.

CATS. Although cats are found in nearly a third of American households, their bites are far less common than dog bites. According to one study, cats inflict perhaps 400,000 harmful bites in the United States each year. Cat bites typically cause less tissue damage, but they carry a higher risk of **infection** (30-40%) than dog bites (15-20%). Young girls are the most likely to be bitten by cats.

HUMANS. There are approximately 70,000 human bites each year in the United States. They can be just as serious a medical problem as a bite from an animal. Because the human mouth contains a multitude of potentially harmful microorganisms, these tend to become have a higher infection rate than those inflicted by animals.

Arthropods

Arthropods are invertebrates such as insects, arachnids, crustaceans, and other subgroups of the phylum Arthropoda—a group that encompasses more than 700,000 species. The list of arthropods that bite or sting is extensive and includes lice, bedbugs, fleas, mosquitoes, blackflies, ants, chiggers, ticks, centipedes, scorpions, and other creatures. Spiders, bees, and wasps are the three that people encounter most often.

SPIDERS. In the United States, only two kinds of venomous spider have a truly life-threatening bite: black widow spiders and brown recluse spiders. The black widow, which is found in every state but Alaska, is probably the most infamous widow spider. It prefers dark, dry places such as barns, garages, and outhouses, and also lives under rocks and logs. Disturbing a female black widow or her web may provoke a bite. Red widow spiders are far more rare, but can be found in parts of Florida; their sting is also quite venomous. Brown recluse spiders also prefer sheltered places, including clothing, and may bite if disturbed.

BEEES AND WASPS. Bees and wasps will sting to defend their nests or if they are disturbed. Species common to the United States include honeybees, bumblebees, yellow jackets, bald-faced hornets, brown hornets, and paper wasps. More than 50 Americans die each year after being stung by a bee, wasp, or fire ant. Almost all of those deaths are caused by allergic reactions to the venom, not by its toxicity.

Snakes

There are 20 species of venomous snakes in the United States; they're found in every state except Maine,

Alaska, and Hawaii. Each year about 8,000 Americans receive a venomous snakebite, but no more than about 15 die; most of the deaths are from rattlesnake bites.

The venomous snakes of the United States are divided into two families: Crotalidae (pit vipers) and Elapidae. Pit vipers, which take their name from the small heat-sensing pit that lies between each eye and nostril, are responsible for about 99% of the venomous snakebites suffered by Americans. The group includes rattlesnakes, copperheads, and cottonmouths (also called water moccasins). This type of snake delivers its venom through two long, hinged fangs in the upper jaw. Some pit vipers carry a potent, fast-acting venom that can damage the **brain** and **spinal cord**. The venom of others, such as the copperheads, is less harmful.

The Elapidae include two kinds of venomous coral snakes indigenous to the southern and western states. Because coral snakes are bashful creatures that come out only at night, they almost never bite humans, and are responsible for only about 25 bites a year in the United States. Coral snakes also have short fangs and a small mouth, which lessens the risk of a bite actually forcing venom through the skin and subcutaneous tissues into muscles or veins. However, if ingested, their venom is quite poisonous.

Marine animals

Several varieties of marine animal bite or sting, including sharks, jellyfish, stingrays, anemones, and even a few types of coral. Although only a few have venom powerful enough to kill, they can inflict painful injuries. As with spider and bee stings, allergic individuals can also have anaphylactic reactions to these bites.

Causes and symptoms

Mammals

DOGS. A typical dog bite results in a laceration, puncture, or crush injury. Infected bites usually cause **pain**, cellulitis (inflammation of the connective tissues), and a pus-filled discharge at the wound site within 8–24 hours. Most infections are confined to the wound site, but microorganisms in dogs' mouths can cause systemic and possibly life-threatening infections such as sepsis and **meningitis**, especially among people with compromised immune systems that decrease their resistance to infection. Rabies is rare among pet dogs in the United States, most of which have been vaccinated against the disease. Tetanus is also a rare complication.

CATS. Cat scratches and bites can transmit the *Bartonella henselae* bacterium, which can lead to cat-

scratch disease, an uncommon and unpleasant but not usually life-threatening illness. The mouths of cats and dogs contain many of the same microorganisms, and many of the same types of infections can result.

Cat bites are mostly found on the arms and hands. Sharp cat teeth typically leave behind a deep puncture wound that can reach muscles, tendons, and bones, which are vulnerable to infection because of their comparatively poor **blood** supply. This is one reason why cat bites are much more likely than dog bites to become infected. People are also less inclined to give cat bites immediate medical attention, increasing the risk that infection will set in. Infected cat scratches on fingers or toes, in fact, have been known to spread inward to the bone, and result in the need for amputation of the digit.

HUMANS. Although children often bite other children, these bites are hardly ever severe. Most human bites that require medical attention result from fights (raising the possibility of domestic or **child abuse**), sexual activity, medical and dental treatment, and seizures. They can transmit a wide range of dangerous diseases, including hepatitis B, **syphilis**, **tuberculosis**, and HIV.

Human bites fall into two categories: occlusional (true) bites and clenched-fist injuries. The former present a low risk of infection. The latter, which are very infectious and can permanently damage the hand, usually result when a fist hits teeth during a fight. People often wait before seeking treatment for a clenched-fist injury, with the result that about half of such injuries are infected by the time they are seen by a medical professional.

Arthropods

SPIDERS. People do not always feel a black widow's bite. The first (and possibly only) evidence that a person has been bitten may be a mild swelling of the injured area and two red puncture marks showing where the spider's fangs entered the skin. Within a short time, however, some victims begin to experience severe muscle cramps and rigid abdominal muscles. Other possible symptoms include excessive sweating, nausea, vomiting, headaches, and vertigo as well as breathing, **vision**, and speech problems.

A brown recluse spider's bite can lead to necrotic arachnidism, in which the tissue in an area of up to several inches around the bite becomes necrotic, producing an open sore that can take months or years to heal completely. About 40% of all bites are accompanied by more severe symptoms: **fever**, chills, **edema**, nausea, vomiting, dizziness, muscle and joint pain, and a measles-like rash. The bite becomes hard and inflamed, and may turn gangrenous. In most cases, fortunately, the bite simply

produces a hard, painful, itchy, and discolored area that heals without treatment in two to three days.

BEEES AND WASPS. The familiar symptoms of bee and wasp stings include pain, redness, swelling, and itchiness in the area of the sting. Multiple stings can have much more severe consequences. If an allergic reaction occurs, there can be life-threatening symptoms of facial swelling, throat closure, tongue swelling, and airway blockage within a very short time.

Snakes

Many pit viper and coral snake bites (20–60%) fail to poison (envenom) their victims, or manage to introduce only a small amount of venom into the victim's body. The **wounds**, however, can still become infected by the harmful microorganisms that snakes carry in their mouths.

Venomous pit viper bites usually begin to swell within 10 minutes and are sometimes painful. Other symptoms include edema at the wound site, skin blisters, discoloration, weakness, sweating, nausea, faintness, dizziness, bruising, and tender lymph nodes. Symptoms of severe **poisoning** include tingling in the scalp, fingers, and toes, muscle contractions, an elevated **heart** rate, rapid breathing, large drops in body temperature and **blood pressure**, vomiting of blood, and **coma**.

Coral snake bites are painful but may be hard to see. After some time has passed, a bitten person begins to experience the effects of the venom, which include tingling at the wound site, weakness, nausea, vomiting, excessive salivation, and irrational behavior. Nerves in the head and neck can become paralyzed for six to 14 days, causing double vision, difficulty swallowing and speaking, **respiratory failure**, and other problems. Six to eight weeks may be needed before normal muscular strength is regained.

Marine animals

JELLYFISH. Jellyfish venom is delivered by barbs called nematocysts that are located on the creature's tentacles. They sting anyone who brushes up against them, causing a red lesion that is instantly painful and itchy. The pain can continue up to 48 hours. Severe cases may lead to necrosis, muscle spasms and cramps, vomiting, nausea, **diarrhea**, headaches, excessive sweating, and other symptoms. In rare instances, cardiorespiratory failure results.

STINGRAYS. Stingrays carry their venom in their tail spines, which can inflict deep puncture wounds. If, as often happens, pieces of spine become embedded in the wound, an infection can result. Most people are injured

by a stingray when they inadvertently step on one that's resting, and are lashed in the ankle by its tail. Stingray venom produces immediate, excruciating pain that lasts several hours. Sometimes the victim suffers a severe reaction, including vomiting, diarrhea, hemorrhage, a drop in blood pressure, and cardiac arrhythmia.

Diagnosis

Mammals

DOGS. Gathering information on the circumstances of a dog attack is a crucial part of bite treatment. Among other things, medical professionals need to know when the attack occurred (the chances of infection increase dramatically if the wound has been left untreated more than eight hours) and what led to the attack (unprovoked attacks are more likely to be associated with rabid animals). The patient's general health must also be assessed, including tetanus immunization history and possible **allergies** to medication.

A **physical examination** demands careful scrutiny of the wound, with special attention to possible bone, joint, ligament, muscle, tendon, nerve, or blood-vessel damage that may have been caused by deep punctures or severe crush injuries. Experts advise that serious hand injuries should be evaluated by a surgeon who specializes in such cases. Most of the time, laboratory tests to identify the microorganisms in bite wounds are ordered only if infection is present. X rays and other diagnostic procedures may also be necessary.

CATS. The diagnostic procedures used for dog bites also apply to cat bites.

HUMANS. Anyone who has received a human bite must be tested for hepatitis B and other diseases; ideally, the biter should be tested as well. Clenched-fist injuries require evaluation by a hand surgeon. Because many people will deny having been in a fight, medical professionals are advised to always consider lacerations over the fourth and fifth knuckle—a typical clenched-fist injury—to be evidence of a bite wound, no matter what an individual says. Medical professionals should also look for other indications of spousal or child abuse when evaluating human bites.

Arthropods

SPIDERS. Spider bites always require medical attention, although victims are often not aware that they've been bitten. To make matters worse, unless the spider is seen biting the victim, identifying which species is responsible is difficult. If possible, the spider should be

captured and taken to the emergency room or doctor's office for identification.

Snakes

Diagnosis relies on a physical examination of the victim, information about the circumstances of the bite, and a look at the snake itself (if it can safely be brought in for identification). Blood tests and **urinalysis** supply important data on the victim's condition. Chest x rays and EKG (electrocardiogram) may also be necessary.

Treatment

Mammals

DOGS. Minor dog bites can be treated at home. The American Academy of Family Physicians recommends gently washing the wound with soap and water and then applying pressure to the injured area with a clean towel to stop the bleeding. Next, apply antibiotic ointment and a sterile bandage to the wound. To reduce swelling and fend off infection, ice should be applied and the injured area kept elevated above the level of the heart. The wound should be cleaned and ointment reapplied twice a day until healing is complete.

Any dog bite that does not stop bleeding after 15 minutes of pressure must be seen by a medical professional. The same is true for bites that are deep or gaping; for bites to the head, hands, or feet; and for bites that may have broken a bone, damaged nerves, or caused a major injury of another kind. Bite victims must also watch for signs of infection: fever, redness, swelling, warmth, increased tenderness, and pus at the wound site. Diabetics, people with **AIDS** or **cancer**, individuals who have not had a tetanus shot in five years, and anyone else who has a medical problem that can increase susceptibility to infection should seek medical treatment no matter how minor the bite appears.

Medical treatment of dog bites involves washing the wound with an anti-infective solution. Dead and/or damaged tissue may be need to be removed, and any person whose tetanus shots are not up to date should receive a booster. Some wounds are left open and allowed to heal on their own, from the inside out, while others require stitches (stitching may be delayed a few days if infection is a concern). Many emergency departments prescribe **antibiotics** for all people with dog bites, but some researchers suggest that antibiotics are usually unnecessary and should be limited to those whose injuries or other health problems make them likely candidates for infection. A follow-up visit after one or two days is gen-

erally required for anyone who has received bite treatment.

Other than death by trauma, the biggest threat from a dog bite is rabies (although no one in the United States has contracted rabies from a dog bite for many years). Dogs who bite people should be contained and tested for rabies, unless the owner can prove the animal has been immunized. If this is not possible, a rabies vaccine series for the victim is effective if administered within two days of the bite.

CATS. Because of the high risk of infection, people who are bitten by a cat should always see a doctor. Cat scratches do not require professional medical treatment unless the wound appears infected or the victim has a weakened **immune system**. Cats, like dogs, can also transmit rabies, and cats that inflict a bite should be contained and tested for rabies, unless their immunization history is known.

Medical treatment for cat bites generally follows the procedures used for dog bites. Experts advise, however, that cat-bite wounds should always be left open (not stitched) to prevent infection. Persons bitten by cats are also more likely to receive antibiotics as a preventive measure.

HUMANS. Human bites should always be examined by a doctor. Such bites are usually treated with antibiotics and left open because of the high risk of infection. A person who has been bitten may also require immunization against hepatitis B and other diseases. A follow-up visit is required after an occlusional bite. Persons who are being treated for a clenched-fist injury will require a daily follow-up examination for three to five days.

Arthropods

SPIDERS. Brown recluse spider bites require immediate medical attention. Put an antiseptic on the bite, apply ice to reduce swelling, then get the patient to a doctor as quickly as possible. **Analgesics, antihistamines,** and a tetanus shot are the standard course of treatment, along with erythromycin and other antibiotics to combat infection. If necrosis results, the affected areas may need debridement.

Experimental treatment includes steroids to combat the hemolysis that can result from the spider venom. Surgical excision of the bite once eschar has developed may be an effective way to remove the venom and prevent further tissue damage. Interestingly, the leprosy drug dapsone has shown some promise in this area, and may prevent the need for surgery. Hyperbaric oxygen treatments may also restore blood flow to dying tissue. A

promising antivenin has been developed, but it's not yet available for clinical use.

Black widow spider bites also need a doctor's care. Apply ice to the bite, then take the patient to an emergency room. If necessary, antivenin is administered. In less severe cases, the symptoms are treated with **calcium** and **muscle relaxants** for spasms, along with drugs to lower blood pressure.

BEEES AND WASPS. Most stings can be treated at home. A stinger can be scraped off the skin with a razor blade, fingernail, credit card, or piece of paper; using tweezers may push more venom out of the venom sac and into the wound. The area should be cleaned and covered with an ice pack. Aspirin and other pain medications, oral antihistamines, and calamine lotion can relieve the pain, itching, and swelling.

The biggest risk from a bee sting is anaphylactic reaction to bee or wasp venom. This requires immediate medical attention. The danger signs, which usually begin within minutes after a sting, (but may not appear for several hours) include nausea, chest pain, **hives** (both internal and external), abdominal cramps, diarrhea, and difficulty swallowing or breathing. These last symptoms can be life threatening if not treated immediately. Patients with a history of allergic response to stings are prescribed a self-injecting kit of adrenaline and antihistamine.

Snakes

Although most snakes are not venomous, any snakebite should immediately be examined at a hospital. While waiting for emergency help to arrive, the victim should wash the wound site with soap and water, and then keep the injured area still and at a level lower

An insect bite caused this person's lower lip to swell.
(Custom Medical Stock Photo. Reproduced by permission.)

than the heart. Ice should never be used on the wound, and no attempts should be made to extract the venom. Making a cut at the wound site is also dangerous. It is important to stay calm and wait for emergency medical aid.

When a snakebite victim arrives at a hospital, the medical staff must determine, if they can, whether the bite was inflicted by a venomous snake and, if so, how much venom the person received. Careful monitoring helps resolve doubtful cases. Fortunately, the effects of some snakebites can be counteracted with antivenin. Minor rattlesnake envenomations can be successfully treated without antivenin, as can copperhead and water moccasin bites. However, coral snake and the more dangerous rattlesnake envenomations require antivenin. Other treatment measures include antibiotics to prevent infection and a tetanus booster injection.

Marine animals

JELLYFISH. To stop envenomation from tentacles that cling to skin, various substances should be applied, depending on the species that delivered the sting. Vinegar, baking soda, meat tenderizer (papain), and other substances will neutralize nematocysts. Applying the wrong substance, however, can cause the nematocysts to fire again, increasing the dose of venom and the degree of pain for the victim. Once the tentacles have been neutralized, they can be scraped off, saved, and given to medical personnel for identification and diagnosis. Ice, topical anesthetics, antihistamines, steroids, and a tetanus booster can prevent further complications. As with bee stings, allergic reactions may occur, requiring emergency medical care.

STINGRAYS. Stingray wounds should be washed with salt water and then soaked in very hot water for 30–90

minutes to neutralize the venom. Afterwards, the wound should be examined by a doctor to ensure that no pieces of spine remain.

Alternative treatment

Arthropods

Several alternative self-care approaches are used to treat bee, wasp, and other minor arthropod stings, including aromatherapy, ayurvedic medicine, flower remedies, herbs, **homeopathy**, and nutritional therapy. The efficacy of these treatments has not been proven, however, and if alternative therapy delays the administration of traditional medical attention for dangerous bites or stings the risk of severe consequences increases.

Prognosis

Mammals

It is important to realize that apparently even minor bites can have serious consequences, and that prompt treatment is the key to a good outcome. Infected bites may require hospitalization and can be fatal if neglected. Surgery may be needed for severe bites.

Arthropods

SPIDERS. Even without treatment, adults tend to recover from black widow bites after two to three days. The risk of death, though rare, is highest for very young children, the elderly, and people with high blood pressure.

BEES AND WASPS. The pain and other symptoms of a bee or wasp sting normally fade after a few hours. People who are allergic to such stings, however, can experience a severe and occasionally fatal reaction.

Snakes

A snakebite victim's chances of survival are excellent if medical aid is rendered in time. Some bites, however, result in amputation, permanent deformity, or loss of function in the injured area.

Marine animals

STINGRAYS. Stingray venom only rarely kills its human victims.

Health care team roles

Persons trained in **first aid** provide initial support. **Emergency medical technicians** provide life support and transportation to medical facilities. Physicians

trained in emergency or environmental medicine supervise treatment of bite victims. Registered nurses support, treat, and care for patients in emergency rooms and other hospital departments. Surgeons debride and repair serious bite wounds. Laboratory technicians process fluid and tissue specimens. Pathologists interpret test results. Physical therapists provide therapeutic services during the recovery period.

Prevention

Mammals

DOGS. The risk of a dog bite can be reduced by avoiding sick or stray dogs, staying away from dogfights (people often get bitten when they try to separate the animals), and not provoking or upsetting dogs while they are sleeping, eating, or tending their puppies. Infants and young children must never be left alone with a dog. Pit bulls, rottweilers, and German shepherd dogs—breeds that caused nearly half of all fatal dog attacks in the United States between 1997 and 2000—are potentially dangerous pets in households where children live or visit. All dog breeds benefit from obedience training and spaying or neutering to lessen the chances of aggressive behavior.

CATS. Warn children to stay away from strange cats and to avoid rough play and other behavior that can anger cats and cause them to bite.

Arthropods

SPIDERS. Common-sense precautions include exercising caution when clearing webs out of garages, out-houses, and other places favored by venomous spiders; keeping one's hands away from places where spiders may be lurking; and, when camping or vacationing, checking clothing, shoes, and sleeping areas.

BEEES AND WASPS. When outdoors, avoid bee and wasp nests, and don't eat sweet food or wear bright clothing, perfumes, or fragranced cosmetics that attract bees and wasps.

Emergency medical kits containing self-injecting epinephrine to counter anaphylactic **shock** are available for people with a history of allergic response to insect stings; these should be carried with them at all times. People who suspect they are allergic should consult an allergist about immunotherapy shots that can build up resistance to bee and wasp venom.

Snakes

Mowing the lawn, trimming hedges, and removing brush from the yard discourages snakes from living close

to homes. Use tongs to move brush, lumber, and firewood in case snakes are lying beneath them. Similarly, golfers should never use their hands to retrieve golf balls from a water hole, since snakes can be hiding in the rocks and weeds. Caution is also necessary when walking through weedy or grassy areas, and children should be prevented from playing in weedy, vacant lots and other places where snakes may live. Leather boots and long pants offer hikers and campers some protection from bites. Approaching a snake, even a dead one, can be dangerous, for recently killed snakes can still inflict a venomous bite if there is contact with the fangs.

Marine animals

JELLYFISH. Obey posted warning signs at the beach. Also, since jellyfish tentacles are transparent and can be up to 120 ft (36.5 m) long, great caution must be exercised whenever a jellyfish is sighted nearby.

STINGGRAYS. Shuffling while walking through shallow areas that may be inhabited by stingrays will disturb the water, causing the animal to move before it can be stepped on.

KEY TERMS

Antibiotics—Substances used to fight bacteria that cause infection.

Antibodies—Substances in the blood created by the body to combat infection.

Antihistamines—Drugs that treat allergic reactions by acting against a substance called histamine, which the body releases as part of its immune response.

Antivenin—An antitoxin to a specific animal venom. Antivenin is extracted from the blood serum of horses (or other animals) that have been immunized against the toxin.

Blood serum—The component of blood plasma that remains after coagulation.

Debridement—Removal of dead and/or damaged tissue.

Edema—Excessive fluid buildup in a body tissue.

Eschar—Sloughed off dead tissue.

Hemolysis—Breakdown of red blood cells.

Necrosis—Dead skin, muscle, bone, or other tissue in the body caused by insufficient blood flow.

Pus—A thick yellowish or greenish fluid composed of the remains of dead white blood cells, pathogens, and decomposed cellular debris; a definite sign of infection.

Sepsis—A serious systemic infection caused by bacteria that have entered the bloodstream through a wound.

Bladder ultrasound

Definition

A noninvasive method of assessing bladder volume and other bladder conditions using ultrasonography to determine the amount of urine retention or post-void residual urine.

Purpose

Bladder ultrasound is used in the acute care, rehabilitation, and long-term care environments. It is a noninvasive alternative to bladder palpation and intermittent catheterization used to assess bladder volume, urinary retention, and post-void residual volume in postoperative patients who may have decreased urine output; in patients with urinary tract infections (UTIs), urinary incontinence, enlarged prostate, urethral stricture, neurogenic bladder, and other lower urinary tract dysfunctions; or in patients with **spinal cord** injuries, stroke, diabetes, and mental handicaps that may reduce the sensation of bladder fullness, thereby interfering with appropriate

voiding. Bladder ultrasound may be used in rehabilitation for bladder assessment and training. Bladder ultrasound is used to evaluate bladder function in nursing home residents to monitor for UTIs, urinary incontinence, urinary retention, and bladder dysfunction associated with other medical conditions (e.g., pelvic organ prolapse).

Precautions

There are no contraindications for bladder ultrasound. However, users should be aware of errors in measurement that may occur. For the most accurate results, patients should be in a relaxed, supine (lying down) position, and the ultrasound scanning head should not be moved during the scan if a portable device is used. Measurements may be distorted in patients with staples or sutures, an indwelling catheter, or scar tissue. Fluid in a pelvic cyst or tumor may be misinterpreted as bladder volume.

Description

Bladder ultrasound is conducted using a portable, battery-operated ultrasound scanner that consists of a small, handheld unit and an attached ultrasound probe. It may also be performed with a conventional **ultrasound unit**. The probe, which is placed on the patient's abdomen over the bladder, holds a motorized scanning head with an ultrasonic transducer that transmits sound waves in a fanlike array that are reflected back from the patient's bladder to the transducer. Data from multiple cross-sectional scans of the bladder are then transmitted to a computer in the handheld unit, which automatically calculates bladder volume. The handheld unit also contains an integral digital screen and printer for displaying the bladder volume measurements. The entire scan only takes a minute or two, is noninvasive and painless, and eliminates the discomfort, embarrassment, and risks associated with catheterization.

The bladder ultrasound procedure is also referred to as bladder scanning or the bladderscan, after the brand name of the most widely available portable bladder ultrasound device. A dedicated portable bladder ultrasound scanner ranges in cost from approximately \$6,000 to \$10,000.

Although general-purpose ultrasound scanners, such as those used in the radiology department, can be used to measure bladder volume, they may be inconvenient for regular use at the patient's bedside due to their size and are much more expensive than portable units. However, they are often used for bladder ultrasound if there is no portable unit in the facility.

KEY TERMS

Post-void residual volume—The amount of urine remaining in the patient's bladder after voiding.

Transducer—The part in the ultrasound scanning head that transmits acoustic energy and converts it into electrical energy to produce image data.

Ultrasonography—An imaging modality that uses sound waves to produce anatomical images and measurements.

Preparation

Before scanning, the end of the transducer scanning head should be wiped with alcohol and allowed to dry. Ultrasound transmission gel should then be applied to the end of the scanning head. The portable bladder ultrasound device should be set to either male or female; the male setting should be used for a female patient who has had a hysterectomy. To begin scanning, the tip of the scanning head should be positioned approximately one inch (2.5 cm) superior to the symphysis pubis and pointing toward the bladder. During scanning, the scanning head should be held stationary when obtaining measurements. For obese or elderly patients, abdominal flesh may need to be gently moved to one side while scanning to obtain more accurate results.

Aftercare

After scanning is completed, the ultrasound gel should be wiped from the patient's skin and the scanning head. The scanning head should then be cleaned with alcohol. Bladder volume measurements can then be printed out and attached to the patient's chart. Depending on the bladder volume measured, urethral catheterization is performed to relieve urine retention if the patient cannot void on his/her own. If the patient has an indwelling catheter, the bladder volume measurement may indicate a need for catheter irrigation or checking for catheter blockage. The bladder scan may need to be repeated, depending on the catheterized or voided urine volume obtained.

Complications

There are no complications associated with the bladder ultrasound procedure.

Results

In general, if the bladder volume measured is greater than 300 milliliters, urethral catheterization or patient

voiding to relieve urine retention should be performed. Clinical studies have demonstrated that using the bladder ultrasound scan instead of intermittent catheterization to measure urine retention reduces the risk of urinary tract infections.

Health care team roles

In the acute care setting, the nurse and physician are responsible for monitoring urine output in postoperative patients. In the long-term care and rehabilitation settings, the primary responsibility for monitoring urine output and/or bladder function lies with the nursing staff. Device manufacturer representatives provide in-service training to nursing staff on using the bladder ultrasound scanner. Clinical and nurse managers may also implement bladder scanning protocols and results and outcomes tracking, particularly when bladder ultrasound replaces intermittent catheterization protocols with the goal of reducing catheterization-related costs and infections.

Bleeding disorders

Definition

Bleeding disorders are disruptions in the body's ability to control **blood** clotting. Patients with these conditions bleed easily for longer periods of time than normal.

Description

Coagulation, or clotting, is a complex process involving at least 20 components of the blood, including various enzymes, messenger chemicals, and **proteins**. Under normal circumstances, the components necessary for coagulation circulate in the blood. When an injury occurs, they act together in a series of chain reactions to form a clot and prevent uncontrolled bleeding. Several disorders affect the blood's clotting components and diminish normal clotting capability. For people with these disorders, even a small injury could make them bleed to death.

Anatomy of a blood clot

In healthy individuals, clots begins when fibrin, an insoluble protein that forms the skeleton of the clot, forms at the wound site from fibrinogen, a soluble protein present in plasma. This chemical change is made possible by thrombin, an enzyme that itself is only created from the compound prothrombin when an injury occurs. Once fibrin strands are formed at the wound site, they trap platelets that flow past them. Platelets then initiate the contraction of damaged **blood vessels** so that less blood is lost. They also help plug damaged blood vessels and work with plasma to accelerate blood clotting.

Hemophilia A

Hemophilia A, also known as classic hemophilia, is a genetic disorder carried by females but expressed almost exclusively in males. The disorder is characterized by a lack of factor VIII, a glycoprotein found in blood plasma that, like all coagulation factors, is essential for blood clotting. Hemophilia causes uncontrolled

bleeding, often internally, which is not only painful, but can permanently damage muscles and joints. The disease can be mild to severe, depending on how much (or little) factor VIII the body produces. Hemophilia A affects about 20,000 Americans, and is found worldwide in about 1:10,000 males; the most severe form is less common, appearing in 1:16,000 males.

Hemophilia B

This X-linked genetic disorder, sometimes called Christmas disease (after one of the first patients in whom it was recognized) is a deficiency of the blood clotting factor IX, or plasma thromboplastin component, which is normally produced by the **liver**. Like hemophilia A, patients with hemophilia B bleed uncontrollably when injured, and the disease is carried almost exclusively by females; males are almost exclusively afflicted. The degree of severity depends where on the gene the defect is found. Hemophilia B is relatively rare, occurring in at least 1:50,000 people; some estimates are 1:25,000.

Hemophilia C

Hemophilia C is extremely rare, occurring in about 1:100,000 people; it is the only type of hemophilia that can be expressed equally in either males or females. It is marked by a deficiency of the blood clotting factor XI, although, unlike hemophilia A and B, the level of factor XI does not correspond to the disease's severity. Hemophilia C is especially prevalent (1:10,000) among Ashkenazi Jews; in Israel it is estimated to affect 8% of the population.

Disseminated intravascular coagulation disorder (DIC)

Unlike hemophilia, DIC, also known as consumption coagulopathy or defibrination syndrome, is neither hereditary nor common. It is almost always caused by another disease or condition, which in turn activates abnormal and uncontrolled clotting. This causes many small blood clots to form throughout the body, giving the disease its name. This overproduction of clots depletes the supply of clotting factors and platelets necessary to prevent hemorrhage when an injury (or surgery) occurs. Patients with DIC will bleed abnormally even though there is no history of coagulation disorder.

Thrombocytopenia (TCP)

Thrombocytopenia is a group of bleeding disorders characterized by severely diminished platelet counts, which cause internal bleeding. TCP can occur during **pregnancy**, as a reaction to certain medications, when the spleen and lymph produce antibodies against

platelets, or for no known reason, a type called idiopathic TCP.

Other bleeding disorders

Von Willebrand's disease (vWD), also called pseudo-hemophilia B, vascular hemophilia, or angiohemophilia, is a hereditary disorder, that, like hemophilia, is connected with a factor VIII deficiency and causes uncontrolled bleeding. Unlike hemophilia, however, the true deficiency is the von Willebrand factor, a blood plasma protein that helps transport and protect factor VIII platelets and also helps platelets adhere to tissue at wound sites and also. A further distinction is that both males and females can be affected, making vWD the most common type of bleeding disorder. There are three types of the disease: the first two are mild; the third is the most severe, and must be inherited from both parents.

Hypoprothrombinemia, or factor II deficiency, is a lack of prothrombin (or factor II) that can lead to hemorrhage. The genetic type of the disorder is very rare, and must be inherited from both parents to emerge. Acquired factor II deficiency can result from **vitamin K** deficiency, liver disease, and several types of gastrointestinal disorders.

Factor VII deficiency, also called proconvertin deficiency or serum prothrombin conversion accelerator (SPCA) deficiency, can be either congenital or acquired through disease, use of anticoagulants, or malnutrition. The congenital form is often diagnosed when newborns react to the trauma of birth with intracranial bleeding. The disease is quite rare, with 1:500,000 people, both males and females, afflicted.

Causes and symptoms

Hemophilia

Hemophilia A is usually inherited through a complex genetic system that passes a recessive gene on the female chromosome. If a woman carries the hemophilia gene, each of her male children has a 50% chance of having hemophilia; each female child has a 50% chance of carrying the gene. About a third of all hemophilia patients develop the disease with no known genetic risk; these cases, called sporadic hemophilia, are assumed to be the result of spontaneous genetic mutation.

Hemophilia A is suspected with when patients exhibit numerous large, deep bruises along with painful and swollen joints caused by internal bleeding. Mild hemophilia may first be discovered when prolonged bleeding follows a surgical procedure. If this involves bleeding into the neck, head, or digestive tract, or of the bleeding

is caused by an injury, emergency measures may be required.

Hemophilia B

Hemophilia B is also hereditary but less common than hemophilia A. Its severity varies from mild to severe, although mild cases are more common. Hemophilia B symptoms are similar to those of hemophilia A, including numerous large and deep bruises and prolonged bleeding. The more dangerous symptoms are those that represent possible internal bleeding, such as swollen joints or bleeding into internal organs upon trauma.

Hemophilia C

Nearly 50% of patients with this disorder experience no symptoms, but others may notice blood in their urine, nosebleeds, or bruising. Although joint bleeding seldom occurs, some patients will experience bleeding long after an injury occurs. Some women will experience prolonged bleeding after **childbirth**.

Disseminated intravascular coagulation

DIC has a number of causes, and it is not thoroughly understood why or how they lead to the coagulation problem. It is known, however, that DIC's underlying causes share factors that affect proteins, platelets, or other clotting factors and processes. For example, uterine tissue can enter the mother's circulation during prolonged labor, thus introducing foreign proteins into the blood; the venom of some exotic snakes can activate one of the clotting factors; severe head trauma can expose blood to **brain** tissue. No matter the cause, the results are a malfunction of thrombin (an enzyme) and prothrombin (factor II), which activate the fibrinolytic system, releasing clotting factors in the blood. DIC can alternate from hemorrhage to thrombosis, and both can exist, which further complicates diagnosis and treatment.

Symptoms may include minute hemorrhage spots on the skin, and purple patches or hematomas caused by bleeding in the skin. Patients may also bleed from surgery or intravenous injection (IV) sites. Related symptoms include vomiting, seizures, **coma**, shortness of breath, **shock**, severe **pain** in the back, muscles, abdomen, or chest.

Thrombocytopenia

Thrombocytopenia, a defective or decreased production of platelets (thrombocytes), may be acquired or congenital. The most common cause of acquired TCP is medication use—mainly heparin or **chemotherapy** agents (also some **antibiotics**). Symptoms include sudden onset

of petechia or purpura, or bleeding into mucous membranes (such as nosebleeds). The disorder may also be evident as blood in vomit or stools, or unusually heavy menstrual flow in women. Some patients show none of these symptoms, but complain of fatigue and general weakness.

Thrombocytopenia has several causes, most of which are more commonly acquired as a result of another disorder. Common underlying disorders include leukemia, drug toxicity, or aplastic anemia, all of which lead to decreased or defective production of platelets in the bone marrow. Other diseases, such as severe **infection**, disseminated intravascular coagulation, and cirrhosis of the liver may destroy platelets outside the marrow. The idiopathic form most commonly occurs in children, and is most likely the result of production of antibodies in the spleen and liver that destroy platelets.

Other bleeding disorders

Von Willebrand's disease is caused by a defect in the von Willebrand clotting factor, a blood chemical that regulates the production and availability of factor VIII. In rare cases, it may be acquired. Symptoms include easy bruising, bleeding in small cuts that stops and starts, abnormal bleeding after surgery, and abnormally heavy menstrual bleeding. Nosebleeds and blood in the stool with a black, tarlike appearance are also signs of von Willebrand's disease.

Hypoprothrombinemia is a very rare deficiency in prothrombin, or factor II, a glycoprotein formed and stored in the liver. Unlike hemophilia, both parents must be carriers for the disease to occur. Under normal conditions, prothrombin is converted to thrombin as part of the clotting cascade, which activates fibrin and begins the process of coagulation. Some patients may show no symptoms while others will suffer severe hemorrhaging. Patients may experience easy bruising, profuse nosebleeds, postpartum hemorrhage, excessively prolonged or heavy menstrual bleeding, and postsurgical hemorrhage. Hypoprothrombinemia may also be acquired rather than inherited, usually as a result of vitamin K deficiency caused by liver diseases, newborn hemorrhagic disease, or a number of other factors.

Factor VII deficiency causes varying types and degrees of bleeding, depending on the severity of the disease. Patients may bleed from the gums or nose, within the skin, or into the joints, **stomach**, intestine, and urinary tract. Women may experience heavy menstrual bleeding.

Diagnosis

There are hundreds of different tests to detect various bleeding disorders, each one geared to the hallmarks

of the specific disease. In addition to blood tests, physicians will compile a medical history and perform a **physical examination**. In the case of acquired **blood coagulation** disorders, information such as prior or current diseases and medications will be important in determining the cause of the bleeding disorder.

Hemophilia A

Hemophilia A (factor VIII deficiency) will be diagnosed with laboratory tests detecting presence of clotting factor VIII, factor IX (to distinguish it from hemophilia B), and others, as well as the presence or absence of clotting factor inhibitors.

Hemophilia B

Tests for hemophilia B look for diminished levels of factor IX, along with analyses of prothrombin and thromboplastin.

Hemophilia C

Hemophilia C (factor XI deficiency) is diagnosed with a test to measure the amount of factor XI in the blood.

Disseminated intravascular coagulation

Disseminated intravascular coagulation can be diagnosed through a number of laboratory tests that measure the concentration of platelets and fibrinogen in the blood with normal counts and prolonged prothrombin time. Other supportive data include diminished levels of factors V, VIII, and fibrinogen, hemoglobin, and other chemicals. Since many of the test results also indicate other disorders, the physician may have to put together several results to reach a diagnosis of DIC. Serial tests may also be recommended, because a single examine at one moment in time may not reveal the process that is occurring.

Thrombocytopenia

Tests for thrombocytopenia include **coagulation tests** revealing a decreased platelet count, prolonged bleeding time, and others. If these tests indicate that platelet destruction is causing the disorder, the physician may order bone marrow examination.

Other bleeding disorders

Von Willebrand's disease will be diagnosed with laboratory tests that show prolonged bleeding time, absent or reduced levels of factor VIII and von Willebrand factor, a normal platelet count, and others.

Hypothrombinemia is diagnosed by medical history and tests that measure deficiencies in vitamin K, prothrombin, and clotting factors V, VII, IX, and X.

Factor VII deficiency can be diagnosed with blood tests that show a diminished level of factor VII in the blood, along with other blood tests showing a prolonged prothrombin time and normal partial thromboplastin time.

Treatment

For mild bleeding disorders, treatment may involve drugs that help the body increase the amount of clotting factors available. In severe cases, however, bleeding may only stop if the missing clotting factor that is replaced through fresh frozen plasma or cryoprecipitate, the blood fraction containing factor VIII. Every care must be taken to ensure that these infusions are free of HIV and other contaminants. Unfortunately, for many patients, this was not always the case, and many hemophiliacs, like Ryan White, contracted **AIDS**. New bioengineered therapies that rely on recombinant DNA technology should prevent any possibility of transferring HIV/AIDS.

Hemophilia A

Mild-to-moderate forms of hemophilia A may be controlled with desmopressin acetate, a synthetic form of a pituitary hormone that rapidly increases that amount of available factor VIII and von Willebrand factor. This drug is called DDAVP in the injectable form, and Stimate when formulated as a nasal spray. Severe bleeding episodes will require transfusions of human blood clotting factors. Many hemophiliacs, however, have become resistant to this form of treatment and have developed antibodies against it. For these patients, a synthetic protein called factor VIIa (tradename NovoSeven) can increase coagulation or prevent bleeding episodes altogether. Factor VIIa is made with recombinant DNA technology. Fetal tissue implants and gene therapies are also being studied as possible treatments for hemophilia.

Hemophilia B

The treatment for hemophilia B is similar to that for hemophilia A, with the infusion of synthetic and human blood products, such as factor IX concentrate or factor IX complex (prothrombin) concentrate, to promote coagulation.

Hemophilia C

Hemophilia C is most often treated with plasma, since concentrates of factor XI are not universally available in the United States, due to the disease's extreme rarity.

KEY TERMS

Blood clot—A clump of blood that forms as a result of coagulation when a blood vessel is injured. Without this process a person would bleed to death from a relatively small wound.

Coagulation—The blood's change from a liquid to a semisolid state through chemical reaction.

Clotting factor—Any of several components normally found in blood that are essential for clotting to occur.

Enzyme—A substance that causes a chemical reaction, usually a protein. Enzymes are secreted by cells.

Hemorrhage—Abnormal, uncontrolled bleeding from the blood vessels, usually internally.

Heparin—An anticoagulant; a drug used to dissolve or prevent the formation of blood clots.

Idiopathic—Refers to a disease of unknown cause.

Petechiae—Small pinpoint bruises caused by bleeding under the skin.

Platelets—Also called thrombocytes, these are small, colorless particles found in the only in mammalian blood that help form clots, keep various body chemicals in circulation, and devour foreign bodies, such as viruses.

Purpura—Purplish discoloration of the skin caused by bleeding into the skin and mucous membranes.

Thrombosis—Formation of a clot that either blocks or partially blocks a blood vessel. The thrombus may lead to infarction, or tissue death.

Disseminated intravascular coagulation

Treatment for DIC depends on what other disease is causing it. If the patient is not yet actively bleeding, the underlying cause should be dealt with. This supportive treatment may eliminate the DIC and the need for emergency measures. In some instances, heparin, an anticoagulant, is used to dissolve the small clots throughout the body; given that DIC can result in hemorrhage, this therapy is controversial. If bleeding has begun, however, the patient may need infusions of blood, platelets, plasma, and other blood products. Heparin should not be used to treat DIC caused by heatstroke, snakebite, trauma, mismatched transfusions, and acute problems resulting from

obstetrical complications, nor should it be administered to patients with head injuries or **central nervous system** bleeding.

Thrombocytopenia

Secondary acquired thrombocytopenia is best alleviated by treating the underlying cause or disorder. Sometimes, no treatment is necessary; the condition will resolve by itself. If treatment is required, it will depend on the underlying cause. Platelet transfusions can help alleviate TCP caused by chemotherapy, for example. In other cases, **corticosteroids** or immune globulin may be given to improve platelet production.

Other bleeding disorders

Von Willebrand's disease often requires no treatment because the bleeding is mild and controllable. DDAVP can help raise levels of the Von Willebrand factor and is the treatment of choice for many cases. However, if trauma or surgery is scheduled there are several methods that will reduce bleeding time and replace factor VIII, which will consequently replace the von Willebrand factor. This may include infusion of cryoprecipitate or plasma. For severe bleeding, infusions of a viral inactivated factor VIII products such as Humane-P, Alphanate, and Koate DVI may be required.

Hypoprothrombinemia may be treated with concentrates of prothrombin. Acquired cases are often treated with vitamin. In bleeding episodes, the patient may receive plasma products.

Factor VII deficiency patients may be treated with normal plasma or concentrates containing factor VII or the biomedically engineered VIIa.

Prognosis

The prognosis for patients with mild forms of bleeding disorders is good; many lead normal lives and enjoy a normal life expectancy. Untreated bleeding episodes, however, cause severe muscle and joint pain that eventually becomes permanent damage. Any incident that causes blood to collect in the head, neck, or **digestive system** can be fatal without immediate medical attention.

The clots that form throughout the body with DIC can produce **gangrene** in the fingers, nose, or genitals, and can even cause strokes. The prognosis depends on early intervention and treatment of the underlying condition.

Health care team roles

Patients must communicate with their health care providers before undergoing procedures or tests that

could cause bleeding. The best care is obtained when treatment is coordinated by a health care team with expertise in the field. The Centers for Disease Control and Prevention found that patients with severe or moderate hemophilia had 60% less mortality and morbidity when their treatment was coordinated by a comprehensive hemophilia treatment compared to those not seen by a comprehensive hemophilia treatment center.

Other health care providers, such as counselors, may help patients cope with their conditions or illnesses. Support groups can also be helpful in understanding the specific condition and in achieving goals for personal wellness.

Prevention

It is not always possible to prevent bleeding disorders. Some acquired conditions may be prevented by preventing underlying diseases such as cirrhosis, or discontinuing medications whose side effects cause bleeding. Hereditary disorders can be predicted with prenatal testing and **genetic counseling**. Severe bleeding episodes may be prevented by refraining from activities that could cause injury, such as contact sports.

Blood

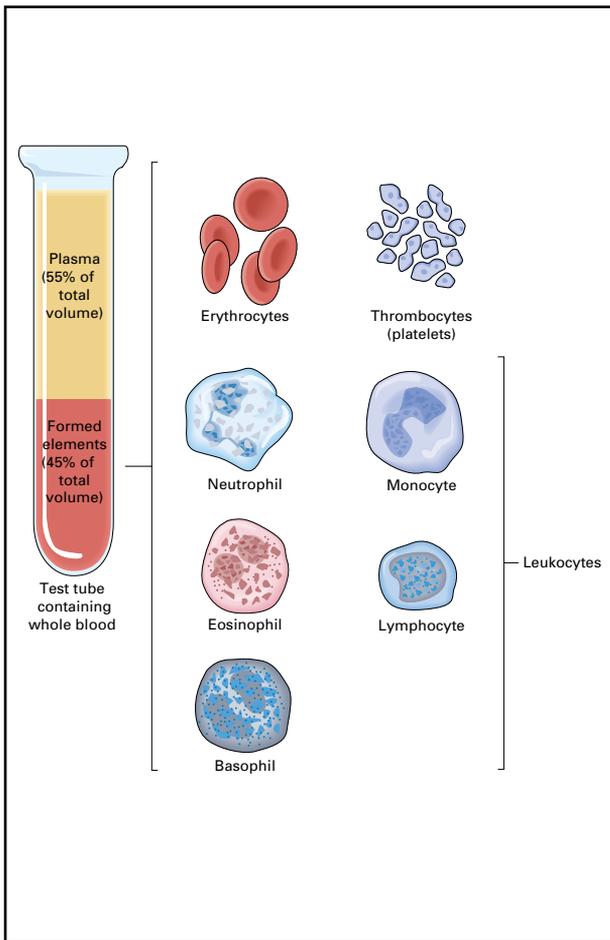

Definition

Blood is a liquid connective tissue that performs many functions in the body, including transport of oxygen, carbon dioxide, nutrients, waste products, and hormones; clotting; and defense against microorganisms. Blood consists of blood cells suspended in plasma, a fluid that contains **proteins**, salts, and other substances. When a blood sample is placed in a test tube and spun rapidly (a process called centrifugation), the heavier blood cells sink to the bottom of the test tube, while the straw-colored plasma floats on top.

Description

All vertebrates circulate blood within **blood vessels**. Because blood is enclosed within blood vessels, the circulatory systems of vertebrates are called closed circulatory systems. (Some invertebrates have open circulatory systems that do not contain blood vessels and circulate a blood-like fluid called hemolymph.)

The human body contains about 4 to 6.3 qt (4 to 6 L) of blood. Men have more blood than women, due to the presence of higher levels of testosterone, a hormone that regulates sex characteristics and function and also stimulates red blood cell formation. Plasma makes up 55% of the blood, while the blood cells constitute the other 45%. The various types of blood cells are red blood cells (erythrocytes), white blood cells (leukocytes or leucocytes), and platelets.

The major components of blood. (Delmar Publishers, Inc. Reproduced by permission.)

Plasma

Plasma contains mostly water, which accounts for 91.5% of the plasma content. The water acts as a solvent for carrying other substances.

PLASMA PROTEINS. Proteins account for 7% of plasma. The higher concentration of protein in blood prevents water from moving from the blood into the interstitial fluid. Without this osmotic protection, water would move from the blood into the interstitial fluid, causing a rapid loss of blood volume.

The most abundant of the plasma proteins is albumin, a protein also found in egg white. Albumin concentration is four times higher in the blood than in the interstitial fluid (the watery fluid that bathes tissues, but is located outside and between cells). This high concentration of albumin in plasma serves an important osmotic function.

Other proteins that are present in plasma are immunoglobins and fibrinogen. Immunoglobins, also called antibodies, are proteins that function in the **immune response**. Antibodies attach to invading **bacteria** and other microorganisms, marking them for destruction by immune cells. Fibrinogen is a protein that functions in a complex series of reactions that leads to the formation of blood clots.

OTHER PLASMA COMPONENTS. The other components of plasma are salts, nutrients, enzymes, hormones, and nitrogenous waste products. Together, these substances account for 1.5% of plasma. The salts present in plasma include sodium, potassium, **calcium**, magnesium, chloride, and bicarbonate. These salts function in many important body processes. For instance, calcium functions in **muscle contraction**; sodium, chloride, and potassium function in nerve impulse transmission in nerve cells; and bicarbonate regulates pH. These salts are also called electrolytes. An imbalance of electrolytes, which can be caused by **dehydration**, can be a serious medical condition. Many gastrointestinal illnesses, such as cholera, cause a loss of electrolytes through severe **diarrhea**. When electrolytes are lost, they must be replaced with intravenous or oral solutions of water and salts.

The remaining substances present in plasma are elements that the plasma is transporting from one place to another. For instance, plasma contains nutrients that nourish tissues. The nutrients found in plasma include amino acids, the building blocks of proteins; glucose and other sugars; and fatty acids and glycerol, the components of **lipids (fats)**. In addition to nutrients, plasma also contains enzymes, or small proteins that function in chemical reactions, and hormones, which are transported from glands to body tissues. Waste products from the breakdown of proteins are also found in plasma. These waste products include creatinine, uric acid, and ammonium salts. Blood transports these waste products from the body tissues to the **kidneys**, where they are filtered from the blood and excreted in the urine.

Red blood cells

The human body contains an estimated 25 trillion red blood cells; approximately 4.8 million to 5.4 million are found in every microliter of blood. The structure of a red blood cell is eminently suited to its primary function, the transport of oxygen from the **lungs** to body tissues. Red blood cells are very small (about 6 nanometers wide), shaped like a disk, and contain a small depression on either side. Their small size allows them to squeeze through the tiniest of blood vessels (capillaries). In addition, their size allows a greater diffusion of oxygen across

the blood cells' plasma membranes than if the cells were larger—because blood contains so many of these small cells, their combined surface areas translate into an extremely large surface area for the diffusion of oxygen. The disk shape and the depressions on either side also contribute to a greater surface area.

TRANSPORT OF OXYGEN. Red blood cells are unusual in that they do not contain nuclei or mitochondria, the cellular organelles in which aerobic **metabolism** (the breakdown of nutrients that requires oxygen) is carried out. Instead, red blood cells acquire energy through metabolic processes that do not require oxygen. The lack of nuclei and mitochondria therefore allow the red blood cell to function without depleting its cargo of oxygen, leaving more oxygen for the body tissues.

The molecule that binds oxygen in red blood cells is called hemoglobin. Hemoglobin is a large, globular protein consisting of four protein chains surrounding an **iron** core. Hemoglobin is densely packed inside the red blood cell; in fact, hemoglobin accounts for a third of the weight of the entire red blood cell. Each red blood cell contains about 250 molecules of hemoglobin.

In the lungs, oxygen diffuses across the red blood cell membrane and binds to hemoglobin. As blood circulates to the tissues, oxygen diffuses out of the red blood cells and enters tissues. The waste product of aerobic metabolism, carbon dioxide, then diffuses across red blood cells and binds to hemoglobin. Once circulated back to the lungs, the red blood cells discharge their load of carbon dioxide, which is then breathed out of the lungs. However, only 7% of carbon dioxide generated from metabolism is transported back to the lungs for exhalation by red blood cells; the majority is transported in the form of bicarbonate, a component of plasma.

HEMOPOIESIS. Red blood cells are formed in red bone marrow from precursor cells called pluripotent stem cells. The process of red blood cell formation is called hemopoiesis (alternatively, hematopoiesis). In adults hemopoiesis takes place in the marrow of ribs, vertebrae, the breastbone, and the pelvis. On average, a red blood cell lives only three to four months. Constant wear and tear on the red blood cell membrane, caused by squeezing through tiny capillaries, contributes to the red blood cell's short life span. Worn out red blood cells are destroyed by phagocytic cells (cells that engulf and digest other cells) in the **liver**. Parts of red blood cells are recycled for use in other red blood cells, such as the iron component of hemoglobin.

White blood cells

White blood cells are less numerous than red blood cells in the human body; each microliter of blood con-

tains 5,000 to 10,000 white blood cells. The number of white blood cells increases, however, when the body is fighting off **infection**. Their numbers are maintained until the **immune system** detects the presence of a foreign invader. When the immune system is activated, chemicals called lymphokines stimulate the production of more white blood cells.

White blood cells function in the body's defense against invasion and are key components of the immune system. They usually do not circulate in the blood vessels, and are instead found in the interstitial fluid and in lymph nodes. Lymph nodes are composed of lymphatic tissue and are located at strategic places in the body. Blood filters through the lymph nodes, and the white cells present in the nodes attack and destroy any foreign invaders.

TYPES OF WHITE BLOOD CELLS. The human body contains five types of white blood cells: monocytes, neutrophils, basophils, eosinophils, and lymphocytes. Each type of white blood cell plays a specific role in the body's immune defense system.

Under a **microscope**, three kinds of white blood cells appear to contain granules within their cytoplasm. These three types are the neutrophils, basophils, and eosinophils. Together, these three types of white blood cells are called granulocytes. The granules are specific chemicals that are released during the immune response. The other two types of white blood cells, the monocytes and lymphocytes, do not contain granules. These types are known as the agranular leukocytes.

Monocytes, which comprise 3% to 8% of the white blood cells, and neutrophils, which comprise 60% to 70% of white blood cells, are called phagocytes. They ingest and digest cells, including foreign microorganisms such as bacteria. Monocytes differentiate into cells called macrophages. Macrophages can be fixed in one place, such as in the **brain** and lymph nodes, or can "wander" to areas where they are needed, such as the site of an infection. Neutrophils have an additional defensive property: they release granules of lysozyme, an enzyme that destroys cells.

Basophils comprise 0.5% to 1% of the total composition of white blood cells and function in the body's inflammatory response. **Allergies** are caused by an inflammatory response to relatively harmless substances, such as pollen or dust, in sensitive individuals. When activated, basophils release various chemicals that cause the characteristic symptoms of allergies. Histamines, for instance, cause the runny nose and watery eyes associated with allergic reactions; heparin is an anticoagulant that slows blood clotting and encourages the flow of blood to the site of inflammation, inducing swelling.

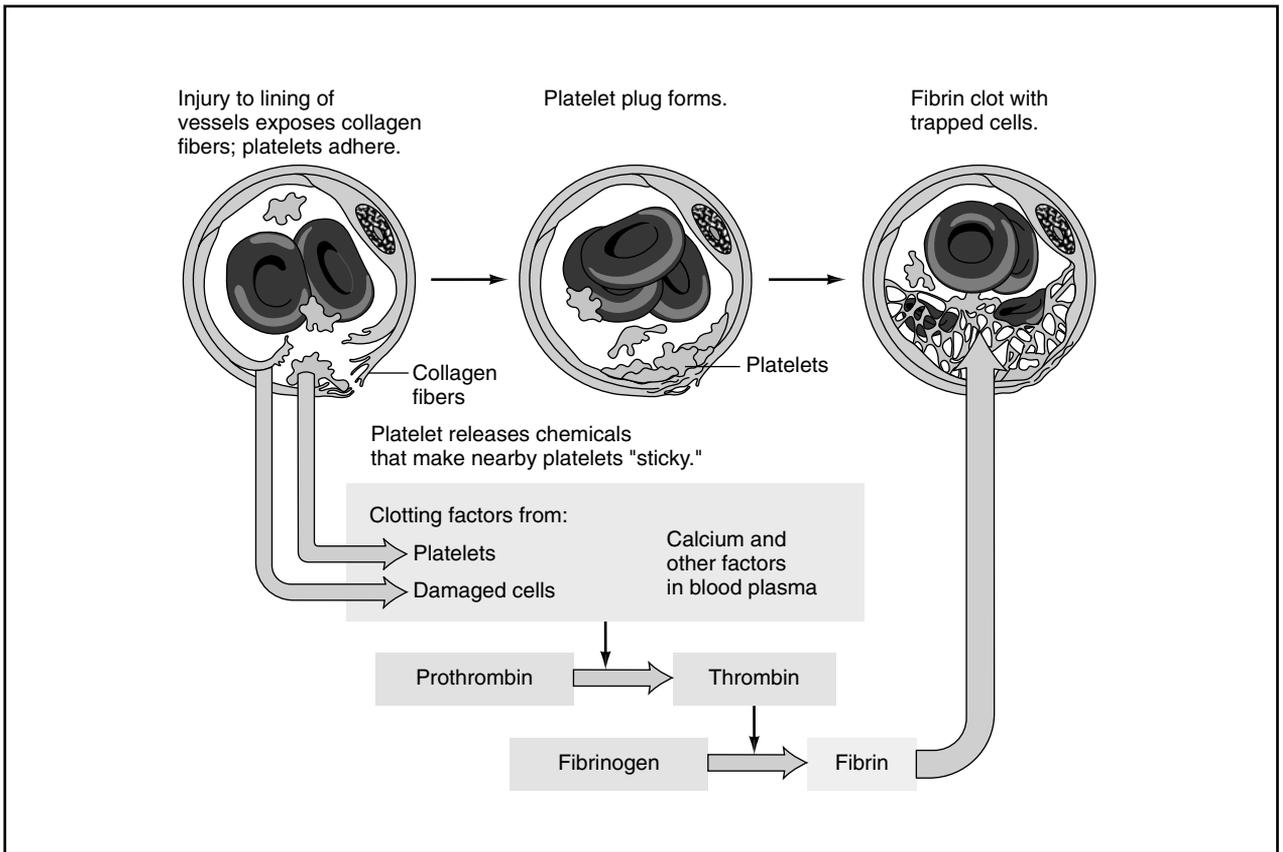

Illustration of blood clotting. (Illustration by Hans & Cassidy. Courtesy of Gale Group.)

Eosinophils, which comprise 2% to 4% of the total composition of white blood cells, are believed to counteract the effects of histamine and other inflammatory chemicals. They also phagocytize bacteria tagged by antibodies.

Lymphocytes, which comprise 20% to 25% of the total composition of white blood cells, are divided into two types: B lymphocytes (also called B cells) and T lymphocytes (also called T cells). The names of these lymphocytes are derived from their origin. T lymphocytes are named for the thymus, an organ located in the upper chest region where these cells mature; and B lymphocytes are named for the bursa of Fabricius, an organ in birds where these cells were discovered.

T lymphocytes play key roles in the immune response. One type of T lymphocyte, the helper T lymphocyte, activates the immune response when it encounters a macrophage that has ingested a foreign microorganism. Another kind of T lymphocyte, called a cytotoxic T lymphocyte, kills cells infected by foreign microorganisms. B lymphocytes, when activated by helper T lymphocytes, become plasma cells, which in turn secrete large amounts of antibodies.

All white blood cells arise in the red bone marrow. However, the cells destined to become lymphocytes are first differentiated into lymphoid stem cells in the red bone marrow. These stem cells undergo further development and maturation in the spleen, tonsils, thymus, adenoids, and lymph nodes.

Platelets

Platelets are not cells; they are fragments of cells that function in blood clotting. Platelets number about 250,000 to 400,000 per liter of blood. Blood clotting is a complex process that involves a cascade of reactions that leads to the formation of a blood clot. Platelets contain chemicals called clotting factors. These clotting factors first combine with a protein called prothrombin. This reaction converts prothrombin to thrombin. Thrombin, in turn, converts fibrinogen (present in plasma) to fibrin. Fibrin is a thread-like protein that traps red blood cells as they leak out of a cut in the skin. As the clot hardens, it forms a seal over the cut.

This process works for relatively small cuts in the skin. When a cut is large, or if an artery is severed, blood loss is so severe that the physical pressure of the blood

leaving the body prevents clots from forming. In addition, in the inherited disorder called **hemophilia**, one or more clotting factors are lacking in the platelets. This disorder causes severe bleeding from even the most minor cuts and bruises.

Platelets have a short life span; they survive for only five to nine days before being replaced. Platelets are produced in red bone marrow and are broken off from other red blood cells.

Role in human health

Blood substitutes

Researchers hope to create synthetic blood substitutes to ease the burden of dwindling blood donations that are needed to meet the demand for surgeries, transfusions, and emergencies. Currently under development are blood substitutes that use perfluorocarbons or modified hemoglobin to carry oxygen to tissues.

Perfluorocarbons are long, fatty hydrocarbon chains containing fluorine that have the ability to pick up oxygen in lungs and release it into tissues. The artificial blood is a mixture of perfluorocarbons with saline (physiological salt water) using surfactants, substances that allow the mixing of oil and water. The solution then can be administered to patients. Over time, as the artificial blood helps deliver oxygen to tissues, the perfluorocarbon molecules are exhaled from the body.

Hemoglobin solutions contain hemoglobin that has been isolated from red blood cells and chemically altered to increase its lifespan in the bloodstream and to ensure adequate oxygen-carrying capabilities.

Strictly, these substances are not whole blood substitutes since they only have the ability to carry oxygen and cannot replace the other important functions of blood. However, they would be valuable in eliminating the risk of transmitting disease during transfusions as well as preventing accidental blood type mismatches.

ABO BLOOD GROUPS. An interesting aspect of red blood cells is that they carry certain proteins, called antigens, on their plasma membranes. These antigens are responsible for the various blood groups known as A, B, AB, and O:

- A person with A antigens is type A and has antibodies to B antigens.
- A person with B antigens is type B and has antibodies to A antigens.
- A person with both antigens is type AB and does not have antibodies to either antigen.

- A person with none of the antigens is type O and has antibodies to both A and B antigens.

These combinations are necessary to know when performing a blood transfusion. For instance, if a type A individual donates blood to a type B individual, the A antibodies in the recipient's B blood will react with the A antigens of the donor's A blood. This reaction, called the agglutination reaction, causes the blood cells to clump together. Agglutination can be fatal. Until blood typing was worked out early in this century, many deaths from blood transfusions occurred due to incompatibility of antigens and antibodies.

HLA ANTIGEN GROUPS. Like red blood cells, the plasma membranes of white blood cells also contain antigens. These surface antigens are called the human leukocyte associated (HLA) antigens. Like the red blood cell types, these HLA antigens represent different white blood cell "groups." When a person receives an organ transplanted from a donor, the recipient and the donor must have the same HLA antigen group for the transplant to be successful. If the donor and recipient are two different HLA antigen groups, the recipient's body will "reject" the organ; in other words, the recipient's immune system will be activated by the foreign cells of the organ and initiate an immune response against the organ.

Common diseases and disorders

Sickle cell anemia

Sickle cell anemia is an inherited disorder caused by a defect in one of hemoglobin's four protein chains. The defective hemoglobin distorts the shape of the red blood cells and injures the red blood cell membrane. Water and potassium leak from the cells, causing the red blood cells to become rigid and "sickle-shaped." As a result of these changes, oxygen transport is severely interrupted and circulation of the blood through the blood vessels can become blocked. These irregular blood cells do not carry as much oxygen as their normally shaped counterparts. Although the prognosis for individuals with sickle cell anemia was historically poor, improvements in life expectancy and quality have been made due to early diagnosis and treatment.

Hemophilia

Hemophilia is hereditary group of **bleeding disorders** that results in insufficient clotting and excessive bleeding. Types are hemophilia A, hemophilia B, and von Willebrand's disease. Hemophilia A is the most common type. It results from a deficiency in clotting factor VIII. Only males have this sex-linked disease, but women may be carriers. Uncontrolled bleeding, both internal and

KEY TERMS

Aerobic metabolism—Metabolic processes that require oxygen.

Antibody—An immune protein that marks foreign microorganisms in the body for destruction by other immune cells.

Antigen—A protein that is attached to a cell's plasma membrane.

Centrifugation—A laboratory procedure in which a test tube of blood or other liquid is spun at a high speed.

Clotting factor—A set of substances released by platelets that function in the clotting mechanism.

Electrolytes—The salts and other substances present in the plasma that function in crucial body processes.

Fibrin—A protein that functions in the clotting mechanism; forms mesh-like threads that trap red blood cells.

Fibrinogen—The inactive form of fibrin present in plasma; activated by clotting factors released by platelets.

Hemoglobin—The protein found in red blood cells that binds oxygen; consists of four protein chains surrounding an iron core.

Hemophilia—A genetic disorder in which one or more clotting factors are not released by the platelets; causes severe bleeding from even minor cuts and bruises.

Hemopoiesis—The process of red blood cell formation in the bone marrow.

Histamine—A chemical released by basophils during the inflammatory response; causes blood vessels to dilate.

Immunoglobulin—An antibody.

Inflammatory response—A type of non-specific immune response; involves the release of chemicals from basophils that increase blood circulation and white blood cell migration to the affected area.

Interstitial fluid—The fluid that bathes cells.

Lymph node—A small structure located at several points in the body; consists of lymphatic tissue that filters blood and removes microorganisms.

Lymphocyte—A type of white blood cell; includes B and T lymphocytes.

Lysozyme—An enzyme released by neutrophils that kills cells.

Lymphoid stem cell—The cell from which B and T lymphocytes are derived.

Phagocytize—To engulf and digest a cell.

Plasma cell—The cell derived from the B lymphocyte, which secretes antibodies.

Pluripotent stem cell—The type of stem cell from which red blood cells and more white blood cells are derived in the bone marrow.

Sickle cell anemia—A genetic disorder caused by a defect in one of hemoglobin's four protein chains; causes red blood cells to be sickle-shaped.

external, may be caused by the smallest of injuries. Treatment involves clotting factor supplementation, and transfusions are common when blood is lost, or prophylactically.

Human immunodeficiency virus

Human **immunodeficiency virus** (HIV), the causative agent of acquired immune deficiency syndrome (**AIDS**), attacks and kills T lymphocytes. This disease cripples the immune system and leaves the body helpless to stave off infections. As AIDS progresses, the number of helper T lymphocytes drops from a normal 1,000 per cubic millimeter to below 200.

Blood coagulation

Definition

Blood coagulation is the process that causes blood to clot and helps prevent excessive blood loss when a vein or artery is pierced or broken.

Description

Blood coagulation is the body's natural way of preventing its blood supply from being lost through a cut, puncture, or other trauma to **blood vessels**. All of the components necessary for coagulation are found in the blood. The coagulation process involves a series of **proteins**, protein cofactors, and enzymes that interact on membrane surfaces. It is normally activated by damaged tissue.

Function

Normal blood coagulation is a complex process that involves 20 to 30 components, called blood coagulation factors, and a series of complex chemical reactions. When a blood vessel is injured, platelets in the area of the damage clump together and stick to the edges of the cut to begin the coagulation process. Platelets are fragments of cells containing clotting factors. These clotting factors combine with a protein called prothrombin in a reaction that converts prothrombin to thrombin. Thrombin then converts fibrinogen (a protein present in plasma) into long, sticky threads of another protein called fibrin. The fibrin forms a mesh-like net over the opening and traps red blood cells as they try to leak out of the cut. As the clot hardens, it forms a protective seal over the cut.

The platelets also release messengers into the blood that perform additional functions including: constriction of the damaged blood vessels to reduce bleeding, attracting more platelets to the injury site to enlarge the clot, and activating other clotting factors, such as fibrinogen.

Role in human health

The ability of the blood to form a self-sealing clot when a blood vessel is injured is crucial. Without coagulation, a cut or puncture wound, no matter how minor, would continue to bleed and quickly lead to death. A deficiency in any of the protein coagulation factors can result in hemorrhages following injury. In some coagulation disorders, such as **hemophilia**, the deficiency is due to an inherited defect. In others, the deficiency is due to an acquired condition, such as **vitamin K** deficiency.

Common diseases and disorders

Hemophilia is an inherited coagulation disorder characterized by the blood's inability to clot. Both types of the disorder, hemophilia A and hemophilia B, are caused by an inherited sex-linked recessive trait, with the defective gene located on the X chromosome. This means only males are affected with the disorder but females can carry the abnormal gene and pass it on to their children.

About 80% of hemophiliacs have type A, which is the result of a deficiency of clotting factor VIII. Symptoms can vary and include bruising, spontaneous bleeding, bleeding into joints, hemorrhaging in the gastrointestinal and urinary tracts, and most notably, prolonged bleeding even from the most minor of cuts.

Prevention of injury is paramount for people with the disorder. When bleeding occurs, the standard treatment is infusion of blood plasma with concentrations of

KEY TERMS

Coagulation—The process of becoming gel-like or solid.

Enzymes—Numerous complex proteins produced by cells in the body and catalyze specific biochemical reactions at body temperatures.

Hemorrhaging—Heavy or uncontrollable bleeding.

Protein cofactor—A substance that acts in conjunction with protein to bring about certain effects.

X chromosome—A sex chromosome that usually occurs in pairs in females and single in male cells.

clotting factor VIII. This clotting factor has been cloned through **genetic engineering**, eliminating the possibility that the blood may contain **viruses** such as hepatitis and human **immunodeficiency** virus (HIV). Hemophilia A occurs in about one out of 10,000 males.

Hemophilia B (also called Christmas disease) is a result of a deficiency of clotting factor IX. Symptoms are generally the same as for type A. Treatment is usually infusion of blood plasma with clotting factor IX. The condition occurs in one out of about 70,000 males.

The most common coagulation disorder is thrombosis, which is a blood clot that blocks otherwise normal blood vessels. This is most disastrous when the clot blocks a blood vessel leading to the **heart** (causing a heart attack), **brain** (causing a stroke), a limb, or other organ.

Thrombocytopenia is a blood disease characterized by an abnormally low number of platelets in the bloodstream. The normal amount of platelets is usually between 150,000 and 450,000 cells per microliter of blood. When this number drops below 150,000, the patient is said to be thrombocytopenic. This blood disorder is one of the most common causes of hemorrhaging.

Treatment and management

Individuals at high risk for developing clots or those who have had them previously can prevent further clots by taking anticoagulant drugs, such as sodium warfarin and heparin. Anticoagulant drugs help prevent the formation of harmful clots in the blood vessels by reducing the blood's ability to clump together. Although these drugs are sometimes called blood thinners, they do not actually thin the blood. Furthermore, this type of medicine will

not dissolve clots that have already formed, although the drug may prevent an existing clot from worsening. Because these drugs affect the blood's ability to clot, they can increase the risk of severe bleeding and heavy blood loss. Anticoagulant drugs must be used exactly as directed and a physician should be consulted regularly while taking the medicine.

Medications called fibrinolytic agents are sometimes used to dissolve clots and include streptokinase, urokinase, and tissue plasminogen activator. These are most commonly used for thrombosis.

Blood culture

Definition

A **blood culture** is a lab test designed to detect the presence of **bacteria**, yeast, or **fungi** in the bloodstream.

A routine blood culture involves injecting a sample of the patient's blood into two bottles of sterile nutrient broth (one for aerobes and one for anaerobes), incubating the bottles at 35°C, and monitoring the bottles for growth over a period of five days. For positive cultures, it also involves identifying any organism that grows and performing antibiotic sensitivity tests to determine which **antibiotics** will be effective in treating the **infection**.

Purpose

Physicians normally order this test for patients with symptoms of bacteremia. Symptoms can include **fever**, chills, mental confusion, **anxiety**, rapid heartbeat, hyperventilation, blood clotting problems, and **shock**. These symptoms are especially significant if the patient already has another illness or infection, is hospitalized, or has trouble fighting infections because of a weak **immune system**. Because bacteremia can be a serious clinical condition that, untreated, can lead to death, a blood culture should be performed as soon as an infection is suspected. Early detection will give the patient the best chance for effective treatment and survival.

Blood cultures are sometimes used to determine the causes of infections in other parts of the body because these infections often spread to the blood. For example, bacterial **pneumonia** (an infection of the lung) and infectious **endocarditis** (an infection of the inner layer of the **heart**, including the heart valves) are known to leak bacteria into the bloodstream. Other sources might be **boils**, urinary tract infections, and oral bacteria spread during mouth trauma (such as injury or dental treatment).

Precautions

Patients who have **bleeding disorders** or are taking blood thinners might have trouble with bleeding following a venipuncture. Before having a blood sample drawn, such patients should tell the phlebotomist about their condition.

Description

There are many variables involved in performing a blood culture. Before ordering a blood culture, the physician must make the following decisions based on a knowledge of infections and the patient's clinical condition and medical history.

- type of blood culture that will best target the suspected microorganism
- number of blood cultures to request
- how often the blood cultures should be performed

Some factors influencing these decisions are the patient's symptoms or previous culture results, and whether or not the patient has had recent antibiotic therapy.

Types, numbers, and timing of blood cultures

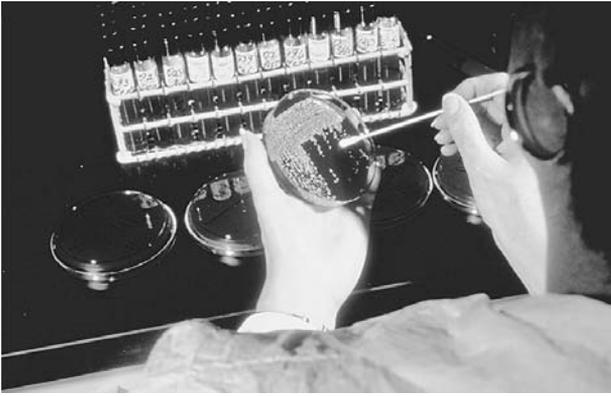

Several groups of microorganisms can cause blood infections. These groups include bacteria (both aerobes and anaerobes), yeast, fungi, **viruses**, and mycobacteria. Routine blood culture medium will normally grow both aerobic and anaerobic bacteria, yeast, and most fungi. Viruses, mycobacteria, and certain other fungi require special media or special collection techniques and a longer incubation period. For example, *Histoplasma* is a fungus that requires a six-week incubation period.

A single set of blood cultures, which consists of two bottles of growth medium (one for aerobes and one for anaerobes) is not recommended. Two to three sets are usually adequate. After a blood infection has been diagnosed, confirmed by culture, and treated, an additional blood culture might be performed to ensure that the infection is gone.

Timing can be an important factor in performing blood cultures. Most blood infections are intermittent bacteremias, which means the microorganisms enter the blood at various times. For such infections, blood drawn randomly might miss the microorganisms. Since the microorganisms enter the blood 30–90 minutes before the person's fever spikes, collecting the culture just after the fever spike offers the best probability of finding the microorganism. The second and third cultures can be collected at the same time, but from different areas of the body. The physician might want to have the collections spaced at 30-minute or one-hour intervals. In continuous bacteremias, such as infective endocarditis, microorganisms are always in the blood, so the timing of culture collection is less important. Blood cultures should always be collected before antibiotic treatment begins, if possible. However, some studies of the effectiveness of automated computer-assisted blood cultures in detecting microorganisms in the blood of newborns show that the newer technology with improved media is faster in detecting positive cultures even when antibiotic therapy had already been started.

Laboratory analysis

Bacteria are the most common microorganisms found in blood infections, so routine blood cultures target bacterial growth, although they also support the growth of many other microorganisms. Laboratory analysis of a bacterial blood culture differs slightly from that of a **fungal culture**, and significantly from that of a viral culture.

Cultures on agar plates. (Photograph by T. McCarthy, Custom Medical Stock Photo. Reproduced by permission.)

For a routine blood culture, 20 ml of blood is drawn from the patient (see Preparation), put directly into a paired set of blood culture bottles (aerobic and anaerobic), and delivered to the lab immediately for incubation.

For a blood culture to be successful, the laboratory must complete several processes:

- Provide an environment suitable for microbial growth.
- Detect growth when it occurs.
- Identify any microorganisms that grow.
- Test any isolated microorganisms against certain antibiotics to determine which antibiotic will be effective.

The broth in the blood culture bottle is the first step in providing an environment suitable for microbial growth. It contains all the required nutrients. A commonly used medium for blood culture is tryptic soy broth supplemented with amino acids and **carbohydrates**. The aerobic bottles have ideal conditions for growing aerobes, while the anaerobic bottles have ideal conditions for growing both strict anaerobes and facultative anaerobes. The second step is providing an ideal temperature for growth by placing the bottles in an incubator at body temperature (35°C).

To detect growth when it occurs, the laboratories can monitor the bottles by a daily manual (visual) method. Visual signs of growth include cloudiness or a color change in the broth, gas bubbles, or clumps of bacteria. Many laboratories use one of the newer continuous-monitoring blood culture (CMBC) systems. CMBC systems are considered important technical advances in blood cultures. The instruments automatically monitor the bottles containing the patient's blood for evidence of microorganisms, usually every 10 minutes. A common approach is to measure the production of carbon dioxide in the culture medium which causes a color change that is sensed

by the instrument. Many data points are collected daily for each bottle, and input into a computer for analysis. Sophisticated mathematical calculations can determine when microorganisms have grown. When growth is detected, an alarm is triggered to alert the technologist. This, combined with more frequent blood tests, make it possible to detect microbial growth earlier. In addition, all CMBC system instruments have the detection system, incubator, and agitator in one unit.

To identify any microorganisms that grow, the laboratory does a **Gram stain** and a subculture. If there is no evidence of growth after five days, the laboratory usually performs a Gram stain and subculture before discarding a bottle and reporting a negative result.

For the subculture, a drop of blood is placed on a culture plate and spread over the surface of the plate. The plate is then placed in an incubator at 35°C. If a bacterium is isolated, the laboratory identifies it using biochemical tests and the Gram stain. The bacterium is also tested against many different antibiotics to see which antibiotics can effectively treat the infection. This process is called sensitivity (or susceptibility) testing.

All test results are reported to the physician as soon as possible. An early report, known as a preliminary report, is usually available after one day. This report indicates whether any bacteria have been found yet and, if so, the results of the Gram stain. The next preliminary report might include a description of the bacteria growing on the subculture. The laboratory notifies the physician immediately when an organism is found and as soon as sensitivity tests are complete. Sensitivity tests could be complete before the bacterium is completely identified. The final report, which might not be available for five to seven days, includes a complete identification and a list of the antibiotics to which the bacterium is sensitive.

Preparation

To prevent contamination from the patient's skin, the blood sample must be drawn using strict sterile technique. Before drawing the blood, the phlebotomist should disinfect the skin by swabbing it first with 70% alcohol, then with iodine in a circular motion, starting at the puncture site and moving outward. The iodine should be allowed to dry completely before the blood culture is drawn. During this time, the caps of the blood culture bottles should be removed and the rubber stoppers should be cleansed with 70% alcohol.

Aftercare

After drawing the blood sample, the phlebotomist should use alcohol to remove the iodine from the skin to prevent hypersensitivity. Then, to reduce bruising, pressure should be applied to the puncture site until the bleeding stops. If the patient is taking blood thinners or has a blood disorder that causes bleeding, special care should be taken to ensure that the bleeding has stopped completely before pressure is withdrawn.

Complications

After having blood drawn, the patient might feel dizzy or faint, and might have discomfort or bruising at the puncture site. Warm packs can relieve discomfort.

Results

A negative (normal) blood culture indicates that there are no microorganisms growing in the patient's bloodstream. However, a single negative set of blood cultures does not completely rule out a blood infection. Three sets of negative cultures are needed to rule out bacteremia. False negatives can occur for the following reasons:

- Antibiotic therapy was started before the blood was drawn.
- Time of blood collection was inappropriate.
- Environment was not right for growth.
- Fastidious bacteria did not grow.

A positive blood culture indicates that microorganisms are growing in the patient's bloodstream. Finding the same microorganism in more than one set of bottles helps to rule out the possibility of contamination from poor collection or handling techniques. The physician's skill in interpreting the results is essential in distinguishing a blood culture that is positive because of a true infection from one that is positive because of contamination.

In a true bacteremia, the patient's clinical condition is consistent with a blood infection caused by the microorganism that was isolated. The microorganism usually grows soon after the bottles are incubated, is usually found in more than one set of bottles, and is often the cause of an infection somewhere else in the patient's body.

When a culture is positive because of contamination, the patient's clinical condition usually is not consistent with an infection from the microorganism that was isolated. The microorganism is often one that is commonly found on the skin and that rarely causes infection. It is

KEY TERMS

Aerobe—An organism that grows in the presence of oxygen. If an aerobe cannot grow without oxygen, it is called a strict or obligate aerobe.

Anaerobe—An organism that grows in the absence of oxygen. If an anaerobe cannot grow when oxygen is present, it is called a strict or obligate anaerobe. An anaerobe that can also grow in the presence of oxygen is called a facultative anaerobe.

Bacteremia—Bacteria in the blood.

Continuous bacteremia—A kind of bacteremia in which bacteria are always in the blood.

Intermittent bacteremia—A kind of bacteremia in which the bacteria enter the blood at various time intervals.

Phlebotomist—A person who draws blood from a vein.

Venipuncture—The puncture of a vein to withdraw a blood sample.

usually found in only one set of bottles after several days of incubation. Contaminated cultures frequently contain more than one microorganism.

Health care team roles

Several health care professionals work together to ensure a successful blood culture. The physician uses his training and expertise to decide when a blood culture should be ordered. A phlebotomist, or sometimes a nurse, collects the blood, and the clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) monitors the cultures and performs appropriate tests when the cultures are positive.

Blood gas analysis

Definition

Blood gas analysis, also called arterial blood gas (ABG) analysis, is a procedure to measure the partial pressure of oxygen (O₂) and carbon dioxide (CO₂) gases and the pH (hydrogen ion concentration) in arterial blood.

Purpose

Blood gas analysis is used to diagnose and evaluate respiratory diseases and conditions that influence how effectively the **lungs** deliver oxygen to and eliminate carbon dioxide from the blood. The acid-base component of the test is used to diagnose and evaluate metabolic conditions that cause abnormal blood pH.

Because high concentrations of inhaled oxygen can be toxic and can damage lungs and eyes, repeated blood gas analysis is especially useful for monitoring patients on oxygen, for example, **premature infants** with lung disease, so that the lowest possible inhaled oxygen concentration can be used to maintain the blood oxygen pressure at a level that supports the patient. In intubated patients under artificial ventilation, monitoring the levels of arterial carbon dioxide and oxygen allow assessment of respiratory adequacy so that the rate or depth of ventilation, the ventilator dead space, or airway pressure can be changed to preserve the patient’s optimal physiologic balance.

The measurement of arterial blood pH and carbon dioxide pressure with subsequent calculation of the concentration of bicarbonate (HCO₃⁻), especially in combination with analysis of serum electrolytes, aids in the diagnosis of many diseases. For example, **diabetes mellitus** is often associated with a condition known as diabetic acidosis. Insulin deficiency often results in the excessive production of ketoacids and lactic acid that lower extracellular fluid and blood pH. Unabated acid-base disorders are life threatening. Acidosis is associated with severe consequences, including **shock** and cardiac arrest, and alkalosis with mental confusion and **coma**.

Precautions

The syringe used to collect the sample for a blood gas analysis must contain a small amount of heparin to prevent clotting of the blood. It is very important that air be excluded from the syringe both before and after the sample is collected. The syringe must be filled completely and never exposed to air. For transportation, the syringe should be capped with a blind hub, placed on ice, and immediately sent to the laboratory for analysis to guarantee the accuracy of the results.

A blood gas analysis requires a sample of arterial blood in order to evaluate **gas exchange** by the lungs. Arterial puncture is associated with a greater risk of bleeding than venipuncture. The test may be contraindicated in persons with a bleeding disorder such as **hemophilia** or low platelet count. During the arterial puncture, the patient may feel a brief throbbing or cramping at the puncture site. In cases where the primary concern is ascertaining that the blood is adequately oxygenated, a **pulse oximeter** may be used in lieu of arterial blood gas analysis. Medical personnel must follow standard precautions for prevention of exposure to bloodborne pathogens when performing arterial blood collection.

Description

The sample of choice for blood gas analysis is arterial blood. This is usually collected from the radial artery in the wrist, but in cases where no radial pulse is obtained, the femoral or brachial artery may be used. The sample may also be collected from an arterial line after flushing the line to remove excess anticoagulant and fluid. In neonates and in adults when arterial puncture is contraindicated or unsuccessful, a capillary blood sample may be used.

The sample is inserted into an analytical instrument that uses electrodes to measure the concentration of hydrogen ions (H⁺), which is reported as pH, and the partial pressures of oxygen [PO₂] and carbon dioxide PO₂ gases. The pH-measuring electrode consists of a special

glass membrane that is selectively permeable to hydrogen ions. An electrical potential develops across the inner and outer surfaces of this membrane that is related to the log of hydrogen ion activity in the sample. A Severinghaus electrode is used to measure PCO_2 . The measuring principle is the same as for hydrogen ions, except that the electrode tip is covered with a gas permeable membrane, so that the pH change is proportional to carbon dioxide diffusing from the sample to the electrode surface. The PO_2 is measured using a polarographic (Clark) electrode. Oxygen diffuses from the sample to the cathode, where it is reduced to peroxide ions. The electrons come from a silver anode that is oxidized, generating current in proportion to oxygen concentration at the cathode. Electrode signals are dependent upon temperature as well as concentration, and all measurements are performed at 37°C . Since the *in vivo* pH and levels of oxygen and carbon dioxide are temperature dependent, results may need to be adjusted for the patient's actual temperature. Portable blood gas analyzers are available that can be used at the bedside.

Blood gas analyzers calculate blood bicarbonate concentration using the formula: $\text{pH} = 6.1 + \text{Log bicarbonate}/.0306 \times \text{PCO}_2$. They also calculate oxygen content, total carbon dioxide, base excess, and percent oxygen saturation of hemoglobin. These values are used by physicians to assess the extent of hypoxia and acid-base imbalance.

Preparation

Patients do not need to restrict food or drink before the test. For patients receiving **oxygen therapy**, the oxygen concentration must remain constant for 20 minutes before sample collection; if the test is specifically ordered to be without oxygen, the gas must be turned off for 20 minutes before the blood sample is taken to guarantee accurate test results. The patient should breathe normally during sample collection.

Infants and children may require physical and psychological preparation appropriate to the child's age. A parent or other trusted adult may be enlisted to restrain the child during sample collection.

Aftercare

After the blood sample has been taken, the health care practitioner or patient applies pressure to the puncture site for about 10 minutes or until bleeding has stopped, after which a dressing is applied. The patient should rest quietly while applying pressure to the puncture site and be observed for signs of bleeding or impaired circulation at the puncture site.

A blood gas analyzer from Corning Corporation.

Reproduced by permission.)

Complications

Complications posed by the arterial puncture are minimal when the procedure is performed correctly, but may include bleeding or delayed bleeding or bruising at the puncture site, or, rarely, impaired circulation around the puncture site.

Results

Normal values

The following results are for arterial blood at sea level (at altitudes of 3,000 feet and above, the values for oxygen are lower).

- Partial pressure of oxygen (PO_2 75–100 millimeters of mercury (mm Hg). Note that PO_2 values normally decline with age.
- Partial pressure of carbon dioxide PCO_2 35–45 mm Hg.

KEY TERMS

Acid—A chemical compound that reacts with a base to form a salt, that can give off hydrogen ions in water solution, or that contains an atom that can accept a pair of electrons from a base.

Acidosis—A blood condition in which the pH is < 7.35 and the bicarbonate concentration is below normal.

Alkalosis—A blood condition in which the pH is > 7.45 and the bicarbonate concentration is above normal.

Base—A chemical compound that reacts with an acid to form a salt, that takes up or accepts protons, or that contains an atom with a free pair of electrons to be donated to an acid.

Buffer—A chemical substance that resists changes in pH in response to changes in acid and base concentration; a buffer system consists of a weak acid or weak base in combination with its salt.

Hemoglobin—The red-colored, iron-containing protein in red blood cells that carries oxygen to the tissues.

Heparin—A biochemical that may be isolated from various animal tissues that has anticoagulant properties.

Ketoacidosis—An excessive level of acid accompanied by an increase in the level of ketones in blood that occurs as a complication of diabetes mellitus; ketones are substances normally processed by the liver from fats.

Oxygen saturation of hemoglobin—The percentage of hemoglobin that is bound to oxygen.

pH—An exponential measurement scale for expressing the concentration of acid in solution $\text{pH} = -\log [\text{H}^+]$.

- pH: 7.35–7.45.
- Oxygen content (O_2CT): 15–23 volume%.
- Oxygen saturation (SaO_2): 94%–100%.
- Concentration of bicarbonate (HCO_3^-): 22–26 millimoles per liter (mEq/liter).

Total CO_2 is often reported with blood gas analysis results and is defined as the sum of carbonic acid and bicarbonate concentrations. Normally, the ratio of bicarbonate to carbonic acid at physiological pH is about 20:1,

thus, the total CO_2 is normally about 5% higher than the bicarbonate value.

The A-a gradient (alveolar-arterial PO_2 difference) is calculated from the partial pressures of oxygen and carbon dioxide as returned from the blood gas analysis, and the partial pressure of oxygen in the air and a factor called the respiratory quotient that are specific to the site of the test. A normal value for A-a gradient may be estimated as one-fourth the patient's age plus 2.5.

Abnormal results

Values that differ from the normal values may indicate the presence of respiratory, metabolic, or renal diseases.

For most clinical decisions, the bicarbonate value, PCO_2 , and pH are used to evaluate acid-base status. The pH value defines the magnitude of the disturbance and the bicarbonate and PCO_2 determine the cause. The bicarbonate level is under the control of the **kidneys**, which may increase or decrease bicarbonate blood levels in response to pH changes. Bicarbonate is also the principal blood buffer anion, and it functions as the conjugate base to increase pH. PCO_2 is the respiratory component because it is regulated by the lungs. It is determined by the concentration of dissolved carbon dioxide (anhydrous carbonic acid) and is the principal acid component of the blood. Abnormal results are classified on the basis of pH and whether the abnormal pH is caused by the metabolic or respiratory component. pH <7.35 indicates acidosis, either metabolic (non-respiratory) or respiratory, and pH >7.45 indicates alkalosis.

Metabolic or non-respiratory acidosis is characterized by pH <7.35 (i.e. increased $[\text{H}^+]$) and decreased $[\text{HCO}_3^-]$. In most cases, the decrease in pH stimulates the respiratory center causing hyperventilation. The loss of carbon dioxide that results serves to decrease the severity of the acidosis and is referred to as compensation. Metabolic acidosis is caused by bicarbonate deficit which may result from increased H^+ formation or ingestion, from decreased H^+ excretion, or failure to produce or retain bicarbonate. Common causes of metabolic acidosis are diabetes mellitus, **alcoholism**, lactic acidosis (associated with hypoxia), acid **poisoning**, renal failure, renal tubular acidosis (an inherited defect of the renal tubules), and **diarrhea**.

Respiratory acidosis is caused by deficient ventilation that results in retention of carbon dioxide. The pH is <7.35, and PCO_2 is increased. If time has permitted renal compensation, the $[\text{HCO}_3^-]$ is somewhat increased. Respiratory acidosis is associated with airway obstruction such as occurs with asthmatic bronchial spasm, bronchitis, and **emphysema**; pulmonary diseases such as

severe **pneumonia** and pulmonary fibrosis; thoracic conditions such as multiple broken ribs and kyphoscoliosis. Respiratory acidosis is also caused by neuromuscular disease, and by depression of the respiratory center in the **brain** due to drugs, head trauma, or cranial tumor. The blood gas analysis results may deviate only slightly from normal values, and pH may even fall within the normal range (compensated respiratory acidosis) in cases of chronic compared to acute acidosis.

Metabolic alkalosis is caused by excess blood bicarbonate and usually involves a renal factor. Metabolic alkalosis is characterized by pH >7.45 and elevated $[\text{HCO}_3^-]$. The PCO_2 is usually elevated due to respiratory compensation. Metabolic alkalosis can be caused by mineralocorticoid excess (e.g. Cushing's or Conn's syndromes), which promotes increased acid excretion and bicarbonate retention by the kidney. Other causes are diuretic therapy, vomiting, severe **dehydration**, hypokalemia (low blood potassium), and hypoparathyroidism.

Respiratory alkalosis is caused by hyperventilation. The pH is >7.45 and the PCO_2 is low. If the kidneys are functioning normally and given sufficient time, the HCO_3^- will be decreased in compensation. Respiratory alkalosis may be caused by hyperventilation psychologically induced (**anxiety**), by drugs that stimulate the respiratory center, excessive ventilation therapy, and mild hypoxia.

A decrease in PO_2 is a sensitive measure of respiratory function and hypoxia. In addition to ventilation defects that also result in increased PCO_2 , PO_2 will be low in persons with poor ratios of ventilation to perfusion; mild emphysema and other gas diffusion defects; pulmonary arterial-venous shunts; and those breathing air with a low oxygen content. Elevated PO_2 is caused by excessive administration of oxygen which can lead to optic nerve damage and acidosis by displacing hydrogen ions from hemoglobin.

It is important to note that in cases of **carbon monoxide poisoning** the PO_2 will be normal, but life-threatening hypoxia may be present. Blood gas analyzers calculate the oxygen saturation of hemoglobin from PO_2 , temperature, and pH. In cases of CO poisoning, the calculation will be falsely elevated. Accurate assessment of hypoxia in CO poisoning requires direct measurements of carboxyhemoglobin and oxygen saturation of hemoglobin by oximetry or colorimetry methods.

Health care team roles

A physician, nurse, respiratory care technician, or laboratory technician collects the blood sample by arteri-

al puncture and sees to the timely and appropriate transport to the laboratory for analysis. A member of the health care team should observe the patient for 10–15 minutes to ensure that bleeding from the puncture site has stopped. Blood gas measurements are performed by a registered respiratory therapist, RRT; certified respiratory technician, CRTT; clinical laboratory scientist CLS (NCA) or medical technologist MT (ASCP); clinical laboratory technician CLT (NCA) or medical laboratory technician MLT (ASCP). A physician interprets the blood gas analysis results with a thorough understanding of the acid-base chemistry and physiology of blood and in view of the clinical situation, and applies the results to the diagnosis, treatment, and management of the patient.

Blood gases

Definition

Blood gases are defined as the mixture of gases, including oxygen (O_2), carbon dioxide (CO_2), and nitrogen (N_2), dissolved in the fluid fraction of blood.

Description

Oxygen from the air is transported from the **lungs** to all tissues of the body, where it is needed for **metabolism**; and carbon dioxide, a by-product of metabolism, is taken from the tissues to the lungs to be eliminated.

Respiration

The overall process of delivering oxygen to the tissues and carrying carbon dioxide away is called respiration. When the blood reaches the tissues, oxygen diffuses into the cells, and carbon dioxide diffuses from the cells into the blood. In the lungs, the air enters a branching complex of multiple air sacs, called alveoli, where tiny capillaries separate the air from the red blood cells by only a very thin membrane, about 0.3 μm thick. During respiration the inspired air is filtered and moistened by the nose and tracheal linings and is completely saturated with water vapor by the time it enters the alveolar sac.

In the alveolus, oxygen diffuses into the blood, and carbon dioxide diffuses out of the blood to mix with the alveolar air. Diffusion is a very rapid process, and the gases do not have time to totally equilibrate across the alveolar membrane. A small pressure difference for each gas develops. About 2% of the blood flow through the lungs bypasses the pulmonary capillaries and does not become oxygenated; thus, the partial pressure of oxygen is somewhat higher in the alveolus than in the blood. This pressure difference, calculated for the lung as a whole, is called the arterial-alveolar (A–a) gradient.

Composition of gases in air

Dry air is made up of 20.98% oxygen, 0.04% carbon dioxide, 78.06% nitrogen, and 0.92% other gases (mostly argon). In blood-gas analysis, the content of the gases oxygen and carbon dioxide are reported in terms of their partial pressures, with normal values for oxygen (PO_2) of 75 mm to 100 mm of mercury (mm Hg) and for carbon dioxide (PCO_2) of 35 to 45 mm Hg. The partial pressure of water vapor in the lung, where the air is completely water-saturated, at body temperature (98.6°F, or 37°C) is 47 milliliters of mercury (mm Hg).

Function

As blood circulates through the body, oxygen diffuses from the area of higher partial pressure. The blood moves toward the area of lower partial pressure, the cells, and carbon dioxide diffuses from the cells into the blood. In the lung, oxygen diffuses into the blood, where it is taken up by hemoglobin, and carbon dioxide diffuses out of the blood, to be exhaled.

Oxygen

Oxygen in the blood is carried by hemoglobin. The hemoglobin content of normal blood is about 15 to 16 grams per 100 ml, and each gram of hemoglobin binds

about 1.34 ml of oxygen gas. Thus, arterial blood contains about 20 ml of oxygen per 100 ml when fully saturated. The volume of oxygen in the blood, the O_2 content, is dependent on the hemoglobin concentration and does not provide as good a measure of lung function as the partial pressure of oxygen (PO_2) in arterial blood.

The amount of oxygen in the blood relative to the carrying capacity of the hemoglobin is called the oxygen saturation. The oxygen saturation of hemoglobin is directly proportional to the PO_2 ; the relationship is not linear but is described by a sigmoidal (S-shape) curve. Oxygen saturation is affected by the acid-base status of the blood: at a given PO_2 , the degree of oxygen saturation may be lowered by increasing the acidity of the blood. Oxygen saturation is expressed as a percentage; hemoglobin in arterial blood is about 97% saturated, while the more acidic venous blood is about 75% saturated.

Carbon dioxide

Carbon dioxide is formed in the cells during aerobic metabolism and diffuses into the capillaries, where only a small amount remains dissolved. It enters the red blood cells, where carbonic anhydrase quickly catalyzes its conversion to carbonic acid, which dissociates to hydrogen ion and bicarbonate. About two-thirds of the bicarbonate diffuses out into the plasma and is replaced by chloride in the red cell. The hydrogen ion binds to hemoglobin, and is transported to the lungs.

Arterial blood normally contains an amount of bicarbonate that is the equivalent of about 50 ml of carbon dioxide gas per 100 ml of blood. About 5 ml of additional carbon dioxide enters the blood in the capillaries and is converted to bicarbonate and hydrogen ion, making the blood more acidic and causing the pH to drop from 7.4 to 7.36. On reaching the lungs, the bicarbonate and hydrogen ion are converted back to carbon dioxide, which diffuses into the alveoli for exhalation. Over a period of 24 hours at rest, about 200 ml of carbon dioxide, the equivalent of 12,500 milliequivalents of acid, is produced by metabolism and eliminated via the lungs. The carbonic-acid concentration can change in seconds in response to hypo- or hyperventilation, while changes in the bicarbonate concentration take much longer—hours or days—because elimination by the kidney is relatively slow.

Carbon monoxide

Small amounts of carbon monoxide (CO) are produced during metabolism. Carbon monoxide binds tightly to hemoglobin to form a CO-hemoglobin complex called carboxyhemoglobin in which the binding of oxygen molecules is prevented. Thus, carbon monoxide reduces the oxygen saturation of hemoglobin at any

given PO_2 . City dwellers and smokers are exposed to a much higher level of carbon monoxide in the air: in heavy smokers, as much as 10% of hemoglobin may be carboxyhemoglobin.

Nitrogen and other gases

The nitrogen and other gases inhaled are, under normal circumstances, inert and play no role in human health. A painful and potentially fatal condition, called **decompression sickness** or the bends, can be caused by formation of nitrogen bubbles in the blood and tissues by moving too quickly from areas of higher atmospheric pressures to lower pressures, such as when deep-sea divers return too quickly to the surface of the water.

Role in human health

Acid-base balance in the blood

Carbon dioxide in the blood is transported as bicarbonate, since carbon dioxide combines with water to form carbonic acid:

which is in equilibrium with hydrogen ions and bicarbonate:

The concentration of hydrogen ions (H^+) determines the pH, a measure of the acidity, of the blood. The carbonic acid-bicarbonate equilibrium is an example of a buffer system and is involved in the maintenance of the **acid-base balance** in the body. The pH of the blood is related to the ratio of bicarbonate to carbonic acid, which is normally about 20:1. The carbonic acid-bicarbonate buffering system is extended by the body's ability to convert carbonic acid to carbon dioxide (catalyzed by the enzyme carbonic anhydrase) and the removal of CO_2 in respired air. In addition, the body has the ability to eliminate hydrogen or bicarbonate ions via the **kidneys** to maintain pH.

Since most body systems function best at a pH near 7.4, the pH of the body must be maintained within a narrow range. When the blood pH is higher or lower than the normal level of 7.35 to 7.45, enzymes may function less effectively or not at all, nerve and muscle activity weakens, and finally all metabolic activity is undermined.

Proteins also function as buffers; hemoglobin in particular is an important buffering agent in the blood. Oxygen-bound hemoglobin is a stronger acid than hemoglobin without oxygen, and tends to release hydrogen ions; when hemoglobin is exposed to the lower oxygen concentrations in the capillaries, oxygen is released, the

Normal arterial blood gas values

Arterial	Term infant	Child	Adult
pH	7.26–7.41	7.35–7.45	7.35–7.45
PaCO ₂	34–54 mm Hg	35–45 mm Hg	35–45 mm Hg
PaO ₂	60 mm Hg	75–100 mm Hg	75–100 mm Hg
O ₂ sat	40%–95%	95%–98%	95%–98%
CO ₂ content	20–28 mEq/L	18–27 mEq/L	23–29 mEq/L
Base excess	–7 to –1 mEq/L	–4 to +2 mEq/L	–2 to +2 mEq/L

SOURCE: Rothstein, J.M., S.H. Roy, and S.L. Wolf. *The Rehabilitation Specialist's Handbook*. 2nd ed. Philadelphia: F.A. Davis Co., 1998

hemoglobin becomes a weaker acid, and hydrogen ions are taken up. The relationship between pH and the ability of hemoglobin to bind oxygen, which is reflected in saturation levels of hemoglobin in arterial versus venous blood, is known as the Bohr effect.

Buffer base and base excess

The buffer base is the sum of all anionic buffer components in the blood, including bicarbonate, sulfates, and phosphates. The base excess refers to how much a patient's buffer base is higher than normal, and is expressed in terms of the amount of acid in milliequivalents per liter (mEq/L) that would have to be added to the patient's blood to bring it to a normal pH of 7.4. Many physicians rely only on the difference between the patient's bicarbonate and an average value for bicarbonate of 24 mEq/L as an indication of the need for bicarbonate replacement. However, the base excess is more meaningful, since other buffers are taken into account and is accurate also in anemic patients, where the buffering capacity of hemoglobin is diminished. Base excess can be negative in value for acidotic patients; that is, acid would have to be taken away to bring the pH to normal.

The clinical determination of how much bicarbonate to administer in the treatment of severe acidosis is usually based on the base excess of the blood. The base excess of blood, however, is not a true indication of the base excess of the extracellular fluid (ECF) of the whole body. Only blood contains hemoglobin, and other extracellular fluids have different protein contents and buffering capacities. Furthermore, fluid distribution in the body varies with the state of hydration, and ECF as a percentage of body weight varies with age and fat content. In general, however, the recommendation for bicarbonate therapy is 0.1 to 0.2 mEq × body weight × base excess.

KEY TERMS

Acid—A chemical compound that reacts with a base to form a salt, that can give off hydrogen ions in water solution, or that contains an atom that can accept a pair of electrons from a base.

Acidosis—A blood condition in which the pH is <7.35 and is below normal.

Alkalosis—A blood condition in which the pH is >7.45 and is above normal.

Alveoli—Air sacs of the lungs located at the termini of the bronchial passageways.

Base—A chemical compound that reacts with an acid to form a salt, that takes up or accepts protons, or that contains an atom with a free pair of electrons to be donated to an acid.

Buffer—A chemical substance that resists changes in pH in response to changes in acid and base concentration; a buffer system consists of a weak acid or weak base in combination with its salt.

Carbonic anhydrase—An enzyme that catalyzes the reversible reaction of carbon dioxide with water to form carbonic acid in red blood cells.

Hemoglobin—The red-colored, iron-containing protein in red blood cells that carries oxygen to the tissues.

Ketoacidosis—An excessive level of acid accompanied by an increase in the level of ketones in blood that occurs as a complication of diabetes mellitus; ketones are substances normally processed by the liver from fats.

Metabolism—The physical and chemical processes carried out by an organism to produce, maintain, and destroy material substances and to make energy available.

pH—An exponential measurement scale for expressing the concentration of acid in solution $\text{pH} = -\log [\text{H}^+]$.

Control of respiration

The levels of blood gases act to control the rate of respiration. The aortic and carotid bodies, special chemical receptors near the aorta and carotid arteries, respond to changes in the levels of acid, carbon dioxide, or oxygen, stimulating the **brain** respiratory centers in the brain stem to regulate the speed and depth of breathing. When blood acid is increased, such as during diabetic

ketoacidosis, or when there is a rise in CO_2 during the increased metabolism of **exercise**, respiration is stimulated. The respiratory centers in the brain also respond directly to increases in PCO_2 and stimulate respiration. The resulting deep, rapid breathing acts to mix alveolar air with CO_2 -poor air to decrease the carbon dioxide in the blood as it passes by the alveolus, and the reduction in CO_2 returns the blood toward normal. Lack of oxygen can also weakly stimulate respiration. Oxygen levels usually play little role in the regulation of respiration in healthy individuals at normal altitudes, but at very low PO_2 (i.e., <60 mm Hg), as in patients suffering from severe chronic bronchitis and **emphysema**, respiration can be stimulated.

Common diseases and disorders

Disorders involving the levels of blood gases are primarily diagnosed on the basis of disturbances in the acid-base balance as acidosis or alkalosis. Acid-base disorders may be respiratory or nonrespiratory (metabolic) in origin, or of mixed origin.

Acidosis with elevated PCO_2 is classified as respiratory acidosis. Causes include:

- airway obstruction due to chronic conditions such as bronchitis or emphysema, or acute causes such as bronchospasm or aspiration of foreign material
- neuromuscular diseases such as poliomyelitis, motor-neuron disease, or tetanus, or due to neurotoxins such as botulin or curare
- pulmonary diseases including **pneumonia** and pulmonary fibrosis, and extrapulmonary thoracic disorders such multiple broken ribs or kyphoscoliosis
- respiratory-center depression due to cerebral trauma or tumor, or secondary to anesthesia or application of sedatives

Alkalosis with depressed PO_2 is classified as respiratory alkalosis. Causes include:

- hypoxia due to high altitude, anemia, or pulmonary disease
- hyperventilation, whether voluntary or secondary to trauma, **infection**, cerebral tumor, or ingestion of a respiratory stimulant
- pulmonary **edema** or embolism
- artificial overventilation

Acidosis with depressed PCO_2 and bicarbonate is classified as nonrespiratory, or metabolic, acidosis. Causes include:

- diabetic or alcoholic ketoacidosis

- acid **poisoning**, including secondary to alcohol poisoning
- decreased elimination of acid due to renal failure
- loss of bicarbonate, such as during diarrhea

Alkalosis with elevated PO_2 and bicarbonate is classified as nonrespiratory, or metabolic, alkalosis. Causes include:

- loss of unbuffered acid due to gastrointestinal and/or renal disturbances
- chronic ingestion of antacid preparations, or a high-fruit, low-protein diet

A low value for PO_2 (hypoxemia) is also indicative of respiratory disturbance. Hypoxemia may be caused by:

- low inspired levels of oxygen, such as at high altitude
- hypoventilation due to respiratory depression or neuromuscular disease
- mixing of arterial and venous blood, as in cyanotic congenital **heart** disease
- impaired oxygen diffusion as in pulmonary fibrosis
- chronic diseases of airway obstruction, such as bronchitis and emphysema

Blood pressure

Definition

Blood pressure is the pressure of the blood against the blood vessel walls as blood flows through the vessels.

Description

The **heart** beats about 60 to 70 times a minute. With each beat as the heart contracts, a surge of blood is pumped from the heart into the arteries. The pressure in the artery walls during this surge is measured as the systolic blood pressure (a higher number). Between beats, the heart is relaxed and there is much less pressure on the artery walls. This is measured as the diastolic blood pressure (a lower number). Blood pressure is given as two numbers written as 120/80 mm Hg and is measured with a device called a **sphygmomanometer** in millimeters (mm) of mercury (Hg). The pressure depends on the amount of blood pumped through the heart in addition to the resistance and elasticity of the **blood vessels** to the amount of blood flowing.

Function

Blood pressure is necessary to sustain life. It continuously forces blood carrying oxygen and nutrients from the heart to the organs and tissues of the body. Blood pressure levels can go up or down in the course of a day depending on activity and **stress** levels, medications, or diet.

A person's blood pressure is determined by the contraction of the heart's ventricles, which pump blood into the aorta and subsequently throughout the body. The normal adult blood pressure has a systolic number of 120 and a diastolic number of 80. Systolic pressure is taken when the heart contracts; diastolic pressure is taken when the heart is relaxed.

Normally, about 5.5 quarts (5.25 liters) of blood goes through the heart and blood vessels each minute, an amount called cardiac output. The body is dependent on its volume of blood to maintain blood pressure. If a person experiences heavy blood loss, blood pressure will plunge. Similarly, an increase in blood volume, in cases like water retention, will cause blood pressure to rise.

The brain's medulla contains a cluster of nerves, called the cardiovascular center, that control heart rate, the contraction of the ventricles, and blood vessel diameter. Sensory receptors monitor the stretching of blood vessel walls. During **exercise**, the heart rate rises and the ventricles contract more forcefully. The cardiovascular center then monitors the dilation (expansion) or constriction of peripheral blood vessels. For example, the blood vessels to organs directly involved the exercise will expand. Blood flow to **skeletal muscles** may increase by a factor of 10 and that to the heart and skin can triple. Simultaneously, constriction will occur in the blood vessels of the **digestive system**.

The sensory receptors in the walls of blood vessels continually monitor blood pressure. When the receptors

Classification of blood pressure (BP)

Category	Range (mm Hg)	Recommendation
Normal BP	Systolic <140; diastolic <85	Recheck in 2 years
High-normal BP	Diastolic 85–89	Recheck in 1 year
Mild hypertension	Diastolic 90–104	Confirm within 2 months
Moderate hypertension	Diastolic 105–114	Evaluate within 1 month
Severe hypertension	Diastolic ≥115	Evaluate immediately or within 1 week
Borderline isolated systolic hypertension	Systolic 140–159; diastolic <90	Confirm within 2 months
Isolated systolic hypertension	Systolic ≥160; diastolic <90	Confirm within 2 months

SOURCE: Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.

detect an increase in aortic pressure, for example, the cardiovascular center directs the lowering of the heart rate and the stretching of blood vessels, which decreases the blood pressure. A decrease in blood pressure causes an increased heart rate and vasoconstriction.

As people age, the blood vessels become less flexible and the heart muscle is less strong, resulting in a smaller output and lower maximum heart rate. Systolic pressure tends to rise as a person ages. **Coronary artery disease**, which causes the blood vessels in the heart to receive inadequate oxygenation, can cause chest **pain** or heart attack. Atherosclerosis (clogging of the arteries) can also cause an increase in blood pressure.

Role in human health

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC) develops high blood pressure prevention and control recommendations for healthcare providers. According to the JNC, optimal blood pressure (BP) measurement is a systolic blood pressure (SBP) of 120mm Hg or less and a diastolic blood pressure (DBP) of 80mm Hg or less. Blood pressure is still considered normal at levels of 130mm Hg SBP or less and 85mm Hg DBP or less.

Periodic **blood pressure measurement** is recommended every one to two years for adults with normal blood pressure. A healthcare provider should determine the frequency of blood pressure measurement based on each patient's individual risk factors for high blood pressure. Individual risk factors that contribute to high blood pressure, such as diabetes, a family history of high blood pressure, a diet high in fat and cholesterol, being African-American, elderly, overweight, a smoker, or heavy drinker, are important to consider when advising patients on the frequency of periodic blood pressure measurement. Prevention and management of high blood pressure requires not only active participation by the patient but also education and support from health care

providers. **Patient education** is a shared responsibility among physicians, nurses, dietitians, and allied health professionals. While patient education is time-consuming, it is very important to the process of maintaining health and preventing disease.

Common diseases and disorders

High blood pressure, also called **hypertension**, is a cardiovascular disease affecting nearly 50 million Americans. The higher than normal pressure pushes blood against the artery walls causing the heart to work harder in order to pump blood to the body. The JNC defines high blood pressure as a systolic blood pressure (SBP) of 140mm Hg or greater, a diastolic blood pressure (DBP) of 90mm Hg or greater, or taking high blood pressure (antihypertensive) medications.

High blood pressure often has no warning signs or symptoms. So, if it is not identified or treated, high blood pressure can damage the arteries and organs causing serious medical problems over time. If not properly managed, high blood pressure can increase the risk of developing, among other problems, the following:

- Atherosclerosis, also called “hardening of the arteries”—High blood pressure can cause atherosclerosis or a thickening and narrowing of the blood vessel walls. This can slow or prevent blood flow through the arteries and may lead to heart attack or stroke.
- Stroke—High blood pressure can cause the arteries to narrow and lead to a stroke if a blood clot blocks one of the narrowed arteries (thrombotic stroke) or if a weakened blood vessel in the **brain** ruptures (hemorrhagic stroke).
- Coronary heart disease—High blood pressure can cause the coronary arteries to narrow and harden. The coronary arteries carry oxygen to the heart muscle so it can function to pump blood to the body. If blood cannot flow properly through the coronary arteries to the heart, the heart cannot get enough oxygen. This can cause chest pain (angina). If the blood flow to the heart mus-

cle is blocked, it can cause a heart attack. Heart disease is the leading cause of death in the United States.

- **Congestive heart failure**—Over years, uncontrolled high blood pressure can cause the heart muscle to compensate by becoming larger (dilatation) to allow more blood to fill it, by thickening the heart muscle (hypertrophy) to pump more forcefully, or by beating faster to increase circulation. According to the National Institutes of Health, uncontrolled high blood pressure increases the risk of **heart failure** by 200%, compared with those who do not have high blood pressure.
- **Kidney failure**—Over years, high blood pressure can damage the blood vessels of the kidney. The damage may cause the **kidneys** to no longer filter waste from the blood adequately, which could require dialysis treatment or possibly a kidney transplant.

The cause of high blood pressure is usually unknown, in which case it is called primary or essential hypertension. This cannot be cured. However, it can be easily diagnosed and, in most cases, controlled with lifestyle modifications and/or medications.

Lifestyle modifications

Some of the lifestyle modifications for high blood pressure prevention and management include:

- Weight loss if the patient is overweight. As weight increases, blood pressure rises.
- Cutting down on alcohol, no more than one drink per day for women and no more than two drinks per day for men.
- Decreasing salt and sodium, saturated fat, and cholesterol.
- Increasing physical activity, especially aerobic activity 30 to 45 minutes on most days.
- Stopping smoking.

Medications

High blood pressure medications work in various ways. They can affect the force of the heartbeat, the blood vessels, and the amount of fluid in the body. Some of the different types of medications prescribed to treat high blood pressure are:

- Diuretics, also called “water pills,” decrease the amount of fluid in the body by flushing excess water and sodium from the body through the urine.
- Beta blockers make the heart beat less often and with less force by reducing nerve impulses to the heart and blood vessels.

KEY TERMS

Angiotensin converting enzyme (ACE) inhibitor—A drug used to decrease pressure inside blood vessels.

Artery—A blood vessel that carries blood from the heart to the body.

Beta blocker—A drug used to slow heart rate and reduce pressure inside blood vessels.

Calcium channel blocker—A drug used to relax blood vessels and the heart muscle.

Cardiovascular—The heart and blood vessels.

Congestive heart failure—A cardiovascular disease that involves the heart muscle’s diminished or loss of pumping ability, generally causes fluid that cannot be completely ejected from the heart to back up in the lungs.

Diastolic blood pressure—The lower number of a blood pressure measurement or the pressure when the heart is at rest.

Diuretic—A drug that eliminates excess fluid in the body.

Fat—One of the nutrients that supply calories to the body.

Hypertension—High blood pressure.

Hypertrophy—Enlargement of tissue or an organ.

Millimeter (mm)—A unit of measurement equal to one-thousandth of a meter.

Risk factors—Behaviors, traits, or conditions in a person that are associated with an increased chance (risk) of disease.

Sign—An objective observation of an illness.

Sphygmomanometer—A manual device used to measure blood pressure.

Symptom—Any indication of disease noticed or felt by a patient.

Systolic blood pressure—The higher number of a blood pressure measurement or the pressure when the heart is contracting.

- **Calcium channel blockers** relax the blood vessels by preventing calcium from entering the muscle cells of the heart.
- **Alpha blockers** relax the blood vessels by way of the nervous system. They decrease renin secretion, which is involved in angiotensin II formation.

- Vasodilators widen blood vessels by relaxing the muscle in the vessel walls.
- Angiotensin converting enzyme (ACE) inhibitors relax the blood vessels by preventing angiotensin II from being formed.

High blood pressure can sometimes be traced to a cause such as an adrenal gland tumor, kidney disease, hormone abnormalities, birth control pills, or **pregnancy**. This is called secondary hypertension and can usually be cured if the cause disappears or is corrected.

Blood pressure measurement

Definition

Measurement of the pressure exerted by the circulating **blood** on the walls of the **blood vessels**, especially the arteries.

Purpose

The purpose of **blood pressure** measurement is to establish a baseline and detect any abnormalities from the normal state. Measurement is also performed to monitor the effectiveness of medication and other methods used to control **hypertension**.

Blood pressure should be routinely checked every one to two years. Hypertension often has no symptoms that would make the patient immediately aware that there is a problem and the patient may have had high blood pressure for many years. In most cases there is no known cause for the condition.

Precautions

As there may be no prior knowledge of the patient's previous blood pressure for comparison, it is important that the nurse is aware of the wide range of normal values that apply to patients of different ages. The inflated cuff can cause slight discomfort and this should be taken into account when dealing with very ill patients.

Description

Blood pressure is usually recorded by measuring the force of the blood in the **heart** where the pressure is greatest, during the contraction of the ventricles as blood is pumped from the heart to the rest of the body (systolic pressure), and during the period when the heart is relaxed between beats and pressure is lower (diastolic pressure).

The flow, resistance, quality, and quantity of blood circulating through the heart, and the condition of the arterial walls are all factors that influence the blood pressure. If blood flow in the arteries is restricted, the reading will be higher.

Hypertension is an elevation in the blood pressure above normal values, with the diastolic pressure being the indicator most commonly used.

Hypotension is a reduction in the blood pressure below normal values.

The blood pressure is taken using a **sphygmomanometer**, a hand bulb pump, and a cuff that is the correct size to give a more accurate reading. Children and

Technique for blood pressure measurement. (Delmar Publishers, Inc. Reproduced by permission.)

adults with smaller or larger than average-sized arms require special sized cuffs appropriate for their needs.

The sphygmomanometer may be electronic or mercury-based. The mercury-based unit has a manually inflatable cuff attached by tubing to the unit that contains mercury and is calibrated in millimeters of mercury. The electronic unit is similar, but is mercury free and inflates and deflates automatically with the reading displayed digitally. Blood pressure can be measured with either unit, although electronic units are becoming more commonplace.

To record blood pressure, the patient should be seated with the left arm bent slightly, the palm facing upwards and the arm bare or with the sleeve loosely rolled up. With an electronic unit, the cuff is placed level with the heart and wrapped around the upper arm, one inch above the elbow. Following the manufacturer's guidelines, the cuff is inflated and then deflated automatically and the nurse records the reading.

If the blood pressure is monitored manually, a cuff is placed level with the heart and wrapped firmly but not too tightly around the arm one inch above the elbow over the brachial artery, with any creases in the cuff smoothed

out. A **stethoscope** is placed over the brachial artery in front of the elbow, the cuff is then inflated until the artery is occluded and no sound is heard through the stethoscope. The cuff is then inflated a further 10 mm Hg above the last sound heard. The valve in the pump is slowly opened no faster than 5 mm Hg per second to deflate the pressure in the cuff to the point where a tapping sound is heard over the brachial artery. This point is noted as the systolic pressure. The sounds continue as the pressure in the cuff is released and the artery is no longer occluded. At this point, the noises are no longer heard and this is noted as the diastolic pressure.

With children, the tapping noise changes to a soft muffled sound. That point is noted as the diastolic pressure, as commonly in children, sounds continue to be heard as the cuff deflates to zero.

The results are charted with the systolic pressure first, then by the diastolic pressure in the following manner, xxx/xx (e.g. 120/70).

Preparation

Medical staff should explain the procedure fully to the patient and reassure them that recording their blood

KEY TERMS

Blood pressure—The pressure of the blood in the arteries measured in millimeters of mercury by a sphygmomanometer or by an electronic device.

Diastolic—Minimum arterial blood pressure during ventricular rest.

Hypertension—High blood pressure.

Hypotension—Low blood pressure.

Pre-eclampsia—A toxic disease occurring in pregnancy with symptoms including hypertension.

Systolic—Maximum arterial blood pressure during ventricular contraction.

pressure is part of normal health checks and that it is necessary to ensure their health is being correctly monitored. The appropriate sized cuff should be used for the patient to give an accurate reading.

The test can be performed at any time but is best performed when the patient has been resting for at least five minutes so that any exertion, such as climbing stairs prior to the test, will not unduly influence the outcome of the reading.

Devices should be checked and calibrated annually by a qualified technician to ensure accurate readings.

Aftercare

Make the patient comfortable. The medical staff should be notified if the blood pressure measurement is above or below normal values. Repeated measurements are required for screening purposes. One elevated reading does not mean that hypertension is present.

Complications

Certain physical or psychological conditions can affect a blood pressure measurement by elevating or lowering the reading. These include the following factors:

- stress, anger, or fear
- drugs, prescribed and illegal
- pre-eclampsia in pregnant women
- neurological disorders
- urological disorders
- cardiological disorders
- shock

- hemorrhage
- burns

There is a nationwide initiative to ban the sale of mercury thermometers and mercury devices for monitoring blood pressure. Health activists are concerned about mercury contaminating the environment after disposal of this equipment. Several states have banned the use of products containing mercury and stores such as Wal-Mart, CVS, and Kmart have already stopped selling mercury thermometers. According to a study by the Mayo Clinic in March 2001, mercury-free devices can monitor information without compromising accuracy. The Environmental Protection Agency (EPA) “Reducing Mercury Use in Health Care” in October 1999 advises using alternative devices to avoid the need for increased regulations in years to come and to protect human health and wildlife by reducing unnecessary exposure to mercury.

Results

The normal values for blood pressure measurement is a systolic pressure of 120 mm Hg and a diastolic pressure of 70-80 mm Hg.

Mild hypertension is a diastolic pressure above 90 mm Hg.

The American Heart Association states that a systolic pressure above 130-139 mm Hg needs to be watched carefully.

Significant hypertension is a systolic pressure above 200 mm Hg.

The blood pressure measurement is recorded and compared with normal ranges for the patient’s age and medical condition. Based on the results a decision is made as to whether any further action is required.

Hypertension increases the risk of serious diseases such as heart attack and stroke.

Health care team roles

Older children and parents may ask questions about specific concerns they have regarding their blood pressure measurement or a particular disease. The nurse can provide counseling on the normal values of blood pressure, the prevention of illness and injuries, or suggest visiting the patient’s doctor who can advise on additional methods to help maintain a healthy blood pressure.

Blood specimen collection

Definition

Blood specimen collection is performed routinely to obtain blood for laboratory testing. Blood can be obtained from venous access devices and sometimes by fingerstick. Blood is most frequently obtained via a peripheral vein puncture (venipuncture).

Purpose

Blood is usually drawn and collected in order to perform a variety of laboratory tests. Specimens are often sent to help diagnose conditions such as electrolyte imbalances, to screen for risk factors like high cholesterol levels, and to monitor the effects of treatments and medications.

Precautions

Although obtaining blood specimens is a routine function, it is one of the riskiest procedures nurses per-

form. To increase the safety of blood collection, these precautions should be followed:

- Avoid using syringes. Use vacuum tube blood-collection devices instead, preferably those with needle-stick prevention features.
- Do not use a needle when withdrawing blood from a peripheral intravenous line or from a central venous access device. Using a needleless system allows the blood to be drawn directly into specimen containers.
- Do not use an exposed needle to inject blood into specimen containers or vacuum tubes.

When drawing blood, the health care professional should follow **universal precautions** as set forth by the Centers for Disease Control and Prevention (CDC). Universal precautions help reduce the risk of exposure of the health care professional's skin and/or mucus membranes to infectious materials. It includes the use of a variety of protective barriers, such as gloves, masks, gowns, and eyewear. Good hand washing practices before and after drawing blood also reduce the exposure risk.

These precautions were designed to prevent the transmission of hepatitis B virus (HBV), human **immunodeficiency** virus (HIV), and other bloodborne pathogens. Universal precautions apply to blood, semen, vaginal secretions, and any other body fluids containing blood. They also apply to tissues, as well as pleural, cerebrospinal, synovial, peritoneal, pericardial, and amniotic fluids. Universal precautions do not apply to stool, nasal secretions, sputum, sweat, tears, urine, saliva, and vomit unless these visibly contain blood.

Description

Prior to obtaining blood specimens, the nurse should assess the patient, noting factors that may affect test results, including medications, **pregnancy**, age, and sex. Make sure the patient has followed any special instructions, which could include fasting for a number of hours or taking a medication at a certain time.

Patients should also be assessed for their knowledge level regarding the tests ordered. Instruct the patient as needed about the test and the procedure itself. Although most blood work does not require any special consent, some tests, like those for HIV, usually do. If needed, obtain consent prior to collecting the specimen.

There are four patient "rights" the nurse should consider when collecting blood specimens. These rights are:

- Right specimen. Make sure the specimen collected is the specimen ordered.

A health care professional uses a needle and syringe to take a blood sample from a patient. (Photograph by Faye Norman. Science Source/Photo Researchers. Reproduced by permission.)

- **Right time.** Certain blood tests must be obtained at specific times. For example, when drawing antibiotic levels, trough specimens should be obtained immediately prior to the next dose. The time to draw peak levels may be dependent upon whether the antibiotic is given intravenously, orally, or intramuscularly.
- **Right patient.** Always verify the patient's identification before drawing a blood specimen. The person drawing the specimen should also label the container it is drawn into.
- **Right method.** Always follow universal precautions when performing a venipuncture.

Before puncturing, the patient's skin should be cleaned. Povidone-iodine (Betadine) can be used, or alcohol, unless an ETOH level is being drawn (alcohol on the skin may elevate an ETOH result). Povidone-iodine should always be used if blood cultures are to be drawn.

Techniques to find a vein include lowering the arm into a dependent position to help dilate the veins; applying warm soaks on the arm to improve venous dilation; and having the patient open and close the fist after apply-

ing a tourniquet. The health care provider can also attempt to palpate a vein where it is expected to be, since veins can often be felt, yet not seen. Arteries pulsate and have a thick wall. Thrombosed veins feel cord-like, and roll easily.

There are three veins in the antecubital (the inner or front surface of the forearm) area that are appropriate for venipuncture: the medial, cephalic, and basilic veins. The vein of choice is the medial, because it is usually the closest to the skin's surface, the largest, and usually the least painful to puncture. If the antecubital sites cannot be accessed, wrist and hand veins are also acceptable for venipuncture.

Venipuncture is usually done using a vacuum container (Vacutainer) system. This system consists of vacuumized specimen tubes, a needle, and a plastic holder. When the tube is placed into the holder and pressed against the needle, negative pressure results, and blood is pulled into the tube. Normally, a 21-gauge needle is used to collect blood. Occasionally, depending on the test ordered and specific patient circumstances, a larger or smaller diameter needle may be appropriate. Never insert the needle at greater than a 30 degree angle. Doing so

increases the possibility of passing through the vein and into those structures lying underneath, raising the chances of permanent injury to the patient.

A number of other guidelines should be considered when performing venipunctures for blood specimen collection. These include:

- Avoid drawing blood from an arm affected by a stroke or neurological injury that has resulted in a loss of sensation. The patient may not be able to alert you if they experience **pain** or other problems.
- Avoid drawing blood from the arm on the affected side if a woman has had a mastectomy (full or partial breast tissue removal).
- Avoid areas with extensive scarring. Scar tissue is difficult to puncture.
- Attempt to collect the blood specimen from the opposite arm if a patient is receiving intravenous fluids, since fluid may dilute the blood sample.
- Do not use a site that is swollen, affected by certain skin conditions like eczema, or is infected.
- Use the right specimen tubes. Using the wrong tubes will cause the specimen to be rejected by the laboratory.
- Try using pediatric tubes when a patient has fragile veins that may not provide a large enough specimen. Though the smaller tubes store less blood, they will still give reliable results.
- Remove the tourniquet when the final tube of blood to be drawn is filling.
- Send the specimen to the laboratory as soon as possible.

Blood collection tubes come with a variety of colored stopper caps, and may contain additives. The following tubes are the most commonly used types:

- **Red top.** This tube contains no additives. It is used for a variety of tests, including blood typing and cross-matching.
- **Tiger top or serum separator tube (SST).** This tube contains a polymer gel and clot activator. When placed in a centrifuge, the serum is separated out. The SST is commonly used for blood chemistries.
- **Lavender top.** These tubes are used primarily for obtaining complete blood counts. They contain EDTA, an anticoagulant additive that chelates **calcium**.
- **Dark green top.** Green top tubes contain the anticoagulant heparin and are often used to obtain lithium and ammonia levels.

KEY TERMS

Hemoconcentration—An increased concentration of larger molecules and formed elements in the blood.

Hemolysis—The destruction of red blood cells which leads to the release of hemoglobin from within the red blood cells into the blood plasma.

- **Light blue top.** The light blue top tubes contain sodium citrate, an agent that removes calcium, and are used to obtain protime (PT) and prothrombin time (PTT).
- **Light gray top.** This specimen tube contains sodium fluoride and potassium oxylate, antiglycolytic agents that preserve glucose for up to five days. The tube is used primarily to obtain glucose levels.

It is important that blood collection tubes be drawn in a certain order to avoid the cross-contamination of additives between tubes. It is recommended that tubes be drawn in the following order:

- **Yellow-black stopper (blood culture tube).**
- **Red top.**
- **Light-blue top.** This should not be the first tube drawn. If a coagulation assay is ordered alone, draw a non-additive tube first (red or SST), then draw the light-blue top tube.
- **Additive tubes in the following order:** dark green, lavender, light gray.

All tubes containing additives should be thoroughly mixed. Not doing so can result in inaccurate test results.

Venipuncture is not always possible or appropriate for the blood specimen required. In these cases, a fingerstick or heelstick may be the method of choice for obtaining the specimen.

The best locations for fingersticks are the third and fourth fingers of the patient's non-dominant hand. Avoid using the center, tip, or side of the finger. Avoid sticking areas that are thick or callused, where there is little soft tissue, or where the bone is close to the surface. Do not puncture a finger that is swollen, cyanotic (blue because of oxygen deficiency), or scarred. The fingerstick is done using a sterile lancet. The first drop of blood should be wiped away, as this first drop tends to contain extra fluid from the tissues. Instead of firmly milking the finger, it should only be gently massaged to gain drops of blood. Milking can squeeze tissue fluid into the drops of blood and alter laboratory results.

A heelstick is the preferred method of blood collection on a newborn baby or infant. In order to increase the flow of blood to the heel, the baby's heel should be prewarmed. (Avoid using too high a temperature as a baby's skin is easily injured.) The site to be punctured should be cleaned with alcohol, then dried with a dry cotton ball. The baby's foot should be held firmly to avoid sudden movements, then the side of the heel is punctured using a sterile lancet. Puncturing the center area of the heel should be avoided, as this can injure the underlying bone. Gentle pressure can be used to increase the flow of blood. To avoid diluting the specimen with excess tissue fluid, do not apply too much pressure.

After performing either a fingerstick or heelstick, a gauze pad or cotton ball should be applied for about a minute, making certain the bleeding has stopped.

Preparation

The patient should be instructed about what blood tests have been ordered and why. Furthermore, explain the procedure and what the patient can expect. Ask the patient if anyone has had trouble drawing blood from him or her in the past. This may be an alert to potential problems in finding an appropriate vein. Also ask the patient what position would be most comfortable for them when drawing the specimen. Venipuncture makes many patients nervous, and having them lie down may help them to relax and better tolerate the procedure.

Aftercare

After obtaining the ordered specimens, remove the needle from the vein and discard into a puncture-proof container. Pressure should be applied to the site for about a minute (longer if the patient is on any anticoagulants). After applying pressure, inspect the site for any signs of bleeding or hematomas. Apply a bandage to the site. The specimen containers should then be labeled and sent to the laboratory. Make sure the patient is comfortable and not experiencing any adverse effects before allowing them to get up.

Complications

Though venipuncture is routinely done and relatively safe, there are a few complications that can occur, including hematoma formation, hemolysis, and hemoconcentration. In addition, excessive bleeding can occur, and many patients have been known to faint during the procedure.

Health care team roles

Blood specimen collection is performed primarily by nurses and phlebotomists. The physician orders the laboratory tests. The nurse is responsible for instructing the patient regarding the procedure and assessing the patient's response. In addition, the nurse should be knowledgeable about the implications laboratory results may have on patient care.

Blood vessels

Definition

Blood vessels compose a continuous system of channels through which blood transports oxygen and nutrients to and waste materials from all body tissues.

Description

Structure

All blood vessels (except capillaries) share a similar three-layered structure. The innermost layer, called the tunica intima, is composed of a monolayer of endothelial cells called the endothelium. The tunica intima helps to restrict the entry of substances into the vascular wall, control blood vessel diameter, and regulate coagulation.

The hollow center of a blood vessel is called the lumen and is the space through which blood flows.

The middle layer is called the tunica media and is separated from the tunica intima by a sheath of high-flexible material called the internal elastic lamina. The tunica media is composed of a circular arrangement of smooth muscle cells, collagen, and elastic fibers; it composes the bulk of the wall of most arteries but in veins is thinner and contains fewer smooth muscle cells. Smooth muscle contains contractile elements that are responsible for contraction (vasoconstriction) and relaxation (vasodilation). The tunica media, therefore, imparts strength, elasticity, and contractile abilities to the vessel wall.

Surrounding the tunica media is the tunica adventitia (the two layers are separated by the external elastic lamina). This outermost layer contains a matrix of collagen and elastic fibers that support fibroblasts (cells that secrete the fibrous **proteins** collagen and elastin), nerves, and vasa vasorum (small blood vessels that supply the walls of large arteries and veins with oxygen and nutrients).

Arteries and arterioles

Arteries are blood vessels that carry blood away from the **heart**. Arterial blood is oxygen-rich, with the exception of blood carried by the pulmonary artery from the heart to the **lungs** to be oxygenated. The aorta is the largest artery in the human body and originates at the left ventricle of the heart. This vessel and its major branches (the common carotid, common iliac, subclavian, and brachiocephalic arteries) are called elastic arteries because they expand and recoil in response to the pulsing flow of blood and to changing blood volume.

The elastic arteries branch to become muscular arteries, vessels with thick walls that transport blood to specific organs. Muscular arteries give rise to resistance vessels; these include small arteries and arterioles. As arteries become smaller, their walls become thinner and are composed of less collagen and elastin. The walls of small arteries have multiple layers of smooth muscle cells, while arterioles have only one or two. Resistance vessels are thus less stretchy but more active in regulating the flow of blood into capillary beds.

Anastomoses are formed where arteries and arterioles merge to provide alternative channels for blood delivery. They provide collateral circulation in the event that an artery becomes occluded (blocked).

Exchange vessels

Exchange vessels include capillaries and postcapillary venules. The walls of capillaries are composed of only a tunica intima (a thin layer of endothelial cells). The average diameter of the lumen is just large enough to

allow erythrocytes (red blood cells) to pass through in single file. Exchange vessels are the site where gases, nutrients, and wastes are exchanged between blood and surrounding tissues.

There are three major type of capillaries: continuous, fenestrated, and discontinuous. Continuous capillaries are the most abundant type in the human body and are found in skin, muscle, lungs, and the **central nervous system**. They have low permeability and therefore allow only limited passage of substances across the capillary wall. Fenestrated capillaries are much more permeable than continuous capillaries; their walls contain circular pores or fenestrae closed by a thin diaphragm. Discontinuous capillaries, also called sinusoids, have gaps between endothelial cells that are large enough to allow even erythrocytes to pass through the capillary wall. They are found in the **liver**, spleen, and bone marrow, as well as some endocrine glands.

The capillary bed is a network of capillaries that connect arterioles with venules; there are typically 10 to 100 capillaries per bed. Arterioles give rise to either capillaries or metarterioles, vessels that are wider than true capillaries and directly connect arterioles to venules. True capillaries branch off arterioles or metarterioles and are encircled at their origin by the precapillary sphincter, permitting the regulation of blood flow into the capillary. Arteriovenous (A-V) shunts are anastomoses that bypass the capillary bed completely; they are frequently seen in tissues that require increased blood flow.

Veins and venules

Veins are blood vessels that carry blood from the capillary beds to the heart. Capillaries give rise to venules (small veins that have walls composed of a thin layer of endothelial cells), which in turn converge to form veins. Blood from the head, neck, and arms is carried to the superior vena cava, while the inferior vena cava receives blood from the trunk and legs; these large veins empty into the right atrium of the heart. The veins carry blood that is oxygen-poor, with the exception of the pulmonary vein, which carries oxygenated blood from the lungs to the heart.

The walls of veins are thinner and the lumens larger than those of arteries. They can accommodate a large blood volume and may act as blood reservoirs, containing up to 70% of the body's total blood volume. Veins and venules are therefore called capacitance vessels. Most veins have a system of valves, paired folds of the tunica intima that prevent the backflow of blood.

KEY TERMS

Anastomoses—Connections formed where arteries and arterioles merge to provide alternative channels for blood delivery.

Arteries—Blood vessels that carry blood away from the heart.

Diastolic pressure—Diastole is the period in which the left ventricle relaxes so it can refill with blood; diastolic pressure is therefore measured during diastole.

Hydrostatic pressure—Force per unit area exerted by a fluid (blood) against a vessel wall.

Lumen—The hollow center of a blood vessel.

Osmotic pressure—The pressure required to prevent osmosis of fluid across a semi-permeable membrane. It is an indirect measurement of the water and solute concentrations of the solution.

Systolic pressure—Systole is the period of the cardiac cycle in which the aortic valve opens and blood flows into the aorta; systolic pressure is the maximal pressure during systole.

Tunica intima, media, adventitia—The three layers that compose the walls of large arteries and veins.

Vasa vasorum—Small blood vessels that supply the walls of large arteries and veins with oxygen and nutrients.

Veins—Blood vessels that carry blood from the capillary beds to the heart.

Function

Blood pressure

Blood pressure is defined as the force per unit area that flowing blood exerts on the wall of a vessel; it can be represented by the equation $Blood\ pressure = flow \times resistance$. Blood pressure is typically expressed in mm Hg (read as “millimeters of mercury”). It is usually recorded as two numbers: systolic pressure over diastolic pressure. Systole is the period of the **cardiac cycle** in which the aortic valve opens and blood flows into the aorta; systolic pressure is the maximal pressure during systole. Likewise, diastole is the period in which the left ventricle relaxes so it can refill with blood; diastolic pressure is therefore measured during diastole. It is generally assumed that a healthy young adult should have a blood

pressure of 120/80 mm Hg (i.e. systolic pressure of 120 mm Hg and diastolic pressure of 80 mm Hg).

Blood pressure is proportional to blood flow (the amount of blood flowing through a vessel per unit time) and vascular resistance. Pressures vary throughout the **cardiovascular system** depending on the type and size of blood vessel. The highest systemic blood pressure is found in the aorta and diminishes progressively along the arterial system; it reaches its lowest point in the veins.

There are a number of factors that influence blood pressure. An individual’s physical characteristics (i.e. sex, age, weight, race, or socioeconomic status) may positively or negatively affect blood pressure. Activities such as eating, drinking, sleeping, or smoking cause changes in pressure, as do mental activities or emotions such as **anxiety** or apprehension. Various disorders such as atherosclerosis, anemia, and **diabetes mellitus** have adverse effects on blood pressure.

Capillary dynamics

The capillary bed is the site at which gases, nutrients, and wastes are exchanged between the blood and surrounding tissues. It is surrounded by interstitial fluid, or lymph, which is produced by the **lymphatic system**. Substances are moved between blood and interstitial fluid across the capillary wall by means of diffusion (movement from a high to a low concentration). Oxygen and nutrients move from the blood to interstitial fluid, while carbon dioxide and wastes move in the opposite direction. Gases such as oxygen or carbon dioxide and lipid-soluble nutrients diffuse across the **cell membranes** of endothelial cells. Small openings in the capillary wall called slit pores or clefts exist where endothelial cells border each other; small water-soluble nutrients or wastes may diffuse through these clefts.

There are two types of pressure that are involved in capillary dynamics. Hydrostatic pressure is the force per unit area exerted by a fluid (blood) against a vessel wall. Colloid osmotic pressure is the pressure required to prevent osmosis of fluid across a semi-permeable membrane. Transcapillary filtration is determined not only by these pressures inside the blood vessels, but also by the same pressures outside the blood vessels. Osmotic pressure is an indirect measurement of the relative concentrations of water and solute in a solution; the higher the osmotic pressure of the solution, the lower the water concentration and therefore the higher the solute concentration of the solution. In a capillary, osmotic forces are exerted primarily by proteins, which are relatively impermeable to the capillary wall.

Role in human health

The 2001 “Heart and Stroke Statistical Update,” published by the American Heart Association, states that cardiovascular diseases (CVD) have been the leading cause of death in the United States every year since 1900, with the exception of 1918. CVD accounted for 40.6% of all U.S. deaths in 1998; over 60 million Americans are estimated to suffer from one or more CVD.

There are numerous factors that increase the risk of cardiovascular disease. These include:

- Major risk factors: tobacco smoke, race, genes, diabetes mellitus, high cholesterol levels, **hypertension**, physical inactivity, and **obesity**.
- Contributing risk factors: **stress**, high triglycerides, alcohol, oral contraceptives, **pregnancy**, **menopause**, and Syndrome X (a cluster of risk factors that include obesity, glucose intolerance, hypertension, and high cholesterol).

Blood vessels and blood flow can respond to a variety of local control factors, including neural (such as **shock**) or hormonal impulses (such as anger or fear). Blood vessels themselves can also grow (a process called angiogenesis) or remodel themselves in response to diseases such as ischemia and hypertension.

Common diseases and disorders

- Atherosclerosis: According to the American Heart Association, atherosclerosis accounts for nearly 75% of all cardiovascular-related deaths. It involves the accumulation of **lipids** and other substances on the inner lining of an artery; the area of buildup is called a plaque. As a result, the arterial wall thickens and hardens, losing elasticity. Thrombi (blood clots) form when plaques rupture; if these occlude the artery, a heart attack or stroke may result.
- Stroke: A stroke occurs when the **brain** has been deprived of oxygen due to interrupted blood flow, often caused by a blood clot or burst blood vessel. Depending on the area of the brain that is damaged, neurological damage may be reversible or irreversible and may include **coma**, **paralysis**, visual or speech problems, seizures, or impaired memory.
- Varicose veins: Permanent changes in the diameter and/or length of veins may result from damage to or failure of the venous valves. Gravity, obesity, pregnancy, and increasing age may also play a role in the development of varicose veins.
- Hemangiomas: These are usually benign vascular anomalies that may result in small, harmless birthmarks or sacs of vascular tissues of varying sizes that

may protrude from the skin. Hemangiomas are often only cosmetic blemishes but may, depending on their location, cause obstruction of the airway, block **vision**, or obstruct a vital organ.

- Aneurysm: An aneurysm results from the dilation of the wall of a blood vessel due to the weakening of the wall by disease, high blood pressure, or congenital defects. An abdominal aortic aneurysm is the most common type. A ruptured aneurysm is a serious medical emergency and requires surgical intervention.

Body positioning in x-ray studies

Definition

Body positions in x-ray exams are based on body part, suspected defect or disease, and condition of the patient. The radiographer, also known as the x-ray tech or more formally as the radiologic technologist, uses standardized body positions in performing an x-ray exam. Positions are learned by the radiographer according to body part in relation to body habitus, anatomical position and bisecting planes, and relationship of the body to the x-ray equipment.

Purpose

Since many body parts overlay other internal structures, the radiographer uses positioning of the body part as well as specific positions of the x-ray equipment to obtain clearer views of the overlapping structures. X-ray exams usually consist of two or more radiographs, taken in orthogonal planes or variations to the relationship of body part and x-ray equipment. Exams require radiographs to be taken at 90 degrees to each other where anatomy is superimposed over important structures, where alignment of fracture ends is questioned, or for localization of **foreign bodies**. Exams require a minimum of three radiographs when joints or articulations are in the area of interest, although some referring physicians may ask for only two. This allows for evaluation of the bones and well as the joints.

Precautions

The radiographer applies principles of immobilization in performing the exam. The use of immobilization has two purposes. First, the patient's safety is of primary importance to the radiographer. Second, immobilization assists the patient in maintaining the applied body position during the exam. Some x-ray exams require the patient to suspend breathing during the exposure such as for chest x rays. Suspension of breathing is a method of immobilization that the patient voluntarily performs. In other cases, the radiographer assists the patient in maintaining a position with the use of radiolucent sponges or other positioning aids.

Radiation protection is used to reduce or prohibit x-ray exposure to areas of the body that are biologically sensitive. The determinants of x-ray exposure include time spent under irradiation, distance of x-ray unit, and shielding practices. The most common practice of radiation protection is to protect the reproductive organs, especially in children and young adults. It is standard practice to question women of childbearing age if there is a possibility of **pregnancy**. Radiographic exams are not usually performed on pregnant women as the developing fetus is biologically sensitive to radiation.

Description

The use of body positioning requires an understanding of terminology that refers to the relationship of the body to the x-ray equipment and to anatomical references. All body positions and exam requirements are expressed in terms of projection, position, and view. A projection refers to the path the x rays take through the body, from entrance to exit. Position describes the body and its relationship to the x-ray film device (film cassette,

image intensifier, image receptor). View is not a positioning term but instead is used in discussion the radiograph. For example, the physician orders an upright chest x ray with two views of an ambulatory patient. The standard positions are P. A. (back to front) and lateral (from the side). The radiographer positions the patient standing at the x-ray image receptor for a posterior-anterior projection (the x rays pass from the patient's back to the front) and a left lateral projection (patient's left side closest to image receptor and x rays pass from the patient's right to left). Body positioning may also require adjacent areas be addressed, i.e., moving the arms out of the way.

Anatomical position

Anatomical position is the fundamental term used in body positioning. In this position, the patient is standing and facing front. The arms are down at the sides and the palms are turned forward so that you can see them. Feet are pointed straight ahead and the toes are lying down on the floor. The surface of the body that is facing front is known as the anterior, or ventral, surface. Any anatomical structure located in the half of the body that is adjacent to the anterior surface is considered to be anterior within the body. The surface of the body facing the rear is the posterior, or dorsal, surface. Any anatomical structure located in the half of the body that is adjacent to the posterior surface is considered to be posterior within the body. The body is also discussed in right and left sides using an imaginary line dividing the sides through the body's center.

Posture and relationship to x-ray equipment

X-ray exams are performed with either stationary or mobile equipment. Stationary equipment may be specialized for upright exams such as a chest x-ray unit or panoramic chair unit. Some stationary equipment only allows for the patient to lie down on a table for the exam. Other stationary equipment has a rotating table that allows for upright exams in addition to having the patient lie on the table. Mobile, or portable, x-ray equipment can accommodate a variety of patient positions. Regardless of the equipment used, the same principles and terminology of positioning are applicable.

Positions for x-ray exams may require description of posture, that is, whether the patient is to be lying down, standing, or seated. The patient's physical condition or ability to cooperate may also affect the positioning procedures used for the exam. If the patient is standing, the body is referred to as upright or erect. The general term for lying down is recumbent. It is necessary to describe the position as face up or face down. Supine position of a

patient describes lying on the back and facing up in anatomical position. Prone position describes the patient lying on the abdomen and facing down. For comfort, the patient may turn the head to the side unless the part to be x-rayed is the face, head, or neck. For some exams, the patient is slanted in a head-down position known as Trendelenburg.

Descriptions of the patient's position also varies by the projection. If an oblique projection is required, the body or body part (or the x-ray tube) is rotated 45 degrees from anatomical position. The side and surface closest to the image receptor describe the position. For example, a left anterior oblique describes the patient as having the left, anterior surface of the body closest to the receptor at 45 degrees from anatomical position. Another variation of position is decubitus. In the decubitus position, the patient is lying down and the x rays pass through the patient 90 degrees from the table or bed surface. In a lateral decubitus, the patient is lying on either the right or left side and the x-ray beam passes through the patient from anterior to posterior or posterior to anterior. The position is named for the side that the patient is lying on, i.e., left lateral decubitus describes the patient as lying on their left side. Lateral decubitus positions are used to image the chest or abdomen when it is necessary to demonstrate the presence of an air-fluid interface. In a dorsal decubitus, the patient is supine and the x rays pass through the body from right to left or left to right. This type of position is commonly used in lateral x rays of the spine when the patient cannot be moved into a standard lateral position.

Additional anatomical and movement terms

Additional terms are used to describe relationships of body parts or directions. These terms are often paired describing opposites. Cephalic, or superior, describes a direction toward the head of the body while caudal, or inferior, refers to the feet or away from the head. Proximal describes the source or beginning, i.e., the knee is proximal to the ankle. Distal directs you away from the source or beginning. Medial refers to the middle or toward the center of the body while lateral refers to the outside or away from the center. The surfaces of the hand and foot have special anatomical terms. Plantar refers to the sole of the foot, dorsum to the top or anterior surface of the foot, and palmar to the palm of the hand.

Movements of the joints are also important in body positioning. Flexion refers to decreasing the angle between two parts such as the bending of the elbow. Its opposite movement is extension. The hyperextended joint is straightened beyond neutral or bent so as to increase the normal angle beyond neutral. In describing

A technologist positions a patient's arm for an x ray.

(Photograph by Will & Deni McIntyre. Science Source/Photo Researchers. Reproduced by permission.)

flexion and extension of the spine, bending forward is flexion, neutral position is extension, and bending backward is hyperextension. Movement of the arms or legs toward the body's median line is known as adduction while moving them away from the body is abduction. Specialized movements are used to demonstrate stress on a joint. Such movements of the ankle and foot are performed without moving the leg. They are described as eversion, an outward movement, and inversion, an inward movement. Other specialized movements may be described for their effect on adjacent joints or articulations. If the hand is supinated, it is in anatomical position (palm facing up). If pronated, the palm faces down. X-ray exams of the shoulder may require views of both pronation and supination of the hand to completely evaluate structures of the head of the humerus as it articulates in the shoulder joint.

KEY TERMS

Articulation—A joint, a connection between bones.

Orthogonal planes—Intersecting planes, planes at right angles to each other.

Position—A body posture such as upright, recumbent, supine, prone, lateral, also the description of the posture of an anatomical part such as oblique.

Radiograph—X-ray image, either physical (on film or paper) or digital.

Radiographer—Allied health professional who performs diagnostic imaging exams using x rays, magnetic resonance imaging, computed tomography, sonography, and others.

Body habitus

The body habitus describes the basic body shape. Body shape is important in x-ray exams as the size, shape, and position of the organs varies by body type. The technologist should adjust the x-ray unit accordingly, in order to obtain an adequate image. There are four terms used to describe body habitus:

- Hyperstenic (large to massive). Chest and abdomen are broad and deep, **lungs** are short, diaphragm is high.
- Stenic (average).
- Hypostenic (slender).
- Asthenic (very slender). Chest is narrow, shallow, and long so diaphragm is low.

In the hyperstenic patient, the **stomach** typically lays across the abdomen at or above waist level. The stomach of a stenic patient is shaped like a comma laying slightly skewed from left to right and centered at the waistline. The stomach of a hypostenic patient is elongated into a “J” shape and may extend into the pelvis. Since the astenic patient appears to have little abdominal space between the diaphragm and pelvis, the stomach is quite long and slender lying primarily in the pelvis. An understanding of body habitus and the relationship of the organs in the chest, abdomen, and pelvis are essential in positioning for upper and lower gastrointestinal exams. In addition, other positioning considerations are important, including posture, respiration, and stomach contents.

Preparation

Most x-ray exams require little if any preparation by the patient. In many cases, the change from street clothes to a hospital gown is all that is required. Some exams may require the patient to fast for several hours while others may require ingestion of a radiopaque liquid that will define the gastrointestinal system in the radiographs. Special imaging procedures such as nuclear medicine, sonography, or **magnetic resonance imaging** may have additional preparation requirements.

Aftercare

Few x-ray examinations require aftercare. If the examination required an injection of medication or contrast media, instructions will be given about the contrast and care of the puncture site. Following examination of the gastrointestinal system, patients are typically instructed to drink plenty of fluids and are advised how the exam may affect bowel movements.

Complications

Complications following x-ray exams are rare. If an injection is required or catheter is used, there may be the typical complications at the puncture site—bruising, bleeding, and discomfort. Patients should be advised of the possibility of complications from their exam, preferably in writing.

Health care team roles

Although the radiographer actually performs the examination in most cases, there are other members of the health care team in the radiology department or imaging center. Many facilities have transport personnel whose job it is to move patients in and out of the imaging rooms and department. These individuals are trained in the safe handling of patients and support equipment as well as proper lifting techniques and **universal precautions** against infections. Many hospitals provide a radiology nurse to perform injections, assist the physician in special procedures, or provide patient care as required. The radiologist will interpret the resulting images.

Boils

Definition

Boils, also called furuncles, and carbuncles are bacterial infections of hair follicles and surrounding skin that form pustules (small blister-like swellings containing pus) around the follicle. A carbuncle results when several boils merge to form a single deep **abscess** with several heads, or drainage points.

Description

Boils and carbuncles are firm reddish swellings about 0.2–0.4 inches (5–10 mm) across that are slightly raised above the skin surface. They are sore to the touch. A boil usually has a visible central core of pus; a carbuncle is larger and has several visible heads. Boils occur most commonly on the face, back of the neck, buttocks,

upper legs and groin area, armpits, and upper torso. Carbuncles are less common than single boils; they are most likely to form at the back of the neck. Males are more likely to develop carbuncles.

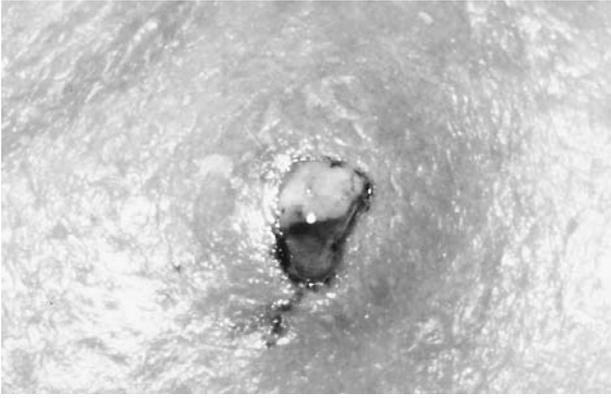

Boils and carbuncles are common problems in the general population, particularly among adolescents and adults. People who are more likely to develop these skin infections include those with:

- diabetes, especially when treated by injected insulin
- alcoholism or drug abuse
- poor personal hygiene
- crowded living arrangements
- jobs or hobbies that expose them to greasy or oily substances, especially petroleum products
- allergies or **immune system** disorders, including **HIV infection**
- family members with recurrent skin infections

Causes and symptoms

Boils and carbuncles usually are caused by *Staphylococcus aureus*, a bacterium that causes an infection in an oil gland or hair follicle, or they might be caused by other **bacteria** or **fungi**. Although the surface of human skin is usually resistant to bacterial infection, *S. aureus* can enter through a break in the skin surface—including breaks caused by needle punctures for insulin or drug injections. Hair follicles that are blocked by greasy creams, petroleum jelly, or similar products are more vulnerable to infection. Bacterial skin infections can be spread by shared cosmetics or washcloths, close human contact, or by contact with pus from a boil or carbuncle.

As the infection develops, an area of inflamed tissue gradually forms a pus-filled swelling or pimple that is painful to touch. As the boil matures, it forms a yellowish head or point. It may either continue to swell until the point bursts and allows the pus to drain, or it may gradually be reabsorbed into the skin. Boils can cause a lot of **pain** when they occur in the ear canal, nose, or other sensitive areas. It takes between one and two weeks for a boil to heal completely after it comes to a head, discharges pus, and crusts over. The bacteria that cause the boil can spread into other areas of the skin and even into the bloodstream if the skin around the boil is squeezed. If the infection spreads, the patient will usually develop chills and **fever**, swollen lymph nodes (lymphadenitis), and red lines in the skin running outward from the boil. Fatigue and general discomfort are other possible symptoms.

Boils often occur from a bacterial infection in a hair follicle or skin gland. (Custom Medical Stock Photo. Reproduced by permission.)

Furunculosis is sometimes used to refer to recurrent boils. Many patients have repeated episodes of furunculosis that are difficult to treat because their nasal passages carry colonies of *S. aureus*. These bacterial colonies make it easy for the patient's skin to be re-infected. They are most likely to develop in patients with diabetes, HIV infection, or other immune system disorders.

Carbuncles are formed when the bacteria infect several hair follicles that are close together. Carbunculosis is sometimes used to refer to the development of carbuncles. The abscesses spread until they merge with each other to form a single large area of infected skin with several pus-filled heads. Patients with carbuncles may also have a low-grade fever or feel generally unwell.

Diagnosis

The diagnosis of boils and carbuncles is usually made by the patient's primary care doctor on the basis of visual examination of the skin. In some cases involving recurrent boils on the face, the doctor may consider acne as a possible diagnosis, but, for the most part, boils and carbuncles are not difficult to distinguish from other skin disorders.

S. aureus can easily be cultured in the laboratory if the doctor needs to rule out inclusion cysts or deep fungal infections that gardeners sometimes get. The doctor can take a culture from pus taken from the boil or carbuncle to confirm the diagnosis of a staphylococcal infection. He or she can also culture the patient's nasal discharge to test for the presence of a *S. aureus* colony.

Treatment

Some boils heal spontaneously before progressing to pustules. Often, they become pustules that eventually burst, drain and then heal by themselves. Boils usually occur and are healed in about two weeks. Patients who have boils that take longer than two weeks to heal should see a doctor. Other reasons to seek professional medical advice are if boils recur, are located on the spine or the middle of the face, or are accompanied by symptoms such as fever. These boils are most at risk for spreading the infection.

Patient and family education

Patient education is an important part of the treatment of boils and carbuncles. Patients need to be warned against picking at or squeezing boils because of the danger of spreading the infection into other parts of the skin or bloodstream. It is especially important to avoid squeezing boils around the mouth or nose because infection in these areas can be carried to the **brain**. Patients should also be advised about keeping the skin clean, washing their hands carefully before and after touching the boil or carbuncle, avoiding the use of greasy cosmetics or creams, and keeping their towels and washcloths separate from those of other family members. Some doctors may recommend an antiseptic soap or gel for washing the infected areas. People who have boils often benefit from applying warm compresses several times a day to help the boils come to a head and drain.

If the patient has had several episodes of furunculosis, the doctor may examine family members or close contacts to see if they are carriers of *S. aureus*. In many cases, some of the family members may also need treatment for boils or carbuncles. Skin infection and re-infection involving small groups or clusters of people are being reported more frequently in the United States.

Medications

Boils are usually treated with application of topical antibiotic creams, such as clindamycin or polymyxin, following the use of hot compresses to help the infection drain, which speeds healing.

Carbuncles and furunculosis are usually treated with oral **antibiotics** as well as topical antibiotic creams or ointments. The specific medications that are given are usually dicloxacillin (Dynapen) or cephalexin (Keflex); erythromycin may be given to patients who are allergic to penicillin. The usual course of oral antibiotics is 5–10 days, although patients with recurrent furunculosis may be prescribed oral antibiotics for longer periods. Furunculosis is also treated with a combination of

dicloxacillin and rifampin (Rifadin). Still, many experts agree that topical antibiotics help very little once the boil has formed.

Patients with bacterial colonies in their nasal passages are often given mupirocin (Bactroban) to apply directly to the lining of the nose.

Surgical treatment

Boils and carbuncles that are very large, or that are not draining, may be opened by a doctor with a sterile needle or surgical knife to allow the pus to drain. The patient is usually administered a local anesthetic if a knife is used as surgical treatment of boils is painful, and frequently leaves noticeable scars.

Alternative treatment

Naturopathic practitioners usually recommend changes in the patient's diet as well as applying herbal poultices to the infected area. The addition of **zinc** supplements and **vitamin A** to the diet has been reported to be effective in treating boils. The application of a paste or poultice containing goldenseal root (*Hydrastis canadensis*) is recommended by naturopaths on the grounds that goldenseal helps to kill bacteria and reduce inflammation.

Homeopaths maintain that taking the proper homeopathic medication in the first stages of a boil or carbuncle will bring about early resolution of the infection and prevent pus formation. The most likely choices are *Belladonna* or *Hepar sulphureus*. If the boil has already formed, *Mercurius vivus* or *Silica* may be recommended to bring the pus to a head.

A variety of herbal remedies can be applied topically to boils to fight infection. These include essential oils of bergamot (*Citrus bergamia*), chamomile (*Matricaria recutita*), lavender (*Lavandula officinalis*), and sage (*Salvia officinalis*), as well as tea tree oil (*Melaleuca* spp.). Herbalists also recommend washing the skin with a mixture of goldenseal and witch hazel. To fight the inflammation associated with boils, herbalists suggest mixing marsh mallow (*Althaea officinalis*) ointment, tinctures (herbal solutions made with alcohol) of blue flag (*Iris versicolor*) or myrrh (*Commiphora mol mol*), and slippery elm (*Ulmus fulva*) into a poultice.

Prognosis

The prognosis for most boils is excellent, although some patients suffer from recurrent carbuncles or furunculosis. In addition, though the spread of infection from boils is relatively unusual, there have been deaths reported from brain infections caused by squeezing boils on the

KEY TERMS

Abscess—A localized collection of pus in the skin or other body tissue.

Carbuncle—A large, deep skin abscess formed by a group or cluster of boils.

Follicle—The small sac at the base of a hair shaft. The follicle lies below the skin surface.

Furunculosis—A condition in which the patient suffers from recurrent episodes of boils.

Pustule—A small raised pimple or blister-like swelling of the skin that contains pus.

upper lip or in the tissue folds at the base of the nose. Some patients also experience permanent scarring of the skin.

Health care team roles

Nurses help to educate patients about how to avoid infection of boils, ensure proper healing, and prevent recurrence. The nurse might also take a culture of the affected area to confirm the doctor or nurse practitioner's diagnosis. If in-office surgery to drain the boil is indicated, the nurse might assist in preparation for the procedure and during the procedure.

Prevention

There are some precautions that people can take to minimize the risk of developing bacterial skin infections:

- Cleanse the skin properly with soap and water, and take showers rather than tub baths.
- Do not share washcloths, towels, or facial cosmetics with others.
- Cut down on greasy or fatty foods.
- Always wash hands before touching the face.
- Consider using antiseptic soaps and shower gels.
- Consult a doctor if furunculosis is a persistent problem—it may indicate an underlying disease such as diabetes.

Bone cancer see **Sarcomas**

Bone densitometry

Definition

A bone densitometry test, or scan, is designed to check for **osteoporosis**, a disease that occurs when the bones become thin and weak. Osteoporosis happens when the bones lose **calcium** and other **minerals** that keep them strong. Osteoporosis begins after **menopause** in many women, and worsens after age 65, often resulting in serious **fractures**. These fractures may not only bring disability, but may affect longevity. As many as one-fourth of women who fracture their hip after age 50 die within one year.

Most people today will get a bone density scan from a machine using a technology called dual energy x-ray absorptiometry, or DEXA. This machine takes a picture of the bones in the spine, hip, total body and wrist, and calculates their density. If a DEXA machine is not available, bone density scans can also be done with dual photon absorbtometry (measuring the spine, hip and total body) and quantitative computed tomography scans (measuring the spine). Bone density scanners that use DEXA technology to just measure bone density in the wrist (called pDEXA scans) provide scans at some drugstores. Yet these tests are not as accurate as those that measure density in the total body, spine or hip—where most fractures occur. The DEXA scanner is most commonly found in large medical groups and medical centers.

Two newer devices are also available to check bone density. The Sahara Clinical Bone Sonometer, introduced in 1998, uses the velocity of sound waves to determine bone density. The device is much smaller than the DEXA scanner and requires that the seated patient place the foot in the scanner for about one minute. The device sends

ultrasound waves through the heel. Since the device is much smaller and cheaper than the DEXA machine, it is found most commonly in doctor's offices. The second device, introduced in 2000, is the Alara MetriScan, a tabletop scanner that allows clinicians to perform the test in a doctor's office. The patient puts the nondominant hand on the device's platform and the scan is done by x-raying the fingers.

Purpose

A bone density scan measures the strength of an individual's bones and determines the risk of fracture.

Precautions

The test is not recommended for people who cannot lay flat for the test, and people with **heart failure** or back problems. People who are severely overweight may not be able to take the test if the machine cannot support their weight.

Description

To take a DEXA bone density scan, the patient lies on a bed underneath the scanner, a curving plastic arm that emits x rays. These low-dose x rays form a beam that scans the patient. During the test, the scanner moves to capture images of the patient's spine, hip or entire body. A computer then compares the patient's bone strength and risk of fracture to that of other people in the United States at the same age and to young people at peak bone density. Bones reach peak density at age 30 and then start to lose mass. The test takes about 20 minutes to do and is painless. The DEXA bone scan costs about \$250. Some insurance companies and **Medicare** cover the cost. pDEXA wrist bone scans in drugstores are available for about \$30.

A patient may need a bone density scan and can discuss this with the doctor if he or she:

- is near menopause
- has broken a bone after a modest trauma
- has a family history of osteoporosis
- uses steroid or antiseizure medication
- has had a period of restricted mobility for more than six months
- has **hypertension** (high **blood** pressure)
- smokes

Bone densitometry scans are used primarily in women, due to the relationship between bone density loss and menopause. However, there are some instances

where a bone density scan may be in order for men with the following risk factors:

- low testosterone levels
- a family history of osteoporosis
- has been taking glucocorticoids (a group of steroids involved in carbohydrate, fat, and protein metabolism)
- has hyperparathyroidism (the presence of excess of the parathyroid hormone parathormone that is associated with calcium utilization)
- has suffered a fracture with a minimum amount of trauma
- has or has had **prostate cancer** that was treated with hormones or radiation

Preparation

The patient wears comfortable but loose clothing, such as a sweatsuit, and lies on the table underneath the scanner. The patient must not be wearing any metal objects that would interfere with the scan, including zippers, fasteners, and jewelry.

Aftercare

No post-treatment procedures or care are required following a bone densitometry scan.

Complications

The DEXA bone scan exposes the patient to only a small amount of radiation—about one-fiftieth that of a **chest x ray**.

Results

The patient's bone density is compared with the normal bone density (called a T-score.) A T-score above 1 means that a patient has a better bone mass than is typical. Scores from 0 to -1 mean that the patient has normal bone mass and should repeat the test in two to five years.

If patients' T-scores range from -1 to -2.5, they have low bone mass and are at risk for osteoporosis. A T-score below -2.5 means osteoporosis is already evident. These patients should have a repeat bone density scan every year or two to assess the response to therapy.

Health care team roles

The DEXA test is done primarily by a radiology or nuclear medicine technician. The ultrasound and hand x-ray scans are administered mainly by registered nurses (RNs). The tests are reviewed and treatment prescribed

KEY TERMS

Calcium—A mineral that helps build bone. After menopause, when women start making less of the bone-protecting hormone estrogen, they may need to increase their intake of calcium.

DEXA bone density scan—A bone density scan that uses a rotating x-ray beam to measure the strength of an individual's bones and his or her fracture risk.

Osteoporosis—A disease that occurs when the bones lose the calcium and structure that keep them strong. It often occurs after menopause (around age 50) in women and in old age in men.

by a physician. RNs also help educate the patient on the role **nutrition** and **exercise** play in bone health.

Bone density test see **Bone densitometry**

Bone marrow aspiration and biopsy

Definition

Bone marrow aspiration, which is also called bone marrow sampling, is the removal by suction of the soft, spongy semisolid tissue (marrow) that fills the inside of the long and flat bones. Bone marrow biopsy, or needle core biopsy, is the removal of a small piece (about 0.75 by 0.06 inch, or 2 by 0.16 cm) of intact bone marrow. The bone marrow is where **blood** cells are made.

Purpose

Examination of the bone marrow may be the next step that follows an abnormal clinical finding, abnormal **complete blood count** (CBC), and/or an abnormal peripheral blood smear. It may be performed following an abnormal bone image such as the finding of a mass lesion on x ray.

A biopsy of bone marrow shows the intact tissue, so that the fat cells, lymphocytes, plasma cells, fibrous connective tissue cells, and other cells can be seen in their overall structure, and in their relationships to each other. Bone marrow biopsy is used to:

- Aid in the diagnosis and management of any form of leukemia or other myeloproliferative condition such as multiple myeloma.
- Rule out or identify bone marrow infiltration of other malignancies such as Hodgkin's disease, non-Hodgkin's lymphoma, and metastatic carcinoma.
- Monitor the effects of **chemotherapy** and the response or lack of response to treatment of blood disease.
- Evaluate the success of bone marrow transplantation.
- Diagnose certain genetic diseases (e.g., lipid storage disease).
- Investigate pancytopenia (a decrease of all blood cells in peripheral blood), neutropenia (decreased phagocytic white blood cells), or thrombocytopenia (decreased platelets).
- Diagnose an **infection** of unknown origin.
- Investigate rare **anemias** for which a cause cannot be found or which does not respond to treatment as anticipated.

- Obtain intact bone marrow for laboratory analysis.
- Diagnose some types of **cancer** or anemia and other blood disorders.
- Identify the source of an unexplained **fever** (e.g. granulomatous lesions).
- Diagnose fibrosis of bone marrow and myeloma when bone marrow aspiration has failed to provide an appropriate specimen.

The combination of aspiration and biopsy procedures are commonly used together to ensure the availability of the best possible bone marrow specimen. The aspirate is collected at the same time as the bone core biopsy by attaching a syringe to the bone marrow needle and withdrawing the sample before the cutting blades are inserted and the bone core is removed. The aspirate is the sample of choice for studying and classifying the nucleated blood cells of the bone marrow (e.g., determining the ratio of immature white blood cells to red blood cells, the M:E ratio). The biopsy is the only sample that shows the blood forming cells in relation to the structural and connective tissue elements (i.e., the microarchitecture) of the bone marrow. It is the best sample to evaluate the cellularity of the bone marrow (the percentage of blood forming tissue versus fat).

Precautions

The bone marrow procedure is performed with strict attention to **aseptic technique** and **universal precautions** for the prevention of transmission of bloodborne pathogens. Fixation fluids, slides, and tubes with proper anticoagulant should be at the bedside so that the specimen can be preserved immediately and slides prepared that are of suitable quality. **Obesity** can affect the ease with which a bone marrow biopsy can be done, and the results can be affected if the patient has had radiation therapy at the biopsy site.

Description

Bone marrow aspiration and biopsy are performed by a pathologist, hematologist, or oncologist with special training in this procedure. The procedure may be performed on an outpatient basis. In adults, the specimen is usually taken from the posterior superior iliac crest (hip). The sternum may be used for aspiration, but is less desirable because it carries the risk of cardiac puncture. Other sites that are rarely used are the anterior superior iliac crest or a spinous process of a vertebra, a spinal column bone. When the patient is a child, the biopsy site is generally the anterior tibia, the larger of the two bones in the lower leg. A vertebra may also be used.

The skin covering the biopsy site is cleansed with an antiseptic, and the patient may be given a mild sedative. The patient is positioned, and a local anesthetic such as lidocaine is administered first under the skin with a fine needle and then around the bone at the intended puncture site with a somewhat larger gauge needle. After the area is numb a small incision is made in the skin and the biopsy needle is inserted. Pressure is applied to force the needle through the outer bone and a decrease in resistance signals entry into the marrow cavity. The needle most often used for bone marrow biopsy is a Jamshidi trephine needle or a Westerman-Jensen trephine needle. A syringe is placed on the hub of the needle and 1-2 mL of the bone marrow is aspirated into the syringe. In some instances, the marrow cannot be aspirated because it is fibrosed or packed with neoplastic cells. The syringe is removed and the medical technologist uses this sample to prepare several smears containing small bone spicules. Another syringe is fitted onto the needle hub and another sample of 3 mL is removed and transferred to a tube containing EDTA for analysis by flow cytometry, cytogenetic testing or other special laboratory procedure. Following aspiration, the cutting blades are inserted into the hollow of the needle until they protrude into the marrow. The needle is then forced over the tips of the cutting blades and the needle is rotated as it is withdrawn from the bone. This process captures the core sample inside the needle. A wire probe is inserted at the cutting end and the bone marrow sample is pushed through the hub of the needle onto sterile gauze. The specimen is used to make several touch preparations on glass slides or coverglasses and is transferred to a fixative solution.

In the laboratory the aspirate slides are stained with Wright stain or Wright-Giemsa stain. The biopsy material is sectioned onto glass slides and stained with hematoxylin-eosin, Giemsa, and Prussian blue stains. Prussian blue stain is used to evaluate the amount of bone marrow **iron** and the other stains are used to evaluate cell morphology. In addition, special stains may be used that aid in the classification of malignant white blood cells.

Preparation

The physician should be told of any medication the patient is using and any **heart** surgery that the patient has undergone.

Aftercare

After the needle is removed, the biopsy site will be covered with a clean, dry pressure bandage. The patient must remain lying down and is observed for bleeding for one hour. The patient's pulse, breathing, **blood pressure**, and temperature are monitored until they return to

Medical workers filter the bone marrow following aspiration. (Custom Medical Stock Photo. Reproduced by permission.)

normal. The biopsy site should be kept covered and dry for several hours.

The patient should be able to leave the clinic and resume most normal activities immediately. Patients who have received a sedative often feel sleepy for the rest of the day; so driving, cooking, and other activities that require clear thinking and quick reactions should be avoided. Walking or prescribed **pain** medications usually ease any discomfort felt at the biopsy site, and ice can be used to reduce swelling.

A doctor should be notified if the patient:

- Feels severe pain more than 24 hours after the procedure.
- Experiences persistent bleeding or notices more than a few drops of blood on the wound dressing.
- Has a temperature above 101°F (38.3°C). Inflammation and pus at the biopsy site and other signs of infection should also be reported to a doctor without delay.

Complications

A small amount of bleeding and moderate discomfort often occur at the biopsy site. Rarely, reactions to anesthetic agents, infection, and hematoma (blood clot) or hemorrhage (excessive bleeding) may also develop. In rare instances, the heart or a major blood vessel is pierced when marrow is extracted from the sternum during bone marrow biopsy. This can lead to severe hemorrhage.

KEY TERMS

Aspiration—A procedure to withdraw fluid and cells from the body.

Connective tissue—Cells such as fibroblasts, and material such as collagen and reticulin, that unites one part of the body with another.

Fibrosis—A condition characterized by the presence of scar tissue, or reticulin and collagen proliferation in tissues to the extent that it replaces normal tissues.

Hematologist—A specialist who treats diseases and disorders of the blood and blood-forming organs.

Hematoma—Blood that collects under the skin, forms a blood clot, and causes swelling.

Hemorrhage—Heavy bleeding.

Lymphocytes—Certain white blood cells that have an immune function. The lymphocytes are composed of three main cell lines; B lymphocytes, T lymphocytes, and natural killer (NK) cells.

Myeloma (multiple myeloma)—A tumor of plasma cells that originates in bone marrow and usually spreads to more than one bone.

Needle biopsy—The procedure of using a large hollow needle to obtain a sample of intact tissue.

Pathologist—A medical doctor that specializes in the study of diseases and laboratory tests.

Plasma cells—Cells in the blood and bone marrow that are formed from B lymphocytes, and that produce antibodies.

White blood cells (leukocytes)—Cells of the blood that are composed of neutrophils, monocytes, lymphocytes, eosinophils, and basophils.

Results

Healthy adult bone marrow contains yellow fat cells, connective tissue, and red marrow that produces blood. Bone marrow is evaluated for cellularity, megakaryocyte production, M:E ratio, differential (classification of blood forming cells), iron content, lymphoid, bone, and connective tissue cells, and bone and blood vessel abnormalities. The bone marrow of a healthy infant is primarily red (75-100% cellularity), but the distribution of blood forming cells is very different than adult marrow. Consequently, age related normal values must be used.

Microscopic examination of bone marrow can reveal leukemia, granulomas, myelofibrosis, myeloma, lymphoma, or metastatic cancers, bone marrow infection, and bone disease. Bone marrow evaluation is usually not needed to diagnose anemia, but may be useful in cases that cannot be classified by other means.

Health care team roles

A physician requests or orders the procedure. The aspirate and biopsy are most often performed by a hematologist or pathologist that has been trained in the procedure. The analysis of the bone marrow is done by a pathologist, and a written report is added to the patients medical record. A histologic technician performs special stains for bone marrow. Clinical laboratory scientists/medical technologists perform smear reviews and analysis of bone marrow cells by flow cytometry. Cytogenetic technologists may perform chromosomal analysis of bone marrow white blood cells.

Bone radionuclide scan

Definition

A bone scan is a diagnostic imaging procedure used to evaluate abnormalities involving bones and joints. A radionuclide is injected intravenously, and its distribution in the **skeletal system** is analyzed to detect certain diseases or conditions.

Purpose

Bone scans are performed to evaluate metastases, trauma, arthritis, metabolic diseases, bone marrow hyperplasia, and Paget's disease. Bone scans are most frequently ordered to investigate the cause of bone **pain** or to check whether a **cancer** originating in another organ has spread to the bones. For example, certain cancers, such as breast and prostate, are most likely to spread, or metastasize, to the bones. If metastases are found, periodic bone scans may be ordered to determine if therapeutic treatment has been effective.

If there is a suspected fracture that is not revealed on x ray, a bone scan is performed to confirm the suspicion of a fracture. When an abnormality is found on an x ray of a bone, a bone scan may be helpful in determining the nature of the abnormality. **Infection** in the bone (osteomyelitis) can be detected or confirmed by a bone scan, often days or weeks before an x ray would reveal it. Bone scans are useful in diagnosing early arthritic changes, and monitoring both the progression of the disease and the effectiveness of treatment. Unexplained pain may be evaluated with a bone scan, because it can demonstrate **fractures** which are difficult to detect on x ray. Bone scans can be used to see if artificial joints have loosened or become infected. Suspected **child abuse** may be evaluated with a bone scan, due to its ability to see an overall pattern of repeated trauma. Abnormalities caused by altered circulation to the bone may be diagnosed with a bone scan.

Precautions

The use of a radioactive substance is required to perform a bone scan, and therefore women who are pregnant should not have this test unless her physician indicates that the benefit will outweigh the risks. If a woman is breastfeeding, she will be advised to stop for a specified period of time, usually for one day, depending on the dose. A patient who is unable to remain still for an extended period of time may require light sedation for a bone scan.

Description

This test is performed in a radiology or a nuclear medicine facility, either in a hospital department or an outpatient x-ray center. The patient usually sits or lies down while a radioactive substance is injected through a vein in the arm. For a bone scan, the radionuclide used is specifically chosen because it accumulates in bone tissue. The patient then waits from three to four hours for the substance to collect within the skeletal system. Excess radionuclide is excreted through the **urinary system** and it is customary that, during the waiting time, the patient will be asked to drink several glasses of water. Patients are free to get up and move around as they desire during the waiting time. Just before the scanning begins, the patient will be asked to empty their bladder so that pelvic bones will not be obscured by residual radioactivity collected in the bladder. During the scan, the patient lies on his or her back on a table, but may be repositioned onto the **stomach** or side during the study. It is important for the patient not to move, except when directed by the technologist.

The radionuclide scanner, sometimes called a gamma camera, or scintillation camera, is positioned against the body part to be examined. Either the camera, the table, or both, may change position during the study. For a total body bone scan, the patient is scanned from head to foot, over a period of 30 to 60 minutes. Images are obtained both anteriorly and posteriorly and occasionally, a lateral image may be obtained. Patients should experience no discomfort from this examination. A special kind of bone scan, called a SPECT (Single Photon Emission Computed Tomography) scan may be added, to study a particular part of the body in more detail. Suspected diseases of the hips, lower back, or jaw are often evaluated using this study. It usually takes an additional 30 to 45 minutes. The camera circles completely around the area in question and helps pinpoint the location of the abnormality being evaluated.

Another variation is called a triple-phase, or three-stage, bone scan, which demonstrates **blood** flow to the bones. The procedure is the same, except the scanning takes place immediately after the radioactive substance is injected for approximately 20 minutes after the injection, and then again two to four hours later.

Preparation

Some specialized blood studies should be drawn before this study is performed. Jewelry or metallic objects need to be removed. No other special physical preparation is required. The patient should understand that there is no danger of any significant radioactive exposure to themselves or others, as only small amounts of the radioisotope

are used. The total dose of radiation absorbed is minimal, often less than the amount received from ordinary x rays. The radionuclide scanner does not emit any radiation at all, but detects and records it from the patient.

Aftercare

Fluids are encouraged after the scan to aid in the excretion of the radionuclide. It is almost completely eliminated from the body within 24 hours.

Complications

There are no complications associated with this test.

Results

The normal appearance of the scan will vary according to the patient's age. In general, a uniform concentration of radionuclide uptake is present in all bones in a normal scan. A high concentration of radionuclide occurs in areas of increased bone **metabolism**. These regions appear brighter and may be referred to as "hot spots." They may indicate healing fractures, tumors, infections, inflammations, or other processes which trigger new bone formation. Lower concentrations of radionuclide may be called "cold spots." Poor blood flow to an area of bone, or bone destruction from tumor may produce a cold spot. The bone scan is a very sensitive test and can detect subtle conditions more readily than other studies. However, it is not a very specific examination, and often cannot distinguish exactly what disease process is causing an abnormality. Results need to be correlated with the patient's medical history, and other radiologic and laboratory studies to make a definite diagnosis.

Health care team roles

Bone scans are performed by a nuclear medicine technologist. In most facilities, the nuclear medicine technologist is a trained individual with certification. The technologist administers the radioactive material, obtains pertinent medical history from the patient, and instructs the patient about the procedure. The data collected is interpreted by a doctor who is a radiologist or nuclear medicine specialist and the results of the bone scan are obtained from the referring physician. Since there is no preparation for this test the services of other medical personnel are generally not required.

Bone x rays

Definition

Bone x rays are a diagnostic imaging test in which ionizing radiation passes through the bone. This enables an image of the bone to be produced either digitally or on film.

Purpose

Bone x rays are ordered to detect disease or injury to the bones, such as broken bones (**fractures**), tumors, or other problems. They are often used to rule out a fracture vs soft-tissue injury. They can determine bone density, texture, erosion, and changes in bone relationship and anatomy. Bone x rays also evaluate the joints for diseases such as **osteoarthritis**.

Precautions

Precautions should be taken to protect patients from unnecessary exposure to radiation. Patients should be shielded with lead aprons as much as possible especially when undergoing numerous x rays over short periods of time. Women of childbearing age who could be pregnant should avoid x rays of their pelvic region, lumbar spine, and abdomen unless absolutely necessary. The fetus is especially at risk during the first trimester of **pregnancy**. If other types of x rays are necessary, a lead apron should be used to shield the abdominal and pelvic regions.

Description

X rays are a common diagnostic test in which a form of energy called ionizing radiation penetrates the patient's body. In bone x rays, electrical current passes through an x-ray tube and produces a beam of ionizing radiation that passes through the bone(s) being examined. This produces a picture of the inside of the body on film. The physician reads the developed film on a wall-mounted light box.

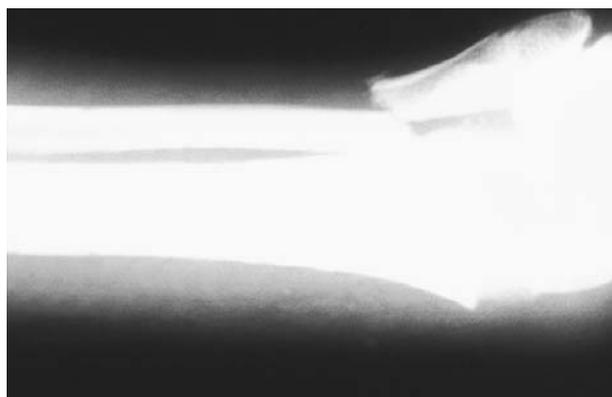

Alternatively, digital x rays are a new type of x ray in which conventional equipment is used to take the x ray but the image is produced via computer. In a digital x ray, the image is created on a reusable plate. After being read by a laser reader, the information is sent in digital form to a storage unit connected to a computer network from which the radiologist reads the image. An electronic report can then be sent to the patient's physician. In addition, these digital images can be reviewed by any radiologist that has access to the digital viewers anywhere in the world.

Bone x rays can detect injury or disease from many causes, including malfunctions in the patient's bone chemistry, bone breaks, and bone fractures. X rays are especially helpful in diagnosing simple and incomplete fractures that cannot be detected during a **physical examination**. X rays can also be used to check the position of the fracture site. Some bone diseases can be definitively diagnosed with bone x rays, while others may require additional tests.

Osteoporosis, a common bone disease, can be detected in bone x rays, but other tests are then ordered to determine the extent of the disease. For osteomalacia and rickets, a **blood** test and x rays of the affected bone are usually definitive; in some cases a bone biopsy (microscopic analysis of a small amount of tissue) is also done. In a rare bone disease called Paget's disease, x rays may be used in conjunction with bone, blood, and urine tests to make a diagnosis. In another rare bone disease, fibrous dysplasia, bone x rays or a bone biopsy (microscopic analysis of a small amount of tissue) are used to confirm the diagnosis. Bone x rays are definitive in diagnosing osteogenesis imperfecta. For osteomyelitis, bone x rays are used in conjunction with a blood test, bone scan, or needle biopsy to make the diagnosis. For arthritis, x rays of the bone commonly taken, and are occasionally combined with blood tests. In bone tumors, bone x rays are helpful but they are not always definitive.

Bone x rays are performed by a radiographer (technologist), and interpreted by a radiologist. They are taken in a physician's office, radiology unit, outpatient clinic, or diagnostic clinic. Bone x rays generally take a few minutes to complete. There is little or no discomfort associated with the test, but some people find it difficult to remain still or in the positions required for the image. The results are often available in minutes.

During the test, the patient lies on a table or sits on a stool (for most upper extremities). The technologist taking the x ray will check the patient's positioning and place the x-ray machine over the part of the body being examined. After asking the patient to remain motionless, he or she

X rays are used to “see” bone problems, such as this ankle fracture. (Custom Medical Stock Photo. Reproduced by permission.)

steps out of the area and sets appropriate technical factors to create the proper exposure, and takes the x ray.

Preparation

The patient is asked to remove clothing, jewelry, and any other metal objects from the area being x rayed. If appropriate, a lead shield will be placed over other body parts to minimize exposure to radiation.

Aftercare

The patient can immediately resume normal activities.

Complications

The human body contains some natural radiation and is also exposed to radiation in the environment. There is a slight risk from exposure to radiation during bone x rays, however, the amount of radiation is small and the risk of harm is very low. If reproductive organs are exposed to radiation, genetic alterations may occur. Excessive or repeated doses of radiation can cause changes in other types of body tissue. In addition, the radiology professional is continually monitored for his/her occupational exposure. This data is reviewed by a physicist monthly. If the exposure level exceeds the safety level, the technologist or radiologist is removed from that area temporarily while the exposure data and radiation safety measures are evaluated.

Results

Normal bones show no fractures, dislocations, or other abnormalities. Results indicating the presence of bone injury or disease differ in appearance according to the nature of the injury/disease. For example, fractures

KEY TERMS

Arthritis—A disease of the joints that arises from wear and tear, age and less often from inflammation.

Osteogenesis imperfecta—Also called brittle bones, this is a condition present at birth in which bones are abnormally fragile, brittle, and break easily.

Osteomalacia—A disease in which bones gradually soften and bend.

Osteomyelitis—An infection of the bone marrow and the bone.

Osteoporosis—A disease which occurs primarily in post-menopausal women in which the amount of bone is reduced or skeletal tissue wastes away.

Paget's disease—A disease, whose cause is unknown, which is generally found in older people. Symptoms include bone pain, bowed legs, curves spine, and broken bones. Another name for this disease is osteitis deformans.

Radiographer—A person who takes x rays. Must be registered with the American Registry of Radiologic Technology (ARRT).

show up as clear breaks in the bones, while osteoporotic bone has the same shape as a normal bone on an x ray but is less dense.

Health care team roles

The radiology professional most likely in contact with the patient having bone x rays is the radiologic technologist. He or she should take a moment to explain the procedure that the patient will have, especially if this patient has had an injury. The patient's fear of **pain** can be profound, and because the technologist must touch and/or move the patient, care should be taken to calm the fears of the patient. In addition, the technologist must protect him- or herself from exposure to the patient's bodily fluids, and unnecessary radiation where possible.

Training

A technologist must complete a 24 month **radiologic technology** program, that consists of didactic (classroom) and clinical education and rotations. The student radiographer will rotate through all areas of radiology. Upon completion, they will take a national registry exam

given by the American Registry of Radiologic Technology (ARRT) that will encompass areas of physics, radiation safety, exposure factors, positioning, anatomy and physiology, and chemistry. The technologist that performs bone x rays is a highly trained professional and must comply with continuing education yearly.

Brain

Definition

The brain is the part of the **central nervous system** (CNS) inside the **skull** (the part outside the skull is the **spinal cord**). It gives rise to cognitive thought processes and controls various body functions including muscular activity, speech, sight, **hearing**, breathing, and digestion.

Description

The brain is the organ that is located inside the skull and is connected to the spinal cord. The brain has four major parts: the brainstem, the cerebellum, the diencephalon, and the cerebral hemispheres.

The brainstem is located at the base of the brain and connects the brain to the spinal cord. The brainstem has three parts: the medulla oblongata, the pons, and the midbrain. Nine of the twelve cranial nerves originate in the brainstem. The brainstem is responsible for controlling basic functions that require no cognitive thought, such as **blood pressure**, digestion, breathing, and **heart** rate. The brainstem is also the information freeway between the cerebral hemispheres and the spinal cord.

The cerebellum is located immediately below the back part of the cerebral hemispheres and is attached to the brainstem through bands made of nerve fibers called peduncles. The cerebellum plays a major role in balance, coordination, and the learning of motor skills. Damage to the cerebellum can result in incoordination, otherwise known as ataxia.

The diencephalon lies above the midbrain and houses the thalamus and the hypothalamus. The thalamus serves as a major relay system between the brainstem and the cerebral hemispheres. The hypothalamus is involved in controlling a variety of functions that don't require conscious thought (autonomic functions) such as appetite, **blood** pressure, thirst, temperature, and sexual arousal.

The largest part of the human brain is the cerebrum. It is divided into left and right cerebral hemispheres by a deep groove called the longitudinal fissure. A band of fibers called the corpus callosum connects the hemispheres with each other. Each cerebral hemisphere has four major parts called lobes. In addition, there is a fifth small lobe called the island (insula) hidden deep inside each hemisphere. The four major lobes are named for the bones of the skull closest to which they lie: the frontal, parietal, temporal, and occipital lobes.

The frontal lobe is located in the front part of the brain and is responsible for higher cognitive functions such as speech, problem-solving, planning, organizing, awareness, motor activity, **memory** storage, and intelligence. The frontal lobe is also involved in emotions and other aspects of personality.

The parietal lobe is located behind the frontal lobe and is the highest part of the brain. The parietal lobe is involved in perceptions such as touch, **pain**, and pressure. It also discriminates fine sensations such as the weight of an object. In addition to sensory processing,

the parietal lobe is also involved in understanding language and in writing.

The temporal lobes form the side parts of the cerebral hemispheres at the level of the ears. The temporal lobes control hearing, speech, **smell**, and memory.

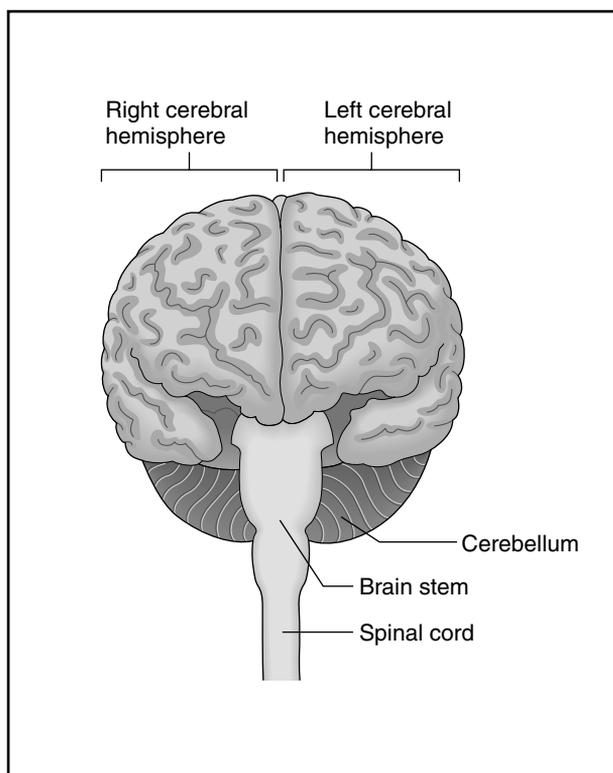

The fourth lobe, located in the back of the head, is the occipital lobe. It is involved in the processing of visual information, such as the recognition of shapes and colors.

The outer surface of the cerebral hemispheres is arranged in convolutions known as gyri (singular "gyrus") which are separated by grooves called sulci (singular "sulcus"). Two sulci are especially important as borders between lobes: the central sulcus lies between the frontal and parietal lobes; the lateral sulcus separates the temporal lobe from the frontal and parietal lobes.

The brain is composed not only of solid matter but also of four ventricles. These ventricles are the two lateral ventricles inside the hemispheres, the third ventricle inside the diencephalon, and the fourth ventricle located among the cerebellum, the medulla oblongata, and the pons. The third ventricle is connected to the fourth ventricle by a narrow channel called the cerebral aqueduct. Cerebrospinal fluid (CSF) flows in the ventricles and in the cerebral aqueduct. The CSF serves to protect the brain by cushioning it from dangerous shocks that would otherwise injure it. It also carries nutrients to the brain cells and transports waste products away from them.

Other protectors of the brain include the blood-brain barrier and the meninges. The blood-brain barrier prevents foreign substances in the blood from entering the brain. The meninges are membranes consisting of connective tissue which cover the brain in three layers. The outermost of these layers, the dura mater, is the thickest and toughest of the three. The middle layer, the arachnoidea, is loosely attached to the third layer by fibers resembling a spider's web. The innermost layer, the pia mater, is made of a delicate connective tissue which has many **blood vessels**.

The names of the meninges have a fascinating story behind them. Medieval European scientists borrowed heavily from Arab anatomists who were in turn building upon ancient Greek science. The Arabs called the meninges "the tough covering, the spider-web covering, and the delicate covering." The Arabic word for "covering" could also mean "mother" or "matrix." The Arabic terms for the outer and inner layers were mistranslated into Latin for "hard" (dura) mother, and "tender, devoted" (pia) mother, but the Arabic made no such personification and was merely contrasting a rough, tough covering with a fine, delicate one. However, the Europeans did

Frontal view of the exterior of the brain. (Delmar Publishers, Inc. Reproduced by permission.)

get the Arabic for “like a spider’s web” (Latin *arachnoidea*) correct.

The microanatomy of the brain is highly specialized and organized. The brain is composed of two major types of cells called **neurons** and glial cells.

There are several types of neurons including motor neurons, sensory neurons, and interneurons. Neurons are the basic operating cells of the brain. They are specially designed to communicate rapidly with other neurons and with organs. They do this by sending electrical signals known as action potentials down the length of their axons.

Axons are fiber processes of neurons (they are unique to neurons) that generally conduct electrical impulses away from the cell body of the neuron. The word “axon” comes from the Greek word for an axis and refers to the fact that the axon is the central part of the nerve fiber. Specialized glial cells called oligodendrocytes generally wrap the axons of the neurons in myelin.

A dendrite is a protoplasmic process of a neuron that conducts electrical impulses toward the cell body of the neuron. Usually it spreads out into many branches (its name comes from the Greek *dendron* meaning “tree” because of its resemblance to the branches of a tree).

The other type of glial cell in the brain is the astrocyte, which aids the neuron in its function.

Cell bodies of neurons, part of their processes, and glia form the gray matter of the brain. The gray matter which forms the outer layer of the cerebrum is called the cerebral cortex. This cerebral cortex contains from about nine to fourteen billion nerve cells and weighs on average 1.3 lb (581 g). Of this 1.3 lb, only 0.044 lb (20 g) is made up of cell bodies (that is, approximately one part in thirty). Another part of the cerebral gray matter forms a few islands called basal ganglia. Basal ganglia are masses of gray matter located deep within each cerebral hemisphere. These groups of neurons help regulate body movement and facial expressions.

Inside, the cerebral hemispheres are made largely of white matter. Axons form this white matter, and it is the high lipid content of their myelin coating that gives the white matter its characteristically white color.

Neurons communicate by releasing chemical compounds called neurotransmitters. The major neurotransmitters in the brain are serotonin, dopamine, acetylcholine, gamma-aminobutyric acid (GABA), and glycine. Neurotransmitters bind to protein receptors on the surface of the neuron and cause changes to occur inside the neuron. It is believed that many psychiatric diseases are due to imbalances in these chemical neurotransmitter systems.

Function

The brain is the ultimate controller of the human body and performs functions with and without conscious thought. The brain enables the mind to conduct conscious thoughts and feelings. The brain allows human beings to respond to the environment. It also regulates functions without conscious thought such as digestion, blood pressure, balance, and sleep.

The brain allows one to interpret and respond to the stimuli given to the five senses: **taste**, touch, hearing, smell, and **vision**. The brain helps us learn to recognize a certain smell or remember how to ride a bike. The brain enables human communication. The brain contains regions devoted to speech production and speech comprehension. Certain regions of the brain are employed in reading, and writing. The brain is also involved in reproductive behavior and regulates the release of sex hormones. The hypothalamus in the brain tells the body when it is time to drink and when it is time to eat. The brain also regulates sleep and **biological rhythms**. The brain is likewise involved in generating emotions and largely determines personality.

It is within the cerebral cortex that impulses are received, analyzed, and answered. The body contains

nerve cells that are specialized for detecting environmental events and other cells that are specialized for producing movement. Information in the form of light, sound waves, odors, tastes as well as contact with objects is gathered from the environment by specialized cells which are called sensory neurons. In response to this information, movements are performed by the contraction of muscles, which are controlled by motor neurons. Communication between sensory neurons and motor neurons is carried on by interneurons.

Specialized sensory cells of the ear called cells of Corti perceive sound waves and send corresponding impulses to the brain, where they reach the projector auditory center which is located in the superior temporal gyrus (field 41 of Brodmann). The cells of this center receive and analyze the separate impulses. Near this field 41 is located field 37, the associative auditory area, cells of which form one integral or complete auditory image of the object from the separate impulses sent by the neurons of field 41. If we destroy field 37, the person can hear sounds but cannot make sense out of them. For example, he or she can hear the speech sounds “p” and “e” and “n” but does not imagine a pen as a result of hearing these sounds. The parietal lobe contains a sensory area which is located in the post-central gyrus (fields 1, 2, 3 of Brodmann), and in the nearby part of the superior parietal lobulus (fields 5, 7 of Brodmann). In this area, impulses of general sensation such as touch, pain, pressure, and temperature are interpreted. The occipital lobe contains the visual region which is located in the area of the calcarine sulcus (field 17 of Brodmann) and an adjacent area (fields 18, 19, of Brodmann). In this visual area, the impulses arising from the retina of the eye are interpreted.

The frontal lobe contains the motor area (field 4 of Brodmann) with about 25,000 giant pyramidal neurons. It is located in the precentral gyrus, the superior frontal gyrus, and the paracentral lobulus. The uppermost part of the precentral gyrus together with the paracentral lobulus controls the movement of the legs. The hindmost part of the superior frontal gyrus controls the movement of the torso. The middle part of the precentral gyrus controls the movement of the arms, and the lowest part of the precentral gyrus controls the movement of the neck and head. The premotor area located in front of the motor area is responsible for coordination and integration of movements. If one suffers destruction of the back part of the middle frontal gyrus, one can still wiggle one’s fingers, but one cannot write, although the movement of the corresponding muscles is normal, because writing requires a high degree of coordination and integration of hand and finger movements.

KEY TERMS

Axon—A fiber process of a neuron that generally conducts electrical impulses away from the cell body of the neuron.

Cell body—The part of a neuron that contains the nucleus and other cell organelles.

Dementia—Decline in mental ability.

Dendrite—A protoplasmic process of a neuron that conducts electrical impulses toward the cell body of the neuron. Usually it spreads out into many branches.

Neuron—The highly specialized cell that is the basic structural and functional unit of the nervous system.

The brain controls the functions of the body that do not require conscious thought (the autonomic functions). Located in the medulla oblongata are the centers controlling digestion, breathing, the functioning of the heart, blood vessels, of the **urinary system**, and of the glands which produce saliva, tears, and sweat.

The sympathetic and parasympathetic nerves extending from these centers cause the arousal and inhibition of these systems. The sympathetic nerves speed up the heart, raise the blood pressure, dilate the pupils of the eyes, contract the sphincters of the hollow organs, and relax the longitudinal muscles. They prepare a person for crisis situations and they remain active during **stress**.

The parasympathetic nerves slow the heart, lower the blood pressure, constrict the pupils of the eyes, relax the sphincters of the hollow organs, and help promote the digestion and absorption of nutrients.

Common diseases and disorders

There are hundreds of diseases and disorders of the brain. There are conditions in which learning is impaired, for example, disorders of speech called aphasia and disorders in writing called dyslexia. There are disorders of thought, such as **schizophrenia** and Tourette syndrome. Mood disorders include depression, mania, and **anxiety**. There are also disorders of sleep such as insomnia and narcolepsy. The brain is subject to strokes and to **cancer**. The brain can also cause seizures in which neurons uncontrollably fire electrical signals. This is the hallmark of epilepsy. The basis of drug abuse and addiction is intertwined with reward pathways in the brain. There are several diseases which are involved

in mental retardation, such as Fragile X syndrome and lissencephaly. There are also several diseases in which neurons degenerate or die. These diseases are collectively known as neurodegenerative diseases, and clinical symptoms depend on where in the brain the neurons are dying.

- **Alzheimer's disease.** Alzheimer's disease usually occurs later in life and is characterized by a decline in cognitive functions such as memory, judgment, and reasoning. The hallmark of Alzheimer's disease is deposits in the brain of a protein called amyloid beta. These deposits are found in abnormal structures called neurofibrillary tangles. Risk factors for Alzheimer's disease include mutation in genes that are responsible for production of the following **proteins**: amyloid precursor protein, presenilin-1, presenilin-2, and apolipoproteins. However, the role of these proteins in the development of the disease is not known.
- **Huntington's disease.** Huntington's disease is a genetic disease in which neurons in the brain that are involved in controlling movement die. This leads to uncontrollable, jerky, and spastic movements. There is also slowness of movement, difficulty in swallowing, and **dementia**. Huntington's disease occurs in the fourth or fifth decade of life and usually results in death 10 to 12 years after the first symptoms appear. The gene involved in the disease is responsible for producing a protein called huntingtin, but the role this protein plays in causing the disease is not clear.
- **Parkinson's disease.** Parkinson's disease is a disorder of bodily movement caused by the death of neurons that release the neurotransmitter dopamine. Symptoms include tremor, slowness of movement, rigidity, and a loss of **reflexes**. It is a progressive disease in which patients become unable to move. There are cases of inherited Parkinson's disease in which a gene linked to alpha-synuclein has been identified. However, the role alpha-synuclein may play in Parkinson's disease is not clear.

Brain tumor

Definition

A **brain tumor** is an abnormal growth of tissue, either malignant (cancerous) or benign (noncancerous), in the brain. Each year, more than 17,000 brain tumors are diagnosed in the United States.

Description

Benign brain tumors

A benign brain tumor is composed of slow-growing noncancerous cells that never spread (by local extension or any other means) beyond the site where they originate. Common benign tumors are meningiomas, acoustic neuromas, **pituitary gland** tumors, craniopharyngiomas, germinomas, pinealomas, and hemangioblastomas. Even though a tumor is benign it may still be dangerous because, depending on its location, it may be inoperable and/or affect one or more brain functions.

Benign brain tumors have clearly defined borders, can often be removed completely, especially if they are on the brain's surface, and are unlikely to recur. Benign brain tumors do not infiltrate nearby tissues but as they continue to grow can cause severe **pain**, permanent brain damage, and death. Benign brain tumors sometimes become malignant.

Malignant brain tumors

A brain tumor is considered malignant if it contains **cancer** cells. Unlike other tumors, these spread by local extension and rarely metastasize beyond the brain. About half of all brain tumors are malignant.

Malignant brain tumors do not have distinct borders. They tend to grow rapidly, increase intracranial pressure, and metastasize to other parts of the brain or **spinal cord**. It is highly unusual for malignant brain tumors to spread beyond the **central nervous system** (CNS).

Primary brain tumors

Primary brain tumors originate in the brain. They represent about 1% of all cancers and 2.5% of all cancer deaths.

Metastatic or secondary brain tumors

Most brain tumors do not originate in the brain; they are metastases from other primary cancer sites. Approximately 25% of all cancer patients develop secondary or metastatic brain tumors when cancer cells spread from another part of the body. Secondary brain tumors are most apt to occur in patients who have melanoma, breast, colon, kidney, or **lung cancer**. Brain metastases can develop on any part of the brain or spinal cord.

Patient demographics

Primary brain tumors may develop at any age, but are most common in children between the ages of three and 12, and in adults aged 40–70. Primary brain cancer is the second-most common cause of cancer death between birth and the age of 34, and the third-most common cause of cancer death in men aged 35–54. Primary tumors of the brain and central nervous system are associated with **AIDS** in some patients.

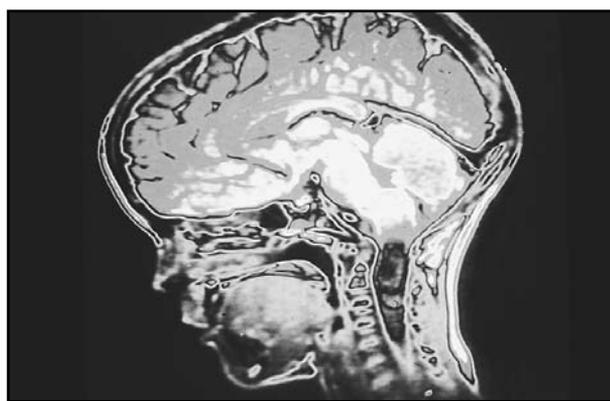

Naming and grading brain tumors

A brain tumor's name describes its origin, how it grows, and the cell type it contains. A tumor in an adult is also graded or staged according to the extent or degree to which it is malignant; how rapidly it is growing, and how likely it is to invade other tissues; and how closely its cells resemble normal cells. (The less normal a tumor cell appears, the faster it is likely to grow.)

Low-grade tumors usually have well-defined borders. Some low-grade brain tumors form or are encapsulated (enclosed) in cysts. Low-grade brain tumors grow slowly, if at all. They may spread throughout the brain, but rarely metastasize to other parts of the body.

Mid- and high-grade tumors grow more rapidly than low-grade tumors; these tumors usually infiltrate healthy tissue. Their growth pattern makes it difficult to remove the entire tumor, and they recur more often than low-grade tumors.

A single brain tumor can contain several different types of cells. The tumor's grade is determined by the highest-grade (most malignant) cell detected under a **microscope**, even if most of the cells in the tumor are less malignant. An infiltrating tumor is a tumor of any grade that grows into surrounding tissue.

A magnetic resonance imaging (MRI) scan of brain tumor located at the base of patient's brain. (Photograph by Howard Sochurek, *The Stock Market*. Reproduced by permission.)

Types of brain tumors

Glioblastomas, also known as gliomas, are the most prevalent primary brain tumors. They arise from glial tissue, which supports and nourishes cells that send messages from the brain to other parts of the body. Gliomas can be either malignant or benign. Astrocytomas, ependymomas, and mixed glioblastomas are three of the most common types.

ASTROCYTOMAS. Named for their star-shaped cells and the tumor's radiating tentacles, astrocytomas can develop on any part of the brain or spinal cord. Noninfiltrating astrocytomas grow slowly, and rarely spread to nearby tissue. Mild-to-moderately anaplastic (malignant) astrocytomas with well-differentiated borders grow more quickly, and tend to infiltrate surrounding tissues. These are grade I and II astrocytomas.

Anaplastic, or grade III astrocytomas, look more abnormal and grow more rapidly than noninfiltrating or mild-to-moderately anaplastic tumors. Grade IV astrocytomas are also called glioblastoma multiforme (GBM) tumors. Accounting for 30% of all primary brain tumors, GBMs are the most common brain tumors in middle-aged adults. GBMs are also the most malignant of all brain tumors. Because they contain a greater mixture of cells than any other brain tumor, they are the most difficult to treat.

EPENDYMOMAS. Also called ependymal tumors, ependymomas account for 9% of all gliomas, 5% of all intracranial tumors, and are the most common brain tumors in children and adolescents. They begin in the ependymal cells that line the central canal of the spinal cord and the ventricles of the brain, where cerebrospinal fluid (CSF) is manufactured.

Ependymomas are often benign, have well-differentiated borders, resemble normal cells, and grow very slowly. The cells of anaplastic ependymomas look abnormal and grow more rapidly than the cells of benign tumors.

MIXED GLIOMAS. These heterogeneous tumors contain elements of astrocytomas, ependymomas, and/or oligodendrogliomas. These rare tumors usually occur in middle-aged adults, grow slowly, and do not usually spread beyond the part of the brain where they originate. Mixed gliomas follow the patterns of growth related to the highest-grade cells they contain.

Nonglial brain tumors

MEDULLOBLASTOMAS. Scientists once thought medulloblastomas (MDLs) developed from glial cells. These fast-growing malignant tumors are now believed to originate in embryonal cells not normally present in the body after birth. They are sometimes called primitive neuroectodermal tumors (PNET).

MDL tumors are most common in children and are found more often in males than females; only 30% occur in adults. MDL tumors usually originate in the cerebellum and often metastasize to other parts of the brain via cerebrospinal fluid. They rarely metastasize beyond the brain and spinal cord.

MENINGIOMAS. Meningiomas, which represent more than 20% of all primary brain tumors, originate in the meninges (the membranes that cover the brain and spinal cord). These tumors are usually benign and most often occur in women aged 30–50 years old. Meningiomas grow so slowly that the brain can sometimes become accustomed to their presence. Meningiomas compress brain tissue rather than invade it, and may grow to be quite large before any symptoms appear.

ACOUSTIC NEUROMA. These benign tumors, also known as vestibular schwannomas, are named for the cells in which they originate. In this case, the tumor is named for the Schwann cells, which produce myelin, the material that sheaths all nerves. Acoustic neuromas are usually found on the auditory nerve, which controls **hearing**. They are twice as common in women as in men, and are most often diagnosed in patients between the ages 30–60.

Acoustic neuromas grow very slowly, and many patients adapt to the **hearing loss** balance problems, and tinnitus that are the tumors' earliest symptoms. As the tumor progresses, it can press on the nerves that control movement and sensation in the face, and cause headaches and facial numbness or tingling. The patient

may have trouble walking, swallowing, or controlling eye movements, and the sense of **taste** can be affected. An acoustic neuroma that grows large enough to press on the brainstem can be deadly.

CHILDHOOD BRAIN TUMORS. Brain tumors that occur in children are treated differently than those found in adults because they usually appear in different parts of the brain, cause different symptoms, and require different treatment because of the patient's age and stage of development. They also often have a better prognosis than adult tumors.

Brain tumors are rare in children—only about 2,200 are diagnosed in the United States each year. Children under seven are most likely to be afflicted, with boys affected more often than girls. Headaches, nausea, vomiting, difficulty walking, **vision** problems, and changes in schoolwork are the chief symptoms.

Unlike adult tumors, childhood brain tumors are identified primarily by their location, either supratentorial (above the tentorium, the membrane that separates the brain from the cerebellum) or infratentorial (below the tentorium). Astrocytomas and ependymomas are common supratentorial tumors. Infratentorial tumors include medulloblastomas, astrocytomas, and ependymomas.

Causes and symptoms

The causes of primary brain tumors are unknown, but people who work with vinyl chlorides, polycyclic hydrocarbons, nitrosoureas, and certain pesticides have a greater-than-average risk of developing them. There is no evidence that **head injury** causes brain tumors, but researchers are trying to determine the relationship, if any, between brain tumors and **viruses**, genetic susceptibilities, and long-term exposure to electromagnetic fields.

Although brain tumor symptoms resemble those of many other illnesses, the presence of a brain tumor may be suspected in patients who have persistent headaches with vomiting or convulsions; progressive deterioration of sight, speech, hearing, touch; or deterioration in the ability to use an arm, hand, foot, or leg. Symptoms often do not appear until the tumor grows large enough to displace, damage, or destroy delicate brain tissue.

Diagnosis

When a patient experiences one or more of the above symptoms, a primary care physician will perform a focused **physical examination**, take a detailed medical history, and conduct a basic neurologic examination to evaluate:

- balance and coordination

- abstract thinking and **memory**
- eye movements
- hearing, touch, and sense of **smell**
- reflexes
- control of facial muscles and movements of the head and tongue
- awareness

If the results of these examinations suggest a patient may have a brain tumor, the patient is referred to a neurologist or neurosurgeon, who will recommend any or all of several diagnostic tests:

- a computed tomography scan (CT scan) to reveal brain abnormalities
- magnetic resonance imaging (MRI) to detect tumors beneath the bones of the **skull**
- electroencephalography (EEG) to measure the electrical activity in the brain when seizures are suspected
- angiography can outline a tumor and the **blood vessels** that lead to it
- a lumbar puncture (spinal tap) to see if spinal column pressure has increased and if the spinal fluid contains tumor cells

Interpreting these images and results enables the physicians to determine whether a tumor is present, but biopsy (microscopic examination of tumor tissue) is the only way to identify its cell type.

Treatment

Patients with brain tumors are treated by multidisciplinary teams of highly skilled specialists whose decisions are based on test results; tumor size, position, and growth pattern; the patient's history and current medical status; and the patient's wishes.

Surgery

Surgery is the treatment of choice for accessible brain tumors that can be removed without causing serious neurological damage. A craniotomy, the procedure performed most often, allow surgeons to remove as much of the tumor as possible and send a specimen to the laboratory for microscopic analysis. The operation also creates an entry channel for **chemotherapy** drugs and forms of radiation that are implanted in the brain.

Prior to surgery, patients are often given **corticosteroids** and other medications to reduce swelling of brain tissue and anticonvulsants to prevent or control seizures. Preoperative radiation treatments may also be administered to reduce tumor size.

Patients whose benign brain tumors can be completely removed may not require any additional postoperative treatment, however, periodic physical and neurologic examinations and CT or MRI scans are usually recommended to determine whether the tumor has returned. Surgeons cannot be absolutely sure that every bit of an infiltrating or metastasizing tumor has been removed and microscopic growth may still exist, so radiation and chemotherapy are used to eradicate malignant cells that may have escaped the scalpel.

If a tumor cannot be completely removed, debulking (removing a major portion of it) can alleviate symptoms, enhance the sense of well-being, and increase the effectiveness of other treatments.

Radiation therapy

External **radiotherapy** is generally delivered on an outpatient basis, and directs radiation to the tumor and the area around it. Implant radiation therapy involves placing radioactive material into channels made in the brain. Left in place permanently, or for a short time, these radioactive pellets, sometimes called seeds, release measured doses of radiation each day. Patients are usually hospitalized for observation during the several days the pellets are most active. Immediate family are encouraged to keep a distance or use protective gear, in some instances, during this period.

Stereotactic radiosurgery involves fitting the patient with a frame to stabilize the head, using imaging techniques to determine the exact location of tumor cells, and using a sophisticated instrument called a gamma knife to administer radiation precisely to that point.

Chemotherapy

One or more **anticancer drugs** may be taken by mouth or injected into a **blood** vessel, muscle, or the cerebrospinal fluid to kill malignant cells. Chemotherapy may be used in combination with radiation and surgery as part of initial treatment, or used alone to treat tumors that recur in the same place or in another part of the body. When a young child has a brain tumor, chemotherapy is often used to eliminate or delay the need for radiation.

Other treatments

If a brain tumor cannot be eradicated, treatment is designed to make the patient as comfortable as possible and preserve as much neurologic function as possible. The patient's physician may prescribe **analgesics** to relieve pain, anticancer drugs to limit tumor growth, anticonvulsants to control seizures, and steroids to reduce swelling of brain tissue.

KEY TERMS

Central nervous system (CNS)—The division of the nervous system that consists of the brain and spinal cord.

Cerebrospinal fluid (CSF)—Clear lymph-like liquid that fills brain cavities and protects the brain and spinal cord.

Craniotomy—Surgical procedure in which part of the skull is removed (then replaced) to allow access to the brain.

Gamma knife—High-dose radiation treatment for intracranial tumors.

Intracranial—Located within or on the surface of the brain; within the cranium (skull).

Malignant—A cancerous or life-threatening tumor.

Melanoma—A particularly deadly type of skin cancer that develops in the melanocytes, or skin-pigmenting cells.

Metastasis—Spread of disease, particularly cancer, from one part of the body to another.

Potential therapies

Researchers are exploring ways to empower chemotherapy drugs to penetrate the blood-brain barrier (which protects the CNS by separating the brain from blood circulating throughout the body), and attack cancer cells that have infiltrated tissue inside it. The goal is to target these drugs to certain types of cells or cell-growth mediators, keeping healthy brain tissue unaffected.

Researchers also are investigating:

- less-invasive surgical procedures
- methods of incorporating chemotherapy drugs into tumor cells to reduce the need for radiation
- laboratory techniques that enable physicians to select the chemotherapy drugs most likely to kill particular types of tumors
- gene therapy in which genetically engineered material is transported to tumor cells by viruses that infect tumor cells and convert them to normal cells, stop their growth, or kill them

Alternative therapies have not been demonstrated to cure brain tumors and should never be substituted for conventional therapy. However, complementary therapies (used with, not instead of, standard treatments) may

help some patients cope with the **stress** of illness and side effects of their treatment. Among these are biofeedback training, massage, **meditation**, and botanical and homeopathic treatments.

Biofeedback can teach patients to influence and control **heart** rate, muscle tension, and other stress-related body functions. Some patients claim that guided imagery (visualization) helps them feel healthier and more in control of their disease.

Massage, meditation, guided imagery, and reflexology help some patients relax; while **yoga** is said to soothe the body, spirit, and mind while reducing the other effects of stress. **Hydrotherapy** uses ice, liquid, and steam to improve circulation and relieve pain. Body work and **therapeutic touch** may help relieve pain and other symptoms.

Some patients and practitioners incorporate botanical therapies, homeopathic treatment, traditional Chinese medicine treatments, changes in diet, and use of dietary supplements as complementary therapies.

Health care team roles

Brain tumor diagnosis and treatment involves a multidisciplinary team of health care professionals. In addition to primary care physicians, such as a family practitioner or an internist, the treatment team may include a neurologist, neurosurgeon, pathologist, radiologist, as well as clinical specialists and **advanced practice nurses**, physical and occupational therapists, radiologic and laboratory technicians, and dietitians and nutritionists. Social workers and case managers help with arrangements for home-care treatment or interim facility care.

Patient education

Before, during and after treatment, nurses and allied health professionals should inform and educate patients and families about the risks and complications of any planned diagnostic test, intervention or treatment. It is important to realize that in order for **informed consent** to be valid, the surgeon or other physician must be the one to offer initial information on the pros and cons of therapies. Patients and families should be taught about some of the common side effects of treatment including weight loss, malnutrition, increased risk of **infection**, pain, fatigue, and depression.

Occupational therapists can teach patients and families new ways to approach daily tasks. Physical therapists, **physical therapy** assistants, and speech therapists can help patients who have difficulty keeping their balance, expressing their thoughts, speaking, or swallowing. Children may need special tutors and counseling before

and after returning to school. For patients who have incurable brain tumors, hospice care can provide a supportive environment and specially trained health professionals to help patients manage pain and remain comfortable, whether at home or in a treatment facility.

Prognosis

The patient's prognosis depends on the location of the tumor and its cell type. A patient whose tumor is discovered early and removed completely may make a full recovery, but the surgery itself may harm or destroy normal brain tissue. This can result in additional problems, such as seizures, weakness, personality changes, or thought, speech, and coordination difficulties. Although these postoperative problems may initially be more severe than the symptoms produced by the tumor, they usually diminish or disappear over time.

Consequences of radiation therapy

Cells killed by radiation can cluster in the brain, resembling tumors. These dead-cell clusters can cause headaches, seizures, and memory loss. Children treated with radiation may lose some of their eyesight and develop learning problems. Radiation damage to the pituitary gland can hinder normal growth and development.

Consequences of chemotherapy

Some anticancer drugs may cause kidney damage and other temporary or permanent dysfunction, such as tingling in the fingers and ringing in the ears.

Inoperable tumors

Brain tumors that cannot be removed may cause irreversible brain damage and death.

Prevention

Since the causes of primary brain tumors have not been determined conclusively, there is no known way to prevent them. The best way to prevent secondary or metastatic brain tumors is to reduce risk factors such as:

- poor **nutrition** and a low-fiber diet; since these contribute to development of intestinal cancers
- smoking, which can cause lung cancer
- excessive alcohol consumption, which is associated with **liver cancer**
- excessive exposure to the sun, which can cause melanoma

Breast biopsy

Definition

A breast biopsy is the removal of breast tissue for examination under a **microscope** by a pathologist. This can be accomplished surgically (excisional biopsy), or by withdrawing tissue through a needle (aspiration biopsy).

Purpose

A biopsy is recommended when a significant abnormality is found which cannot be identified conclusively by imaging studies. The abnormality in question might be a finding on breast self-examination, on routine physical or gynecological examination, or on a mammogram. Signs of concern in addition to palpable lumps include:

- severe breast **pain**
- changes in the size of a breast or the nipple
- changes in the shape of the breast or nipple
- pitting, dimpling or redness of the breast skin.
- nipple redness, irritation or inversion of the nipple which is new
- changes in the pattern of veins visible on the surface of the breast
- some types of nipple discharge

If imaging studies are not decisive, the differentiation of **cancer** from a benign breast condition must be determined using a biopsy. However, in pre-menopausal women, it may be appropriate to follow a lump by physical exam for one to two menstrual cycles before considering biopsy.

Precautions

Physical exam is not sufficient for evaluating significant breast abnormalities. About 30% of abnormalities thought to be benign by physical exam turn out to be cancerous, and 60% of those thought to be malignant prove to be benign.

The type of biopsy recommended should be considered carefully. The best approach will depend upon whether the area can be felt, how well it can be seen on mammogram or ultrasound, and how suspicious it feels or appears. Specialized equipment is needed for different types of biopsy, and availability may vary. Generally, needle biopsy is less invasive and much less expensive than surgical biopsy. It is appropriate for most, but not all situations. However, some surgeons feel that it is less accurate.

Description

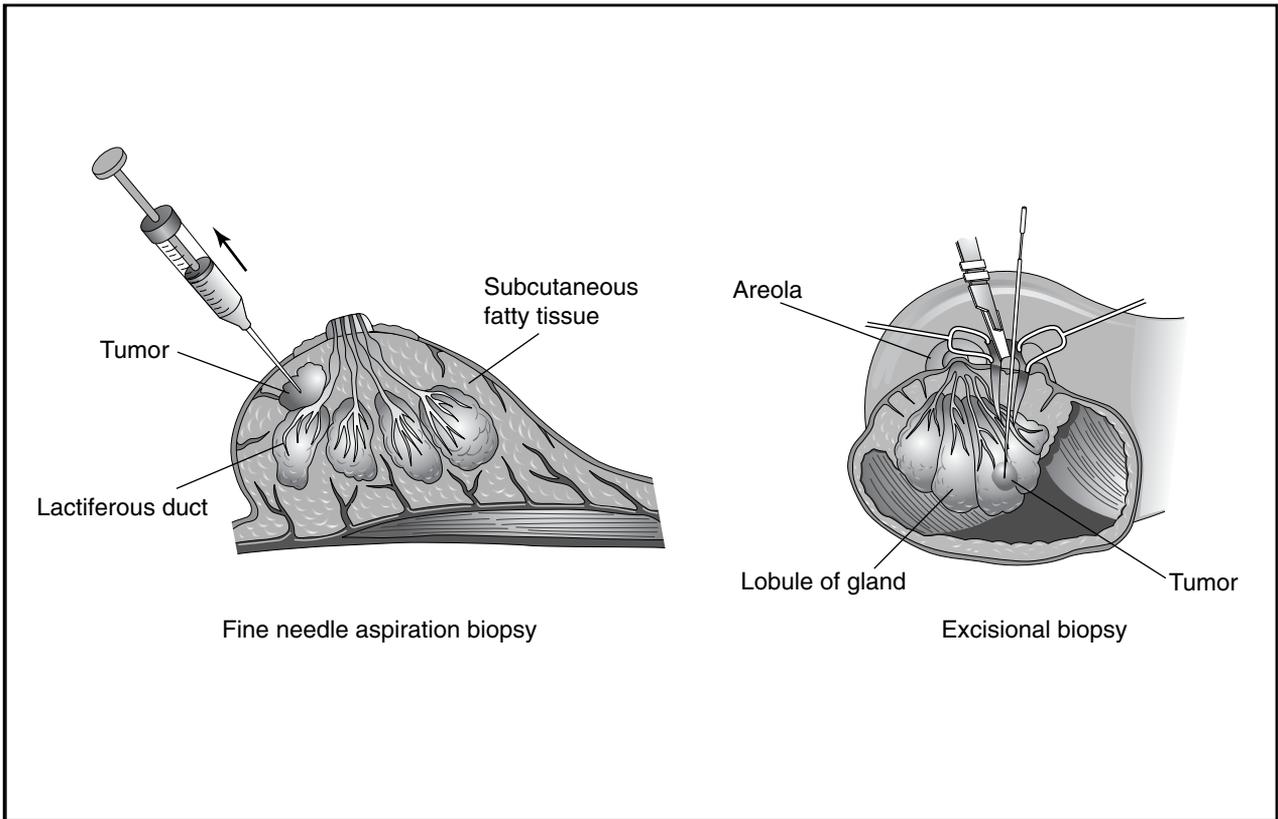

The least invasive of biopsy procedures is the needle biopsy. A needle biopsy removes part of the suspicious area for examination. There are two types, aspiration biopsy using a fine needle, and large core needle biopsy. Either of these may be called a percutaneous needle biopsy. Percutaneous refers to a procedure done through the skin.

A fine needle aspiration (FNA) biopsy uses a very thin needle to withdraw fluid and cells that can be studied. It can be performed in a doctor's office, clinic, or hospital. Local anesthetic may be used, but is sometimes withheld, as the injection may be more painful than the biopsy needle. The area to place the needle may be located by touch. No specialized equipment is needed. This procedure is simple and inexpensive, but FNA biopsies also have the highest rate of false negative results (i.e., no cancer is found in the sample, but cancer is present at the biopsy site). FNA is very useful for biopsy of lumps suspicious for being benign cysts by physical exam and/or ultrasound. If the contents of the cyst can be completely aspirated, prove to be non-bloody fluid, and the cyst does not recur, no further biopsy is needed.

A large core needle biopsy uses a larger diameter cutting-type needle to remove small pieces of tissue, about the size of a grain of rice. It can be performed in a clinic or hospital that has the appropriate facilities. Local anesthetic is routinely used.

Ultrasound is used to guide needle placement for some lesions. The patient lies on her back or side. After the area is numbed, a sterile gel is applied. The physician places a transducer, an instrument about the size of an electric shaver, over the skin. This produces an image from the reflection of sound waves. A special needle, usually in a spring loaded device, is used to obtain the tissue. The procedure is observed on a monitor as it is happening.

If the suspicious area is seen best with x ray, a stereotactic device is used. This means that x rays are taken from several angles. This information is input into a computer, which analyzes the data and produces an image that is used to guide the needle to the correct site. The patient may be sitting up, or she may be lying on her **stomach**, with her breast positioned through an opening in the table. The breast is held firmly but comfortably between a plastic paddle and a metal plate, similar to those used for mammograms. Several samples will be taken because a growth might have both benign and malignant areas in it. X rays may be taken before, during, and after the tissue is drawn into the needle, to confirm that the correct spot is biopsied. This procedure may also

A fine needle aspiration biopsy uses a very thin needle to withdraw fluid and cells from the breast to be examined. An excisional biopsy is a surgical procedure in which the entire area of concern and some surrounding tissue is removed for analysis. (Illustration by Electronic Illustrators Group.)

be referred to as a stereotactic core biopsy, or a mammotomy. Stereotactic needle biopsies are just as successful as the mammographically guided open biopsy discussed below.

There are two types of surgical breast biopsy considered here, excisional and incisional. An excisional biopsy is a surgical procedure, where the entire area of concern and some surrounding tissue is removed. It is usually done as an outpatient procedure in a hospital or free-standing surgery center. The patient may be awake, and is sometimes given a sedative. The area to be operated on is numbed with local anesthetic. Infrequently, **general anesthesia** is used. An excisional biopsy itself usually takes under one hour. The total amount of time spent at the facility depends on the type of anesthesia used, whether a needle localization was done (see below), and the extent of the surgery.

If a mass is very large, an incisional biopsy may be performed. In this case only a portion of the area is removed and sent for analysis. The procedure is the same as an excisional biopsy in other respects.

If the abnormality is not palpable, a needle localization must be done before the actual surgery. After local anesthetic is administered, a fine wire is placed in the area of concern. Either mammogram or ultrasound guidance is used to place the tip of the wire in the lesion. The patient is awake and usually sitting up. The surgeon then proceeds with an open biopsy, and removes the wire from the target tissue. A mammogram of the specimen is then taken to assure the abnormality intended has been sufficiently biopsied.

Preparation

No food restrictions are necessary for needle biopsy; however, it may be advisable to eat lightly before the procedure. This is especially important if the patient will be lying on her stomach for a stereotactic biopsy. A surgical breast biopsy may require the patient to have nothing to eat or drink for a period of time before the operation. This will typically be from midnight the night before, if general anesthesia is planned.

KEY TERMS

Biopsy—Removal of a sample of tissue, organ, or gland for microscopic examination.

Aftercare

The skin opening for a needle biopsy is minimal. It may be closed with thin, clear tape, called a Steri-strip, or covered with a small gauze bandage. The patient can return to her usual routine immediately after the biopsy. Strenuous activity or heavy lifting is not recommended for 24 hours. Any bandages can be removed one or two days after the biopsy.

After a surgical biopsy, the incision will be closed with stitches, and covered with a bandage. The bandage can usually be removed in one or two days. Stitches are taken out approximately one week afterward. Depending on the extent of the operation, normal activities can be resumed in approximately one to three days. Vigorous **exercise** may be limited for one to three weeks.

Complications

Bleeding or bruising after the procedure can result in soreness that should disappear within two days. **Infection** is always a possibility when the skin is broken, although this rarely occurs. Redness, swelling, significant drainage or severe pain at the biopsy site indicates a possible infection. Another possible consequence of a breast biopsy is a hematoma. This is a pocket of **blood** at the biopsy site. It is usually absorbed naturally by the body. If it is very large and uncomfortable, it may need to be drained. A surgical breast biopsy may produce a visible scar on the breast. Sometimes this may make future mammograms harder to interpret accurately.

Results

A normal pathology report indicates no malignancy is present. The tissue sample may be further classified as a benign solid tumor of the breast (fibroadenoma) or fibrous connective tissue with tiny cysts (fibrocystic change). Studies have demonstrated that approximately 80% of all breast biopsies result in a benign pathology report. An abnormal pathology report indicates a cancer is present. If a fine needle aspiration biopsy was performed, the pathologist has viewed individual cells under a microscope to see if they appear cancerous. Large core needle biopsy and surgical biopsy will be able to give

more information. This includes the type of cancer, whether it has invaded surrounding tissue, and how likely it is to spread quickly. There are some conditions which are not malignant but indicate high risk for future development of **breast cancer**. If these are identified, more frequent monitoring of the area may be recommended.

Health care team roles

Needle and surgical biopsies are performed by a physician. Radiologic technicians may be involved in many of the procedures described above, such as obtaining mammograms and needle localizations. Nursing staff may assist in surgical biopsies, and monitor patients in the recovery area after procedures. Physician assistants and nurse practitioners may explain the procedure and possible outcomes to the patient. Histology technicians prepare the biopsied tissue by fixation, thin-sectioning, and staining. A pathologist performs the microscopic evaluation of the cells.

Erika J. Norris

Breast cancer

Definition

Breast **cancer** is the abnormal growth and uncontrolled division of cells in the breast. Cancer cells can invade and destroy surrounding tissue, and may metastasize.

size (spread) throughout the body via **blood** or lymph fluid to other parts of the body.

Description

Breast cancer is a leading cause of morbidity (illness) and mortality (death) for women. It is the second most common cause of cancer death among American women; every year, about 180,000 women are diagnosed with the disease.

Every woman is at risk for breast cancer. If a woman lives to age 85, there is one chance in nine that she will develop the condition sometime during the rest of her life. Age is an established risk factor; the risk of developing the disease increases with advancing age. The breast cancer risk of a 25-year-old woman is only one out of 19,608; by age 45, it is one in 93. More than 75% of all breast cancers are detected in women over age 50.

Causes and symptoms

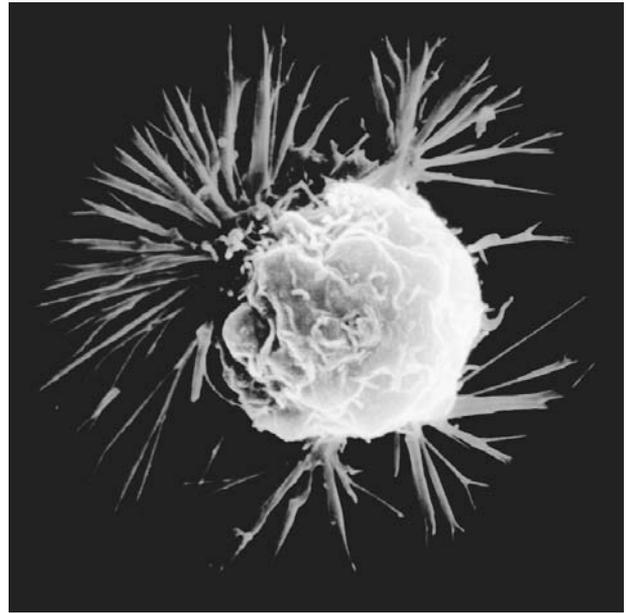

There are a number of risk factors for the development of breast cancer, including:

- family history of breast cancer in first-degree relatives (mother, sister, or daughter)
- early onset of menstruation and late menopause
- reproductive history (women who never had children or have children late in life and women who have never breastfed have increased risk)
- history of abnormal breast biopsies

More than 75% of all breast cancers are diagnosed in women without a family history or other major risk factor for the disease. Inherited gene alterations also place women at risk for developing breast cancer at younger ages. About 20% of cases occur in families with a history of breast cancer. A breast cancer gene was discovered in 1994, however, only about 5% of breast cancers are believed to be related to the gene.

Some studies suggest that high fat diets, **obesity**, radiation exposure, or alcohol consumption contribute to the risk profile. Researchers have found that for certain women, hormone replacement therapy may contribute to the development of breast cancer. While one or more risk factors may boost a woman's chances of developing breast cancer, the interplay of factors is complex.

Not all lumps detected in the breast are malignant (cancerous). Many are benign and may be related to other breast diseases such as fibrocystic breast disease and require no treatment or simply the removal of the lump. All women should be taught to perform regular, monthly breast self-examinations (BSE) to detect any

A breast cancer cell. (Phototake NYC. Reproduced by permission.)

changes in breast tissue. Health professionals should also encourage women to schedule a screening **mammography**, which is a breast x ray that will detect cysts or tumors too small to be found during self-examination.

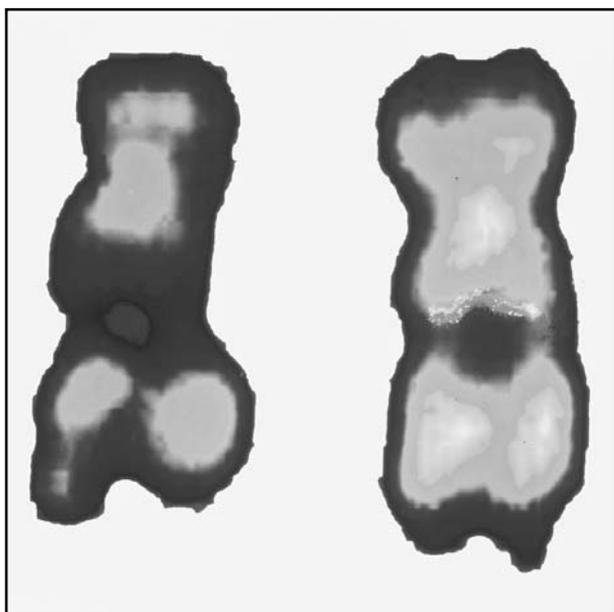

Changes in the breast that may be a sign of breast cancer include:

- lump or thickening in breast or armpit
- changes in a nipple (thickening, pulling in, bleeding, or discharge)
- dimpled or reddened skin over the breast
- change in breast size or shape
- abnormality on a mammogram

Diagnosis

More than 90% of all breast cancers are detected by mammography. The American Cancer Society guidelines recommend screening mammograms every one to two years for women between 40 and 49, and every year after age 50. Women with a family history of breast cancer will be advised to have a mammogram every year at an earlier age.

Typically, mammography screening includes two views of each breast, one from above, and one from the side. Generally, the radiology technician examines the images immediately to make sure no further x rays are needed, or to decide whether an ultrasound may be required.

Magnification of chromosome 17 pair, which carries the breast and ovarian cancer gene. (Custom Medical Stock Photo. Reproduced by permission.)

If an irregularity is detected, such as a mass, changes from earlier mammograms, abnormalities of the skin, or enlargement of the lymph nodes, further testing may be recommended. Diagnostic testing may include ultrasound of the breast, a biopsy, or needle sampling, or consultation with a breast surgeon.

Biopsy of the breast is a removal of breast tissue for examination by a pathologist. An excisional biopsy is a surgical procedure in which the entire lump area and a margin of surrounding tissue are removed for examination. If the mass is very large, an incisional biopsy is performed to remove a portion of the suspicious area. Needle biopsy may be performed using two different methods. An aspiration needle biopsy uses a very fine needle to withdraw cells and fluid from the mass for analysis. A large core needle biopsy uses a larger diameter needle to remove small pieces of tissue from the mass that can be analyzed. These analyses determine whether the mass is benign or cancerous and whether further treatment is required.

To determine if the cancer has metastasized, physicians remove some axillary (underarm) lymph nodes to examine them for the presence of cancer cells. Lymph node dissection, the procedure that determines whether cancer cells are in the lymph nodes, is part of the process of staging (classifying the extent) the cancer. Breast cancer is rated from Stage 0 to Stage IV. The staging process uses an array diagnostic information to describe the extent of disease and includes:

- Stage 1: The cancer is no larger than 0.8 in (2 cm) and no cancer cells are found in the lymph nodes.
- Stage 2: The cancer is no larger than 0.8 in (2 cm) and has spread to the lymph nodes, or is larger than 0.8 in (2 cm), but has not spread to the lymph nodes.
- Stage 3A: The tumor is larger than 2 in (5 cm) and has spread to the lymph nodes, or is smaller than 2 in (5 cm), but has spread to the lymph nodes, which have blended together.
- Stage 3B: Cancer has spread to tissues near the breast or to internal mammary lymph nodes.
- Stage 4: Cancer has spread to skin and lymph nodes near the collarbone or to other organs of the body.

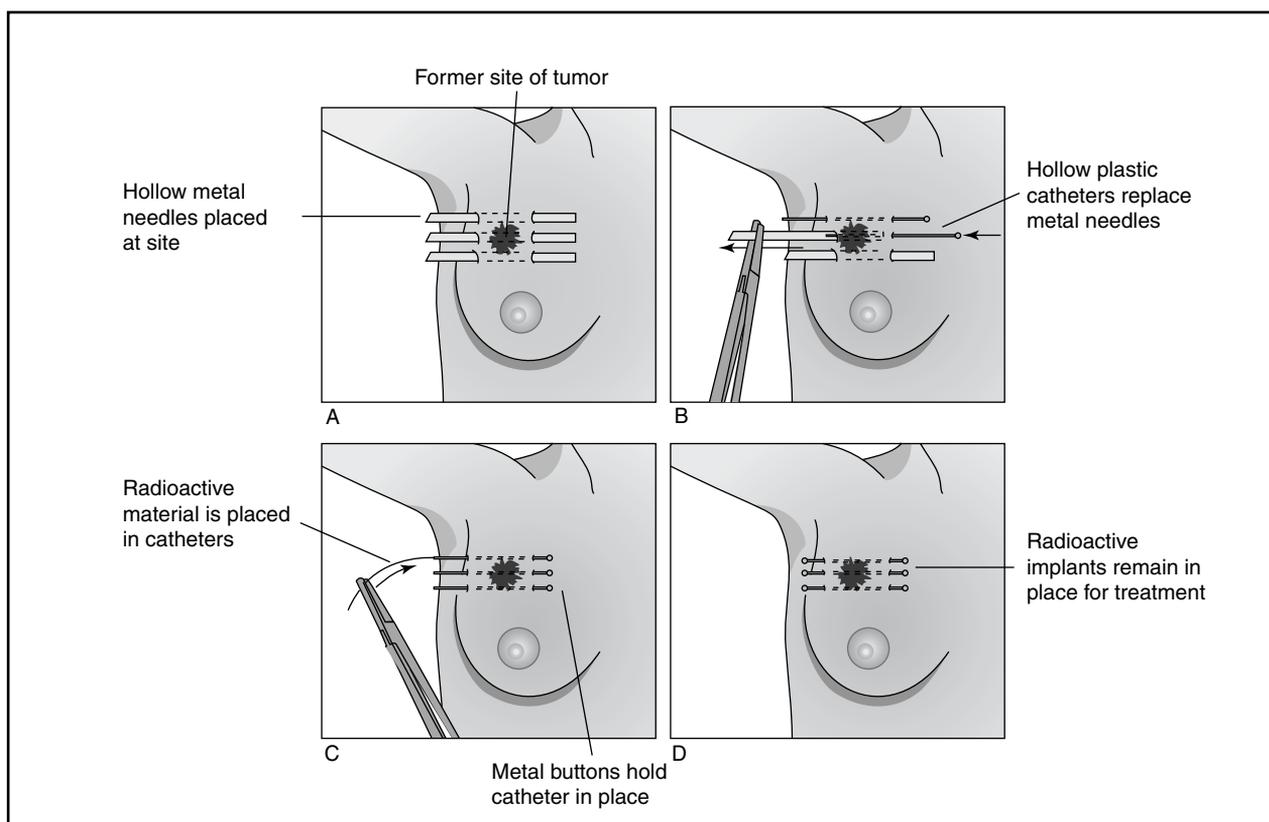

Treatment

Early detection is associated with the best clinical outcomes. Treatment options include surgery with or without **chemotherapy**, or surgery with or without radiation. Sometimes, all treatment modalities may be used in the same patient. Breast cancer is treated locally to eliminate tumor cells from the breast by surgery and radiation, and systemically to destroy cancer cells that have traveled to other parts of the body. Systemic therapy includes the use of chemotherapy and hormonal treatments to reduce the amount of estrogen circulating in the blood.

Lumpectomy is a surgical treatment for newly diagnosed patients with breast cancer. Lumpectomy is considered breast-conserving surgery because only the malignant tumor and a surrounding margin of normal breast tissue are removed. Lymph nodes in the armpit (axilla) may also be removed. This procedure is called lymph node dissection.

It is estimated that at least 50% of women with breast cancer are good candidates for a lymph node dissection. The location, size, and type of tumor are of primary importance when considering breast cancer surgery options. The size of the breast is another factor the surgeon considers when recommending surgery. The patient's psychological outlook, as well as her lifestyle and preferences, should also be taken into account when treatment decisions are made. If the tumor is less than about 1.5 in (4 cm) or there is little risk of recurrence, the patient and physician may opt for lumpectomy, followed by radiation therapy.

Many studies have compared the survival rates of women who have had mastectomy (removal of a breast) with those who have undergone lumpectomy and radiation therapy. The data clearly demonstrate that for women with comparable stages of breast cancer, survival rates are equal between the two groups.

Brachytherapy may be used for treatment of breast cancer. (Delmar Publishers, Inc. Reproduced by permission.)

In some instances, women with later stage breast cancer may be able to have lumpectomy. Chemotherapy may be administered before surgery to decrease tumor size and the chance of metastasis in selected cases.

If the tumor is larger, a total (or simple) mastectomy may be recommended. If the cancer has spread to the chest muscles, a radical mastectomy may be the best treatment option.

In a lumpectomy, the surgeon removes:

- the lump
- a margin of the tissue around the lump or mass
- some of the lymph nodes under the arm (to determine whether the cancer has metastasized)

A new technique that may eliminate the need for removing many axillary lymph nodes is being tested. The term sentinel node biopsy is most frequently used to refer to this method. It is based on the idea that the condition of the first lymph node in the network, which drains the affected area, can predict whether the cancer may have spread to the rest of the nodes. If this first, or sentinel, node is cancer-free, it is thought there is no need to look further. Many patients with early-stage breast cancers

may be spared the risks and complications of axillary node dissection as the use of the sentinel node biopsy continues to increase.

Even if no cancer is found in the nodes, radiation always follows lumpectomy, and treatment may include chemotherapy. Some studies suggest that following lumpectomy, a combination of chemotherapy and radiation offers the best chance of long-term survival.

In a modified radical mastectomy, the doctor removes:

- the entire breast
- axillary lymph nodes
- the lining over the chest muscle, but not the muscles themselves

Today, radical mastectomy is rarely performed, but when necessary, the surgeon removes:

- the entire breast
- the chest muscles
- all of the lymph nodes under the arm

Mastectomy may be combined with breast reconstruction, either during the surgical procedure, postopera-

KEY TERMS

Adjuvant therapy—Treatment involving radiation, chemotherapy, hormone therapy, or a combination of all three.

Aspiration biopsy—The removal of cells in fluid or tissue from a mass or cyst using a needle for microscopic examination and diagnosis.

Benign—Not malignant, non-cancerous.

Biopsy—Surgical removal and testing of tissue to determine if it is malignant.

Estrogen-receptor assay—A test to see if a breast cancer needs estrogen to grow.

Hormone therapy—Treating breast cancer by changing the hormone balance of the body, instead of by using cell-killing drugs.

Lumpectomy—Surgical procedure in which only the cancerous tumor is removed, together with a margin of normal tissue.

Malignant—Cancerous.

Mammography—X-ray imaging of the breast that can often detect lesions in the tissue too small or too deep to be felt.

Mastectomy—Surgical removal of breast(s).

Progestin—A type of hormone used to treat some types of breast cancer.

tively or months later. During surgery, if cancer cells are detected in the lymph nodes, more extensive surgery may be indicated. If the cancer has spread to the nodes, then radiation, chemotherapy, hormone therapy, or a combination of all three will be recommended after surgery. These post-surgical treatments are referred to as adjuvant therapy.

Radiation

Once the cancer has been surgically removed, the oncologist, a specialist in cancer medicine, may recommend radiation to destroy any remaining breast cancer cells. Radiation stops cancer cells from dividing. It works especially well on fast-growing tumors. Unfortunately, it also stops some types of healthy cells from dividing. Healthy cells that divide quickly, such as those of the skin and hair, are most affected. This is why radiation can cause fatigue, skin problems, and alopecia (hair loss).

Chemotherapy

Breast cancer surgery may be followed by chemotherapy, even when it is diagnosed in the earliest stages. Chemotherapy is administered either orally or by intravenous injection. It is usually administered in cycles: anticancer agents are given, followed by a period of time for recovery. Treatment time ranges from four to nine months.

There may be significant side effects with some types of chemotherapy, including nausea and vomiting, temporary hair loss, mouth or vaginal sores, fatigue, weakened **immune system**, and **infertility**. Advances in chemotherapy, especially regimens for early breast cancer, use medications that cause fewer side effects.

Hormone therapy

The growth of some breast cancer cells may be slowed by the antiestrogen drug tamoxifen. Administered orally, tamoxifen travels throughout the bloodstream, affecting all cells in the body. Treatment with tamoxifen continues at least two years, and often as long as five years. Research suggests that tamoxifen may lower the risk of breast cancer recurrence by between 25–35%. Side effects of tamoxifen may include a slightly higher risk of endometrial cancer (cancer of the lining of the uterus). The risk increases if the drug is taken for more than five years. Other side effects include menopause-like symptoms such as weight gain, hot flashes, and mood swings.

Other possible hormone treatments include the use of progestins, estrogens, and androgens. In rare cases, the surgeon may suggest oophorectomy (surgical removal of the ovaries) in pre-menopausal women as a way of eliminating the main source of circulating estrogen, which can boost the growth of some breast tumors.

Stem cell treatment

Stem cell treatment may be used to treat advanced breast cancer. Treatment involves removing stem cells from the patient's bone marrow or blood, and administering very high doses of chemotherapy or radiation to kill cancer cells. Since these high doses of chemotherapy also kill healthy white blood cells, patients are left extremely vulnerable to **infection**. When the stem cells are replaced, they restore the body's ability to combat infection.

Prognosis

The prognosis for breast cancer depends on the type and stage of cancer. Most patients can return to a normal lifestyle within a month or so after surgery. Arm, shoulder, and chest strengthening exercises can help patients

regain strength and flexibility, and avoid lymphedema (swelling resulting from fluid retention).

Despite significant advances in early detection, imaging, and treatment, in 1999, more than 43,000 women in the United States died from breast cancer. There is a five-year survival rate of 97% for women with localized breast cancer, but that drops to 77% for women with cancer that has spread to the axillary lymph nodes, and to 22% for those with distant metastases, such as metastases to **liver, lungs**, bone, or **brain**.

Because of the emotional upset caused by the diagnosis and treatment of breast cancer, counseling or participation in a support group program may benefit some patients. Indeed, many women have found a peer group of breast cancer survivors to be invaluable.

Health care team roles

Patients with breast cancer are usually cared for by a multidisciplinary team of health professionals. The patient's family physician or primary care physician collaborates with specialists such as surgeons and oncologists. Radiologic technicians perform mammograms, x rays, and other imaging studies, and nurses and laboratory technicians may obtain samples of blood, urine, and other laboratory tests.

Before and after any surgical procedures, including biopsies, nurses provide preparatory education to help patients and families. Depending on the tumor stage and treatment plan, patients may also benefit from rehabilitation therapy with physical therapists, nutritional counseling from dietitians, and counseling from social workers or other mental health professionals.

Patient education

It is vitally important for health professionals to instruct and encourage women to perform regular, monthly breast self-examination (BSE). Physicians, nurses, and health educators should use every patient encounter to reinforce the value and importance of BSE.

Prevention

Today, there is no single, proven strategy to prevent breast cancer. For the majority of women at average risk of developing breast cancer, a healthy lifestyle, maintenance of ideal body weight, and regular aerobic **exercise** provide the best known defenses against disease.

Genetic testing enables identification of women with a genetic predisposition to develop breast cancer. Inherited gene alterations, specifically BRCA1 and BRCA2, place women at risk for developing breast cancer at younger ages.

Researchers cannot, however, predict if and when women with genetic predisposition will develop the disease.

Surveillance of women with BRCA1 or BRCA2 mutations includes monthly self-examinations beginning in the late teens, followed by an annual mammography and biannual clinical breast exams, beginning at age 25 to 35. Women with a family history of premenopausal breast cancer are advised to receive clinical breast exams annually and a mammography every one to two years, beginning at age 35.

Traditional medical options for breast cancer prevention among women deemed at highest risk include pharmaceutical intervention—chemoprevention with anti-estrogens such as tamoxifen and raloxifene—and prophylactic mastectomy and oophorectomy. The prophylactic (preventive) surgeries are controversial and, to date, there is insufficient data to determine their efficacy. Many high-risk women choose surveillance, an approach that does not prevent breast cancer, but aims to identify it early, when it is most amenable to treatment.

Breathing, regulation of

Definition

The regulation of breathing is the result of a complex interaction involving a system of sensors, a respiratory control center, and an effector system to carry out its commands to the muscles and organs involved in breathing.

Description

In the body, cells obtain their energy by combining oxygen with various nutrients, producing carbon dioxide as a waste product. Thus, they need a constant supply of oxygen and also need to have the carbon dioxide removed. This is accomplished by breathing, also known as respiration or ventilation, terms used by physiologists to mean the inhaling and exhaling of air.

Breathing is spontaneously initiated in the **central nervous system** and is performed by the body's respiratory system. The overall purpose of this system is to allow the body to inhale the oxygen-containing air, and to exhale the harmful carbon dioxide produced by the metabolic reactions.

Air contains 21% oxygen as a component gas. Air is inhaled into the body through the mouth and nose. It then travels past the throat and voice box (larynx), through the windpipe (trachea), which divides into two main air passages leading to the right and left **lungs**. The two passages divide again in the lungs into smaller branches (bronchi) that separate into even smaller ones (bronchioles or alveolar ducts) much like a tree branches out. These air passages contain little air sacs at their ends called alveoli. There are approximately 150 million alveoli in the human lungs. They have very thin walls that release the oxygen into the **blood**, receiving in exchange its carbon dioxide,

which is then exhaled out of the lungs through the same path leading back to the nose and mouth.

Breathing is an automatic process triggered in a complex area of the **brain** called the brain stem, a part of the brain that connects with the **spinal cord** and its nerves. The brain stem contains the involuntary respiratory control center. This means that breathing is more a reflex activity than an activity based on will, meaning that it happens without our having to think about it or decide that it should occur. Breathing is in fact such a strong reflex that it is very hard to willfully stop breathing for any length of time.

Function

The brain stem respiratory control center regulates breathing with the help of nerves, muscles and special sensors called chemoreceptors. Chemoreceptors are specialized cells that can detect chemical substances in the body and pass that information to nerves that are part of the central nervous system for relay to the respiratory control center. In this way, breathing is constantly monitored and adjusted to maintain appropriate pH and partial pressure of oxygen in the arterial blood, that is the blood coming from the **heart** and that contains the highest levels of oxygen for distribution in the body. The regulation of breathing is a homeostatic control mechanism, meaning that it seeks to maintain the stability of the body's internal environment via negative feedback mechanisms. For example, high levels of carbon dioxide in the body automatically trigger quicker and deeper breathing, which in turn decreases the level of carbon dioxide by increasing the intake of oxygen.

The respiratory control center is the central controlling area for breathing. It receives information from other parts of the body and produces an automatic coordinated response. The response is a reaction that triggers the various organs and muscles involved in breathing and located in different parts of the body to act together. It is located in the lower part of the brain stem, called the medulla oblongata, a scoop-shaped structure connected with the spinal cord. The medulla contains special breathing nerve cells (neurones). One type are the inspiratory neurones, which are active during inhaling and inactive during exhaling. The other type are the expiratory neurones, which are active during exhaling and inactive during inhaling. These two groups of neurones generate an automatic cycle of inhaling and exhaling. This automatic cycle can be modified or even temporarily stopped, depending on the information received by the respiratory control center from a variety of origins, such as **reflexes** from the lungs and airways, informa-

tion from the chemoreceptors, and commands from other areas of the brain.

The major centers providing the information required by the respiratory control center to regulate breathing are the following:

- **Central chemoreceptors.** The central chemoreceptors are located at the bottom of the fourth ventricle (region of the brain stem) and they respond to the acidity—or pH—of the cerebrospinal fluid (CSF), the fluid that bathes the brain and spinal cord. The acidity of any fluid is measured by the pH; this value is related to the number of hydrogen ions present in the fluid. The normal pH of the body is 7.4; values higher than this represent alkaline conditions in the body, meaning a lower amount of hydrogen ions, and values of pH less than 7.4 represent acidic conditions, meaning a higher amount of hydrogen ions. Thus, when the acidity of the CSF changes, the messages sent by the central chemoreceptors to the respiratory control center then have an effect on breathing.
- **Peripheral arterial chemoreceptors.** There are two types of peripheral chemoreceptors: the carotid bodies and the aortic bodies. They are small pieces of tissue containing chemoreceptors that respond to the amounts of oxygen and carbon dioxide in arterial blood. The carotid bodies are located where the common carotid artery divides into the two carotid arteries on both sides of the neck. The aortic bodies are located on the aorta, the body's largest blood vessel, which starts from the heart. The information from the carotid bodies is carried along the ninth cranial nerve and the information from the aortic body is passed along the tenth cranial nerve to the respiratory control center. The information from the carotid bodies is believed to affect the immediate regulation of breathing, breath by breath, by the respiratory control center.
- **Brain.** Breathing can also be voluntary, that is influenced by other parts of the brain, especially the cerebral cortex, the part of the brain where thought processes reside and are responsible for willful action. We can all consciously breathe more deeply and more rapidly (hyperventilation), as for example, before starting heavy **exercise**. Strong emotions can also result in hyperventilation.
- **Lung.** There are various receptors located in the lung that can also affect breathing. For example, a type of receptor in the bronchi respond to irritating inhaled substances and cause coughing, breath holding, and sneezing. Other receptors located in the flexible tissues of the lung and the chest wall are sensitive to stretch. The exact role played by these receptors in the regulation of breathing is not fully understood, but they are

thought to be responsible for various reflexes that have been discovered in laboratory studies performed on animals. These are stretch reflexes that occur when the lung and chest wall are distended so as to prevent further inhaling. Also, when the air volume is low in the lungs, then there are opposite reflexes.

After receiving information, the respiratory control center needs a pathway to send its regulatory messages. This is done by special nerves, called efferent nerves. They leave the respiratory control center and pass down the spinal cord to the diaphragm, and to the muscles located between the ribs (intercostal muscles) and to other muscles located in the neck and used to breathe. The diaphragm is a thin, sheet-like muscle located at the bottom of the chest cavity below the lungs and heart, and it is the most important muscle involved in breathing. When a person inhales, the diaphragm contracts and moves downward, thus stretching the cavity that contains the lungs (thorax or thoracic cavity), while the intercostal muscles contract and widen the thoracic cavity, which results in air filling the lungs through suction. When a person exhales, the diaphragm and intercostal muscles relax, which decreases the size of the thoracic cavity and forces air out of the lungs. During normal breathing, inhaling is an active muscular process. Exhaling is passive and relies on the natural elasticity of the tissues to deflate the lung.

Role in human health

Breathing is an essential activity of the body, required to maintain life. If it is stopped, death quickly follows. Thus, the regulation of breathing is also essential, meaning that any disruption of this function will affect the respiratory ability of the body, with consequences depending on the extent of the impairment.

Common diseases and disorders

If the rate of oxygen intake and of carbon dioxide elimination is not matched by delivery of the first and removal of the second, an imbalance occurs that may result in respiratory abnormalities associated with serious diseases such as **pneumonia** (inflammation of the lungs), **emphysema** (excessive and abnormal accumulation of air in the lungs resulting from a reduction of the area of the lung membranes), **heart failure**, anemia (lack of red blood cells in the blood, resulting in insufficient oxygen), and **asthma** (narrowing of the bronchi). The following conditions are the result of such imbalances:

- **Hypoxia.** Also known as anoxia. It means “without oxygen” and is used to describe a condition of insufficient oxygen being provided to the cells of the body.

KEY TERMS

Acidity—Refers to a compound that is acid or sour. When dissolved in water, acids yield hydrogen ions.

Brain stem—Lowest part of the brain that connects with the spinal cord. It is a complicated neural center with several neuronal pathways between the cerebrum, spinal cord, cerebellum, and motor and sensory functions of the head and neck. It consists of the medulla oblongata, the part responsible for cardiac and respiratory control, the midbrain, which is involved in basic, involuntary body functions, and the pons, where some cranial nerves originate.

Bronchi—Air passages in the lungs.

Central nervous system (CNS)—In humans, the CNS consists of the brain, the cranial nerves and the spinal cord.

Cerebrospinal fluid (CSF)—A clear fluid that contains small quantities of sugar (glucose) and protein. The CSF fills the brain and the central canal of the spinal cord and its normal pH is 7.4. Any change from this value is detected by chemoreceptors.

Chemoreceptors—Specialized cells that can detect chemical substances in the body and relay that information to the central nervous system. The substances detected may be external, such as when an individual smells or tastes something or they can be internal, such as the oxygen or carbon dioxide present in the blood.

Cranial nerve—In humans, there are 12 cranial nerves. They are connected to the brain stem and basically control the head as well as help regulate the organs of the thoracic and abdominal cavities.

Diaphragm—Thin, sheet-like muscle located below the lungs and heart at the bottom of the chest cavity and that separates it from the abdomen. The diaphragm is a breathing muscle, it allows air to get in and out of the lungs by moving up and down. When the diaphragm moves down, a person breathes in. When the diaphragm moves up, the person breathes out.

Homeostasis—Stability of the body's internal environment, achieved by a system of integrated control systems activated by feedback systems. For example, high levels of carbon dioxide in the CSF triggers stronger ventilation in the lungs which in turn decreases the level of carbon dioxide by increasing the intake of oxygen.

Involuntary activity—Activity that is not under the influence or control of the will.

Lungs—Large pair of respiratory—or breathing—organs located in the chest. The lungs bring the oxygen present in the inhaled air into the blood and remove toxic carbon dioxide from the blood.

Metabolism—The sum of all the physical and biochemical processes occurring in the body to produce what is required to maintain life. This includes the transformation of nutrients into energy and the use of energy by the body.

Peripheral chemoreceptors—Chemoreceptors not located in the brain stem. There are two types: the aortic bodies located in the aorta, the largest artery in the body and the carotid bodies located in the carotid arteries that pass on either side of the neck, carrying oxygenated blood from the aorta to the brain.

pH—A measure of the acidity of a solution, or of its hydrogen ion concentration. In the human body, the solution can be the blood or the CSF. The normal pH of body fluids is 7.4.

Reflex—Action or movement of the body that is the sum of involuntary activity.

Respiration—In humans, breathing, meaning the inhaling of oxygen-containing air and the exhaling of carbon dioxide-containing air. It can also refer to the exchange of oxygen and carbon dioxide in the blood. The term respiration has yet another meaning in biochemistry, where it refers to the complex chemical reactions occurring in the body, called oxidation reactions, by which chemical substances transfer electrons and convert energy into forms required to maintain life.

Respiratory system—The organs that are involved in breathing: the nose, the throat, the larynx, the trachea, the bronchi and the lungs.

Trachea—The windpipe, a tube made of fiber and cartilage that connects the voice box (larynx) to the bronchi.

Ventilation—Air entering an exiting the body. Pulmonary ventilation refers to the exchange of air between the lungs and the ambient air and alveoli ventilation refers to the exchange of oxygen and carbon dioxide with the blood.

- Hypoxic hypoxia. This condition is characterized by an inadequate supply of oxygen to the arterial blood and abnormally low partial pressure of oxygen in the arteries. **Cyanosis** (blueness of the skin and membranes) is a major symptom, due to lower levels of hemoglobin, the protein that carries oxygen in the blood.
- Stagnant hypoxia. This is failure to transport oxygen to the tissues and is due to a slow blood flow, as can occur with heart failure.
- Anemic hypoxia. In anemic hypoxia, the partial pressure of oxygen in the arteries is normal, but the oxygen content of the arterial blood is lower than normal.
- Hypercapnia. This means an excess of carbon dioxide.
- Acidosis. Increase of the amount of hydrogen ion (acidity) in the blood and CSF, leading to respiratory acidosis. It occurs when the lungs are not ventilating properly and results in excessive amounts of carbon dioxide in the blood. Non-functional carotid bodies have been shown to cause acidosis.
- Alkalosis. Loss of hydrogen ion in the blood and CSF, leading to respiratory alkalosis, meaning excessive loss of carbon dioxide from the body. An alkaline CSF inhibits the respiratory control center.

Breech birth

Definition

In a breech birth, the presenting part of the fetus, or the part that enters the woman's birth canal first, is the buttocks or leg(s).

Description

In almost 97% of vaginal births, the head is the part of the baby to be born first (i.e., vertex presentation). During a woman's **pregnancy**, the fetus moves freely inside the uterus, cushioned by the amniotic fluid. At 20 weeks' gestation, the midway point in the pregnancy, about 24% of fetuses are in a breech position. By 34 weeks, only about 7% are in a breech position. As the pregnancy progresses towards term (37–42 weeks), the growing fetus has less room in which to turn around, and usually remains more in an inverted (head down) position. However, in about 3–4% of births, the buttocks or feet present first.

There are three types of breech presentations:

- Complete breech, in which the buttocks present first, the baby's thighs are tight against the abdomen, the legs are crossed, and the feet are flexed. In this position, the fetus is curled up tightly in a ball.
- Frank breech, in which the knees are straight (i.e., not bent), and the legs are held tightly against the abdomen and head. This breech position comes closest to filling the pelvic inlet, as would the fetus's head.
- Footling breech, in which one or both legs enter the birth canal first. The fetus appears to be standing in an upright position.

Risks

Risks of a vaginal breech delivery include:

- Prolapse of the umbilical cord. This is especially true in a footling presentation, where the feet and legs are small and provide room for the umbilical cord to slip alongside and into the birth canal. Any pressure on the cord compresses the sides of the cord, decreasing **blood** flow and oxygen to the fetus. This may result in anoxia.
- Entrapment of the head. This occurs when the body of the neonate passes through the cervix, but the head, which is the largest part of the body, cannot fit through the cervical opening. This may occur because the cervix was incompletely dilated at the time of the birth of the baby, or when the head is larger than the pelvic opening.
- Trauma to the head or neck of the neonate during delivery. This could result in permanent **brain** damage or **paralysis** of the infant.
- Trauma to the spine or an arm resulting in fracture of a bone.
- Meconium aspiration. The breech position may cause an early rupture of the amniotic fluid membranes, and meconium (the infant's first stool) may be released. If the neonate breathes in any of the meconium, he or she

risks obstruction of the airway by the meconium, and pneumonia.

- Dysfunctional labor. Because of the fetal breech position, the labor can be drawn out, exhausting the mother, and diminishing her ability to push as the time of delivery approaches.
- Higher level of perinatal morbidity and mortality.

Accurate imaging of the fetus *in utero* has decreased the number of breech births by alerting obstetricians and midwives to this presentation prior to the time of delivery. A technique called external version may be used to encourage the fetus to rotate into a vertex position. This technique will be described below, under “Treatment.” However, as the practice of external version has increased, practitioners have had less experience delivering a breech baby vaginally. A successful vaginal delivery of a breech presentation depends to a great extent on the skill and experience of the practitioner.

Twins present a special challenge, and will take one of several possible birth positions:

- Vertex-vertex. In this, the safest of positions for delivery, the twins both present in the vertex, or head down position. It occurs in about 40–45% of twin births.
- Vertex-breech or breech-vertex. This position offers the most efficient use of the uterine space, but is not the best presentation for delivery. Vertex-breech and vertex-transverse positions occur in about 35–40% of twin births. Breech-vertex positioning occurs in about 15–20% of births.
- Breech-breech presentation occurs in about 15–20% of twin births, and almost always results in cesarian-section birth.

If the second twin entering the birth canal is the larger, there will be a concern that he or she may become stuck because the smaller, first twin did not adequately enlarge the cervical opening. Twins are often born prematurely, and are smaller than full-term infant. The more premature the infant, the greater the chance it will have a smaller body-to-head proportion than the full-term infant. This creates a greater hazard for breech birth, because the small body can come through a less-dilated cervix, and there is a greater chance that the head will get trapped. Accurate imaging of twin positions will play a major role in determining the safest delivery method. An external version of the second twin may be proposed. Version of the first twin is unlikely, as the procedure poses a threat to both twins.

Causes and symptoms

The cause of a particular breech presentation may not be understood about 80% of the time. However, causes of breech presentation may include:

- an inability of the fetus to have full movement inside the uterus
- the position of the placenta, such as a low-lying **placenta previa**, and a short umbilical cord
- decreased muscle tone of the fetus
- a congenital disorder of the fetus, especially neuromuscular in nature
- a space-related problem for the fetus, such as with uterine fibroids
- fetal anomaly, such as hydrocephalus
- uterine structural anomaly, such as a septum trapping the fetus in a breech position
- gestation of less than 40 weeks
- multiple gestation
- hydramnios, in which excess amniotic fluid is produced and the fetus has too much room in which to move

Diagnosis

There are three primary ways in which a breech position is discovered, including imaging, position of the fetal heartbeat, and external palpation on the mother’s abdomen.

Imaging. There are a variety of imaging technologies, varying in safety, cost, and ease of access. **Magnetic resonance imaging (MRI)** is very accurate, but is extremely expensive, not as readily available, and would rarely provide more information than an ultrasound to justify its use. Ultrasound is the most widely used method of imaging during pregnancy, as it uses sound waves instead of radiation, is available in most health care centers, and is cost efficient. Ultrasound is considered safe to use at all stages in pregnancy.

Leopold’s maneuvers consist of a series of four external palpations of the mother’s abdomen to determine fetal position in the uterus. The fetal head is hard and can move separately from the rest of the body. The buttocks feel soft and move with the body. As the time for delivery draws near, a vaginal examination may be required, however, as Leopold’s maneuvers can sometimes be misleading. In a vaginal examination, the baby’s fontanelles are palpated.

Treatment

When dealing with a breech presentation, there are three choices for delivery: attempt to rotate the fetus into a vertex presentation prior to delivery; attempt a trial of vaginal delivery in the breech position; or deliver by cesarian section. Some hospitals may not have the mother attempt a vaginal delivery and instead opt for cesarian section.

The preferred mode of delivery is a vaginal birth with the fetus in vertex presentation. Attempts are therefore made to rotate the fetus from a breech into a vertex position. One method has been to have the mother assume different positions (e.g., knee-chest) in the hope that this would cause the fetus to move into a more favorable position. Research studies have not shown this to be very successful, although periodic anecdotal accounts of success have been reported. In the November 11, 1998 issue of the *Journal of the American Medical Association*, researchers reported on the use of traditional Chinese medicine to cause the fetus to rotate. In this study, moxa, a combustible Chinese herb, was used over a two-week period to stimulate an acupuncture point on the toe. Stimulation of this point is believed to increase fetal activity, during which the fetus then moves into the vertex position. After two weeks of treatment with moxa, 75% of the 130 fetuses studied rotated into the vertex position, while only 48% of the control (no intervention, just routine obstetrical care) fetuses rotated. However, the results of this study has not been replicated.

A more traditional and more commonly used treatment within Western medical standards is external version. In external version, the fetus is rotated manually by the physician, who exerts pressure on the mother's abdomen to cause the fetus to somersault into the vertex position. Medication may be given to the mother to relax the uterine muscles prior to the procedure. The vertex position allows the fetus more mobility and decreases the chance of uterine contractions, which lead to early labor. Before attempting version, however, an ultrasound is performed to confirm the position of the fetus. The timing of version is important. Done too early, the fetus may rotate back into a breech position if too much space is still available. Performed at 35-37 weeks' gestation, the success rate has shown to be up to 65%. In approximately 1-2% of cases, complications arise following version, leading to the need for immediate delivery via cesarian section.

Version should always be done in a hospital, where there are facilities for immediate cesarian delivery available in the cases of cord compression or **placental abruption**. Some research has indicated that giving the mother an epidural for the version procedure increases its

success rate. The version can be accomplished by two health care professionals. Mineral oil may be applied to the mother's abdomen so that the obstetrician's hands can smoothly slide over the surface. The fetal **heart** rate should be monitored closely for any signs of fetal distress, and should be continued for about an hour after the procedure to assure fetal stability. Mothers who are Rh-negative may be given Rh immune globulin, which would prevent incompatibility should fetal-to-mother transfusion occur during the version. About 90% of babies turned by version will remain in this position for delivery.

Version has risks and is contraindicated in the following situations:

- uterine structural anomalies
- third-trimester bleeding
- hydramnios, excess amniotic fluid production
- nuchal cord, or the cord around the baby's neck, (not always seen on ultrasound)
- previous uterine surgery, such as cesarian section, that has weakened the uterine walls
- cephalopelvic disproportion (CPD), a condition in which the baby's head is too big for the mother's pelvic inlet, as evidenced on ultrasound or other imaging tools

When a vaginal breech birth is attempted, the pace of the delivery is very important. Fetal heart rate and uterine contractions need to be closely monitored. During a vertex vaginal delivery, the head is molded coming down the birth canal, and the labor process slows the pace of the delivery. In a breech vaginal birth, the smaller body may slip more quickly through the canal. If the head becomes caught, fetal anoxia (lack of oxygen) can occur. The head does not mold during a rapid breech birth, and if the neonate is allowed to deliver quickly, perhaps due to a detected prolapsed cord, the rapid change in pressure can result in intracranial hemorrhage. To assist the breech delivery, the mother may be asked to assume a squatting position, as this increases the birth canal volume by about 28%. (This position is not popular in the United States.) Forceps may be used to protect the neonate's neck and head from trauma and to assist in the delivery. If the vaginal birth attempt causes fetal distress, an emergency cesarian delivery may be required.

In a cesarian birth, an incision is made through the mother's abdominal wall into the uterus. The amniotic fluid membranes are broken and the neonate is extracted. A vertical incision in the uterus along the mother's abdominal midline is called a classical cut. This provides the fastest access to the infant and may be chosen in the event of an emergency delivery. The fetus can be removed from the uterus in minutes. If a woman has had

KEY TERMS

Cephalopelvic disproportion—When the fetus' head is larger than the mother's pelvic inlet.

Nuchal cord—The term used when the umbilical cord is looped around the fetus' neck in utero.

Presentation—Presentation refers to that part of the fetus' body that enters into the birth canal first.

Prolapsed umbilical cord—When the cord falls into the birth canal, and may even hang out of the mother's vagina. This can cause compression of the cord and lead to decreased oxygen and blood flow to the fetus.

Transverse—In the transverse position, the fetus lies sideways against the birth canal, with a shoulder or arm possibly entering the canal.

the classical uterine incision, she will not be allowed to attempt to deliver vaginally in the future, because the uterine wall rupture can during the next labor. When time permits, the preferred incision is a transverse one, just above the pubic bone. This incision is sometimes referred to as a bikini cut. Healing time is decreased and may allow a woman to successfully deliver vaginally in the future.

Prognosis

About half the attempts of a vaginal breech delivery will result in a cesarian birth. Discovery of breech presentation prior to the time of delivery allows attempts to be made to rotate the fetus. If these attempts prove unsuccessful, a cesarian birth can then be scheduled. A scheduled cesarian allows the mother and her partner to be informed and participate, to some degree, in the process. Anesthesia can be chosen that allows the mother to be awake during the birth of her child. If emergency cesarian delivery is required, the mother will be given a **general anesthesia** to shorten the time required to extract the fetus in distress. If complications do not occur, the prognosis is excellent.

Health care team roles

During a breech birth more nursing personnel may be needed to assist the obstetrician and provide support for the mother. A neonate that has been in a breech position *in utero* may maintain an unusual position for a few days after birth. An explanation by the nurse can greatly reduce the mother's concern that there is something wrong with her baby.

Prevention

None of the known causes of breech presentation mentioned above are preventable, and in many breech presentations, there is no known cause. However, while it is not possible to prevent this presentation, attempts such as version are made to prevent a breech delivery, or to minimize its inherent risks.

Bronchoscopy

Definition

Bronchoscopy is a procedure in which a hollow, flexible tube is inserted into the airways (nose or mouth). The bronchoscope is inserted through the nose (or mouth) provides a view of the tracheobronchial tree and can be used to collect bronchial and/or lung secretions. Tissue biopsy may also be performed via the bronchoscope.

Purpose

During a bronchoscopy, the physician can visually examine the lower airways, including the larynx, trachea, bronchi, and bronchioles. The procedure is used to examine the mucosal surface of the airways for abnormalities that might be associated with a variety of lung diseases. Its use may be diagnostic or therapeutic.

Bronchoscopy may be used to examine and help diagnose:

- diseases of the lung, such as **cancer** or tuberculosis
- a congenital deformity of the **lungs**
- a suspected tumor, obstruction, secretion, bleeding or foreign body in the airways
- airway abnormalities, such as tracheal stenoses
- a persistent cough, or hemoptysis, a cough that includes **blood** in the sputum

Bronchoscopy may be used for the following therapeutic purposes:

- to remove a foreign body in the lungs
- to remove excessive secretions

Bronchoscopy can also be used to collect the following specimens:

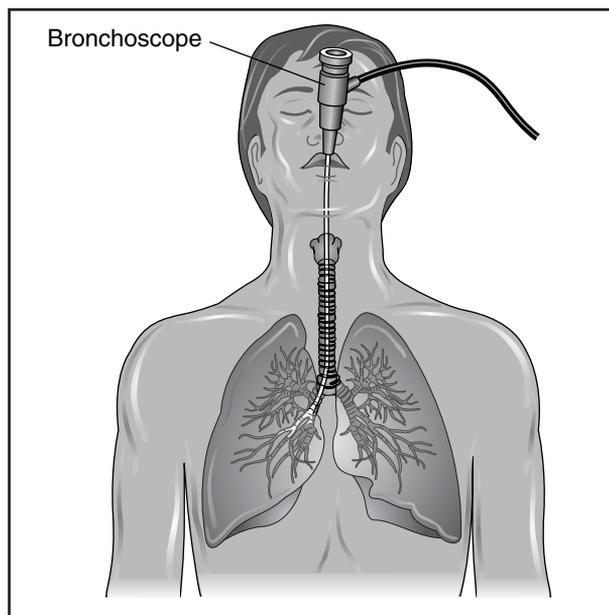

- sputum
- tissue samples from the bronchi or bronchioles
- cells collected from washing the lining of the bronchi or bronchioles

If the purpose of the bronchoscopy is to take tissue samples or biopsy, a forceps or bronchial brush are used to obtain cells. Alternatively, if the purpose is to identify an infectious agent, a bronchoalveolar lavage can be used to gather fluid for culture purposes. If any foreign matter is found in the airways, it can be removed as well.

The instrument used in bronchoscopy, a bronchoscope, is a slender flexible tube that uses fiberoptic technology (very fine filaments that can bend and carry light). There are two types of bronchoscopes, a standard tube which is more rigid and a fiberoptic tube which is more flexible. The rigid instrument doesn't bend, doesn't see as far down into the lungs as the flexible one, and may carry a greater risk of causing injury to nearby structures. Because it can cause more discomfort than the flexible bronchoscope, it requires stronger anesthesia. However, it is useful for taking large samples of tissue and for removing **foreign bodies** from the airways.

Precautions

If the patient has severe **respiratory failure** and cannot breathe adequately on his or her own, the patient should be placed on a ventilator prior to bronchoscopy. It may not be appropriate to perform bronchoscopy on patients who have congestive **heart failure** or have experienced a recent **heart** attack. All patients must be constantly monitored while undergoing a bronchoscopy so that any abnormal reactions can be dealt with immediately.

Bronchoscopy is a procedure in which a hollow, flexible tube is inserted into the airways, allowing the physician to visually examine the lower airways, including the larynx, trachea, bronchi, and bronchioles. It can also be used to collect specimens for bacteriological culture to diagnose infectious diseases such as tuberculosis. (Illustration by Electronic Illustrators Group.)

Description

The procedure is ideally performed in an endoscopy room, but may be performed at the bedside. Follow institutional procedures for preoperative medications. The patient is placed in a supine position or sits upright. A pulmonologist trained to perform a bronchoscopy will spray anesthesia into the patient's mouth or nose. When the anesthetic has taken effect, the bronchoscope will be put into the patient's mouth or nose and passed into the throat. While the bronchoscope is moving down the throat, additional anesthesia is put into the bronchoscope to anesthetize the lower airways. The physician observes the trachea, bronchi, and the mucosal lining of these passageways looking for any abnormalities that may be present.

Alternative procedures

Depending upon the purpose of the bronchoscopy, alternatives may include a **chest x ray** or a computed tomography (CT) scan. If the purpose is to obtain biopsy specimens, one option is to perform surgery, which carries greater risks. Another option is percutaneous biopsy guided by CT.

Preparation

The patient should fast for six to twelve hours prior to the procedure and refrain from drinking any liquids the day of the procedure. Smokers should refrain from smoking for 24 hours prior to the procedure. The bronchoscopy itself takes about 45-60 minutes. Prior to the bronchoscopy, several tests will be done, including chest x ray and blood work. Sometimes a bronchoscopy is done under **general anesthesia**, in which case the patient will have an intravenous (i.v.) line in the arm. More commonly, the procedure is performed under **local anesthesia**, which is sprayed into the nose or mouth. This is necessary to inhibit the gag reflex. A sedative may be given. It is important that the patient understands that at no time will the airway be blocked and that oxygen can be supplied through the bronchoscope. A signed consent form is necessary for this procedure.

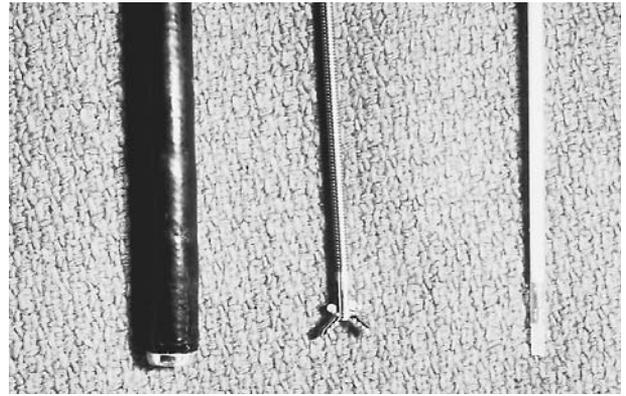

Aftercare

After the bronchoscopy, the **vital signs** (heart rate, **blood pressure**, and breathing) are monitored. Sometimes patients have an abnormal reaction to anesthesia. Any sputum should be collected in an emesis basin so that it can be examined for the presence of blood. If a biopsy was taken, the patient should not cough or clear the throat as this might dislodge any blood clot that has formed and cause bleeding. No food or drink should be consumed for about two hours after the procedure or until the anesthesia wears off. There is a significant risk for choking if anything (including water) is ingested before the anesthetic wears off, and the gag reflex has returned. To test if the gag reflex has returned, a spoon is placed on the back of the tongue for a few seconds with light pressure. If there is no gagging, the process is repeated after 15 minutes. No small or sharp objects are used to test this reflex. The gag reflex should return in one to two hours. Ice chips or clear liquids should be taken before the patient attempts to eat solid food.

The patient should be instructed that after the anesthetic wears off the throat may be irritated for several days.

Patients should notify their health care provider if they develop any of these symptoms:

- hemoptysis (coughing up blood)
- shortness of breath, wheezing or any trouble breathing
- chest **pain**
- fever, with or without breathing problems

Instruments used in bronchoscopy procedures. (Custom Medical Stock Photo. Reproduced by permission.)

Complications

Minor side effects arise from the bronchoscope causing abrasion of the lining of the airways. This results in some swelling and inflammation, as well as hoarseness caused from abrading the vocal cords. If this abrasion is more serious, it can lead to respiratory difficulty or bleeding of the lining of the airways. A more serious risk involved in having a bronchoscopy performed is the occurrence of a pneumothorax, due to puncturing of the lungs, which allows air to escape into the space between the lung and the chest wall. These risks are greater with the use of a rigid bronchoscope than with a fiberoptic bronchoscope. If a rigid tube is used, there is also a risk of chipped teeth. The risk of transmitting infectious disease from one patient to another by the bronchoscope is also present. There is potential for **infection** from endoscopes inadequately reprocessed by an automated **endoscope** reprocessing (AER) system. The Centers for Disease Control (CDC) reported apparent patient-to-patient transmission of infections following bronchoscopic procedures that used bronchoscopes that were inadequately reprocessed by AERs. Investigation of the incidents revealed inconsistencies between the reprocessing instructions provided by the manufacturer of the bronchoscope and the manufacturer of the AER; or that the bronchoscopes were inadequately reprocessed.

Results

Normal tracheal appearance consists of smooth muscle with C-shaped rings of cartilage at regular intervals. The trachea and the bronchi are lined with a mucous membrane.

Abnormal bronchoscopy findings include deformity in the bronchial wall, such as inflammation, stenosis or compression of the trachea, neoplasm, and foreign bod-

KEY TERMS

Anesthesia—A drug used which causes loss of sensation. It is used to lessen the pain of surgery and medical procedures.

Bronchi—The network of tubular passages that carry air to the lungs and allow air to be expelled from the lungs.

Bronchioles—Small airways extending from the bronchi into the lobes of the lungs.

Bronchoalveolar lavage—Washing cells from the air sacs at the end of the bronchioles.

Emesis basin—A basin used to collect a patient's sputum or vomit.

Neoplasm—A new growth or tumor.

Trachea—The windpipe.

ies. Findings of swelling, or ulceration are abnormal. The bronchoscopy may also reveal the presence of atypical substances in the trachea and bronchi. If samples are taken, the results could indicate cancer, disease-causing agents or other lung disease. Other abnormalities include constriction or narrowing (stenosis), compression, dilation of vessels, or abnormal branching of the bronchi. Abnormal substances that might be found in the airways include blood, secretions, or mucous plugs. Any abnormalities are discussed with the patient.

Health care team roles

The test is usually performed by a pulmonologist, a physician specializing in diseases of the lungs. Nursing staff assist with providing education, monitoring the patient, and conducting tests, including checking blood pressure, pulse, and respiratory rate prior to the patient's discharge.

Bruxism

Definition

Bruxism is a habitual grinding or clenching of the teeth. The behavior is usually unconscious, occurs most often during sleep, and is a reaction to periods of **stress** in the patient's life.

Description

Bruxers often unknowingly grind their teeth. Pencils, their fingernails, and the insides of their cheeks may be bitten. This habitual tooth gritting, grinding or clenching can lead to facial **pain** and tooth abrasion. Bruxism is common—as many as one in three people is a bruxer. The condition affects both adults and children. However, it often goes unrecognized until tooth damage is noticed by a dentist.

Causes and symptoms

Personality type may place a patient at risk for bruxism. People who are anxious, angry or stressed are more likely to succumb to the habitual grinding and clenching. Another cause of bruxism is an abnormal dental occlusion, which can cause the teeth to grind more easily due to their positioning. Clenching and grinding the teeth can cause jaw area tissue alterations.

Bruxism causes the teeth to wear and become flat at the tips. The teeth can become so severely worn that the dentin is exposed and sensitive. Bruxism can lead to temporomandibular joint pain and, as a result, the jaw might begin popping and clicking. Some bruxers have tongue indentations—another sign of bruxism.

KEY TERMS

Biofeedback—A training technique used to gain control over autonomic body functions.

Bruxers—People who grind and clench their teeth.

Dentin—The hard material of the main part of the tooth, situated beneath the enamel and contain the pulp.

Occlusion—Contact between the surfaces of the upper and lower teeth when the mouth is closed.

Temporomandibular joint—One of a pair of joints connecting the mandible in the lower jaw to the temporal bone in the skull.

Diagnosis

To diagnose bruxism, the dentist looks for signs of damage, such as chipped enamel, usual tooth wear and tear, radiographic bone changes, and sensitivity. Asking relevant questions can also help dentists make the diagnosis. The questions can include asking patients if their teeth or jaws hurt upon awakening in the morning and if they suffer from worry or stress. The dental exam helps to determine whether the grinding is caused by misaligned teeth or psychological forces.

Treatment

Often, treatment is aimed at getting bruxers to change their behavior. This might involve **relaxation** training and other stress management techniques. If relaxation doesn't suffice, dentists might recommend a plastic mouth appliance to relax the facial muscles and protect the teeth from the grinding and clenching. Another method of treatment is biofeedback. New treatments for bruxism, especially for nocturnal bruxers, are being studied. In some cases, psychological assessment or **psychotherapy** might be recommended.

Prognosis

Childhood grinding and clenching of the teeth are often outgrown by adolescence. By making an effort not to grind or clench their teeth, some people can address the problem successfully. Dental intervention to protect the teeth or correct misalign teeth, as well as attempts at stress and **anxiety** relief, often solve the problem.

Health care team roles

The first signs of bruxism, as well as its related problems, might be noticed by the dental hygienist during professional maintenance care; the patient may be referred to the dentist. Education of the patients about bruxism and options for treatment can be accomplished by the dental hygienist. If the patient comes to his or her primary health care provider complaining of jaw pain, the diagnosis may occur in the clinic or office setting. The patient would be referred to a dentist for a dental appliance.

Prevention

Bruxism precipitated by stress and anxiety can be avoided if patients treat their stress with proper management techniques.

Burns

Definition

Burns are injuries to tissues caused by heat, friction, electricity, radiation, or chemicals.

A patient is treated for burn wounds. (Phototake. Reproduced by permission.)

Description

Burns are characterized by degree, based on the severity of the tissue damage. A first-degree burn causes redness and swelling in the outermost layers of the skin (epidermis). A second-degree burn involves redness, swelling, and blistering, and the damage may extend beneath the epidermis to deeper layers of skin (dermis). A third-degree burn, also called a full-thickness burn, destroys the entire depth of skin, causing significant scarring. Damage may also extend to the underlying fat, muscle, or bone.

The severity of a burn is also judged by the amount of body surface area (BSA) involved. Health care workers use the rule of nines to determine the percentage of BSA affected in persons more than nine years old: each arm with its hand is 9% of BSA; each leg with its foot is 18%; the front of the torso is 18%; the back of the torso, including the buttocks, is 18%; the head and neck are 9%; and the genital area (perineum) is 1%. This rule cannot be applied to a young child's body proportions, so BSA is estimated using the palm of the person's hand as a measure of 1% area.

The severity of a burn will determine not only the type of treatment, but also where the burned individual should receive treatment. Minor burns may be treated at home or in a doctor's office. These are defined as first- or second-degree burns that cover less than 15% of an adult's body or less than 10% of a child's body, or a third-degree burn of less than 2% BSA. Moderate burns should be treated at a hospital. These are defined as first- or second-degree burns that cover 15%–25% of an adult's body or 10%–20% of a child's body, or a third-degree burn on 2%–10% BSA. Critical, or major, burns are the most serious and should be treated in a specialized burn unit of a hospital. These are defined as first- or second-degree burns that cover more than 25% of an adult's body or more than 20% of a child's body, or a third-degree burn of more than 10% BSA. In addition, burns involving the hands, feet, face, eyes, ears, or genitals are considered critical. Other factors influence the level of treatment needed, including associated injuries such as bone **fractures** and smoke inhalation, presence of a chronic disease, or a history of being abused. Children and the elderly are more vulnerable to complications from burn injuries and require more intensive care.

Causes and symptoms

Burns may be caused by even a brief encounter with heat greater than 120°F (49°C). The source of this heat may be the sun (causing a sunburn), hot liquids, steam, fire, electricity, friction (causing rug burns and rope burns), and chemicals (causing a caustic burn upon contact).

Signs of a burn are localized redness, swelling, and **pain**. A severe burn will also blister. The skin may peel, appear white or charred, and feel numb. A burn may trigger a headache and **fever**. Extensive burns may induce **shock**, the symptoms of which are faintness, weakness, rapid pulse and breathing, pale and clammy skin, and bluish lips and fingernails.

Diagnosis

Physicians will diagnose a burn based upon visual examination, and will also ask the burned person or family members questions that help determine the best treatment. They may also check for smoke inhalation, **carbon monoxide poisoning**, cyanide **poisoning**, other event-related trauma, or, if suspected, further evidence of **child abuse**.

Treatment

Burn treatment consists of relieving pain, preventing **infection**, and maintaining body fluids, electrolytes, and calorie intake while the body heals. Treatment of chemical or electrical burns is slightly different from the treatment of thermal burns, but the objectives are the same.

Thermal burn treatment

The first act of thermal burn treatment is to stop the burning process. This may be accomplished by letting cool water run over the burned area or by soaking it in cool (not cold) water. Ice should never be applied to a burn. Cool (not cold) wet compresses may provide some pain relief when applied to small areas of first- and second-degree burns. Butter, shortening, or similar salve should never be applied to a burn since it prevents heat from escaping and drives the burning process deeper into the skin.

If a burn is minor, it may be gently cleaned with soap and water. Blisters should not be broken. If the skin of a burned area is unbroken, and it is not likely to be further irritated by pressure or friction, the burn should be left exposed to the air to promote healing. If the skin is broken or apt to be disturbed, the burned area should be coated lightly with an antibacterial ointment and covered with a sterile bandage. Aspirin, acetaminophen (for

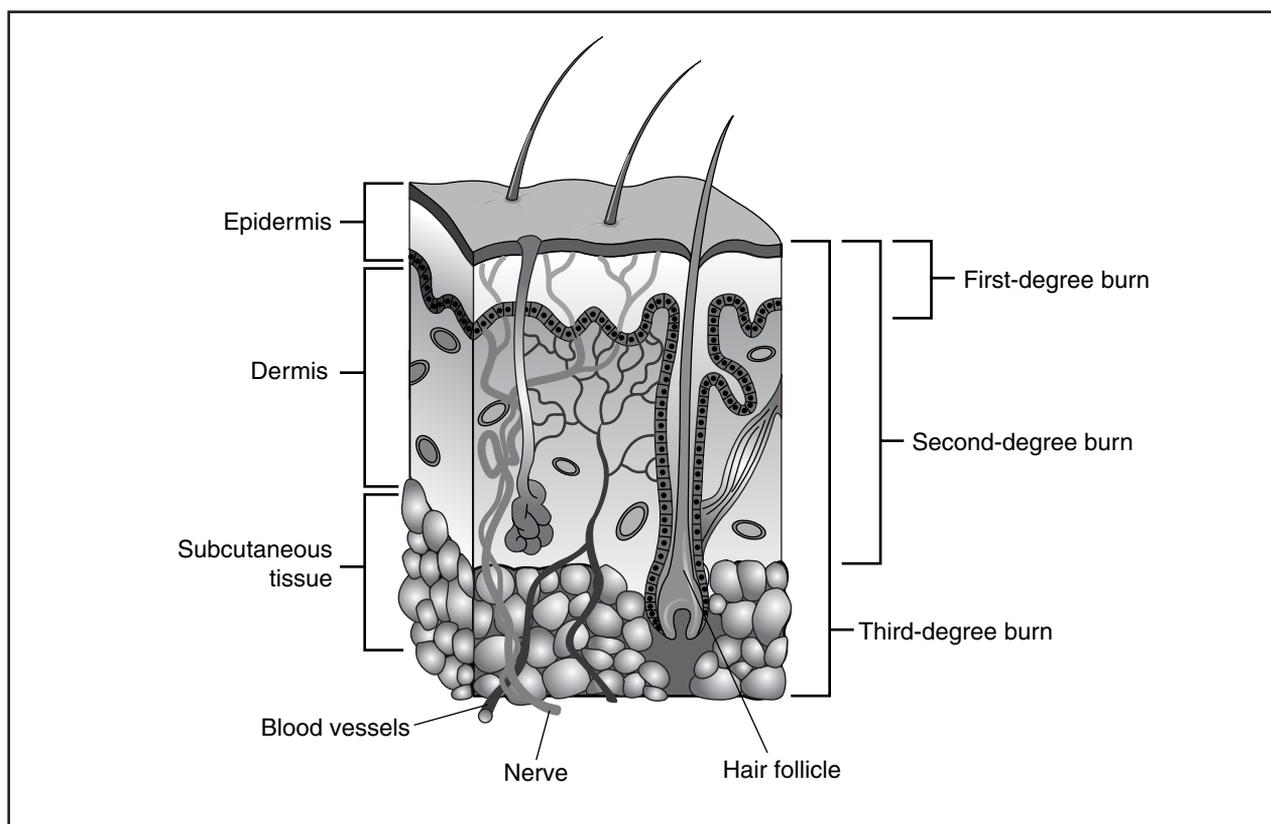

example, Tylenol), or ibuprofen (for example, Advil) may be taken to ease pain and relieve inflammation. Aspirin should not be given to persons under 18 years of age. A doctor should be consulted if any of these signs of infection appear:

- increased warmth, redness, pain, or swelling
- pus or similar drainage from the wound
- swollen lymph nodes
- red streaks spreading away from the burn.

In situations where a person has received moderate or critical burns, lifesaving measures take precedence over burn treatment, and emergency medical assistance must be called. A person with serious burns may stop breathing, and artificial respiration (also called mouth-to-mouth resuscitation or rescue breathing) should be immediately administered. Also, a person with burns covering more than 12% BSA is likely to go into shock. Shock may be prevented by laying the person down and elevating the feet about 12 in (30 cm). Burned arms and hands should also be raised higher than the person's **heart**.

In rescues, a blanket may be used to smother any flames as a person is removed from danger. A person whose clothing is on fire should stop, drop, and roll, or be assisted in lying flat on the ground and rolling to put out the fire. Afterwards, only burned clothing that comes off easily should be removed; any clothing embedded in the burn should not be disturbed. Removing any smoldering apparel and covering the person with a light, cool, wet cloth, such as a sheet but not a blanket or towel, will stop the burning process.

At the hospital, the staff will provide further medical treatment. A tube to aid breathing may be inserted if the burned person's airways or **lungs** have been damaged, as can happen during an explosion or a fire in an enclosed space. Also, because burns dramatically deplete the body of fluids, replacement fluids are administered intravenously. The burned person is also given **antibiotics** intravenously to prevent infection, and may also receive a tetanus shot, depending on an immunization history. Once the burned area is cleaned and treated with antibiotic cream or ointment, it is covered in sterile bandages, which should be changed two to three times a day. Surgical removal of dead tissue (debridement) also takes place. As burns heal, thick, taut scabs (eschar) form, which the doctor may have to cut to improve **blood** flow to the more elastic, healthy tissue beneath. The burned person will also undergo physical and **occupational therapy** to keep the burned areas from becoming inflexible and to minimize scarring.

There are three classifications of burns: first-degree, second-degree, and third-degree burns. (Illustration by Electronic Illustrators Group.)

In cases where the skin has been so damaged that it cannot properly heal, a skin graft is usually performed. A skin graft involves taking a piece of skin from an unburned portion of a burned person's body (autograft) and transplanting it to the burned area. When doctors cannot immediately use the person's own skin, a temporary graft is performed using the skin of a human donor (allograft), either alive or dead, or the skin of an animal (xenograft), usually that of a pig.

A burned person also may be placed in a hyperbaric chamber, if one is available. In a hyperbaric chamber (which can be a specialized room or enclosed space), the person is exposed to pure oxygen under high pressure, which can aid in healing. However, for this therapy to be effective, an injured person must be placed in a chamber within 24 hours of being burned.

Chemical burn treatment

Burns from liquid chemicals must be rinsed with cool water for at least 15 minutes to stop the burning process. Any burn to the eye must be similarly flushed with water. In cases of burns from dry chemicals such as

lime, the powder should be completely brushed away before the area is washed. Any clothing that may have absorbed the chemical should be removed. The burn should then be loosely covered with a sterile gauze pad and the person taken to a hospital for further treatment. A physician may be able to neutralize the offending chemical with another before treating the burn like a thermal burn of similar severity.

Electrical burn treatment

At the site of an accident, before electrical burns are treated, the power source must be disconnected if possible, and the person moved away from it to keep the individual giving aid from being electrocuted. Lifesaving measures again take priority over burn treatment, so breathing must be checked and assisted, if necessary. Electrical burns should be loosely covered with sterile gauze pads and the person taken to a hospital for further treatment.

Alternative treatment

In addition to the excellent treatment of burns provided by traditional medicine, some alternative

KEY TERMS

Debridement—The surgical removal of dead tissue.

Dermis—The basal layer of skin; it contains blood and lymphatic vessels, nerves, glands, and hair follicles.

Epidermis—The outer portion of skin, made up of four or five superficial layers.

Shock—An abnormal condition resulting from low blood volume due to hemorrhage or dehydration. Signs of shock include rapid pulse and breathing, and cool, moist, pale skin.

approaches may be helpful as well. (Major burns should always be treated by a medical practitioner.) The homeopathic remedies *Cantharis* and *Causticum* can assist in burn healing. A number of botanical remedies, applied topically, can also help burns heal. These include aloe (*Aloe barbadensis*), oil of St.-John's-wort (*Hypericum perforatum*), calendula (*Calendula officinalis*), comfrey (*Symphytum officinale*), and tea tree oil (*Melaleuca* spp.). Supplementing one's diet with **vitamin C**, **vitamin E**, and **zinc** also is beneficial for wound healing.

Prognosis

The prognosis is dependent upon the degree of a burn, the amount of body surface covered, whether critical body parts were affected, any additional injuries or complications like infection, and the promptness of medical treatment. Minor burns may heal in five to 10 days with no scarring. Moderate burns may heal in 10–14 days and may leave some scarring. Critical or major burns take more than 14 days to heal and will leave significant scarring. Scar tissue may limit mobility and functionality, but **physical therapy** may overcome these limitations. In some cases, additional surgery may be advisable to remove scar tissue and restore appearance.

Health care team roles

First aid is often administered at the scene of a burn. Paramedics may provide additional treatment and support as they transport a burned person to a hospital or burn center. Emergency physicians or surgeons provide care in a hospital setting. Family physicians may provide care for minor burns in their offices. Nurses provide supportive care. Physical therapists may provide therapy. Counselors, psychologists, or psychiatrists often provide

support after a serious burn occurs. Plastic surgeons may reconstruct severely burned areas of the body.

Prevention

Burns are commonly received in residential fires. Properly placed and working smoke detectors in combination with rapid evacuation plans will minimize a person's exposure to smoke and flames in the event of a fire. Children must be taught never to play with matches, lighters, fireworks, gasoline, or cleaning fluids.

Burns by scalding with hot water or other liquids may be prevented by setting the water heater thermostat no higher than 120°F (49°C), checking the temperature of bath water before getting into the tub, and turning pot handles on the stove out of the reach of children. Care should be used when removing covers from pans of steaming foods and when uncovering or opening foods heated in a microwave oven.

Thermal burns are often received from electrical appliances. Care should be exercised around stoves, space heaters, irons, and curling irons.

Sunburns may be avoided by the liberal use of a sunscreen containing either an opaque active ingredient, such as zinc oxide or titanium dioxide or a nonopaque active ingredient such as PABA (para-aminobenzoic acid) or benzophenone. Hats, loose clothing, and umbrellas also provide protection, especially between 10 A.M. and 3 P.M. when the most damaging ultraviolet rays are present in direct sunlight.

Electrical burns may be prevented by covering unused electrical outlets with safety plugs and keeping electrical cords away from infants and toddlers who might chew on them. Persons should also seek shelter indoors during a thunderstorm to avoid being struck by lightning.

Chemical burns may be prevented by wearing protective clothing, including gloves and eye shields. Chemical agents should always be used according to the manufacturer's instructions and properly stored when not in use.

Bursitis

Definition

Bursitis is the painful inflammation of the bursa, a padlike sac of fluid found in areas of the musculoskeletal system that are subject to friction, such as joints. Bursae cushion the movement between the bones, tendons, and muscles near the joints. Bursitis is most often caused by repetitive movement performed by individuals in the course of their occupations, activities of daily living, or recreational activities.

Description

There are more than 150 bursae in the human body. Usually bursae are present from birth, but they may form in response to repeated excessive pressure. Each sac contains a small amount of synovial fluid, a clear liquid that acts as a lubricant. Inflammation causes **pain** on movement. The most common site for bursitis is the subdeltoid (shoulder), but it also is seen in the olecranon (elbows), trochanteric (hips), knees, heels (Achilles), and toes. The affected area may be referred to as "frozen," because movement is so limited. In the knee there are four bursae, and all can become inflamed with overuse.

Causes and symptoms

The most common cause of bursitis is repeated physical activity using excessive force, but it may also flare up for no known reason. Bursitis may be caused by trauma, proximity to inflammatory disease such as rheumatoid arthritis and **gout**, and it is also associated with acute or chronic **infection**.

Pain and tenderness are common symptoms. If the affected joint is close to the skin, as with the shoulder, knee, elbow, or Achilles tendon, swelling and redness are seen and the area over the joint may feel warm to the touch. The bursae around the hip joint are deeper, and swelling is not obvious. Movement may be limited and is painful. In the shoulder, it may be difficult for the patient

KEY TERMS

Arthritis—The collective name for approximately 100 diseases that are collagen related and inflammatory in origin. The most common are osteoarthritis and rheumatoid arthritis.

Diabetes mellitus—A metabolic disease caused by a deficiency of insulin in type 1 diabetes. Insulin is essential to process carbohydrates in the body. In type 2 diabetes, development of resistance to existing insulin levels results in inadequate blood glucose control.

Gout—A hereditary metabolic disease that is a form of arthritis and causes inflammation in the joints of the distal extremities (the feet and hands). It is more common in men.

Inflammation—The reaction of tissue to injury, or the body's immune response to disease.

Kinesiology—The science or study of movement.

to raise the arm away from the side of the body. When the shoulder is affected, patients report difficulty with activities such as putting on clothes or combing their hair.

In acute bursitis, symptoms appear suddenly. With chronic bursitis, pain, tenderness, and limited movement flare up after **exercise** or strain.

Diagnosis

When a patient has pain in a joint, a careful **physical examination** is performed to determine which type of movement is affected and if there is any swelling. Bursitis will not show up on x rays, although sometimes **calcium** deposits in the joint are seen. If infection is suspected, aspiration of the bursa should be performed and the fluid sent to the laboratory for cell count, **gram stain** and culture. In most cases, the fluid will not be clear. It can be tested for the presence of **bacteria**, which indicate an infection, and crystals, which could indicate gout. In instances where the diagnosis is difficult, a local anesthetic is injected into the painful spot. If the discomfort stops temporarily, then bursitis is suspected.

Treatment

Conservative treatment of bursitis is usually effective. The application of heat, rest, and immobilization of the affected joint area is the first step. A sling may be used for a shoulder injury, and a cane is helpful for patients with hip problems. **Nonsteroidal anti-inflam-**

matory drugs (NSAIDs) like aspirin, ibuprofen, and naproxen, obtained without a prescription, may relieve pain and inflammation. Once the pain decreases, mild to moderate exercise of the affected area may begin. If muscles proximal (near) to the affected joint have become weak or stiff because of the disease or prolonged immobility, exercises to build strength and improve movement are prescribed. A physician or physical therapist prescribes an effective exercise regimen.

If the bursitis is related to an inflammatory condition such as arthritis or gout, then management of the underlying disease is necessary to control the bursitis.

When bursitis does not respond to conservative treatment, an injection into the joint of a long-acting corticosteroid preparation, such as prednisone, may offer the patient immediate and lasting relief. The corticosteroid, which acts to reduce inflammation, is mixed with a local anesthetic and works on the joint within minutes. Usually one injection is all that is needed. It is important that the patient does not overuse the joint too soon because the pain has gone. A gradual build up to normal use is necessary.

Surgery to remove the damaged bursa may be performed in extreme cases.

If bursitis is caused by an infection, then additional treatment is needed. Septic bursitis may be caused by the presence of *Staphylococcus aureus*. This is confirmed by examining a sample of the fluid in the bursa and sending it for culture. Septic bursitis requires treatment with **antibiotics** specifically for the infection, and these antibiotics may be taken by mouth, injected into a muscle, or administered intravenously. The bursa must be drained by needle aspiration two or three times during the first week of treatment. When a patient has such a serious infection, there may be underlying causes such as previously undetected diabetes, or compromised **immune system** defense function, a byproduct of several diseases and some medications, e.g. **chemotherapy**.

Alternative treatments take into consideration the role of diet in bursitis. Dietary changes and vitamin supplements may be helpful. The use of herbs, **homeopathy**, aromatherapy, and **hydrotherapy** may help to relieve symptoms. Ginger has been used to reduce inflammation. Acupuncture has been shown to be effective treatment for hip and shoulder pain caused by bursitis and other conditions. Other therapies that deal effectively with musculoskeletal problems may also be helpful, such as osteopathy, massage, chiropractic, and applied kinesiology.

Health care team roles

The diagnosis of bursitis is usually made by the primary care physician or mid-level practitioner (physician assistant or nurse practitioner). Laboratory technologists are involved in determining whether infection is present in joint fluid and radiology technologists perform radiographic or imaging studies. Nurses, physical therapists, **physical therapy** assistants, and exercise physiologists offer patients instruction about movements to strengthen the muscles surrounding joints and ways to prevent future injuries. For bursitis of the elbow or wrist, an occupational therapist may supervise recovery.

Prognosis

Bursitis usually responds well to treatment, but it may develop into a chronic condition if the underlying cause is not corrected.

Prevention

Aggravating factors should be eliminated if possible, to prevent recurrent bursitis. Over exercising or the repetition of a movement that triggers the condition should be avoided. Regular exercises designed to strengthen the muscles around the joint will also help. When engaging in repetitive tasks, patients should be

advised to take frequent breaks and alternate activities using different parts of the body. To cushion the joints, it is advisable to use cushioned chairs when sitting and foam kneeling pads for the knees. Leaning on the elbows, and kneeling or sitting on a hard surface for a long period of time should be avoided. Avoiding high heels can help female patients avoid bursitis in the heel, and patients should be counseled to replace running shoes as soon as the alignment of the old ones deteriorates with wear.

Caffeine

Description

Caffeine is a drug that stimulates the **central nervous system** (CNS). Caffeine is found naturally in coffee, kola seed kernels or nuts (*Cola nitida*), and a variety of teas. Other foods and beverages, such as chocolate and soft drinks, also contain caffeine, and the drug can be purchased in over-the-counter tablet and capsule form (No Doz, Overtime, Pep-Back, Quick-Pep, Caffedrine, and Vivarin). Some prescription **pain** relievers, medicines for migraine headaches, and **antihistamines** also contain caffeine.

General use

Caffeine makes people more alert, less drowsy, and improves coordination. Combined with certain pain relievers or medicines for treating **migraine headache**, caffeine makes those drugs work more quickly and effectively. Caffeine alone can also help relieve headaches. Antihistamines are sometimes combined with caffeine to counteract the drowsiness caused by those drugs. Caffeine is also sometimes used to treat other conditions, including breathing problems in newborns and in young babies after surgery.

Preparations

Kola can be prepared in decoction or tincture form. To prepare a decoction, mix 1-2 tsp of powdered kola nut in a cup of water. After bringing the water to a boil, sim-

mer the decoction on low heat for 10-15 minutes. Tinctures of kola nut can be purchased at many health food stores or mail order suppliers. A tincture is an herbal preparation made by diluting the herb in alcohol, glycerin, or vinegar. Dosage of kola tincture varies by formula and the symptoms or illness it is supposed to treat, but an average recommended dosage might be 1-4 ml three times daily. Powdered kola nut and kola tinctures should be stored in airtight containers away from direct light to maintain potency.

For over-the-counter caffeine preparations, adults and children age 12 years and older should take 100-200 mg no more than every three to four hours. In timed-release form, the dose is 200-250 mg once a day. Timed-release forms should not be taken less than six hours before bedtime. Caffeine pills or tablets are typically not recommended for children under 12 years of age.

Precautions

If caffeine is administered in a kola preparation, kola should always be obtained from a reputable source that observes stringent quality control procedures and industry-accepted good manufacturing practices. Consumers should look for the designations “U.S.P.” (U.S. Pharmacopeia) or “NF” (National Formulary) on kola nut labeling. Herbal preparations prepared under USP or NF guidelines meet nationally recognized strength, quality, purity, packaging, and labeling standards as recommended by the United States Food and Drug Administration (FDA).

Avoid taking too much caffeine when it is being taken as an over-the-counter drug. Consider how much caffeine is being taken in from coffee, tea, chocolate, soft drinks, and other foods that contain caffeine. Check with a pharmacist or healthcare professional to find out how much caffeine is safe to use.

Caffeine cannot replace sleep and should not be used regularly to stay awake as the drug can lead to more serious **sleep disorders**, like insomnia.

KEY TERMS

Arrhythmia—Abnormal heart rhythm.

Central nervous system (CNS)—The brain, spinal cord, and nerves throughout the body.

Decoction—An herbal extract produced by mixing an herb in cold water, bringing the mixture to a boil, and letting it simmer to evaporate the excess water. The decoction is then strained and drunk hot or cold. Decoctions are usually chosen over infusion when the botanical or herb in question is a root, seed, or berry.

Palpitation—Rapid, forceful, throbbing, or fluttering heartbeat.

Tinctures—A liquid extract of an herb prepared by steeping the herb in an alcohol and water mixture. Tinctures can also be prepared using vinegar or glycerin, instead of alcohol.

Withdrawal symptoms—A group of physical or mental symptoms that may occur when a person suddenly stops using a drug to which he or she has become dependent.

People who use large amounts of caffeine over long periods build up a tolerance to it. When that happens, they have to use more and more caffeine to get the same effects. Heavy caffeine use can also lead to dependence. If an individual stops using caffeine abruptly, withdrawal symptoms may occur, including headache, fatigue, drowsiness, yawning, irritability, restlessness, vomiting, or runny nose. These symptoms can go on for long as a week.

If taken too close to bedtime, caffeine can interfere with sleep. Even if it does not prevent a person from falling asleep, it may disturb sleep during the night.

The notion that caffeine helps people sober up after drinking too much alcohol is a myth. In fact, using caffeine and alcohol together is not a good idea. The combination can lead to an upset **stomach**, nausea, and vomiting.

Older people may be more sensitive to caffeine and thus more likely to have certain side effects, such as irritability, nervousness, **anxiety**, and sleep problems.

Allergies

Anyone with **allergies** to foods, dyes, preservatives, or to the compounds aminophylline, dyphylline, oxi-phylline, theobromine, or theophylline should check with a physician before using caffeine. Anyone who has ever

had an unusual reaction to caffeine should also check with a physician before using it again.

Pregnancy

Caffeine can pass from a pregnant woman's body into the developing fetus. Although there is no evidence that caffeine causes birth defects in people, it does cause such effects in laboratory animals given very large doses (equal to human doses of 12-24 cups of coffee a day). In humans, evidence exists that doses of more than 300 mg of caffeine a day (about the amount of caffeine in two to three cups of coffee) may cause **miscarriage** or problems with the baby's **heart** rhythm. Women who take more than 300 mg of caffeine a day during **pregnancy** are also more likely to have babies with low birth weights. Any woman who is pregnant or planning to become pregnant should check with her physician before using caffeine.

Breastfeeding

Caffeine passes into breast milk and can affect the nursing baby. Nursing babies whose mothers use 600 mg or more of caffeine a day may be irritable and have trouble sleeping. Women who are breast-feeding should check with their physicians before using caffeine.

Other medical conditions

Caffeine may cause problems for people with these medical conditions:

- peptic ulcer
- heart arrhythmias or palpitations
- heart disease or recent heart attack (within a few weeks)
- high **blood pressure**
- liver disease
- insomnia (trouble sleeping)
- anxiety or panic attacks
- agoraphobia (fear of being in open places)
- premenstrual syndrome (PMS)

Side effects

At recommended doses, caffeine can cause restlessness, irritability, nervousness, shakiness, headache, light-headedness, sleeplessness, nausea, vomiting, and upset stomach. At higher than recommended doses, caffeine can cause excitement, agitation, anxiety, confusion, a sensation of light flashing before the eyes, unusual sensitivity to touch, unusual sensitivity of other senses, ringing in the ears, frequent urination, muscle twitches or

tremors, heart arrhythmias, rapid heartbeat, flushing, and convulsions.

Interactions

Using caffeine with certain other drugs may interfere with the effects of the drugs or cause unwanted—and possibly serious—side effects. Certain drugs interfere with the breakdown of caffeine in the body. These include oral contraceptives that contain estrogen, the antiarrhythmia drug mexiletine (Mexitol), the ulcer drug cimetidine (Tagamet), and the drug disulfiram (Antabuse), used to treat **alcoholism**.

Caffeine interferes with drugs that regulate heart rhythm, such as quinidine and propranolol (Inderal). Caffeine may also interfere with the body's absorption of **iron**. Anyone who takes iron supplements should take them at least an hour before or two hours after using caffeine.

Serious side effects are possible when caffeine is combined with certain drugs. For example, taking caffeine with the decongestant phenylpropanolamine can raise **blood** pressure. Very serious heart problems may occur if caffeine and monoamine oxidase inhibitors (MAO) are taken together. These drugs are used to treat **Parkinson's disease**, depression, and other psychiatric conditions. Consult with a pharmacist or physician about which drugs can interact with caffeine.

Because caffeine stimulates the nervous system, anyone taking other **central nervous system stimulants** should be careful about using caffeine.

Calcium

Description

As the most plentiful mineral in the body, calcium plays a key role in the development and maintenance of bones and teeth. Calcium enables the contraction of muscles, including the function of the body's most important muscle, the **heart**. It is also essential for normal **blood** clotting, proper nerve impulse transmission, and the appropriate support of connective tissue.

Almost every segment of the population—women, children, teenagers, men, unborn babies, and the elderly—benefit from calcium in their daily diet. The mineral is an important dietary supplement for those who are undergoing significant periods of bone growth, such as in childhood, and during **pregnancy** and breastfeeding.

Calcium is an effective weapon for the aging population as they combat **osteoporosis**. A condition that simply means “porous bones,” osteoporosis attacks bones when they are their most vulnerable. As the body ages, bones lose more calcium, and it becomes vital to supplement the diet with calcium in order to encourage bone growth and prevent or slow down the process of osteoporosis.

General use

While the body relies on the presence of calcium for many of its everyday functions, the number of reasons why the mineral should be supplemented in the diet are numerous. Calcium is beneficial to everyone, but research has shown that women may benefit more than others. A study in the October 1999 issue of the journal *Obstetrics & Gynecology* found that pregnant women who do not get enough calcium in their diet can increase the bone mineral content of their fetus by about 15% by taking 1,300 mg of a calcium supplement per day during their second and third trimesters. For those women who already consume enough calcium, the additional supplements do not have this effect. Additional research shows that calcium deficiencies lead to preeclampsia during pregnancy, causing high **blood pressure**, swelling, and weight gain greater than one pound per day. The risk of preeclampsia developing lowers by 45–75% for women who receive calcium supplementation.

Premenstrual syndrome (PMS) is another condition women face that may be alleviated by the use of calcium supplements. Researchers at the National Institute of Mental Health (NIMH) concluded that those women who took 1,200 mg of calcium per day reduced their overall PMS symptoms by more than 50%. In the study, calcium supplementation led to the reduction of psychological

PMS symptoms (such as mood swings) by 45%, food cravings by 54%, and bloating and water retention by 36%.

A 1999 study reported that researchers have found that increasing the amount of daily calcium consumed by women may reduce their risk of stroke. Those women in the Nurses' Health Study who took more than 400 mg of calcium daily were at the lowest risk for a stroke, while those who consumed more than 600 mg each day did not have an increased benefit. Researchers believe that the risk of stroke is reduced by calcium from decreased cholesterol levels, or by stopping the formation of blood clots that cause strokes.

For elderly postmenopausal women, the prevention of osteoporosis becomes critical. In order to maintain bone mass during this time, a study conducted in 1999 concluded that a low-dose hormone replacement therapy (HRT) combined with calcium and **vitamin D** supplementation is an effective therapeutic option for prevention of osteoporosis. Estriol, which is used in HRT, appears to be helpful in controlling menopausal symptoms. Results from research regarding this use of estriol on bone density have been contradictory, according to the *Alternative Medicine Review*, with the results showing the most effectiveness coming from Japanese studies.

Calcium alone is frequently prescribed with estrogen at the beginning of **menopause** to treat or prevent osteoporosis. This therapy is recommended to guard against the increased loss of calcium in the bones due to increasing age. As bones lose more calcium they become dense and more brittle, and more vulnerable to the attack of osteoporosis. This condition is most common in people over 70, and in women after menopause, where it may increase the risk of broken hips, ribs, and pelvis, and the weakening of other bones. Increased physical **exercise** is also important for bone strengthening.

Calcium has also been shown to be beneficial to the colon. Among those people taking calcium supplements, research points to a modest reduction in the recurrence of polyps in their colons. Colon polyps are benign tumors that often turn cancerous. Researchers think that calcium binds to carcinogens, preventing abnormal cell growth.

Stemming from its active role in building bone density throughout the body, calcium may prove particularly beneficial for strengthening of the jawbone. Dental researchers at the State University of New York at Buffalo report that calcium supplementation may prevent periodontal disease as it builds a strong jawbone. Periodontal, or gum, disease is an **infection** caused by **bacteria** that deposits in pockets between the teeth and gums, and is the leading cause of tooth loss in the United States. As the infection progresses, the jawbone that

holds a tooth in place is eventually destroyed, causing the tooth to loosen and fall out. The researchers contend that calcium's overall bone-building role would equal a stronger jawbone that would better fight off gum disease.

While supplements of calcium can be found in many forms, research has shown a promising benefit if it is obtained from dairy foods, rather than supplements or leafy greens—calcium in the form of dairy may actually prevent weight gain. Those in the study who consumed at least 1,000 mg of calcium a day (equaling about 3 cups, or 750 ml of skim milk), gained six to seven fewer pounds over two years than those with low-calcium diets. Researchers of Purdue University speculate that calcium probably prevents weight gain by increasing the breakdown of body fat and decreasing its formation. It is important to note, however, that dairy products should be consumed in moderation, as other research conducted has indicated that dairy is not necessarily a good, absorbable calcium source.

Calcium is proving essential to those children around the world who are struck by rickets. Rickets is a deficiency condition in children that effects developing cartilage and newly formed bone throughout the body causing deformities. Often thought to be a result of the inadequate intake of vitamin D from dietary sources or lack of exposure to sunlight, research reported in 2000 has found that children with rickets respond well to calcium supplementation. While rickets is rare in the United States and Europe, it remains a problem in many parts of the world. Researchers conclude that effective treatment for the condition is calcium supplementation alone, or in combination with vitamin D. Osteomalacia, or the adult form of rickets, also responds to calcium supplementation.

Preparations

Calcium may be supplemented in the diet in a variety of ways. A numerous amount of foods are rich in calcium, including dairy products (such as milk, yogurt, and cheese) and leafy green vegetables like turnip greens, broccoli, kale, and collards. Canned salmon, sardines, shrimp, and tofu are also high in calcium. More foods are being fortified with calcium, making it easier to ensure the proper amount of the mineral is consumed. Calcium-fortified foods range from cranberry juice cocktail, cereal and waffles, to orange juice and flour. With almost every segment of the population consuming too little calcium, researchers recommend calcium-fortified foods to increase daily calcium intake.

While the types of food calcium may be obtained from continues to increase, most people still lack enough of the essential mineral. For those who are not getting enough calcium from foods, supplements are an accept-

able alternative. The chemical form of calcium supplements come in five varieties: carbonate, citrate, lactate, phosphate, chelate, and citrate malate. The supplements are available as tablets, syrup, or suspension form. Calcium supplements should be stored at room temperature and away from moisture and sunlight. It should not be stored in the bathroom, and the liquid forms should not be frozen.

Experts state that calcium is best absorbed from the citrate malate form, or the type of calcium found in some juices, but they recommend calcium carbonate for the overall amount of calcium it offers and its affordability. Calcium carbonate can be found in **antacids**, and it is absorbed better when taken with meals. Food slows down the time it takes substances to travel through the gut, giving the calcium more time to be absorbed. Absorption is key for the proper functioning of calcium. Sufficient levels of vitamin D and hydrochloric acid in the **stomach**, and the presence of other **minerals**, such as magnesium and phosphorous are essential for quick absorption.

The body may also be better able to absorb calcium when taken along with ingredients extracted from chicory root. Research indicates that raftilin inulin and raftilose oligofructose, both extracts from chicory root, are dietary fibers that are not digested in the stomach or the **small intestine**. Instead, they are fermented by Bifidobacteria in the colon—beneficially leading to increased calcium absorption throughout the body, with emphasis on bone tissue. Additionally, oligofructose improves the texture and mouthfeel while improving taste and fruit flavors in low-fat yogurts. Inulin is used for fat replacement and fiber enrichment of reduced-fat and fat-free sour cream and whipped topping.

There are many ways to ensure calcium is part of a daily diet, but it is important that the recommended daily allowance (RDA), or appropriate dosage of the mineral be followed. The RDA of calcium for adults is 800 mg; pregnant women and young adults should be certain their intake equals 1,200 mg per day. Adults over 50 should increase their intake to 1,000 mg per day with supplements that include vitamin D.

Calcium supplements may be taken with a large glass of water during or after a meal. Tablets in chewable form must be chewed thoroughly before swallowing, and effervescent tablets should be diluted in cold water or juice before taking. It is recommended that other medications be taken two hours after any calcium supplement. The simultaneous intake of calcium may interfere with the absorption of other drugs. Do not take more than 500 mg of calcium at one time for the best absorption of the mineral.

Precautions

When adding calcium supplements to the diet, it is recommended that it not be taken within one to two hours of eating bran, or whole grain cereals or breads. Large amounts of alcohol or **caffeine** containing beverages or tobacco should be avoided. Large amounts of calcium, phosphates, magnesium, or vitamin D in medication or dietary supplements should not be taken unless directed by a physician. Those with **diarrhea**, stomach trouble, parathyroid disease, sarcoidosis, or **kidney stones** should consult with their physician before taking calcium.

Side effects

Calcium is typically well tolerated by those who add it to their diets, but if the mineral is taken in high levels it can cause several side effects, including: nausea, vomiting, loss of appetite, constipation, stomach **pain**, thirst, dry mouth, increased urination, and weakness. While these side effects are rare, it is even more unlikely to experience the life-threatening symptoms of an irregular or very slow heart beat. If these dangerous symptoms appear while taking calcium, use of the mineral should be discontinued and emergency treatment should be sought. An **overdose** of a calcium supplement may lead to confusion, irregular heartbeat, depression, bone pain, or **coma**.

Interactions

It is important that all over-the-counter (OTC) or prescription medications are reviewed with a physician before beginning calcium supplement.

According to the *Complete Guide to Prescription & Nonprescription Drugs*, 1999 Edition, by H. Winter Griffith, the following are some of the drugs that may cause possible interactions if taken with calcium:

- alendronate
- anticoagulants
- calcitonin
- calcium-containing medicines
- chlorpromazine
- oral contraceptives
- corticosteroids
- digitalis preparations
- diuretics, thiazide
- estrogens
- etidronate

KEY TERMS

Carcinogen—Any substance or agent that produces or instigates cancer.

Preeclampsia—A toxemia of pregnancy that causes increasing hypertension, headaches, and swelling of the lower extremities.

Sarcoidosis—A disease of unknown etiology which causes widespread lesions that may affect any organ or tissue of the body.

Stroke—A hemorrhage into the brain, formation of a clot in an artery, or rupture of an artery that causes sudden loss of consciousness, followed by paralysis.

Cancer

Definition

Cancer is characterized by uncontrolled growth of cells in the body and the ability of these malignant cells to spread (metastasize) to distant sites within the body. If the spread is not controlled, cancer can result in death. Cancer is not just one disease but a group of almost one hundred different types of malignant diseases.

Description

Cancer, by definition, is a disease of the genes. A gene is a small part of DNA, which is the instruction manual of the cell. Genes hold the instructions to make **proteins**, which carry out many of the body's functions. It is these proteins that allow the human body to carry out all the processes that permit people to breathe, think, move, etc.

Throughout people's lives the cells in their bodies grow, divide, and replace themselves. Many genes produce proteins that are involved in controlling the processes of cell growth and division. An alteration (mutation) to the DNA molecule can disrupt some of the genes on the DNA molecule and produce faulty proteins. This causes a cell to lose restraint on growth. The abnormal cell begins to divide uncontrollably and eventually forms a

new growth known as a tumor or neoplasm (medical terms for cancer meaning new growth). In a healthy body the **immune system** can recognize neoplastic (abnormal) cells and destroy them before they get a chance to divide. Even so, some mutant cells may escape immune detection and survive to develop into cancerous growths.

Tumors are divided into two general categories: benign or malignant. A benign tumor is slow growing and does not spread or invade surrounding tissue. Once it is removed it doesn't usually recur. A malignant tumor, on the other hand, invades surrounding tissue and can spread to other parts of the body. Malignant tumors can be removed; however, if the cancer cells have spread to the surrounding tissues, the tumor is likely to recur.

A majority of cancers are caused by changes in the cell's DNA that are due to the environment. Environmental factors that are responsible for causing the initial mutation in the DNA are called carcinogens. Internal factors can cause cancer as well. Certain hormones have been shown to have an effect the growth or control of a particular cell line. Hormones are substances made by one organ and passed through the bloodstream to perform a function in another organ.

While there is scientific evidence that both environmental and genetic factors play a role in most cancers, approximately 5–10% of all cancers are classified as hereditary (genetic). This means a faulty gene that leads to a cancer is passed from parent to child. This poses a greater risk for that particular type of cancer in certain descendants of the family. However, having a cancer-causing gene does not necessarily mean that person will automatically get cancer. Rather, it means that person is predisposed to a type of cancer, or more likely to get this cancer when compared to the general population. Cancers known to have a hereditary tendency in some cases include **breast cancer**, colon cancer, ovarian cancer, skin cancer, and **prostate cancer**.

Aside from genes, certain inherited physiological traits can contribute to cancers. For example, inheriting fair skin makes a person more likely to develop skin cancer, but only if they also have prolonged exposure to intensive sunlight.

There are many different types of cancers. Some of the most common types include:

- **Carcinomas**. These cancers arise in the epithelium (layers of cells in the skin covering the body's surface and lining the internal organs and various glands). About 80% of human cancers fall into this category. Carcinomas can be subdivided into two subtypes: adenocarcinomas, which are cancers that develop in an organ or a gland; and squamous cell carcinomas, cancers that originate in the skin.

- **Melanomas**. This form also originates in the skin, usually in the pigment cells (melanocytes), and can quickly metastasize to internal organs.
- **Sarcomas**. Cancers of the supporting tissues of the body, such as bone, muscle, cartilage, and fat.
- **Leukemias**. Cancers of the **blood** or blood-forming organs.
- **Lymphomas**. Cancer of the **lymphatic system**, the network of vessels and nodes that acts as a filtration system, distributing nutrients to blood and tissue and preventing **bacteria** and other foreign substances from entering the bloodstream.
- **Gliomas**. Cancers of nerve tissue.

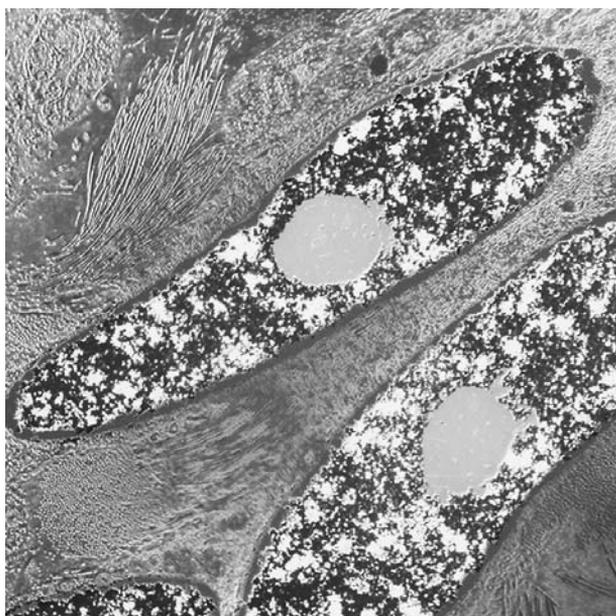

The most common cancers are skin cancer, **lung cancer**, colon and rectal (colorectal) cancer, breast cancer (in women), and prostate cancer (in men). In addition, cancer of the **kidneys**, ovaries, uterus, **pancreas**, bladder, and blood and lymph-node cancer (leukemias and lymphomas) are also included among the 12 major cancers that affect most Americans.

Almost every tissue can give rise to cells that cause cancer and each of these cancers is very different in its symptoms and prognosis. However, there are basic and similar genetic processes that lead to tumor growth in the human body. Genes are responsible for producing proteins that regulate cell growth and division. When these genes do not function properly, the proteins are abnormal and cells can grow uncontrollably. This results in the formation of a tumor. As more genetic mutations (changes) occur in this tumor, it becomes more life-threatening and has a greater chance of spreading to other parts of the body.

Three classes of genes appear to play a role in the development of cancer:

- Proto-oncogenes encourage and promote the normal growth and division of cells. When they are defective, they become oncogenes. Oncogenes are overactive proto-oncogenes that cause excessive cell multiplication that can lead to tumors.
- Tumor suppressor genes act as brakes on cell growth. They prevent cells from multiplying uncontrollably. If these genes are defective there is no control over cell growth and tumors can result.
- DNA repair genes ensure that each strand of DNA is correctly copied during **cell division**. When these genes do not function properly, the replicated DNA is likely to have errors. This causes defects in other genes and can lead to tumor formation in some cases.

Approximately 5–10% of cancers have a hereditary component. In these cancers a child does not inherit can-

A transmission electron micrograph (TEM) of two spindle cell nuclei from a human sarcoma. Sarcomas are cancers of the connective tissue (bone, nerves, smooth muscle).

(Photograph by Dr. Brian Eyden, Photo Researchers, Inc. Reproduced by permission.)

cer from the parents. Rather, a predisposition to cancer is inherited. For example, a faulty tumor suppressor gene may be inherited. This gene is not able to control cell growth but the corresponding gene inherited from the other parent is still functional. Cell growth is under control. However, as a child grows up, radiation, pollution, or any other environmental factor could change the functional gene, making it defective as well. Now, neither of these tumor suppressor genes are functioning, and it is likely that a tumor will develop. Defects in proto-oncogenes and DNA repair genes can be inherited, as well, leaving a person more vulnerable to cancer than the general population.

Some cancers seem to run in families. In these cancers there is no specific gene responsible for the clustering of cancer in a family. However, a particular type of cancer may be seen more often than in the general population. It is suggested that this is due to a combination of genetic and environmental factors.

Cancer kills one out of every four Americans. As of 2001 it was the second leading cause of death in the United States, surpassed only by **heart** disease. More than 1.2 million new cases of cancer are diagnosed every year in the United States. The National Cancer Institute estimates that approximately 8.4 million Americans alive in 2001 had a history of cancer. Some of these people were cured while others were still affected with the disease and possibly undergoing treatment.

Anyone is at risk for developing cancer. Since the occurrence of cancer increases as a person ages, most cases are seen in adults middle-aged or older. Nearly 80% of cancers are diagnosed in people 55 years of age and older.

Lifetime risk is the term used to refer to the probability that an individual will develop cancer over the course of his or her lifetime. In the United States men have a one-in-two lifetime risk of developing cancer. For women, the risk is one in three. Overall, African Americans are more likely to develop cancer than Caucasians and are 33% more likely to die of cancer than Caucasians.

The major risk factors for cancer are tobacco, alcohol, diet, sexual and reproductive behavior, infectious agents, family history, occupation, environment, and pollution.

Tobacco

Eighty-to-ninety percent of lung cancer cases occur in smokers. Smoking has also been shown to be a contributory factor in cancers of mouth, pharynx, larynx, esophagus, pancreas, uterine cervix, kidney, and bladder. Smoking accounts for at least 30% of all cancer deaths. Scientists have shown that inhaling secondhand smoke (passive smoking) can increase one's risk of developing cancer.

Alcohol

Excessive consumption of alcohol is a risk factor in certain cancers such as **liver** and breast cancer. Alcohol, in combination with tobacco, significantly increases the chances that an individual will develop mouth, pharynx, larynx, and esophageal cancers. The combined effect of tobacco and alcohol is greater than the sum of their individual effects. This is called synergy.

Diet and physical activity

One-third of all cancer deaths are due to a poor adult diet. High-fat diets have been associated with cancers of the colon and rectum, prostate, endometrium, and possibly breast. Consumption of meat, especially red meat, has been associated with increased cancer at various sites such as the colon and prostate. Additionally, a high-calorie diet and low level of physical activity can lead to **obesity**, which increases the risk for cancer at various sites including the breast, colon and rectum, prostate, kidney, and endometrium.

Sexual and reproductive behavior

The human papilloma virus, a sexually transmitted disease, has been shown to cause cancer of the cervix.

Having many sexual partners and becoming sexually active early has been shown to increase one's chances of contracting this disease and, therefore, developing cervical cancer. In addition, it has also been shown that women who do not have children or those who have children late in life have an increased risk for both ovarian and breast cancer.

Hormone replacement therapy

As women go through **menopause**, a physician may recommend hormone replacement therapy. This involves taking female hormones (called estrogen and progesterone) to control certain symptoms such as hot flashes and vaginal dryness that occur during this time of a woman's life. Taking estrogen alone can increase the risk for uterine cancer. However, progesterone is often prescribed at the same time to counteract the cancerous effects of estrogen. There is a questionable relationship between hormone replacement therapy and breast cancer as well. As of 2001, this relationship was not fully understood.

Family history

Certain cancers tend to occur more commonly among members of a family. Much of the time this seems to happen by chance, or is due to a common family habit such as cigarette smoking or extended sun exposure. However, certain cancers can occur in excess in some families due to a genetic predisposition that is passed from generation to generation. For example, if the BRCA1 gene is defective in a family, members of that family may have an increased risk to develop breast, colon, ovarian, or prostate cancer. Other defective genes can make persons susceptible to other types of cancer. Therefore, inheriting particular genes can increase a person's chance of developing cancer.

Occupational hazards

There is ample evidence that occupational hazards account for 4% of all cancer deaths. For example, asbestos workers have an increased incidence of lung cancer. Similarly, bladder cancer is associated with dye, rubber, and gas workers; skin and lung cancer with people who are smelters, gold miners and arsenic workers; leukemia is seen more frequently in people who work with glue and varnish; **liver cancer** is more prevalent in PVC manufacturers; and lung, bone, and bone marrow cancer is associated with radiologists and uranium miners.

Environment

High-frequency radiation has been shown to cause human cancer. Ultraviolet radiation from the sun

accounts for a majority of melanoma cases. Other sources of radiation are x rays, radioactive substances, and rays that enter the earth's atmosphere from outer space. Virtually any part of the body can be affected by these types of radiation, especially bone marrow and the **thyroid gland**.

Additionally, being exposed to substances such as certain chemicals, metals, or pesticides, can increase the risk of cancer. Asbestos is an example of a well-known carcinogen, increasing the risk for lung cancer. This risk is increased even further for a smoker who is exposed to asbestos over a period of time.

Causes and symptoms

Cancer is a progressive disease and goes through several stages. Each stage can produce a number of symptoms. Unfortunately, many types of cancer do not display any obvious symptoms or cause **pain** until the disease has progressed to an advanced stage. Early signs of cancer are often subtle and are easily mistaken for signs of other less-dangerous diseases.

Despite the fact that there are several hundred different types of cancers producing very different symptoms, the American Cancer Society (ACS) has established the following seven symptoms as possible warning signals of cancer:

- changes in the size, color, or shape of a wart or a mole
- a sore that does not heal
- persistent cough, hoarseness, or sore throat
- a lump or thickening in the breast or elsewhere
- unusual bleeding or discharge
- chronic indigestion or difficulty in swallowing
- any change in bowel or bladder habits

Other diseases can produce similar symptoms. However, it is important to have these symptoms checked as soon as possible, especially if they linger. The earlier a cancer is diagnosed and treated, the better the chance of it being cured. Many cancers, for example breast cancer, may not have any early symptoms. Therefore, it is important to undergo routine screening tests, such as breast self-exams and mammograms.

Diagnosis

If a person has symptoms of cancer, a physician will begin with a complete medical history and a thorough **physical examination**. The doctor will examine different parts of the body in order to identify any variations from the normal size, feel, and texture of the organ or tis-

sue. In addition to the physical exam, the doctor may order various tests.

Laboratory tests on blood and urine are often used to obtain information about a person's health. If cancer is suspected, a special test can be done that measures the amount of certain substances, called tumor markers, in the blood, urine, or particular tissues. These proteins are released from some types of cancer cells. Thus, the levels of these substances may be abnormal when certain cancers are present. However, laboratory tests alone cannot be used to make a definitive diagnosis of cancer. Blood tests are generally more useful in monitoring the effectiveness of the treatment or in following the course of the disease and detecting any signs of recurrence.

A doctor may look for tumors by examining images of areas inside the body. The most common way to obtain these images is by using x rays. Other techniques used to examine the insides of the body include computed tomography (CT scan), **magnetic resonance imaging** (MRI), and ultrasonography.

The most definitive diagnostic test is a biopsy. In this technique a piece of tissue is surgically removed for examination under a **microscope**. A biopsy provides information about the cellular nature of an abnormality: the stage it has reached, the aggressiveness of the cancer, and the extent of its spread. Further analysis of the tissue obtained by biopsy defines the cause of the abnormality. Since a biopsy provides the most accurate analysis, it is considered the gold standard of diagnostic tests for cancer.

Regular screening examinations conducted by healthcare professionals can result in the early detection of various types of cancer. Early detection means treatment is more likely to succeed. For example, the ACS recommends an annual mammogram (x ray of the breast) for women over the age of 40 years, to screen for breast cancer. It also recommends a **sigmoidoscopy**, in which a thin, lighted tube with a tiny camera is used to view the inside of the colon, every five years for people over the age of 50. This technique can assess the presence of **colorectal cancer**. Self-examinations for cancers of the breast, testes, mouth, and skin can also help in detecting tumors before the symptoms become serious.

Evolutions in molecular biology and the genetics of cancer have led to the development of several tests designed to assess one's risk of getting certain types of cancer. **Genetic testing** involves looking closely at certain genes that have been linked to particular cancers. As of 2001 there were many limitations to genetic testing. Tests could be uninformative and to a very small proportion of individuals tested. Additionally, concerns exist about insurance coverage and employment discrimination for someone who has an increased risk for cancer. As

of 2001 these tests were reserved only for very specific individuals. A hereditary cancer clinic can help assess who may benefit from this type of testing.

Treatment

The aim of cancer treatment is to remove all or as much of the tumor as possible and to prevent the recurrence or spread of the primary tumor. While devising a treatment plan for cancer, the likelihood of curing the cancer must be weighed against the side effects of the treatment. If the cancer is aggressive and a cure is not possible, then treatment should be aimed at relieving the symptoms and controlling the cancer for as long as possible.

Cancer treatment can take many different forms, and it is always tailored to an individual. The decision on which type of treatment is the most appropriate depends upon the type and location of the cancer and the extent to which it has already spread. A physician will also consider an affected person's age, sex, general health status, and personal treatment preferences. Treatment can be local, meaning that it affects cancer cells in the tumor and the surrounding area only. Surgery and radiation are local treatments. Treatment can also be systemic, meaning that the treatment travels through the bloodstream and affects cancer and other cells throughout the entire body. **Chemotherapy**, immunotherapy, and hormone therapy are examples of systemic treatments.

Surgery

Surgery can be used for many purposes:

- **Treatment.** Treatment of cancer by surgery involves removal of the tumor to cure the disease. This is typically done when the cancer is localized to a discrete area. Along with the cancer, some of the surrounding tissue is also removed to ensure that no cancer cells remain in the area. Since cancer usually spreads via the lymphatic system, lymph nodes near the tumor site may be removed for examination.
- **Prevention.** Preventive or prophylactic surgery involves removal of an abnormal-looking area that is likely to become malignant over time. For example, 40% of people with a colon disease called ulcerative colitis ultimately die of colon cancer. Rather than live with the fear of developing colon cancer, these people may choose to have their colons removed in order to reduce their risk of colorectal cancer.
- **Diagnosis.** The most definitive tool for diagnosing cancer is a biopsy. Sometimes a biopsy can be performed by inserting a needle through the skin and aspirating a small amount of fluid or tissue. At other times the only way to obtain a tissue sample is through surgery.

- **Cytoreductive surgery.** This is a surgical procedure in which the surgeon removes as much of the cancer as possible. The remaining cancer cells are then treated with radiation therapy, chemotherapy, or both.
- **Palliative surgery.** This type of surgery is intended to relieve cancer symptoms or slow the progression of disease. It is not designed to cure the cancer. For example, if the tumor is very large or has spread to many places in the body, removing the entire tumor may not be an option. However, by decreasing the size of the tumor, pain may be alleviated. This is known as debulking surgery.

Radiation therapy

Radiation uses high-energy rays to kill cancer cells. This technique may be used instead of surgery. It also may be utilized before surgery to shrink a tumor or after surgery to destroy any remaining cancer cells.

Radiation can be either external or internal. In the external form, the radiation comes from a machine that aims the rays at the tumor. In internal radiation (also known as brachytherapy), radioactive material is sealed in needles, seeds, or wires and placed directly in or near the tumor. Radiation may lead to various side effects, such as fatigue, hair loss, and a susceptibility to infections. However, these side effects can usually be controlled.

Chemotherapy

Chemotherapy is the use of drugs to kill cancer cells. The entire body is exposed to the drugs (systemic therapy) in an effort to destroy the hard-to-detect cancer cells that have spread and are circulating in the body. The cancer cells are affected more dramatically than normal cells because they are rapidly dividing. Chemotherapeutic drugs can be injected into a vein, the muscle, or the skin, or they may be taken by mouth.

When chemotherapy is used before surgery, it is known as primary, or neoadjuvant chemotherapy. Its purpose is usually to reduce the size of the tumor. The more common use of chemotherapy is in adjuvant therapy. In this technique, chemotherapy is given after surgery to destroy any remaining cancer cells and to help prevent cancer from recurring. Chemotherapy can also be used in conjunction with radiation.

Side effects of chemotherapy vary but can include susceptibility to infections, fatigue, poor appetite, weight loss, nausea, **diarrhea**, and hair loss. Decreased fertility can be a long-term side effect in some instances.

Bone marrow failure is a complication of chemotherapy. When high-dose chemotherapy is utilized, bone

Recommendations for cancer screening

Procedure	Frequency
Chest x ray	Not recommended on a routine basis
Sputum cytology	Not recommended on a routine basis
Fecal occult blood testing (FOBT) or sigmoidoscopy	Yearly after age 50
Papanicolaou (Pap) smear	Every 3 years from onset of sexual activity to age 65
Mammography alone or mammography and breast physical examination	Every 1–2 years at ages 50–69; starting at ages 40–49 may be recommended if high-risk

SOURCE: U.S. Preventative Services Task Force, Dept. of Health and Human Services.

marrow failure is anticipated. Bone marrow transplantation (BMT) or peripheral stem cell transplantation (PSCT) are techniques used to treat this complication. Both techniques provide healthy stem cells for an affected person. Stem cells are immature cells that mature into blood cells. Transplanted stem cells replace the patient's stem cells that have been damaged or destroyed by chemotherapy or radiation. This procedure allows an individual to undergo very aggressive treatment for cancer. Those who receive BMT or PSCT have an increased risk of **infection**, bleeding, and other side effects due to the chemotherapy and radiation. Graft-versus-host disease may also occur. This complication develops when the donated marrow reacts against the recipient's tissues. It can occur any time after the transplant. Drugs may be given to reduce the risk of graft-versus-host disease and to treat the problem if it occurs.

Immunotherapy

Immunotherapy, also called biological therapy, is the use of treatments that promote or support the body's immune system response to cancer. The side effects of immunotherapy are variable but include flu-like symptoms, weakness, loss of appetite, and skin rash. These symptoms will subside after the treatment is completed.

Hormone therapy

Hormone therapy is used to fight certain cancers that depend on hormones for their growth. Drugs can be used to block the production of hormones or change the way they work. Additionally, organs that produce hormones may be removed. As a result of this therapy, the growth of the tumor slows and survival may be extended for several months or years.

COMMON PATHOGENS AND THE CANCERS ASSOCIATED WITH THEM	
<i>Causative Agent</i>	<i>Type Of Cancer</i>
Viruses	
Papillomaviruses	Cancer of the cervix
Hepatitis B virus	Liver cancer
Hepatitis C virus	Liver cancer
Epstein-Barr virus	Burkitt's lymphoma
Cancers of the upper pharynx	Hodgkin's lymphoma, Non-Hodgkin's lymphoma, Gastric cancers
Human immunodeficiency virus (HIV)	Kaposi's sarcoma Lymphoma
Bacteria	
<i>Helicobacter pylori</i>	Stomach cancer Lymphomas

(Illustration by Standley Publishing. Courtesy of Gale Group.)

Alternative and complementary therapies

There are certain cancer therapies that have not been scientifically tested and approved. If these unproven treatments are used instead of the standard therapy, this is known as alternative therapy. If they are used along with standard therapy, this is known as complementary therapy. Alternative therapy is considered dangerous because some of these unproven treatments might have life-threatening side effects. Additionally, persons who use alternative therapy may lose the opportunity to benefit from standard, proven therapy. However, some complementary therapies may help to relieve symptoms of cancer, decrease the magnitude of side effects from treatment, or improve a patient's sense of well being. The American Cancer Society recommends that anyone considering alternative or complementary therapy consult a health care team before doing so.

Palliative care

Palliative care, which focuses on the terminally ill, is an extremely important aspect of care. Its goal is to prevent and relieve pain and suffering through symptom management, and addresses not only the physical, but the practical, emotional, and spiritual needs of patients, their families, and caregivers. By viewing dying as a natural process, palliative care helps facilitate what can be termed a "good" death, free from suffering and stress. Many patients and their families are unaware that suffer-

ing at the end of life is no longer necessary. Health care professionals can relieve a patient and their loved ones of much **anxiety** by informing them that appropriate symptom management is readily available.

Hospice care

Hospice care is the environment in which palliative care is given to terminally ill patients. Hospice care can be provided either at home, or in a home-like facility called a hospice. Hospice care focuses on providing the best possible palliative care for the patient until the patient dies.

Prognosis

Most cancers are curable if detected and treated in their early stages. The prognosis for a person with cancer is affected by many factors, particularly the type of cancer and stage of the cancer, the extent to which it has metastasized, and its aggressiveness. In addition, a person's age, general health status, and effectiveness of the treatment being pursued are important factors.

To help predict the outcome of cancer and the likelihood of recovery from the disease, five-year survival rates are used. In the United States, as of 2001, the five-year survival rate for all cancers combined was 59%. This means that 59% of people with cancer are expected to be alive five years after they are diagnosed. These people may be free of cancer, or they may be undergoing treatment. It is important to note that, while this statistic can give some information about the average survival of people with cancer in a given population, it cannot be used to predict the course of cancer for an individual. No two people are exactly alike. The five-year survival rate does not account for differences in detection methods, types of treatments, additional illnesses, and personal behavior of the individual.

Health care team roles

Family physicians, internists, gynecologists, or pediatricians generally make an initial diagnosis of cancer. Other physicians, notable radiologists, and oncologists provide chemotherapeutic and radiologic treatment. Nurses provide emotional and educational support, **home care**, home hospice care, and case management. Counselors and psychologists may provide emotional support to patients and their families. Epidemiologists collect and maintain data related to cancer.

Prevention

According to experts from leading universities in the United States, a person can reduce the chances of getting cancer by following these guidelines:

- eating plenty of fruits and vegetables
- exercising vigorously for at least 20 minutes every day
- avoiding excessive weight gain
- avoiding tobacco (including second hand smoke)
- decreasing or avoiding consumption of animal **fats** and red meats
- avoiding excessive amounts of alcohol
- avoiding the midday sun (between 11 A.M. and 3 P.M.) when the sun's rays are the strongest
- avoiding risky sexual practices
- avoiding known carcinogens in the environment or work place

Certain drugs being used for treatment can also be suitable for prevention. For example, tamoxifen (Nolvadex) has been very effective against recurrence of breast cancer and is now thought to be helpful in the prevention of breast cancer. Similarly, retinoids derived from **vitamin A** are being tested for their ability to slow the progression of, or prevent, head and neck cancers.

KEY TERMS

Benign—A growth that does not spread to other parts of the body. Recovery is favorable with treatment.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Bone marrow—Spongy material that fills the inner cavities of the bones. The progenitors of all the blood cells are produced in this bone marrow.

Carcinogen—Any substance capable of causing cancer by mutating a cell's DNA.

Chemotherapy—Treatment with anticancer drugs.

Epithelium—Layer of cells covering the body's surface and lining the internal organs and various glands.

Hormone therapy—Treatment of cancer by changing the hormonal environment, such as testosterone and estrogen.

Immunotherapy—Treatment of cancer by stimulating the body's immune system.

Malignant—A general term for cells that can break loose from an original tumor, invade, and then destroy other tissues and organs.

Metastasis—The spread of cancer from one part of the body to another.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Sore—An open wound or a bruise or lesion on the skin.

Tumor—An abnormal growth resulting from a cell that lost its normal growth control restraints and started multiplying uncontrollably.

X rays—High energy radiation used in high doses, either to diagnose or treat disease.

Cancer therapy, supportive

Definition

Supportive **cancer** therapy is the use of medications to prevent or counteract the unwanted side effects of cancer treatment.

Purpose

Along with their beneficial effects, many cancer treatments cause uncomfortable and sometimes harmful side effects. Three of the most common untoward effects of cancer treatment are nausea and vomiting, destruction of red and white **blood** cells in bone marrow that results in anemia and neutropenia, and **pain**. Fortunately, several drugs have been developed that specifically target these adverse reactions.

Precautions

The patient should be questioned as to medications being taken, and if adverse reactions have ever occurred. Any **allergies** to foods, dyes, preservatives, or other substances should also be assessed.

Description

Various medications are available for use in supportive cancer therapy. Their use is dependent upon several factors, including the particular treatment the patient is undergoing and the severity of symptoms.

Nausea and vomiting

The prevention and control of nausea and vomiting are extremely important for patients receiving cancer treatment. Unrelieved nausea and vomiting may lead to nutritional deficiencies, **dehydration**, electrolyte imbalances, and a general deterioration of the patient's mental and physical status. The drugs used to treat nausea and vomiting are known as antiemetics. Each falls into one of several categories.

PHENOTHIAZINES. The drugs within this category that are most commonly used as antiemetics include prochlorperazine (Compazine) and promethazine (Phenergan). These drugs can be given orally, intramuscularly, intravenously, and rectally. The most common side effects include extrapyramidal reactions, and sedation. There may be a significant drop in **blood pressure** if the medication is given too rapidly via the intravenous route.

DOPAMINE 2 ANTAGONISTS. Metoclopramide (Reglan) is the most widely used drug for nausea and

vomiting in this category. It may be given either orally or intravenously. Like phenothiazines, it may lead to extrapyramidal reactions. Metoclopramide increases the pressure in the lower esophageal sphincter and increases the rate of gastric emptying, which may be an important factor in its antiemetic effect.

5-HT₃ ANTAGONISTS. Three medications within this category are available in the United States: ondansetron (Zofran), granisetron (Kytril), and dolasetron (Anzemet). They are thought to work by blocking some actions of serotonin. These drugs may be given orally or intravenously. The most common side effects are headache (which can be treated with mild **analgesics**), constipation or **diarrhea**, dry mouth, fatigue and weakness, and dizziness.

In general, 5-HT₃ antagonists are more effective than other antiemetics. However, their effectiveness is improved when they are given in combination with **corticosteroids**.

CORTICOSTEROIDS. Steroids like dexamethasone (Decadron) and methylprednisolone (Prednisone) are occasionally used alone in treating mild to moderate nausea, but more frequently are used in combination with other antiemetic drugs. They may be given orally, intramuscularly, and intravenously. It is not known exactly how corticosteroids work in treating nausea and vomiting, but they may affect prostaglandin activity in the **brain**. In the short-term, steroids may not only relieve nausea, but may also produce a sense of well being and an increased appetite in the patient. Long-term use is usually avoided, as it may cause suppression of the **immune system**, muscle weakness, hyperglycemia, lethargy, weight gain, and mood changes.

CANNABINOIDS. A great deal of interest has been shown in using **marijuana** to treat nausea and vomiting in cancer patients. However, because of both societal and legal restrictions, cannabinoids are usually not among the first drugs selected to treat nausea and vomiting. Two forms of marijuana have been used: marijuana cigarettes and a medicine taken by mouth containing the active chemical component of marijuana. Dronabinol (Marinol) is a synthetic form of the active ingredient in marijuana that is given orally. It makes some people feel drowsy, dizzy, lightheaded, or “high,” with a sense of well being. It takes longer to work than smoked marijuana and may be difficult for patients with nausea and vomiting to keep down. The active ingredients of marijuana are more quickly absorbed from smoking marijuana cigarettes. However, since many patients are unable to tolerate smoking and each marijuana cigarette may vary in its potency, research is being conducted into other ways to

effectively administer marijuana, such as inhalers, nasal sprays, and skin patches.

Patients considering using marijuana to control nausea and vomiting should be encouraged to fully discuss this option with their health care professional. A careful consideration of both the legal and medical issues is important.

BENZODIAZEPINES. Benzodiazepines such as Lorazepam (Ativan) and Alprazolam (Xanax) are valuable tools in the prevention and treatment of nausea and vomiting when given in combination with other antiemetics. They are especially useful in preventing anticipatory nausea and vomiting. The adverse effects of benzodiazepines include lowered blood pressure, sedation, altered perception, and dependence.

Anemia and neutropenia

Anemia and neutropenia are two potentially very serious complications of cancer treatment. Hematopoietic agents and colony stimulating factors help combat these complications by stimulating the bone marrow to produce new cells.

HEMATOPOIETIC AGENTS. A weakened bone marrow occurring as a result of cancer treatment or certain cancers can lead to low erythropoietin levels. Erythropoietin is a hormone produced by the **kidneys** and **liver** in response to low blood oxygen levels or anemia. It stimulates the bone marrow to make new red blood cells. Synthetically made versions of human erythropoietin called epoetin (Procrit, Epogen) can perform the same function.

Epoetin, which is injected, is usually well tolerated by patients. Some side effects may include high blood pressure, tachycardia, minor allergies, **edema**, diarrhea, and **iron** deficiency. Patients taking this medication need to have adequate iron levels in the body. The physician may prescribe iron supplements along with Epoetin. Occasionally Epoetin may cause a flu-like reaction that shows up about one or two hours after an injection. Normally the symptoms will go away within 12 hours. Another possible side effect is bone pain, which may be treated with mild analgesics.

COLONY STIMULATING FACTORS. While **chemotherapy** is in the process of destroying cancer cells, it can also damage cells in the bone marrow, where in addition to other types, white blood cells are produced. White blood cells help to defend the body against infections, so a decreased number is associated with an increased risk for **infection**. The numbers of white blood cells usually drop to their nadir, or lowest value, around 10-14 days after the end of chemotherapy treatment. Normally it takes around

KEY TERMS

Antiemetics—Medications used to alleviate nausea and vomiting.

Extrapyramidal reactions—Muscular rigidity, tremors, and altered gait brought on by certain medications. Also called drug-induced parkinsonism.

Neutropenia—The presence of an abnormally small level of neutrophils in the blood, usually less than 1500-2000 per microliter. Patients with low levels of neutrophils are at high risk for infections.

three to four weeks for the white blood cell count to recover. In order to speed up this process, drugs called colony stimulating factors can be given that can help the bone marrow to produce new white blood cells. Examples of colony stimulating factors are G-CSF (Filgrastim, Neupogen) and GM-CSF (Sargramostim, Leukine). Both are given by injection daily for around seven to 14 days. The patient or caregiver is often taught how to administer the injections.

Colony stimulating factors commonly cause mild bone pain, normally in the pelvis or lower back. This occurs around the same time that the white blood cells come back in the bone marrow. This symptom can be treated with mild analgesics. Other common side effects include headache, skin rash, muscle or joint pain, and itching.

Pain

Approximately 60%-90% of cancer will need some type of pain-relieving therapy, depending on the type and severity of their cancer. For example, cancers of the abdomen can cause intense pain while lymphomas often never cause pain. Supportive cancer therapy for pain can be vitally important. Pain causes suffering and can lead to depression and anger. There are many causes of cancer pain, including:

- Chemotherapeutic drugs may poison nerves in addition to tumors. For example, cisplatin, carboplatin and other cancer drugs can cause peripheral neuropathy, such as burning in the hands and feet.
- Radiation therapy can produce neuropathic pain by scarring nerves (fibrosis) or cause painful skin reactions.
- Tumor spread can cause neuropathic pain, for example, when spinal tumors pinch or press nerves.

- Cancers and various complications can cause somatic pain, such as obstructions in the intestine or urinary tract.
- Surgery can cause both somatic and neuropathic pain.

There are a variety of treatments for cancer pain, depending on its severity. Aspirin, acetaminophen (Tylenol), and other **nonsteroidal anti-inflammatory drugs** (NSAIDs) are often used for mild pain. Moderate pain treatments include codeine, Percocet, Percodan, hydrocodone (Vicodin), and propoxyphene (Darvon). Demerol, Dilaudid, and morphine are some of the drugs used to treat severe pain. These medications have various side effects, some of them potentially serious.

Preparation

The patient should be instructed on the particular medication being administered or prescribed, including the dosage, times of administration, expected side effects, and any potentially adverse reactions. Patients receiving colony stimulating factors may need to be instructed on **subcutaneous injection** technique.

Aftercare

The health care professional should assess the patient's response to the medication administered and if any side effects have occurred.

Complications

As with many medications, serious complications, though usually rare, can and do occur. A physician should be notified quickly if any of the following occur.

Phenothiazines

If **sore throat** and **fever**, unusual bleeding or bruising, or an increase in weakness occur, the physician should be notified. Seizures, severe drowsiness, facial flushing, hallucinations, muscle spasms, trembling and jerking movements may all be symptoms of an **overdose**.

Dolasetron, granisetron, and ondansetron

The physician should be notified immediately if any of the following occur: shortness of breath or other breathing difficulties, chest pain, skin rash, **hives** or itching, and fever. Prompt notification should also take place if patients taking dolasetron experience hematuria, anuria or dysuria; or swelling of the face, feet or legs.

Dronabinol

Dronabinol may worsen some medical conditions, including high blood pressure, **heart** disease, **bipolar**

disorder, and **schizophrenia**. Any new symptoms suggestive of these conditions should be reported to the doctor. A variety of other side effects and possible signs of overdose should also be reported immediately, including tachycardia, difficulty urinating, slurred speech, mood changes, confusion and forgetfulness, sensory changes, and hallucinations.

Epoetin

Certain side effects should be brought to a physician's attention as soon as possible, including headache, visual disturbances, elevated blood pressure readings, tachycardia, edema, and weight gain. The physician should be notified immediately if the patient taking epoetin experiences chest pain or seizures.

Colony stimulating factors

Colony stimulating factors increase the risk of infection because of lowered white blood cell counts. Therefore, any signs of infection, including fever and chills, should be reported to the physician as soon as possible. Other symptoms that should be reported promptly include redness or pain at an injection site; chest pain; tachycardia; difficulty breathing and/or wheezing; and edema.

Results

The goal of antiemetic administration in supportive cancer therapy is relief of nausea and vomiting. For those receiving epoetin or either of the colony stimulating factors, normalized blood cell counts and prevention of infections are the desired results.

Health care team roles

Medications used in the supportive care of cancer patients are ordered by the physician. Some states may allow **advanced practice nurses** to prescribe. The pharmacist is responsible for dispensing the drugs. The nurse plays an important role in both **administering medication**, assessing the response of the patient, and teaching the patient about all aspects of the drug being given.

Carbohydrates

Definition

Carbohydrates are compounds that consist of carbon, hydrogen, and oxygen, linked together by energy-containing bonds. There are two types of carbohydrates: complex and simple. The complex carbohydrates, such as starch and fiber, are classified as polysaccharides. Simple carbohydrates are known as sugars and they are classified as mono- or disaccharides, depending on the number of sugars present. Monosaccharides consist of only one sugar; disaccharides have two sugar molecules bonded together.

Purpose

In the digestive tract, carbohydrates are broken down into the monosaccharide glucose, which provides energy for the body's cells and tissues. Glucose is the body's primary source of fuel.

Precautions

A common concern among consumers is that a high intake of carbohydrate-rich foods will cause weight gain. Consuming too much of *any* particular food can cause an increase in weight, but eating a balanced diet with plenty of fruits, vegetables, and grains will help promote weight

KEY TERMS

Diabetes—A condition characterized by inadequate use of insulin preventing a person from controlling blood sugar levels.

Fructose—Monosaccharide known as fruit sugar.

Galactose—Monosaccharide known as milk sugar.

Glucose—Monosaccharide used for energy; also known as blood sugar.

Lactose—Disaccharide known as milk sugar.

Low-density lipoprotein cholesterol (LDL)—Lipoproteins containing a large amount of cholesterol; transport lipids to other tissues in the body.

Maltose—Disaccharide known as malt sugar.

Sucrose—Disaccharide commonly known as table sugar.

Polysaccharides—Long chains of glucose units linked together.

management. General guidelines recommend that about 55 to 60% of daily calories come from carbohydrates.

Description

Carbohydrates are either simple or complex. Both have four calories per gram, and both are further reduced by the body to glucose, but complex carbohydrates, which undergo most of their digestion in the **large intestine**, take longer to digest. Carbohydrates come almost exclusively from plants, vegetables, and grains. Milk is the only animal-based product that contains a significant amount of carbohydrate.

Simple carbohydrates include the single sugars, or *monosaccharides*, and the double sugars, or *disaccharides*. The monosaccharides include glucose, fructose, and galactose. Disaccharides include lactose, which is made of glucose and galactose; maltose, made of two glucose units; and sucrose, made of glucose and fructose. Monosaccharides can be absorbed directly into the bloodstream, but disaccharides need to be broken down into their monosaccharide components before they can be absorbed.

When food is consumed, the digestion of carbohydrates begins in the mouth, where an enzyme in saliva breaks down starch molecules into the disaccharide maltose. The food then moves into the **stomach** where it mixes with the stomach's acid and other juices. In the **small**

intestine, starch is further broken down into disaccharides and small polysaccharides by an enzyme released from the **pancreas**. Cells lining the small intestine then secrete an enzyme that further splits these disaccharides and polysaccharides into monosaccharides. The cells lining the small intestine can absorb these monosaccharides, which are then taken to the **liver**. The liver converts fructose and galactose to glucose. If there is an excess of fructose or galactose, it may also be converted to fat. Lastly, the glucose is transported to the body's cells by the circulatory system, where it can be used for energy.

When there is an excess of glucose, the muscle and liver cells often convert it to glycogen, which is the storage form of glucose. The muscles store two thirds of the body's glycogen solely for themselves, and the liver stores the other one third, which can be used by the **brain** or other organs. When **blood** glucose levels decline, the body breaks down some of its glycogen stores, and uses the glucose for energy. If blood glucose levels are too high, the excess glucose is taken to the liver where it is converted to glycogen and stored for future use.

Fiber

One of the complex carbohydrates, fiber, is a polysaccharide in which the bonds holding it together cannot be digested by humans. Fiber can be either water-soluble or water-insoluble. Even though these compounds cannot be digested by humans, they serve several important functions. The main function of insoluble fiber is to bind bile acids, which reduces fat and cholesterol absorption. Sources of insoluble fiber include wheat bran, whole grains, and brown rice. Soluble fiber, which helps decrease low-density lipoprotein (LDL) cholesterol, can be found in barley, fruit, legumes, and oats.

Fiber is an extremely important part of the diet. It aids in weight control by displacing calorie-dense **fats** in the diet. Fiber also absorbs water and slows the movement of food through the digestive tract, promoting a feeling of fullness. Recommended intakes of fiber should be about 27 to 40 grams per day.

The food guide pyramid was designed by health professionals to help consumers make nutritious food choices. The bottom and largest portion of the pyramid represents the bread, cereal, rice, and pasta group, and it is recommended that a healthy diet includes six to 11 servings from this food group daily. Three to five servings from the vegetable group and two to four servings from the fruit group are also recommended. These amounts will provide sufficient carbohydrates (including fiber) in the diet.

Complications

When carbohydrate intake is low, there is insufficient glucose production, which then causes the body to use its protein for energy. This ultimately prevents the body's protein from performing its more important functions, such as maintaining the body's **immune system**.

Without carbohydrate, the body also goes into a state of ketosis, in which by-products of fat breakdown, called *ketones*, accumulate in the blood. This causes a shift in the **acid-base balance** of the blood, which can be fatal.

Insulin

Diabetes is a disease in which the body cannot metabolize carbohydrates, and either doesn't make or doesn't respond to insulin, a hormone secreted by the pancreas that is used to transport glucose to the body's cells. In individuals with type 1 diabetes, the pancreas fails to produce insulin, thus causing blood glucose levels to remain the same after meals. This condition is known as hyperglycemia. These individuals must receive daily injections of insulin to control their blood glucose levels. In type 2 diabetes, there may be sufficient insulin, but the body's cells may be resistant to it. Once again, this causes blood glucose levels to rise. Type 2 diabetes can be treated through oral medication and proper diet, although the need for insulin injections may develop later on.

Health care team roles

Registered dietitians and nutritionists are the professionals most qualified to educate individuals on the role of carbohydrates in a healthy diet, as well as the complications associated with low-carbohydrate intakes. Medical doctors and nursing professionals also play an important role in treating carbohydrate-related conditions such as diabetes, while dietitians serve to make recommendations concerning the nutritional needs of these individuals.

Carbon monoxide poisoning

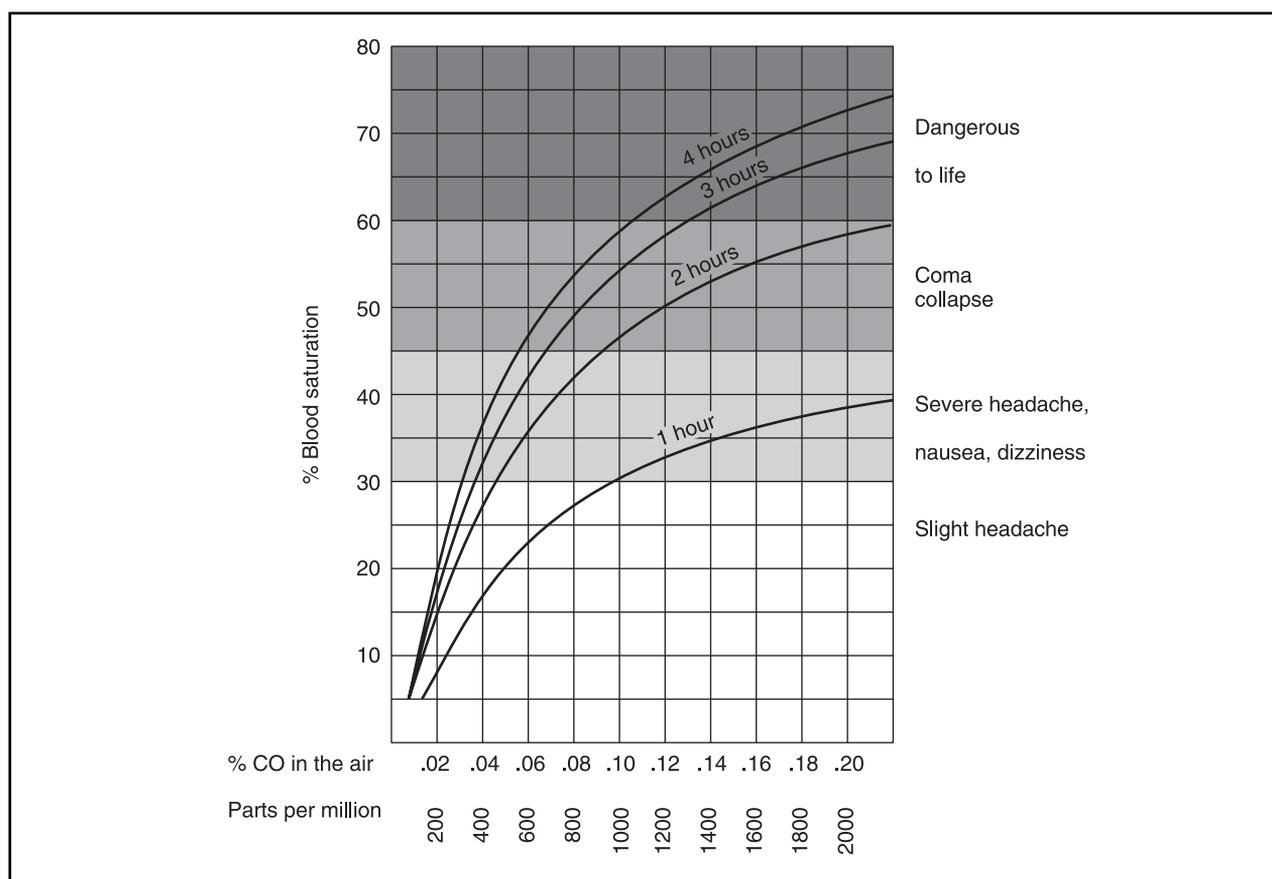

Definition

Carbon monoxide (CO) **poisoning** occurs when carbon monoxide gas is inhaled. CO is a colorless, odorless, highly poisonous gas that is produced by incomplete combustion of fossil fuels. It is found in automobile exhaust fumes, faulty stoves and heating systems, fires, and cigarette smoke. Other sources include wood-burning stoves, kerosene heaters, improperly ventilated water heaters and gas stoves, and blocked or poorly maintained fireplace chimney flues. CO interferes with the ability of the **blood** to carry oxygen. The result is headache, nausea, convulsions, and finally death by asphyxiation.

Description

Carbon monoxide, sometimes called coal gas, has been known to be a toxic substance since the third century B.C. It was used for executions and suicides in early Rome. Today it is the leading cause of accidental poisoning in the United States. According to the *Journal of the American Medical Association*, 1,500 Americans die each year from accidental exposure to CO, and another 2,300 from intentional exposure (suicide). An additional 10,000 people seek medical attention and recover after exposure to CO.

Anyone who is exposed to CO will become sick, and the entire body is involved in CO poisoning. A developing fetus can be poisoned if a pregnant woman breathes CO gas. Infants, people with **heart** or lung disease, or those with anemia may be more seriously affected than otherwise healthy adults. People, such as underground-parking garage attendants, who are exposed to car exhausts in a confined area, are more likely to be poi-

Carbon monoxide, effects under exposure. (Graph by Hans & Cassidy. Reproduced by permission.)

soned by CO. Firefighters also have an elevated occupational risk of inhaling CO.

Causes and symptoms

Normally when a person breathes fresh air into the **lungs**, the oxygen in the air binds with a molecule called hemoglobin (Hb) that is found in red blood cells. This allows oxygen to be moved from the lungs to every part of the body. When the oxygen/hemoglobin complex reaches a muscle where it is needed, the oxygen is released. Because the oxygen binding process is reversible, hemoglobin can be used repeatedly to pick up oxygen and move it throughout the body. After oxygen is released, carbon dioxide binds to hemoglobin and is transported back to the lungs.

Inhaling carbon monoxide gas interferes with this oxygen-transport system. In the lungs, CO competes with oxygen to bind with a hemoglobin molecule. Hemoglobin and CO bind more than 200 times more readily than do Hb and oxygen. The hemoglobin holds on to the CO much more tightly, forming a complex called carboxyhemoglobin (COHb). As a person breathes CO-

contaminated air, more and more oxygen transportation sites on the hemoglobin molecules become blocked by CO. Gradually, there are fewer and fewer sites available for oxygen. This creates a condition called carboxyhemoglobinemia. All cells need oxygen to live. When they do not get enough oxygen, cellular **metabolism** is disrupted and eventually cells begin to die.

The symptoms of CO poisoning and the speed with which molecules of carboxyhemoglobin appear depend on the concentration of CO in the air and the rate and efficiency with which a person breathes. Heavy smokers may live with up to 9% of their hemoglobin already bound to CO, which they regularly inhale in cigarette smoke. This makes them much more susceptible to environmental CO. The Occupational Safety and Health Administration (OSHA) has established a maximum permissible environmental exposure level of 50 parts per million (ppm) of CO over eight hours.

With exposure to 200 ppm for two to three hours, a person begins to experience headache, fatigue, nausea, and dizziness. These symptoms correspond to 15–25% COHb in the blood. When the concentration of COHb

reaches 50% or more, death follows in a very short time. Emergency room physicians usually have the most experience diagnosing and treating CO poisoning, though occupational and environmental health professionals may also see multiple cases.

The symptoms of CO poisoning in order of increasing severity include:

- headache
- shortness of breath (dyspnea)
- dizziness
- fatigue
- mental confusion and difficulty thinking (disorientation)
- loss of fine hand-eye coordination
- nausea and vomiting
- rapid heart rate (tachycardia)
- hallucinations
- inability to accurately execute voluntary movements
- collapse
- lowered body temperature (hypothermia)
- coma (unconsciousness)
- convulsions (seizures)
- seriously low **blood pressure** (critical hypotension)
- cardiac and respiratory failure
- death

In some cases, the skin, nose, mucous membranes, or nails of a person with CO poisoning are cherry red or bright pink. Because the color change doesn't always occur, it is an unreliable symptom on which to base a diagnosis.

Although most CO poisoning is acute (sudden), it is possible to suffer from chronic CO poisoning. This condition exists when a person is exposed to low levels of the gas over a period of days or months. Symptoms are often vague and include (in order of frequency) fatigue, headache, dizziness, sleep disturbances, cardiac symptoms, apathy, nausea, and **memory** disturbances. Little is known about chronic CO poisoning, and it is often misdiagnosed.

Diagnosis

The main reason to suspect CO poisoning is evidence that fuel is being burned in a confined area, for example, a car running inside a closed garage, a charcoal grill burning indoors, or an unvented kerosene heater in a workshop. Under these circumstances, one or more persons suffering from the symptoms listed above,

strongly suggests CO poisoning. In the absence of some concrete reason to suspect CO poisoning, the disorder is often misdiagnosed as **migraine headache**, stroke, psychiatric illness, **food poisoning**, alcohol poisoning, or heart disease.

Confirmation of CO poisoning comes from a carboxyhemoglobin test. This blood test measures the amount of CO bound to hemoglobin in the body. Blood is drawn as soon after suspected exposure to CO as possible.

Other tests that are useful in determining the extent of CO poisoning include measurement of other arterial **blood gases** and pH; a **complete blood count**; measurement of other blood components such as sodium, potassium, bicarbonate, urea nitrogen, and lactic acid; an electrocardiogram (ECG); and a **chest x ray**.

Treatment

The most immediate treatment for CO poisoning is to remove a person from the source of carbon monoxide gas and expose the individual to fresh air. If breathing has stopped or there is no pulse, **cardiopulmonary resuscitation (CPR)** should be started. Depending on the severity of the poisoning, 100% oxygen may be given with a tight fitting mask over an airway as soon as it is available.

Taken with other symptoms of CO poisoning, COHb levels over 25% in otherwise healthy individuals, over 15% in patients with a history of heart or lung disease, and over 10% in pregnant women usually indicate the need for hospitalization. In the hospital, fluids and electrolytes are given to correct any chemical imbalances that may have arisen from the breakdown of cellular metabolism.

In severe cases of CO poisoning, patients are given hyperbaric **oxygen therapy**. This treatment involves placing a person in a special chamber where he or she breathes 100% oxygen at a pressure of more than one atmosphere (the normal pressure the atmosphere exerts at sea level). The increased pressure forces more oxygen into the blood. Hyperbaric facilities are specialized, and are usually available only at larger hospitals or regional trauma centers.

Prognosis

The speed and degree of recovery from CO poisoning depends on the duration and concentration of exposure to the gas. The half-life of CO in normal room air is four to five hours. This means that, in four to five hours, half of the CO bound to hemoglobin will be replaced with oxygen. At normal atmospheric pressures, but breathing 100% oxygen, the half-life for the elimination of CO from the body is 50–70 minutes. In hyperbaric

KEY TERMS

Carboxyhemoglobin (COHb)—Hemoglobin that is bound to carbon monoxide instead of oxygen.

Carboxyhemoglobinemia—A condition characterized by blood saturated with carboxyhemoglobin molecules.

Hemoglobin (Hb)—A molecule of red blood cells that normally binds to oxygen to transport it to cells, where it is required for life.

Hypothermia—Development of a subnormal body temperature, usually less than 96°F (37°C).

pH—A measurement of the acidity or alkalinity of a fluid. A neutral fluid, neither acid nor alkali, has a pH of 7.0.

therapy, at three atmospheres of pressure, the half-life is reduced to 20–25 minutes.

Although the symptoms of CO poisoning may subside in a few hours, some people may show residual memory problems, fatigue, confusion, and mood changes for two to four weeks after their exposure to the gas.

Health care team roles

Trained persons may initiate **first aid** and CPR. **Emergency medical technicians** or paramedics may continue such treatment and initiate oxygen therapy while transporting a patient to a hospital. A physician provides treatment in the emergency department. A physician also supervises treatment in a hyperbaric chamber. A therapist may provide counseling after recovery from CO exposure.

Prevention

Carbon monoxide poisoning is preventable. Particular care should be paid to situations where fuel is burned in a confined area, or where heating equipment is old and in need of replacement. Portable and permanently installed carbon monoxide detectors that sound a warning similar to smoke detectors are available for under \$50. Specific actions that will prevent CO poisoning include:

- Stop smoking. Smokers have less tolerance to environmental CO.
- Have heating systems and appliances installed by a qualified contractor to ensure they are properly vented and meet local building codes.

- Inspect and properly maintain heating systems, chimneys, and appliances.
- Do not use a gas oven or stove to heat the home.
- Do not burn charcoal indoors.
- Make sure there is good ventilation if using a kerosene heater indoors.
- Do not leave cars or trucks running inside a garage.
- Keep car windows rolled up when stuck in heavy traffic, especially when inside a tunnel.

Cardiac catheterization

Definition

Cardiac catheterization (also called **heart** catheterization) is a diagnostic and occasionally therapeutic procedure that allows a comprehensive examination of the heart and surrounding **blood vessels**. It enables the physician to take angiograms, record **blood** flow, calculate cardiac output and vascular resistance, perform an endomyocardial biopsy, and evaluate the heart's electrical activity. Cardiac catheterization is performed by inserting one or more catheters (thin flexible tubes) through a peripheral blood vessel in the arm (antecubital artery or vein) or leg (femoral artery or vein) under x-ray guidance.

Purpose

Cardiac catheterization is most commonly performed to examine the coronary arteries, because heart attacks, angina, sudden death, and **heart failure** most often originate from disease in these arteries. **Coronary artery disease** is the first-ranked cause of death for both men and women in the United States. Cardiac catheterization with coronary **angiography** is recommended in patients with angina (especially unstable angina); suspected coronary artery disease; suspected silent ischemia and a family history of heart attack; ischemic cardiac myopathy; congestive heart failure; congenital heart disease; and pericardial disease. Catheterization is

Doctors at work during a cardiac catheterization procedure. With the patient under a local anesthetic, the catheter is inserted into an artery in the thigh, then guided to the coronary arteries. A dye is then released, revealing blockages. (Photograph by Simon Fraser, Photo Researchers, Inc. Reproduced by permission.)

also recommended for patients with suspected valvular disease, including aortic stenosis or regurgitation and mitral stenosis or regurgitation. In addition, the procedure may be performed after acute **myocardial infarction**; before major noncardiac surgery in patients at high risk for cardiac problems; before cardiac surgery in patients at risk for coronary artery disease; and before such interventional technologies and procedures as stents and percutaneous transluminal coronary **angioplasty** (PTCA).

Cardiac catheterization may reveal the presence of other conditions, including enlargement of the left ventricle; ventricular aneurysms (abnormal dilation of a blood vessel); narrowing of the aortic valve; insufficiency of the aortic or mitral valve; and septal defects that allow an abnormal flow of blood from one side of the heart to the other.

Symptoms and diagnoses that may be associated with the above conditions and may lead to cardiac catheterization include:

- chest **pain** characterized by prolonged heavy pressure or a squeezing pain
- abnormal results from a treadmill **stress** test
- myocardial infarction (heart attack)
- congenital heart defects
- valvular disease

Left- and right-side catheterization

Cardiac catheterization can be performed on either side of the heart to evaluate different functions. Testing the right side of the heart allows the physician to evaluate tricuspid and pulmonary valve function, in addition to measuring blood pressures and collecting blood samples from the right atrium, right ventricle, and pulmonary artery. Catheterization of the left side of the heart is performed to test the blood flow in the coronary arteries as well as the level of function of the mitral and aortic valves and left ventricle. The physician can assess the adequacy of blood supply through the coronary arteries, blood pressures, and blood flow throughout the chambers of the heart, collect blood samples, and take x rays of the heart's ventricles or arteries.

Coronary angiography

Coronary angiography, which is also known as coronary arteriography, is an imaging technique that involves injecting a dye into the vascular system to outline the heart and coronary vessels. Angiography allows the visualization of any blockages, narrowing, or abnormalities in the coronary arteries. If these signs are visible, the cardiologist may assess the patient's readiness for coronary bypass surgery, or a less invasive approach such as dilation of a narrowed blood vessel by surgery or the use of a balloon (angioplasty). Because some interventions may be performed during cardiac catheterization, the procedure is considered therapeutic as well as diagnostic.

Outpatient catheterization

Cardiac catheterization is usually performed in a specially designed cardiac catheterization suite in a hospital, so that any procedural complications may be handled rapidly and effectively. Cardiac catheterization may also be performed on patients presenting to the emergency department with chest pain or chest injuries. The procedure may be performed on an outpatient basis, depending on the patient's pre- and post-catheterization

condition. As of 2000, however, the American Heart Association (AHA) and the American College of Cardiology (ACC) issued a joint statement denying approval of the use of separate cardiac catheterization laboratories that are not part of a hospital, on the grounds that a small number of patients having the procedure on an outpatient basis will have unexpected reactions or complications.

Precautions

Contraindications

Cardiac catheterization is categorized as an invasive procedure that involves the heart, its valves, and coronary arteries, in addition to a large artery in the arm or leg. Cardiac catheterization is contraindicated for patients with the following conditions:

- A bleeding disorder, or anticoagulation treatment with Coumadin (sodium warfarin). These may affect bleeding and clotting during the catheterization procedure.
- Renal insufficiency or poor kidney functioning (especially in diabetic patients), which may worsen following angiography.
- Severe uncontrolled hypertension.
- Severe peripheral vascular disease that limits access to the arteries.
- Untreated active infections, severe anemia, electrolyte imbalances, or coexisting illnesses that may affect recovery or survival.
- Endocarditis (an inflammatory **infection** of the heart's lining that often affects the valves).

Radiation hazards

Cardiac catheterization involves radiation exposure for staff members as well as the patient. The patient's dose of radiation is minimized by using lead shielding in the form of blankets or pads over certain body parts and by choosing the appropriate dose during fluoroscopy. Staff members' exposure to radiation is monitored by the wearing of radiation badges that detect exposure and lead aprons that shield the body. The radiographic/fluoroscopic system may be equipped with movable lead shields that do not interfere with access to the patient and are placed between staff members and the source of radiation during the procedure.

Description

More than 1.5 million cardiac catheterizations are performed every year in the United States, primarily to diagnose or monitor heart disease.

Cardiac anatomy

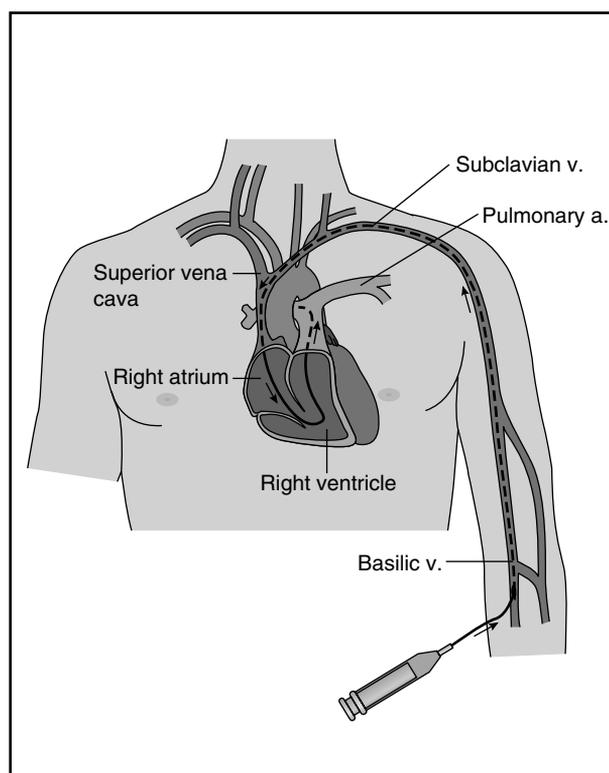

The heart consists of four chambers separated by valves. The right side of the heart, which consists of the right atrium (upper chamber; sometimes called the right auricle) and the right ventricle (lower chamber), pumps blood to the **lungs**. The left side of the heart, which consists of the left atrium (or auricle) and the left ventricle, simultaneously pumps blood to the rest of the body. The right and left coronary arteries, which are the first vessels to branch off from the aorta, supply blood to the heart. The left anterior descending coronary artery supplies the front of the heart; the left circumflex coronary artery wraps around and supplies the left side and the back of the heart; and the right coronary artery supplies the back of the heart. There is, however, a considerable amount of variation in the anatomy of the coronary arteries.

Catheterization procedure

The patient lies on a table on his or her back during the catheterization procedure, connected to monitoring equipment, including an **electrocardiography** device. The insertion site is numbed with a local anesthetic, and access to the vein or artery is obtained using a needle. A sheath, a rubber tube that facilitates insertion of catheters and infusion of drugs, is placed in the puncture site. Under fluoroscopic guidance, a guidewire, which is a thin wire that guides the catheter insertion, is threaded through a brachial or femoral artery and up to the heart. The catheter, a flexible or preshaped tube approximately 32–43 inches (80–110 cm) long, is then inserted over the wire and threaded to the heart. The patient may experience pressure as the catheter is threaded into the heart. The contrast agent or dye used for imaging is then injected so that the physician can view the heart and surrounding vessels. The patient may experience a hot flushed feeling or slight nausea following injection of the contrast medium. Depending on the type of catheterization (left- or right-heart) and the area being imaged, different catheters with various shapes and ends are used.

The radiographic/fluoroscopic system has an x-ray subsystem and video system with viewing monitors that allow the physician to view the procedure in real time using fluoroscopy as well as taking still x rays for documentation purposes. Most newer systems use a digital angiography system that allows images to be recorded, manipulated, and stored digitally on a computer.

The procedure usually lasts about two or three hours. If further intervention is necessary, an angioplasty, stent implantation, or other procedure can be performed. At the end of the catheterization, the catheter and sheath are removed, and the puncture site is closed using a sealing device or manual compression to stop the bleeding. One

Cardiac catheterization procedure. (Delmar Publishers, Inc. Reproduced by permission.)

commonly used sealing device is called Perclose, which allows the doctor to sew up the hole in the groin. Two other devices called AngioSeal and VasoSeal use collagen seals to close the holes in the femoral artery.

Preparation

Before undergoing cardiac catheterization, the patient may have had other noninvasive diagnostic tests, including an electrocardiogram (ECG), **echocardiography**, computed tomography (CT), **magnetic resonance imaging** (MRI), laboratory studies (e.g., blood work), and/or nuclear medicine cardiac imaging. The results of these noninvasive tests may have indicated a need for cardiac catheterization to confirm a suspected cardiac condition, further define the severity of a previously diagnosed condition, or establish the need for an interventional procedure (e.g., cardiac surgery).

Patients should give the physician or nurse a complete list of their regular medications, including aspirin and **nonsteroidal anti-inflammatory drugs** (NSAIDs), because they can affect blood clotting. Diabetics who are taking either metformin or insulin to control their diabetes should inform the physician, as these drugs may

Cardiac monitoring pressures and volumes

Pressure	Normal values
Aortic artery pressure (routine blood pressure)	90–140/60–90 mm Hg
Central venous pressure	2–14 cm H ₂
End-diastolic left ventricular pressure	4–12 mm Hg
Pulmonary wedge pressure	Left atrial: 6–15 mm Hg
Pulmonary artery pressure	15–28/5–16 mm Hg
Systolic left ventricle pressure	90–140 mm Hg
Volumes	
Cardiac index (CI)	2.8–4.2 L/min/m ² for a patient with 1.5m ² of body surface area
Cardiac output (CO)	3–6 L/min
Ejection fraction (EF)	0.67±0.07
End-diastolic volume (EDV)	50–90ml/m ²
End-systolic volume (ESV)	25 ml/m ²
Stroke volume (SV)	45±12 ml/m ²

SOURCE: Pagana, K.D. and T.J. Pagana. *Mosby's Diagnostic and Laboratory Test Reference*. 3rd ed. St. Louis: Mosby, 1997.

need to have their dosages changed before the procedure. Patients should also notify staff members of any **allergies** to shellfish containing iodine, iodine itself, or the dyes commonly used as contrast agents before cardiac catheterization.

Because cardiac catheterization is considered surgery, the patient will be instructed to fast for at least six hours prior to the procedure. A mild sedative may be administered about an hour before the procedure to help the patient relax. If the catheter is to be inserted through the groin, the area around the patient's groin will be shaved and cleansed with an antiseptic solution.

Aftercare

While cardiac catheterization may be performed on an outpatient basis, the patient requires close monitoring following the procedure; he or she may remain in the hospital for up to 24 hours. The patient will be instructed to rest in bed for at least eight hours immediately after the test. If the catheter was inserted into a vein or artery in the leg or groin area, the leg will be kept extended for four to six hours. If a vein or artery in the arm was used to insert the catheter, the arm will need to remain extended for a minimum of three hours.

Most doctors advise patients to avoid heavy lifting or vigorous **exercise** for several days after cardiac catheterization. Those whose occupation involves a high level of physical activity should ask the doctor when they can safely return to work. In most cases, a hard ridge will form over the incision site that diminishes as the site heals. A bluish discoloration under the skin often occurs

at the point of insertion but usually fades within two weeks. The incision site may bleed during the first 24 hours following surgery. The patient may apply pressure to the site with a clean tissue or cloth for 10–15 minutes to stop the bleeding.

The patient should be instructed to call the doctor *at once* if tenderness, **fever**, shaking, or chills develop, which may indicate an infection. Other symptoms requiring medical attention include severe pain or discoloration in the leg, which may indicate that a blood vessel was damaged.

Complications

As with all invasive procedures, cardiac catheterization involves some risks. The most serious complications include stroke, myocardial infarction, and death resulting from clotting or rupture in one of the coronary or cerebral vessels. Other complications include cardiac arrhythmias, pericardial tamponade, vessel injury, and renal failure. The most common complications resulting from cardiac catheterization are vascular-related, including external bleeding at the arterial puncture site, hematomas, and pseudoaneurysms.

The patient may be given anticoagulant medications to lower the risk of developing an arterial blood clot (thrombosis) or of blood clots forming and traveling through the body (embolization).

The risk of complications from cardiac catheterization is higher in patients over the age of 60; those who have severe heart failure; or those with advanced valvular disease.

Allergic reactions related to the contrast agent (dye) and anesthetics may occur in some patients during cardiac catheterization. Allergic reactions may range from minor **hives** and swelling to severe **shock**. Patients with allergies to seafood or penicillin are at a higher risk of allergic reaction; giving **antihistamines** prior to the procedure may reduce the occurrence of allergic reactions to contrast agents.

Results

Normal findings from a cardiac catheterization will indicate no abnormalities in the size or configuration of the heart chamber, the motion or thickness of its walls, the direction of blood flow, or motion of the valves. Smooth and regular outlines on the x ray indicate normal structure of the coronary arteries.

The measurement of intracardiac pressures, or the pressure in the heart's chambers and vessels, is an essential part of the catheterization procedure. Pressure readings that are higher than normal are significant for a

KEY TERMS

Aneurysm—An abnormal dilatation of a blood vessel, usually an artery. It may be caused by a congenital defect or weakness in the vessel's wall.

Angiography—A procedure that allows x-ray examination of the heart and coronary arteries following injection of a radiopaque substance (often referred to as a dye or contrast agent).

Angioplasty—A procedure in which a balloon catheter is used to mechanically dilate the affected area of a diseased artery and enlarge the constricted or narrowed segment. It is an alternative to vascular surgery.

Aortic valve—The valve between the heart's left ventricle and ascending aorta that prevents regurgitation of blood back into the left ventricle.

Arrhythmia—A variation in the normal rhythm of the heartbeat.

Catheter—A flexible or preshaped curved tube, usually made of plastic, used to evacuate fluids from or inject fluids into the body. In cardiac catheterization, a long, fine catheter is inserted through a blood vessel directly into the chambers of the heart.

Computed tomography (CT)—A diagnostic imaging procedure that uses x rays to produce cross-sectional images of the anatomy. It may be performed prior to cardiac catheterization.

Coronary bypass surgery—A surgical procedure that places a shunt to allow blood to travel from the aorta to a branch of the coronary artery at a point below an obstruction.

Echocardiography—An ultrasound examination of the heart that may be performed prior to cardiac catheterization.

Fluoroscopy—A diagnostic imaging procedure that uses x-rays and contrast agents to visualize anatomy and motion in real time.

Hematoma—An accumulation of clotted blood that may occur in the tissue around the catheter insertion site following cardiac catheterization.

Ischemia—A localized deficiency in the blood supply, usually caused either by vasoconstriction or by obstacles to the arterial blood flow.

Magnetic resonance imaging (MRI)—A diagnostic imaging procedure that uses a magnetic field to produce anatomical images. It may be performed prior to cardiac catheterization.

Mitral valve—The bicuspid valve that lies between the left atrium and left ventricle of the heart. "Bicuspid" means that the valve has two flaps.

Percutaneous transluminal coronary angioplasty (PTCA)—A cardiac intervention in which an artery blocked by plaque is dilated, using a balloon catheter to flatten the plaque and open the vessel. It is also called balloon angioplasty.

Pericardial tamponade—The collection of blood in the sac surrounding the heart that causes compression. Tamponade is a possible complication of cardiac catheterization.

Pseudoaneurysm—A dilation of a blood vessel that resembles an aneurysm. Pseudoaneurysms may occur as a complication of cardiac catheterization.

Pulmonary valve—The heart valve that separates the right ventricle and the opening into the pulmonary artery.

Septum—The muscular wall that separates the two sides of the heart. An opening in the septum that allows blood to flow from one side to the other is called a septal defect.

Shunt—A passageway (or an artificially created passageway) that diverts blood flow from one main route to another.

Stent—A small tubelike device made of stainless steel or other material, used to hold open a blocked artery.

Tricuspid valve—The right atrioventricular valve of the heart. It has three flaps, whereas the mitral valve has only two.

patient's overall diagnosis. Pressure readings that are lower, other than those resulting from shock, are usually not significant.

The ejection fraction is also determined by performing a cardiac catheterization. The ejection fraction is a

comparison of the quantity of blood ejected from the heart's left ventricle during its contraction phase with the quantity of blood remaining at the end of the left ventricle's relaxation phase. The cardiologist will look for a normal ejection fraction reading of 60–70%.

Abnormal results are obtained by viewing the still and live motion x rays during cardiac catheterization for evidence of coronary artery disease, poor heart function, disease of the heart valves, and septal defects.

The most prominent sign of coronary artery disease is narrowing or blockage (stenosis) in the coronary arteries, with narrowing greater than 50% considered significant. A clear indication for intervention by angioplasty or surgery is a finding of significant narrowing of the left main coronary artery and/or blockage or severe narrowing in the high left anterior descending coronary artery.

A finding of impaired wall motion is an additional indicator of coronary artery disease, an aneurysm, an enlarged heart, or a congenital heart problem. Using an ejection fraction test that measures wall motion, cardiologists regard an ejection fraction reading under 35% as increasing the risk of complications while also decreasing the possibility of a successful long- or short-term outcome from surgery.

Detecting the difference in pressure above and below the heart valve can verify the presence of valvular disease. The greater the narrowing, the higher the difference in pressure.

To confirm the presence of septal defects, measurements are taken of the oxygen content on both the left and right sides of the heart. The right heart pumps unoxygenated blood to the lungs, and the left heart pumps blood containing oxygen from the lungs to the rest of the body. Elevated oxygen levels on the right side indicate the presence of a left-to-right atrial or ventricular shunt. Low oxygen levels on the left side indicate the presence of a right-to-left shunt.

Health care team roles

A cardiac catheterization team consists of a physician (e.g., interventional cardiologist), a nurse, a circulating nurse, and a radiologic technologist. Nurses assist the physician and monitor the patient during the procedure. Because clinical laboratory equipment may be used during the procedure to monitor certain parameters (e.g., **blood coagulation** time), nursing or other staff should be familiar with the operation of laboratory devices used in the cardiac catheterization suite. The radiologic technologist assists the physician with the operation of the x-ray and fluoroscopy equipment during the procedure and oversees any image processing, printing, and/or storage needs. The radiologic technologist may work with a medical physicist to monitor radiation safety protocols for the patient and staff.

Cardiac cycle

Definition

The cardiac cycle is the sequence of events that occur when the **heart** beats. The cycle has two main phases: diastole, when the heart ventricles are relaxed, and systole, when the ventricles contract. One cardiac cycle is defined as the contraction of the two atria followed by contraction of the two ventricles.

Description

The heart is a muscular organ that works as a pumping system. It takes in **blood** with reduced levels of oxy-

gen from the veins (deoxygenated blood), and delivers it to the **lungs** for oxygenation. When it receives the oxygenated blood back from the lungs, it pumps the blood back into the arteries to be distributed throughout the body.

The heart is divided into four hollow chambers, two on the left and two on the right. The right chambers are the right atrium and the right ventricle. They receive blood from the veins. The left chambers are the left atrium and the left ventricle. They receive blood from the pulmonary circulation, and the left ventricle forces blood into the systemic circulation.

In a cardiac cycle, blood enters the right atrium of the heart from the superior and inferior vena cavae, and flows across the tricuspid valve into the right ventricle. From the right ventricle the blood flows into the pulmonary artery, which is separated from the ventricle by the pulmonary valve. After oxygenation in the lungs, blood returns to the heart via four pulmonary veins that enter the left atrium. From the left atrium, blood flows across the mitral valve and into the left ventricle. From the left ventricle blood is ejected across the aortic valve into the aorta. Together, the mitral and tricuspid valves are known as the atrioventricular valves and the aortic and pulmonary valves as the semilunar valves.

From a mechanical point of view, the cardiac cycle is due to blood movement occurring as a result of pressure differences within the chambers of the heart. In order for blood to flow through a blood vessel or across and heart valve, there must be a force acting on the blood. This force is provided by the difference in **blood pressure** (a pressure gradient) across these structures by the contractions of the heart. Each heart beat, or cardiac cycle, is divided into two phases of contraction and relaxation, stimulated by electrical impulses from the sinoatrial node (SA node), a patch of tissue in the heart that sets the rate of contractions. It contracts itself and then sends nerve impulse to the atria. The time during which ventricular contraction occurs is called systole. The time between ventricular contractions, during which ventricular filling occurs, is called diastole (also known as the relaxation phase).

In early diastole, the ventricles relax, the semilunar valves close, the atrioventricular valves open and the ventricles fill with blood. In mid diastole, the atria and ventricles are relaxed, the semilunar valves are closed, the atrioventricular valves are open, and the ventricles keep filling with blood. In late diastole, the SA node sends an electrical impulse to the atria, which causes the atria to contract and the ventricles to fill with more blood. The electrical signal that causes contraction moves from the atria toward the ventricles. Before it

does, though, it reaches the atrioventricular node (AV node). The AV node delays the signal so that the ventricle can contract all at once rather than a little bit at a time.

Prior to systole, the electrical signal passes from the AV node down the AV bundle, also known as the bundle of His, to the Purkinje fibers. The fibers allow the fast spread of the electrical signal to all parts of the ventricles, and the electrical signal causes the ventricles to contract. Systole begins with the closure of the atrioventricular valves. During systole, the ventricles contract, the semilunar valves open, and blood is pumped from the ventricles to the aorta.

Blood pressure is highest during systole, and lowest during diastole. It has two components, the systolic and diastolic pressure. Normal systolic pressure for an adult is 120 mm Hg, and normal diastolic pressure is 80 mm Hg. These values are commonly recorded as 120/80.

The normal heart beats at a rate of about 72 beats per minute (with a range of 60-100 beats per minute), but can vary with normal daily activity.

The cardiac cycle produces well-known sounds that can be clearly heard with a **stethoscope**. The first heart sound is associated with closure of the atrioventricular valves and signals the start of ventricular systole. The second heart sound is associated with the closure of the semilunar valves and indicates the start of ventricular diastole. A third heart sound is due to the rapid phase of ventricular filling, and a fourth heart sound is due to atrial systole. The two last sounds are usually not loud enough to hear, so neither of them is heard under normal exam procedures.

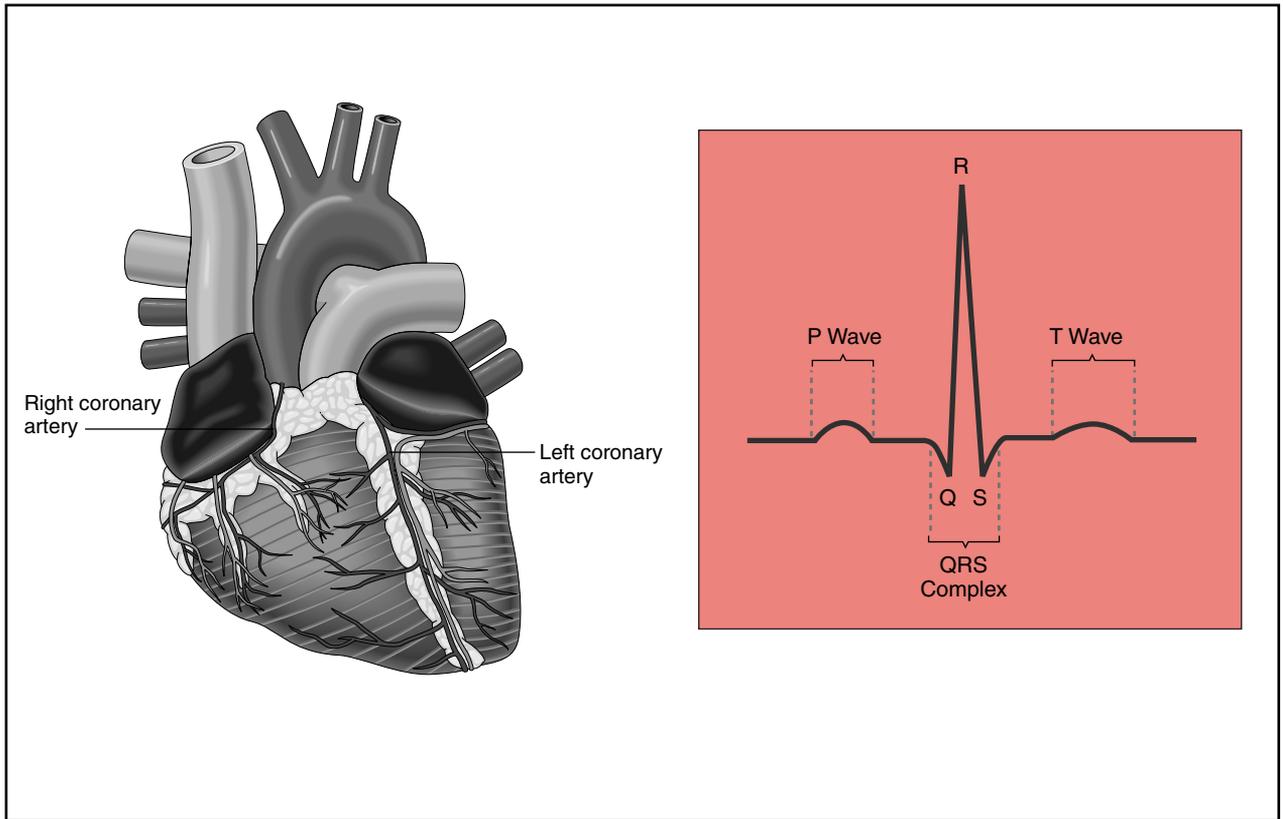

Role in human health

The role of the cardiac cycle is essential to maintain life, as the heart distributes the oxygen-carrying blood required for the functioning of the body.

Common diseases and disorders

Although diseases of the valves are common, and other cardiac disorders can also disrupt normal blood flow, they do not cause an abnormal cardiac cycle per se. Since the normal sequence of events occurs, even though it's impaired, it is considered a normal cardiac cycle (but not a normal heart beat). Most of the common abnormalities in the cardiac cycle are caused by disturbances in electrical conduction of the heart.

Disturbances in the electrical cycle are known as arrhythmias. However, two types of disturbances, sinus tachycardia and sinus bradycardia, do not affect the sequence of events, because they speed up (tachycardia)

The heartbeat is controlled by electric impulses. To the right is a schematic representation of these impulses. (Delmar Publishers, Inc. Reproduced by permission.)

or slow down (bradycardia) the beating of the heart. The other arrhythmias have one of two origins. They can be caused by a lack of normal electrical conduction. For example, a lack of electrical signaling from the sinoatrial node can lead to the placement of an exogenous pacemaker (something that causes the heart to beat other than the sinoatrial node). The other cause of arrhythmias is abnormally strong ectopic (in the wrong place) electrical activity. For example, premature atrial contractions can be caused by excessive electrical activity somewhere in the atrium other than the sinoatrial node. Some arrhythmias may be a combination of the two.

Cardiac cycle disturbances can be complex, but can be dissected by an electrocardiogram (EKG or ECG). They can be caused by a wide variety of problems, including, but not limited to, coronary heart disease, damage to the heart muscle secondary to a heart attack, genetic heart defects, valvular disease of the heart, and medications. Following is a list of common arrhythmias.

Atrial arrhythmias:

- paroxysmal atrial tachycardia
- multifocal atrial tachycardia

- atrial fibrillation
- atrial flutter

Ventricular arrhythmias:

- premature ventricular contractions (PVCs)
- ventricular tachycardia
- ventricular fibrillation

Arrhythmias arising because of abnormalities in the AV node, Purkinje fibers, or bundle of His:

- nodal rhythm
- first degree block
- second degree block
- third degree block
- bundle branch block

KEY TERMS

Aorta—The largest artery of the body that originates from the left ventricle of the heart, arches over the heart to the left, and descends just in front of the spinal column. The aorta divides into three arteries: the brachiocephalic artery (that supplies blood to the brain and head), the left carotid artery, and the left subclavian artery.

Aortic valve—The heart valve that divides the left ventricle and the aorta. Blood from the left ventricle is ejected across the aortic valve into the aorta for further distribution. It opens during contraction of the left ventricle and closes afterwards to prevent the backward flow of blood from the aorta.

Arterial blood pressure—The ejection of blood into the aorta by the left ventricle results in the characteristic aortic pressure pulse. The maximum of the aortic pressure pulse is called the systolic pressure and the lowest pressure in the aorta is called the diastolic pressure.

Arterial pulse pressure—The arterial pulse pressure is the difference between the systolic and diastolic arterial pressures.

Artery—Blood vessel that carries blood away from the heart for distribution throughout the body.

Atrioventricular node (AV node)—Nodal tissue located on the right side of the partition that divides the atria, near the bottom of the right atrium. It delays impulses from the SA node, thus allowing the atria to empty themselves.

Atrioventricular valves—Heart valves located between the atria and the ventricles. They are the mitral valve and the tricuspid valve.

Diastole—The time in between ventricular contractions during which ventricular filling occurs. Also called the relaxation phase.

Diastolic pulse pressure—The pressure exerted on the walls of the arteries during diastole. A normal value ranges around 90 mmHg.

Heart—In humans, the heart is divided into four chambers: the right atrium and ventricle and the left atrium and ventricle. Blood flows from the veins into the right atrium, then to the right ventricle and into the lungs for oxygenation, from where it is returned to the left atrium, then to the left ventricle for distribution to the body via arteries.

Mitral valve—The heart valve that divides the left atrium and the left ventricles. It opens during con-

traction of the left atrium to allow blood flow into the left ventricle and closes to prevent the backward flow of blood to the left atrium.

Oxygenation—The process of adding oxygen to something. Oxygen is added to the blood in the lungs. Oxygen contained in the inhaled air is delivered to the blood, where the oxygen binds to a protein called hemoglobin (which functions as an oxygen-carrier).

Pulmonary artery—Short blood vessel that carries deoxygenated blood from the heart to the lungs.

Pulmonary vein—One of four blood vessels that carry oxygenated blood from the lungs to the heart.

Pulmonary valve—The heart valve that divides the right ventricle from the pulmonary artery.

Semilunar valves—Heart valves shaped like a half-moon that located between the aorta and the left ventricle and between the pulmonary artery and the right ventricle. They are the aortic valve and the pulmonary valve.

Sinoatrial node (SA node)—Also called the pacemaker of the heart. It consists of nodal tissue located in the upper wall of the right atrium. It controls the rate of contraction of the heart by generating nerve impulses that travel throughout the heart wall causing both atria to contract.

Systole—The time during which ventricular contraction occurs.

Systolic pulse pressure—The pressure exerted on the walls of the arteries during the contraction of the heart. A normal value ranges around 150 mmHg.

Tricuspid valve—The heart valve, named for its three cusps, that divides the right atrium from the right ventricle. Blood flows from the right atrium, across the tricuspid valve, and into the right ventricle. When closed, it prevents the blood from flowing back into the right atrium.

Vein—Blood vessel that returns blood to the heart from the body. All the veins from the body converge into two major veins that lead to the right atrium of the heart. These veins are the superior vena cava and the inferior vena cava. The pulmonary vein carries the blood from the right ventricle of the heart into the lungs.

Cardiac marker tests

Definition

Cardiac marker tests identify **blood** analytes associated with **myocardial infarction** (MI), commonly known as a **heart** attack.

Purpose

Cardiac markers help physicians to assess acute coronary syndromes and to identify and manage high-risk patients. Creatine kinase-MB (CK-MB), myoglobin, homocysteine, C-reactive protein (CRP), troponin T (cTnT), and troponin I (cTnI) are all used for assessment of the suspected acute myocardial infarction. CK-MB, cTnT, and cTnI may also be used to identify and manage high-risk patients.

Precautions

C-reactive protein results may be affected by the use of oral contraceptives, NSAIDs, steroids, salicylates, intrauterine devices (IUDs), and overnight sample refrigeration. Homocysteine levels may be affected by smoking, diabetes, and coffee.

Description

Creatine kinase (CK)

Creatine kinase is an enzyme responsible for transferring a phosphate group from ATP to creatine. It is composed of M and/or B subunits that form CK-MM, CK-MB, and CK-BB isoenzymes. Total CK (the activity of the MM, MB, and BB isoenzymes) is not myocardial-specific. However, the MB isoenzyme (also called CK-2) comprises about 40% of the CK activity in cardiac muscle and 2% or less of the activity in most muscle groups and other tissues. In the proper clinical setting, MB is both a sensitive and specific marker for myocardial infarction. MB usually becomes abnormal three to four hours after an MI, peaks in 10 to 24 hours, and returns to normal within 72 hours. However, an elevated serum MB may occur in people with severe skeletal muscle damage (such as in **muscular dystrophy** or a crush injury) and renal failure. In such cases, the CK index (MB divided by total CK) is very helpful. If the index is under 4%, a nonmyocardial cause of a high MB should be suspected. C-MB is considered the benchmark for cardiac markers of myocardial injury. Measurement of CK-MB may be performed via electrophoresis or immunoassays; the latter demonstrates better analytical sensitivity and better precision.

CK-MB isoforms can be used to determine whether thrombolytic therapy (such as treatment with tissue plasminogen activator to dissolve a blood clot in the coronary artery) has succeeded. MB isoforms are different molecular forms of MB found in the circulation. When MB is released into the blood, the terminal lysine of the M subunit is removed by an enzyme in the plasma. This results in a molecule with faster electrophoretic mobility, called CK-2₁. This is the prevalent form of MB in the blood. The slower form, designated CK-2₂, is the unmodified cardiac form of MB. After successful thrombolytic therapy, the unmodified form of MB is rapidly flushed into the blood, causing it to become the dominant isoform.

Myoglobin

Myoglobin is a protein found in both skeletal and myocardial muscle. It is released rapidly after tissue injury and may be elevated as early as one hour after myocardial injury, though it may also be elevated due to skeletal muscle trauma. However, if myoglobin values do not rise within three to four hours after a person shows acute symptoms, it is highly unlikely that he or she had an MI. There are several measurement methods available, including fluorometric, nephelometric, and turbidimetric assays; plus immunochromatography-based tests designed for qualitative, point-of-care testing.

Troponin T and troponin I

Troponin C, I, and T are **proteins** that form the thin filaments of muscle fibers and regulate the movement of contractile proteins in muscle tissue. Skeletal and cardiac forms are structurally distinct, and antibodies can be produced that react only with the cardiac forms of troponin I and troponin T.

Cardiac troponin T (cTnT) and cardiac troponin I (cTnI) are the newest additions to the list of cardiac markers. Troponins are specific to heart muscle. They have enabled the development of assays that can detect heart muscle injury with great sensitivity and specificity. While these markers have been used mainly to aid in the diagnosis of chest-pain patients with nondiagnostic electrocardiograms, they are also used as prognostic indicators of a MI. According to the American Heart Association, "Several studies have identified a measurable relationship between cardiac troponin levels and long-term outcome after an episode of chest discomfort. They suggest that these tests may be particularly useful to evaluate levels of risk. In other words, it's possible that the results of a troponin test could be used to identify people at either low risk or high risk for later, serious heart problems."

Several commercially available quantitative immunoassays are available for the measurement of cTnI and cTnT. There is also a qualitative cTnI test, targeted at bedside testing.

C-reactive protein (CRP)

CRP is a protein found in serum or plasma at elevated levels during a inflammatory processes. The protein can be measured via a variety of methods, including EIA or ELISA, for the quantitative or semiquantitative determination of C-reactive protein in human serum, particle agglutination tests that provide semiquantitative results, and laser and rate nephelometry tests that measure antigen-antibody complexes by light dispersion.

CRP binds to the C polysaccharide of the capsule of *Streptococcus pneumoniae*. It is a sensitive marker of acute and chronic inflammation and **infection**, and in such cases is increased several hundred-fold. Several recent studies have demonstrated that CRP levels are useful in predicting the risk for a thrombotic event. These studies suggest that a high-sensitivity assay for CRP be used that is capable of measuring the very low level normally found in serum (0.1 to 2.5 mg/L). Heart patients who have persistent CRP levels between 4 and 10 mg/L, with clinical evidence of low-grade inflammation, should be considered to be at increased risk for thrombosis. People can be stratified into four groups of increased risk based upon the quartile in which their CRP levels fall.

Homocysteine

Homocysteine is an amino acid. According to the American Heart Association, studies have shown that too much homocysteine in the blood is related to a higher risk of coronary heart disease, stroke, and peripheral vascular disease; and that it may also have an effect on atherosclerosis. High levels of homocysteine are the result of inheritance or dietary excess and have been implicated in vascular-wall injury. One immunoassay is available for it. It is believed that laboratory testing for plasma homocysteine levels can improve the assessment of risk, particularly in patients with a personal or family history of cardiovascular disease, but in whom the well-established risk factors (smoking, high blood cholesterol, high **blood pressure**, physical inactivity, **obesity**, and diabetes) do not exist. Homocysteine levels are obtained via high-performance chromatography with electrochemical detection.

Preparation

These assays require a sample of blood, which is typically obtained via a standard venipuncture procedure. Homocysteine tests require the patient to fast. Homocysteine is stable only in separated refrigerated or frozen plasma for 48 hours.

Aftercare

Discomfort or bruising may occur at the puncture site, or the person may feel dizzy or faint. Applying pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Complications

There are no complications associated with these tests.

Results

Normal results vary, based on the laboratory and method used. Unless otherwise specified, the following information is from the American College of Cardiology and the American Heart Association.

- Total CK: Reference value is 38 to 174 units/L for men and 96 to 140 units/L for women. The values begin to rise within four to six hours and peak at 24 hours. Values return to normal within three to four days.
- CK-MB: Reference value is 10 to 13 units/L. The values begin to rise within three to four hours and peak at 10 to 24 hours. Values return to normal within two to four days.

KEY TERMS

Cardiac marker—A substance in the blood that rises following a myocardial infarction.

Diagnostic window—A cardiac marker's timeline for rising, peaking, and returning to normal after a heart attack.

Myocardial infarction (MI)—Commonly known as a heart attack, a myocardial infarction is an episode in which some of the heart's blood supply is severely cut off or restricted, causing the heart muscle to suffer and die from lack of oxygen.

Myoglobin—A protein that holds oxygen in heart and skeletal muscle. It rises after damage to either of these muscle types.

- Troponin T: Reference value is less than 0.1 ng/mL. The values begin to rise within two to four hours and peak at 10 to 24 hours. Values return to normal within five to 14 days.
- Troponin I: Reference value is less than 1.5 ng/mL. The values begin to rise within two to four hours and peak at 10 to 24 hours. Values return to normal within five to 10 days.
- CK-MB isoforms: Reference value is a ratio of 1.5 or greater. The values begin to rise within two to four hours and peak at six to 12 hours. Values return to normal within 12 to 24 hours.
- Myoglobin: Reference value is less than 110 ng/mL. The values begin to rise within one to two hours and peak at four to eight hours. Values return to normal within 12 to 24 hours.
- Homocysteine: The normal fasting level for plasma is five to 15 micromol/L. Moderate, intermediate, and severe hyperhomocysteinemia refer to concentrations between 16 and 30, between 31 and 100, and less than 100 micromol/L, respectively.
- C-reactive protein: According to the U.S. Food and Drug Administration, in healthy people, reference values are below 5 mg/dL; in various diseases, this threshold is often exceeded within four to eight hours after an acute inflammatory event, with CRP values reaching approximately 20 to 500 mg/dL.

Health care team roles

Cardiac marker tests are usually performed by clinical laboratory scientists, medical technologists, or clinical laboratory technicians.

Cardiac monitor

Definition

The cardiac monitor is a device that shows the heart's electrical activity as a wave pattern on a monitor. It is a bedside monitor.

Purpose

The cardiac monitor continuously shows the cardiac rhythm and sends the electrocardiogram (EKG) tracing to a main monitor in the nursing station. Most commonly used in emergency rooms and critical care areas, cardiac monitoring allows for continual observation of several patients. Aside from monitoring cardiac patients, continuous monitoring is useful for observation of postoperative patients, patients with severe electrolyte imbalances, and other unstable patients. Continuous cardiac monitoring allows for prompt identification and initiation of treatment for cardiac arrhythmias and other conditions.

Precautions

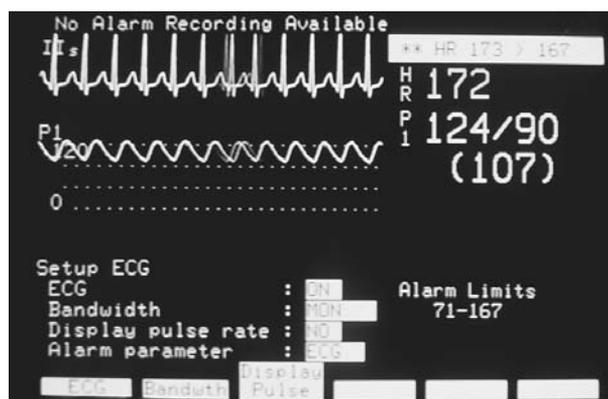

The American Heart Association warns of potential interference between some **pacemakers** and cardiac monitors. Minute ventilation rate-adaptive pacemakers can occasionally interact with certain cardiac monitoring and diagnostic equipment, causing the pacemakers to pace at their maximum-programmed rate. Minute ventilation is sensed in rate-adaptive pacemakers by technology known as bioelectric impedance measurement (BIM). Many medical devices in addition to pacemakers use this technology. When one of these devices is used on a patient with an active, minute ventilation rate-adaptive pacemaker, the pacemaker can erroneously interpret the mixture of BIM signals created in the patient, resulting in an elevated pacing rate. Cardiac monitors, echocardiograph equipment, apnea monitors, respiration monitors, and external defibrillators are common devices that may use BIM technology.

Description

The monitor provides a visual display of the patient's heart rhythm, which is particularly useful information during heart attacks, when patients can develop lethal cardiac arrhythmias. The monitor sounds an alarm if the patient's heart rate goes above or below a predetermined number. An automatic **blood pressure** cuff and a **pulse oximeter**, which measures the oxygen saturation in the **blood**, are also included with some monitors.

Equipment required for continuous cardiac monitoring includes:

- cardiac monitor
- monitor cable
- leadwires
- electrodes
- dry washcloth or gauze pad
- alcohol sponges

Cardiac monitors display vital information for patients in the intensive care unit. (Photograph by Hank Morgan. Science Source/Photo Researchers. Reproduced by permission.)

Preparation

All electrical equipment and outlets are grounded to avoid electrical shock and artifact (electrical activity caused by interference). The nurse should plug in the monitor, turn on power, and connect the cable if not already attached. He or she should connect the lead wires to the proper position and ensure that color-coded wires match the color-coded cable. If the device is not color coded, the right arm (RA) wire should be attached to the RA outlet, the left arm (LA) wire attached to the LA outlet, and so forth. The nurse should open the electrode package, and attach an electrode to each lead wire. The hands should be washed and the procedure should be explained to the patient. Privacy should be ensured for the patient, and the patient should be clean and dry to prevent electrical shock.

Next, the chest should be exposed and the sites selected for electrode placement. Using the rough patch on the electrode, a dry washcloth, or gauze pad, each site should be rubbed briskly until it reddens, but care should be taken not to damage or break the skin. Dead skin cells are removed in this manner, thereby promoting better electrical conduction. Patients who are extremely hairy may need to be shaved prior to application of the electrodes. An alcohol pad is used to clean the sites in patients with oily skin. Areas should dry completely to promote good adhesion. Alcohol should not become trapped beneath the electrode, as this can lead to skin breakdown. In addition to oily skin, diaphoretic skin can cause interference in the recording. To minimize this interference, the electrode site should be rubbed with a dry 4x4 gauze pad before application. The backing of the electrode should be removed, and the gel inspected. If the electrode

KEY TERMS

Amyloidosis—A metabolic disorder, characterized by starch-like formation in tissue structures.

Artifact—Extra electrical activity typically caused by interference.

Cardiomyopathies—Diseases of the heart muscle. Usually refers to a disease of obscure etiology.

Electrodes—Adhesive pads which are placed on the skin and attached to the leads.

Lead—Color coded wires that connect the electrode to the monitor cable.

QRST complex—The combined waves of an electrocardiogram for monitoring the heart.

has dried out, which can happen if the electrode package is opened before immediate use, it should be discarded and another used. The nurse should apply one electrode to each site, press one side of the electrode against the skin, and pull gently. Then, the opposite side of the electrode should be pressed against the skin. The nurse should press two fingers on the electrode in a circular pattern to affix the gel and stabilize the electrode, then repeat for each electrode. *To avoid potential artifact, do not place the electrodes on bony prominences or hairy areas.*

Aftercare

After placing all electrodes, the nurse should observe the monitor and evaluate the quality of the tracing, making size and tracing position adjustments as needed. He or she should confirm that the monitor is detecting each heartbeat by taking an apical pulse and comparing the pulse to the digital display. The upper and lower alarm limits should be set according to institutional policy, and the alarm activated. A rhythm strip should be recorded for the medical record, and labeled with patient name, room number, date, time, and interpretation of the strip.

Complications

There is a potential for skin breakdown at the electrode placement site. The patient may be allergic to the adhesive used, or the electrode may have been left on the skin too long. The electrodes should be removed and new electrodes applied, using hypoallergenic electrodes if necessary.

Results

A normal cardiac tracing shows a regular rate and rhythm with no deviations in the QRST complex (the combined waves of an electrocardiogram). Abnormal results may include bradycardia, or tachycardia, accompanied by the alarm. Q waves (the short initial downward stroke of the QRST complex) are abnormal, and may or may not signal an infarction.

Some causes of noninfarction Q waves are:

- ventricular hypertrophy
- ventricular preexcitation (Wolf-Parkinson-White syndrome)
- cardiomyopathies
- pulmonary embolism
- incomplete left bundle branch block

Causes of changes in ST Segment (part of the EKG between the QRS complex and the T wave) and T Wave (deflection in an EKG that represents electrical activity of the ventricular repolarization) include:

- aberrant conduction
- amyloidosis
- bundle branch block
- cardiomyopathy
- cocaine vasospasm
- electrolyte disturbances
- intracranial hemorrhage
- myocardial metastases
- myocarditis
- paced rhythm
- pancreatitis or acute abdomen
- pericarditis
- physical training
- Prinzmetal's angina
- pulmonary embolism
- tachycardia
- ventricular aneurysm
- ventricular hypertrophy
- ventricular rhythms
- Wolff-Parkinson-White syndrome

Alarm signals are abnormal and must be investigated. A false high alarm rate may be caused by skeletal muscle activity or by the monitor incorrectly interpreting large T waves as a QRS complex, which would double the true heart rate. The electrodes should be repositioned

as needed to ensure that the electrode is not over a major muscle mass and that QRS complex is larger than the T wave. A false low alarm rate may be due to patient movement, or poor contact between electrodes and skin. Electrodes should be reapplied as needed. Artifact is a common abnormal finding, and may be caused by improperly placed electrodes, patient movement, static electricity, seizures, **anxiety**, or chills. The position of electrodes should be checked and static-causing bed linen changed. The cables should not have exposed connectors.

Health care team roles

Cardiac monitoring is usually ordered by a physician. A nurse practitioner or physician assistant can place the electrodes on the patient's body. A nurse provides ongoing care during the monitoring, assesses patient to determine hemodynamic effects of rhythms, and intervenes for dysrhythmias as appropriate. The nurse also instructs the patient and family about the cardiac monitor's use.

Cardiac rehabilitation

Definition

Cardiac rehabilitation is a multi-disciplinary treatment and secondary prevention program for patients with various cardiac disorders, including recovery from **heart attack** and bypass surgery, which includes **exercise**, education, counseling, and lifestyle changes to help the patient return to previous levels of health and functioning and prevent recurrence of cardiac problems.

Purpose

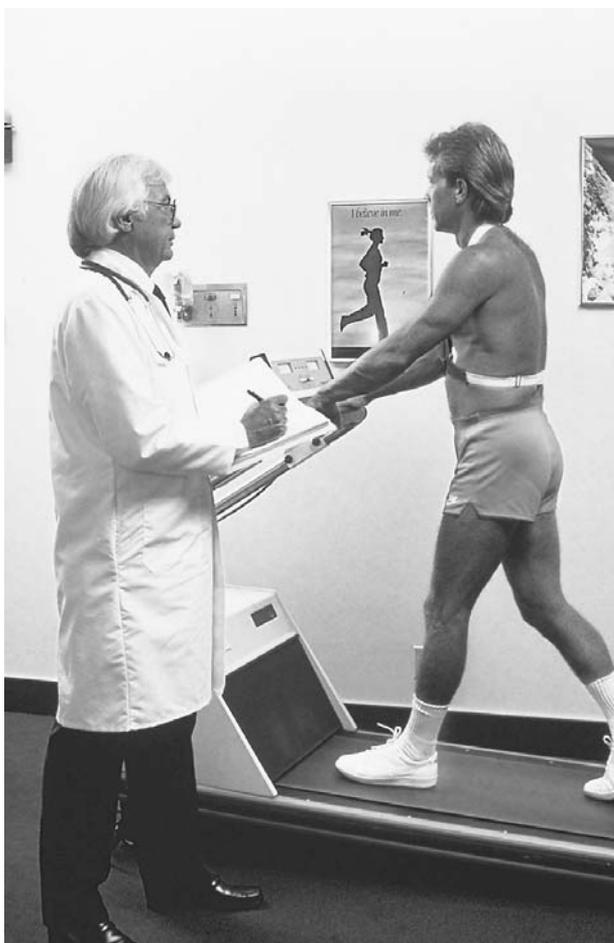

The purpose of cardiac rehabilitation is to provide comprehensive, multifaceted treatment, education, and secondary prevention for cardiac patients and individuals with heart disease risk factors, in order to aid recovery and prevent recurrence of heart problems. Cardiac rehabilitation programs can improve quality of life, help patients return to their previous level of functioning in work and daily life, increase fitness, facilitate heart-healthy behavior changes and management of risk factors, and reduce costs by decreasing frequency and expense of hospital stays.

Precautions

Exercise, or certain kinds of exercise, may be contraindicated in the presence of some medical conditions. Conditions included are acute **heart failure**, angina at rest, second or third degree heart block, excessively low or high **blood pressure**, orthopedic problems, continued ischemia, aortic stenosis or mitral valve disease, or other health conditions in addition to the cardiac disorder. Exercise might also need to be discontinued if certain problems or symptoms such as the following occur: failure of monitoring equipment, lightheadedness, confusion, nausea, angina that occurs while exercising, excessive rise in **blood pressure**, or unusual heart rate. In addition, certain precautions may be taken before any cardiac patient begins an exercise program or session. Some of these include recording heart rate, blood pressure, and cardiac rhythm at each supervised session, and educating the patient in how to prepare for the exercises (proper breathing, dressing appropriately, avoiding smoking, etc.). Any preexisting medical conditions should also be taken into consideration when planning exercise treatments.

Description

Cardiac rehabilitation is a comprehensive, multidisciplinary approach to treatment and secondary preven-

This 40-year-old male works out on a treadmill, monitored by his physician, following heart surgery. (Custom Medical Stock Photo. Reproduced by permission.)

tion for patients with various forms of cardiac disorders, such as post **myocardial infarction** (heart attack), bypass surgery, chronic stable angina pectoris, and heart transplant. It involves a cardiac rehabilitation team, which can be comprised of primary care and specialty physicians, nurses, physical therapists, exercise physiologists, occupational therapists, mental health professionals and dieticians. The physician may choose to participate in various roles, or refer patients to physical therapists and other practitioners or hospital departments.

A specially qualified physical therapist or RN may provide or direct cardiac rehabilitation services. At least one member of the **physical therapy** department or other team of practitioners in charge should be ACLS (Advanced Cardiac Life Support) certified, and a cardiopulmonary specialist should be included. The ACLS certification, which can be obtained during a one-day training course provided by the American Heart

Association, is a level higher than **CPR**, and allows the practitioner to perform intubation and use a defibrillator.

Cardiac rehabilitation can be broken into three phases. Phase I, inpatient treatment in a hospital, can begin as early as 24 hours after a cardiovascular event. Phase II, outpatient treatment, can take place at the hospital, in a community center, in a medical center, or at the patient's home or place of employment. Phase III, referred to as the secondary prevention or maintenance phase, is performed more independently by the patient, with the goal of maintaining benefits and preventing further cardiac problems. An individual patient may participate in cardiac rehabilitation for a few weeks, six months, or longer. Many programs are conducted in groups, but the exercise prescription and other facets of treatment are individually designed to meet the specific medical needs and preferences of each patient.

The main components of a cardiac rehabilitation program are exercise, education, counseling, and behavior modification. Physical therapists may play a large part in the exercise component, as well as some aspects of **patient education**. Some of the goals of exercise are to restore or improve fitness, increase exercise tolerance and functional capacity, regain levels of functioning equivalent to those prior to the disease or surgery, and improve confidence and mood. Exercise and education by a physical therapist or other qualified practitioner can also help the patient manage and improve other risk factors and associated conditions such as diabetes, **obesity**, high blood **lipids** (fats), and **stress**. Inactivity itself is now recognized as a coronary risk factor, and thus exercise is an essential part of treatment for many reasons. A physical therapist may also be especially appropriate for work with cardiac patients who also have musculoskeletal problems. For example, bypass recipients may have problems with mobility of the shoulder or other joints.

The other components of the rehabilitation program may include education about the heart condition and its risk factors, counseling for psychological aspects of heart disease, stress management, vocational or occupational counseling, and guidance in adopting healthier behaviors. Some of the lifestyle or behavioral changes encouraged include smoking cessation and a lower fat diet, and management of other controllable coronary disease risk factors such as smoking, high blood pressure, high cholesterol, obesity, stress, and a sedentary lifestyle.

Many economic and medical benefits have been associated with cardiac rehabilitation, including decreased disability and improved functional capacity, less likelihood of mortality and recurrent morbidity, and decreased medical costs. Another benefit is that the use of electrocardiograph and other forms of objective and sub-

jective assessment in ongoing supervised rehabilitation can lead to detection of problems and adjustments in the patient's treatment. Reasons for cost effectiveness of this form of treatment include reduction in disability and health care costs, fewer re-hospitalizations, and improved productivity. Despite these benefits, only about 11-38% of qualified candidates generally participate. Although many insurance companies cover all or part of a cardiac rehabilitation program, coverage is not available to all patients, and may be limited in terms of length of treatment or conditions covered.

Preparation

A cardiac rehabilitation program is usually prescribed and overseen by a physician, and generally begins in the hospital, under the direction of appropriate hospital departments, and after exercise testing and other preparatory procedures have been administered. An EKG will likely be given before the rehabilitation program begins, and then be used as an ongoing monitoring method by the physical therapist or other rehabilitation team members.

Aftercare

The patient may continue with a maintenance or secondary prevention program, and should maintain the healthy habits they have gained, including regular exercise to maintain improved fitness and associated physical and psychological benefits.

Complications

Patients are closely monitored for any exercise-related health complications, and the rehabilitation team is equipped to detect and manage possible emergencies. Cardiac rehabilitation is a safe treatment option, and serious problems are rare.

Results

Participation in a cardiac rehabilitation program can help the heart patient return to physical and emotional/social well-being and be able to function in their lives and work as near as possible to their pre-illness level of functioning. In fact, their overall quality of life and health may be improved. Patients also learn new ways of taking care of their health so that recurrence of illness or symptoms and re-hospitalization are minimized, and deterioration of existing conditions is less likely.

KEY TERMS

Electrocardiogram (EKG/ECG)—A test that records electrical activity of the heart. It may be used to detect a heart attack, because injured cardiac muscle causes abnormal conduction of electrical impulses.

Ischemia—Shortage of blood supply to a body tissue or organ (to the heart in the case of cardiac ischemia), which can cause tissue death. Cardiac ischemia can lead to heart attack or abnormal cardiac rhythms.

Myocardial infarction (MI)—The medical term for a heart attack. When cardiac ischemia, narrowing of a coronary artery or arteries, decreases blood supply to the heart muscle (myocardium), it can cause muscle tissue death (infarction).

Secondary prevention—The prevention of a recurrence of illness, such as another heart attack.

Health care team roles

After a prescription is made by the primary care physician or cardiac specialist, various health care professionals are involved in the program, including a physical therapist or exercise physiologist, nurses, an occupational therapist, dietician, and mental health professional. A nurse specializing in cardiac rehabilitation, exercise physiologist or physical therapist, or physical therapy department may manage the patient's rehabilitation program, in consultation with a physician.

Cardiogenic shock *see* **Shock**

Cardiopulmonary resuscitation (CPR)

Definition

Cardiopulmonary resuscitation (CPR) is a procedure to support and maintain breathing and circulation on a person who has stopped breathing (respiratory arrest) and/or whose **heart** has stopped (cardiac arrest).

Purpose

CPR is performed to restore and maintain breathing and circulation and to provide oxygen and **blood** flow to the heart, **brain**, and other vital organs. It should be performed if a person is unconscious and not breathing. Respiratory and cardiac arrest can be caused by allergic reactions, an ineffective heartbeat, a heart attack, asphyxiation, breathing passages that are blocked, choking, drowning, drug reactions or overdoses, electric shock, exposure to cold, severe shock, or trauma. CPR can be performed on infants, children, and adults by trained bystanders or healthcare professionals. It should always be performed by the person on the scene who is most experienced in CPR.

Precautions

CPR should never be performed on a healthy person, since it can cause serious injury to a beating heart.

Description

CPR is part of the emergency cardiac care system designed to save lives. Many deaths can be prevented by prompt recognition of the medical situation and notification of the emergency medical system (EMS). This should be followed by early CPR, defibrillation (which delivers a brief electric shock to the heart in an attempt to

get the heart to beat normally), and advanced cardiac life support measures.

CPR must be performed within four to six minutes of the time that breathing stopped in order to prevent brain damage or death. It is a two-part procedure that involves rescue breathing and external chest compressions. To provide oxygen to the person's **lungs**, the rescuer administers mouth-to-mouth breaths, then helps circulate the blood through the heart to vital organs by external chest compressions. Mouth-to-mouth breathing and external chest compression should be performed together, but if the rescuer isn't strong enough to do both, the external chest compressions should be done alone. Some bystanders are reluctant to initiate CPR because of the possible transmission of infectious disease during mouth-to-mouth breathing or their inexperience with CPR. External chest compressions alone have been found to have similar results when compared to mouth-to-mouth breathing and external chest compressions combined. External chest compressions, as well as CPR that is performed inexpertly, are more effective than no resuscitation attempt.

When performed by a bystander, CPR is designed to support and maintain breathing and circulation until emergency medical personnel arrive and take over. When performed by healthcare personnel, it is used in conjunction with other basic and advanced life support measures.

According to the American Heart Association, early CPR and defibrillation combined with early advanced emergency care can increase survival rates for people with a type of abnormal heart beat called ventricular fibrillation by as much as 40%. CPR by bystanders may prolong life during deadly ventricular fibrillation, giving emergency medical service personnel time to arrive.

It must be appreciated, however, that most CPR attempts are not ultimately successful in restoring the victim to a good quality of life. Often, there is brain damage even if the heart starts beating again. CPR is therefore not generally recommended for the chronically or terminally ill or frail elderly. For these people, it is traumatic and not a peaceful end of life.

CPR has been practiced for more than 40 years. Each year, it helps save thousands of lives in the United States. More than five million Americans receive training in CPR through the American Heart Association and the American Red Cross courses annually. In addition to courses taught by instructors, the American Heart Association also has an interactive video called *Learning System*, which is available at more than 500 healthcare institutions. Both organizations teach CPR the same way, but use different terms. They recommend that family members or other people who live with patients at risk of

CPR in basic life support. Figure A: The victim should be flat on his back and his mouth should be checked for debris. Figure B: If the victim is unconscious, open airway, lift neck, and tilt head back. Figure C: If victim is not breathing, begin artificial breathing with four quick full breaths. Figure D: Check for carotid pulse. Figure E: If pulse is absent, begin artificial circulation by depressing sternum. Figure F: Mouth-to-mouth resuscitation of an infant. (Illustration by Electronic Illustrators Group.)

respiratory or cardiac arrest be trained in CPR. A handheld device called CPR Prompt is available to walk people trained in CPR through the procedure, using American Heart Association guidelines.

In 2000, focus groups from the American Heart Association and the American Red Cross joined forces with international councils in order to create a consistent, single description of resuscitation guidelines. These guidelines have been released and many changes in CPR have been instituted. These changes replace the recommendations from their publications in 1992.

Performing CPR

The basic procedure for CPR is the same for adults, infants, and children, with a few modifications for infants and children to account for their smaller size.

PERFORMING CPR ON AN ADULT. In most cases, the first step is to call the emergency medical system for help by telephoning 911. There are exceptions to calling for help first. The new concept of “phone fast” is being recommended for trauma victims, water submersion victims, and medication/drug overdoses. CPR should be started immediately on these types of victims because the rate of survival increases with early rescue efforts. To start CPR, use the following steps:

- The rescuer opens the person’s airway by placing the head face up, with the forehead tilted back and the chin lifted. The rescuer checks again for breathing (three to five seconds), then begins rescue breathing (mouth-to-mouth artificial respiration). He pinches the person’s nostrils shut while holding the chin in the other hand. The rescuer places his mouth against the person’s mouth with the lips making a tight seal, then gently exhales for about one to one and a half seconds. The rescuer breaks away for an instant and then repeats. The person’s head is repositioned after each mouth-to-mouth breath.
- After two breaths, the rescuer checks for indications of blood circulation (regular respiratory inhalations, vomiting, or any attempt to move). If the rescuer is a health care professional, the person’s pulse is checked by moving the hand that was under the person’s chin to the artery in the neck (carotid artery). If the person shows no signs of circulating blood, the rescuer continues rescue breathing until help arrives or the person begins breathing spontaneously. If the person is breathing, the rescuer turns the person onto his or her side.
- If there is no heartbeat, the rescuer performs chest compressions. The rescuer kneels next to the person, placing the heel of one hand in the spot on the lower chest where the two halves of the rib cage come together. The

rescuer puts his other hand on top of the one on the chest and interlocks the fingers. He straightens his arms, leans forward to position the shoulders directly above the hands on the person’s chest, and presses down, using only the palms, so that the person’s breastbone sinks in about 1½-2 in (4-5 cm). The rescuer releases without removing the hands, then repeats about 15 times in 10-15 seconds.

- The rescuer tilts the person’s head and returns to rescue breathing for one or two quick breaths. Then he alternates breathing and heart presses for one minute, and checks for any signs of blood circulation. If the rescuer finds signs of a heartbeat and breathing, CPR is stopped. If the person is breathing but has no pulse the heart presses are continued; if the person has a pulse but is not breathing, rescue breathing is continued. The number of heart presses has recently increased to 15 heart presses to two breaths for single or double rescuer CPR. The recommended number of heart presses is at least 100 a minute. The rationale for this increase relates to establishing adequate heart and brain circulation.
- For children over the age of eight, the rescuer performs CPR the same as on an adult.

PERFORMING CPR ON AN INFANT OR CHILD UNDER THE AGE OF EIGHT. The procedures outlined above are followed with these differences:

- The rescuer administers CPR for one minute, then calls for help.
- The rescuer makes a seal around the infant/child’s mouth (and nose with infants) to give gentle breaths. The rescuer delivers 20 rescue breaths per minute, taking 1½-2 seconds for each breath.
- Chest compressions are given with only one hand for a child and with two or three fingers for an infant. The breastbone is depressed only 1-1½ in (2.5-3.75 cm) for a child and ½-1 in (1-2.5 cm) for an infant, the rescuer gives at least 100 chest compressions per minute.

New developments in CPR

The use of the automated external defibrillator (AED) has saved many lives and is now considered part of the CPR chain of survival. The AED is a machine that is attached to the unresponsive victim, analyzes the heart rhythm and has the ability to shock the victim with electricity. The AED has two pads that have to be placed on the victim’s right upper chest wall and the left lower chest wall. Most cardiac arrest victims have a heart rhythm called ventricular fibrillation and the only way to correct this deadly heartbeat is with electricity. Some airports, airplanes, and shopping malls have automated external

defibrillators onsite with user-friendly instructions, and survival rates in these places have increased significantly.

Preparation

If a person suddenly becomes unconscious, the rescuer should call out for help from other bystanders, and then determine if the person is responsive by shaking him or her gently on the shoulder and asking, loudly, if they are OK. Upon receiving no answer, the rescuer should call the emergency medical system with the exception of the “phone fast” victims. The rescuer should check to see whether the person is breathing by kneeling near the person’s shoulders, looking at the person’s chest, and placing his cheek next to the person’s mouth. The rescuer should look for signs of breathing in the chest and abdomen, and listen and feel for signs of breathing through the person’s lips. If no signs of breathing are present after three to five seconds, CPR should be started.

Aftercare

Emergency medical care is always necessary after successful CPR. Once the person’s breathing and heart-beat have been restored, the rescuer should make him or her comfortable and stay there until emergency medical personnel arrive. The rescuer can continue to reassure the person that help is coming and talk positively until the professionals arrive and take over.

Complications

CPR can cause injury to the person’s ribs, **liver**, lungs, and heart. But these risks must be accepted if CPR is necessary to save the person’s life. As health care professionals, many complications will be apparent in the acute care setting. Medical and nursing management of these complications will be addressed by prioritizing the most traumatic or deadly first.

Health care team roles

CPR and basic life support are important skills to have for anyone in the health care field. Recognition of the need to initiate CPR and the activation of proper resuscitation can save many lives. The international, universal mnemonic used to prompt health care professionals with the basics of CPR quickly is ABCD. This mnemonic stands for:

- Airway: Is the person’s airway open?
- Breathing: Is the person breathing?

Emergency team treating heart attack patient. (Custom Medical Stock Photo. Reproduced by permission.)

- Circulation: Does the person have a pulse (health care professional)? Does the person have any signs of blood circulation (layperson)?
- Defibrillation: Where is the defibrillator (AED)?

Legally, health care professionals coming to a person’s aid in an emergency situation are covered under the federal Good Samaritan Law. Protection under this law requires that the situation be an emergency, that no monetary compensation for the treatment provided, and that the care provided has to be done “in good faith.” In most states, health care professionals have no mandatory obligation to help in an emergency situation, but this law is in place to protect those who do from liability.

Patient education

All health care professionals should emphasize the importance of laypeople in their communities being trained in CPR. Classes are offered through the American Heart Association and the American Red Cross. Many

KEY TERMS

Automated external defibrillator (AED)—A device that analyzes a person's heartbeat and can automatically deliver an electric shock if needed.

Cardiopulmonary—Relating to the heart and the lungs.

Defibrillation—A procedure to stop the type of irregular heart beat called ventricular fibrillation, usually by using electric shock.

Resuscitation—Bringing a person back to life after an apparent death.

Ventricular fibrillation—An irregular heartbeat where the heart beats very fast but ineffectively. Ventricular fibrillation is fatal if not quickly corrected.

hospitals and local health departments have classes available for the public.

Training

CPR training is recommended every two years, and most health care institutions require their workers to obtain certification in Basic Cardiac Life Support (BCLS), which covers CPR. Studies have been done on the differences between video aided/practice training and lecture training. Video and practice training has been found to be the most effective.

Cardiovascular system

Definition

The cardiovascular system includes the **heart** and the **blood vessels** and is responsible for the transport of **blood** throughout the body.

Description

The main components of the cardiovascular system are the heart, arteries, arterioles, capillaries, venules, and veins. Adults have approximately 60,000 miles (96,000 km) of blood vessels. By moving blood throughout this network of vessels, the cardiovascular system supplies all cells of the body with oxygen and nutrients and removes carbon dioxide and other waste products.

The heart

The heart is the focal point of the cardiovascular system. It supplies the driving force for the movement of blood. The heart functions as a pump, actively forcing blood out of its chambers and passively relaxing to allow the next quantity of blood to enter. On refilling, the blood does not get actively sucked into the heart, but moves into the chambers due to the underlying pressure of the cardiovascular system as a whole.

The heart is cone-shaped, pointing down and to the left, and is located left of center of the chest between the **lungs**. The organ is made of three types of tissue: the myocardium (middle layer), the epicardium (outer layer), and the endocardium (thin inner layer). A fluid-filled sac called the pericardium surrounds the heart, helping to reduce friction during contraction. When the myocardium applies force on the blood by contracting, the cells of the tissue become short and thick. The contraction phase of the myocardium is called systole. This is followed by relaxation of the cells, where they become thinner and longer. The relaxation phase is called diastole.

The heart functions as a double pump, with both the right and left heart having a structure to receive blood and a structure to pump the blood. The blood-receiving structures are called the atria and the blood-pumping structures are called the ventricles. During a heartbeat, the two atria contract together, moving the blood from the atria to the ventricles. Then, while the two atria relax and refill, the two ventricles contract, moving the blood out of the heart. This system means that blood leaves the heart in pulsed waves.

The right atrium and ventricle pump blood from the heart to the lungs using a subset of the blood vessels called the pulmonary circulation system. The blood trav-

els to the lungs where it gives off waste carbon dioxide and receives oxygen, then returns to the left side of the heart to be pumped to the rest of the tissues and organs of the body. The blood vessels that carry blood to the body are called the systemic circulation system. In a healthy heart, blood does not pass directly between the left and right sides of the heart. The two atria are separated by a wall known as the atrial septum, and the wall separating the two ventricles is known as the ventricular septum.

Valves within the heart ensure that the blood travels in the right direction. On the right side of the heart, the tricuspid valve allows blood to travel only from the right atrium to the right ventricle. The mitral valve performs the same function on the left side of the heart. As the blood leaves the right ventricle to go to the lungs, the pulmonary valve controls the direction of the blood flow, while the aortic valve functions between the right ventricle and the aorta, the largest artery.

During diastole, when the ventricles relax, the mitral and tricuspid valves open, allowing blood to flow into the ventricles. At the same time, the aortic and pulmonary valves are closed to prevent reentry of the blood that had been pumped from the heart. During systole, when the ventricles contract, the mitral and tricuspid valves close to prevent backflow, and the aortic and pulmonary valves open to allow the blood to leave the heart. There are no valves at the atrial inputs, part of what ensures consistent blood inflow into the ventricles.

The heart works on an electrical conduction system, as the cells contract in response to electrical signals. All cells of the heart can contract spontaneously, with the beginning of the heartbeat dependent on the cells with the most rapid innate rate. These cells are located in the sinoatrial (SA) node of the heart, sometimes called the heart's natural pacemaker. The electrical signal moves from the SA node to the atrium, in a cluster of conducting cells called the atrio-ventricular (AV) node. The slowing of the signal at this point allows the atria to contract slightly before the ventricles, giving the ventricles more time to fill before they contract. The signal passes on to the electrical network of the ventricles, called the His-Purkinje system, which causes the ventricles to contract. The electrical workings of the heart can be visualized using an **electrocardiography unit**.

Overall, heart rate is controlled by signals from the autonomous nervous system to the SA node. The **autonomic nervous system** automatically controls the heart rate as well as many other functions of the body including breathing, **blood pressure**, and excretion. The system is extremely flexible and can double the heart rate in as fast as three to five seconds.

The arteries and arterioles

Blood leaving the heart from either the left or right ventricle enter a network of vessels called the arteries. Arteries are highly elastic vessels, having flexible fibers in their structure and a relatively thick layer of smooth muscle. Larger arteries have three layers—the inner (intima), the middle (media), and the outer (adventitia). Blood flows through the central opening, known as the lumen, which is lined with endothelial cells. The layers of the blood vessels interact to exert major control over blood pressure and where the blood flows. The adventitia contains the nervous control and blood vessels for the arteries, the media contains smooth muscles, and the endothelial layer of the intima is important for sensing environmental changes.

The aorta, the largest artery, branches directly off the left ventricle, and is especially elastic because of the addition of cardiac muscle cells in the area where it branches off the heart. The elastic qualities of arteries are important so that they can expand to receive the blood volume under high pressure, and contract to continue forcing the blood into the rest of the circulatory system. The elasticity of the arteries is a significant component of the blood pressure during diastole, when the ventricles of the heart relax.

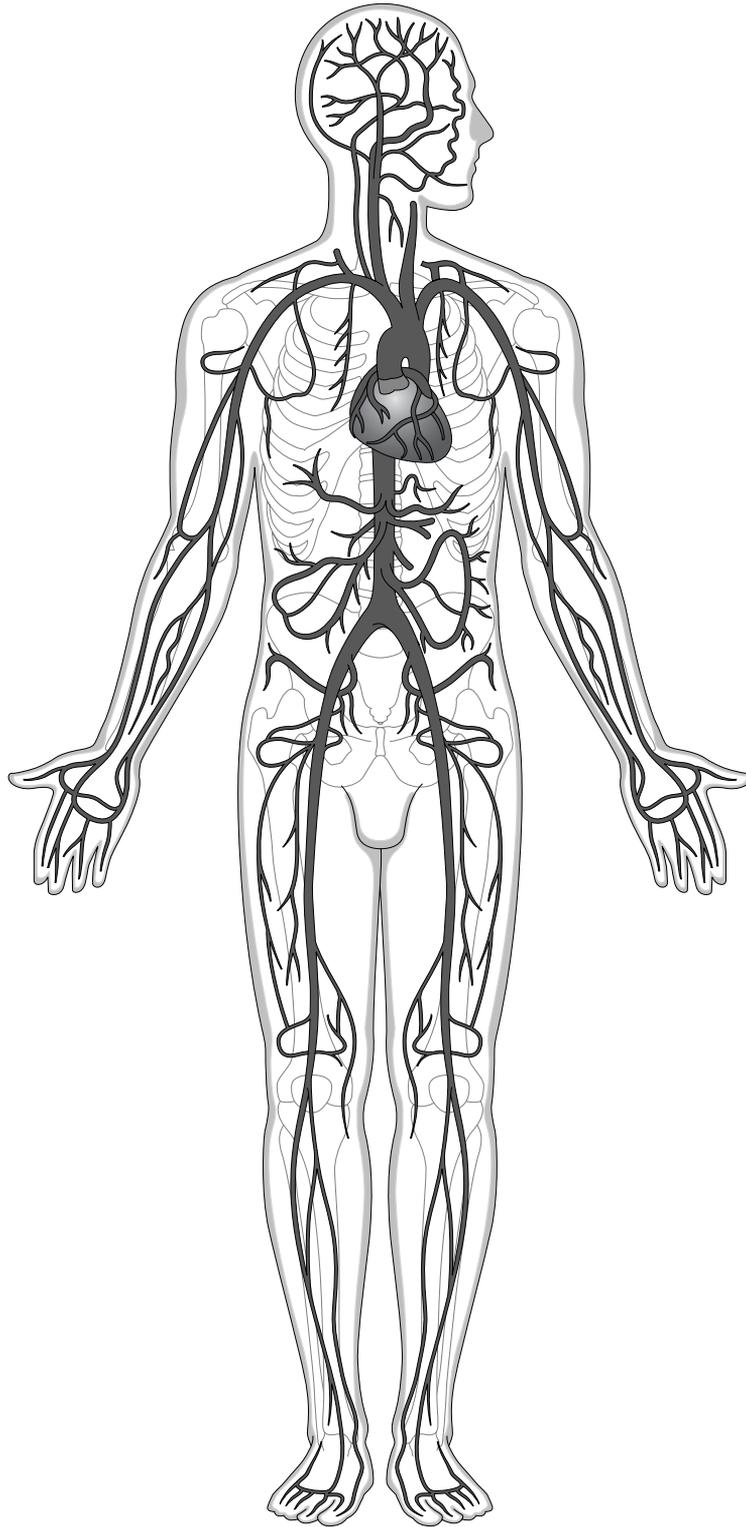

From the left ventricle the coronary arteries, which supply blood to the heart itself, emerge from the aorta. Then the aorta makes a large U-turn in the chest, eventually becoming the abdominal artery. Major branches to the head (carotid arteries), arms (axillary arteries), and legs (femoral arteries) come off this one vessel. The flow of blood in the arteries is pulsile, increasing and decreasing with each heartbeat, about 70 times per minute. The flow of blood in the branch arteries accounts for the pulse that can be felt in the wrists and neck.

The other major artery, the pulmonary artery, carries blood from the right ventricle to the lungs. Although the systemic arteries carry oxygenated blood, the arteries of the pulmonary system carry deoxygenated blood to the lungs. A vessel is called an artery because it carries blood away from the heart, not because the blood it carries contains oxygen.

As arteries move away from the heart, they branch into smaller vessels called arterioles. Arterioles are structurally similar to arteries and play an important role in directing blood to the parts of the body needing it most, such as muscles under stress.

The veins and the venules

The major veins of the body are collectively called the *venae cavae*. The superior vena cava takes in blood

The heart and major veins and arteries of the cardiovascular system. (Courtesy of Gale Group.)

from the arms through the axillary veins, from the head through the jugular veins, and from the heart through the coronary veins. The inferior vena cava collects the blood from the legs from the femoral veins and from the abdomen from the hepatic, portal, and renal veins, among others. Both the superior and inferior venae cavae empty into the right atrium.

The pulmonary vein brings blood oxygenated in the lungs back to the left atrium, so it can be pumped to cells throughout the body. As with arteries, veins are not so named because the vessel carries deoxygenated blood, but by their role in bringing blood back to the heart.

Veins have the same three structural layers as arteries but the layers contain less elastic tissue and muscle components, making the walls thinner and six to ten times more expandable. The blood pressure in veins is lower than in the arteries, so to keep the blood flowing to the heart there are one-way valves that prevent backflow. Additionally, the action of the muscles in the legs help to return the blood to the heart, a mechanism called the venous pump.

As veins move farther from the heart they branch into smaller structures known as venules. The venules end in very thin blood vessels known as the capillaries.

The capillaries

The arteries and the veins are connected by the vessel web of the capillaries. The lumen of these vessels is very small, to the extent that blood cells must line up single file to pass through the thinnest of them. Capillary walls are also very thin, allowing the passage of gases and nutrients between the blood cells and the cells of the body.

The exact role of the capillaries varies depending on the part of the body in which they are located. The capillaries of the pulmonary circulation are found in the air sacs of the lungs, called alveoli, and it is there that the exchange of oxygen into the blood and carbon dioxide out of the blood occurs. In the **kidneys**, the capillaries in the organ's tubules are the point where waste products are taken out of the blood to be excreted in the urine. The capillaries of the intestine are the location where nutrients from digested food are absorbed into the bloodstream. Capillaries serving the muscles bring in oxygen and nutrients and take away carbon dioxide and waste products.

Function

For reference, at any particular point in time, about 9% of the body's blood is located in the pulmonary circulation and about 7% is in the heart's circulation. The

remaining 84% is located in the systemic circulation, with 64% in the veins, 13% in the arteries, and 7% in the arterioles and capillaries. The greater percentage in the veins is due to the less elastic nature of the vessels and the tendency of the blood to pool there.

As the pulmonary circulation has a relatively smaller network of vessels when compared to the systemic circulation, the right side of the heart doesn't have to work as hard as the left side to move the blood. Accordingly, the left side of the heart is larger and more muscular. The passive-filling nature of the heart keeps the unequal balance in blood volume between the pulmonary and systemic circulation. Without active filling, the physical differences between the systemic and pulmonary capillaries such as relative size of the vessel bed and relative elasticity determine the blood distribution. If the heart was a different kind of pump, cardiac characteristics, such as rate or stroke volume (amount of blood pumped by one contraction of the left ventricle) would govern the relative volumes.

One way to visualize the function of the cardiovascular system is to follow the movement of one blood cell throughout the body. The path can begin at the left ventricle, where an oxygenated blood cell is pumped out by contraction of the myocardium, through the aortic valve into the aorta. The cell follows the curve into the abdominal artery and into the axillary artery into the arm. The artery subdivides into smaller and smaller branches, small enough to be called arterioles. Blood is needed at a muscle in the arm, so the arterioles are open to keep a large quantity of blood flowing in that direction. The blood cell continues through smaller vessels until it is in a capillary bed next to a muscle cell.

There the cell gives up its oxygen cargo, takes up carbon dioxide waste produced by the muscle, and begins the journey back to the heart. Travelling through the capillaries to the venules and then into the axillary vein, the cell goes into the superior vena cava and into the right atrium. The right atrium contracts, and the cell moves through the tricuspid valve into the right ventricle. On the next systole, the cell rushes out of the right ventricle, through the pulmonary valve into the pulmonary artery to the lungs. The branches of vessels grow smaller and smaller, until the cell is in the capillaries of the alveoli where it releases the carbon dioxide to the lung space to be exhaled, and picks up another load of oxygen.

Travelling back to the heart through the veins of the pulmonary circulation system, the cell enters the left atrium through the pulmonary vein. When the atrium contracts, the cell goes through the mitral valve into the left ventricle, having made one cycle through the cardiovascular system. In this way, the cardiovascular system sup-

plies all the cells of the body with oxygen and nutrients and carries away carbon dioxide and other wastes.

Role in human health

It is difficult to overestimate the role the cardiovascular system plays in human health, with literally every cell of every tissue dependent on its function for survival. The cardiovascular system is the way the body transports things to and from the body's cells. Oxygen, nutrients, and hormones are carried from the point these substances are made or brought into the body to the cells for their use. Cellular wastes are transported from the cells to the lungs, kidneys, or **liver** to be broken down or removed from the body. The circulatory system is also one of the transport systems (along with the lymph) for the immune cells responsible for protecting the body from disease.

Changes in the functioning of the circulatory system have far reaching effects. A defect of the circulatory system, heart disease, is the number one cause of death in humans. Some of the common names and medical terms for the symptoms of a malfunctioning cardiovascular system include

- chest **pain** (angina pectoris)
- shortness of breath (dyspnea)
- general tiredness (fatigue)
- swelling (edema)
- loss of consciousness (syncope)
- light-headedness (presyncope)
- palpitations (arrhythmia or extrasystoles)
- limb pain or tiredness (claudication)
- abnormal skin color (pallor, **cyanosis**, erythema, necrosis)
- sores on skin (ulceration)
- collapse (**shock**)
- sudden changes in **vision**, strength, coordination, speech, or sensation

Common diseases and disorders

Diagnosing cardiovascular disease can be complicated because often more than one cardiovascular problem exists at the same time in the same person. Symptoms of one problem can mask symptoms of another. Sometimes the multiple problems have a common cause or one cardiovascular problem can be causing another. This can make diagnosis and treatment a difficult task.

High blood pressure

The most common cardiovascular disease is high blood pressure (**hypertension**), affecting one in four Americans (one in three black Americans). Blood pressure is measured in millimeters of mercury, based on how high the pressure in the arteries can raise a column of mercury above baseline using a blood pressure cuff. With a generally accepted normal of systolic to diastolic of 120/80, the disease is categorized into three stages. The systolic measurement, the diastolic measurement, or both can be elevated with hypertension.

Stage 1 disease is present with systolic measurements of 5.12–5.47 in (130–139 mm) Hg, stage 2 with 6.29–7.04 in (160–179 mm) Hg, and stage 3 with 7.08 in (180 mm) Hg or higher. For diastolic measurements, stage 1 occurs from 3.54–3.89 in (90 to 99 mm) Hg, stage 2 with 3.93–4.29 in (100 to 109 mm) Hg, and stage 3 with measurements above 4.33 in (110 mm) Hg. Treatment decisions for hypertension take into account not only the measured blood pressure, but also the presence of other cardiovascular disease, hereditary risk factors, evidence of damage to internal organs, and lifestyle (**stress**, diet, **exercise**).

Primary hypertension is associated with a persistent increase in resistance of blood flow in the arterioles, the smaller branches off the arteries. The precise cause is unknown.

Heart disease

Some specific diseases of the heart include cardiomyopathy, congenital heart disease, heart valve defects, myocardial infarction (heart attack), problems of the pericardium, and arrhythmias. If any of these diseases cause the heart to lose its ability to pump blood effectively, the patient is said to have **heart failure**. Because poor pumping ability often results in an accumulation of fluid in the tissues and lungs, it is often called congestive heart failure.

Cardiomyopathy is a disease of the heart muscle with multiple causes and is the number one reason people undergo heart transplants. Categorized by the type of muscle damage, there are three general types of cardiomyopathy: dilated, hypertrophic, and restrictive. Dilated cardiomyopathy refers to the enlargement of the heart that is a response to the overall myocardial weakness. Many problems can cause dilated cardiomyopathy, including viral infections, excessive alcohol intake, and myocarditis (inflammation of the heart).

Hypertrophic cardiomyopathy is an abnormal overgrowth of the heart muscle. An inherited disease, the overgrown muscle blocks the movement of blood both

into and out of the heart. The most common cause triggering hypertrophic cardiomyopathy is hypertension. Restrictive cardiomyopathy is due to a stiffening of the heart muscle that prevents it from fully relaxing during diastole. This problem is a symptom of other diseases such as hemochromatosis (a defect in **iron** use by the body) or amyloidosis (overproduction of antibodies by the bone marrow that cannot be broken down).

Congenital heart disease is caused by defects of the heart present at birth. Defects can be relatively mild and asymptomatic to severe and life-threatening. Some more common problems are abnormally formed blood vessels that block blood flow, malformed heart valves, incorrect connections between arteries, veins, and the heart, or defects in the atrial or ventricular septa. The most common congenital heart defect is a combination of four problems called the tetralogy of Fallot. With this problem the ventricular septum is incomplete, there is an obstruction to blood flow beneath the pulmonary artery, the aorta is shifted rightward, and the right ventricular wall is thickened.

Any of the hearts valves can obstruct blood flow if they are too stiff (stenosis) or don't close properly and allow blood to leak (regurgitation). Valve problems can cause congestive heart failure or heart enlargement, which can lead to angina or heart arrhythmias. Causes of valve disease include congenital defects, **calcium** deposits, and infections, such as **endocarditis** (a bacterial **infection** of the endocardium, the lining of the heart). Severe valve problems can be treated by removal of the diseased valve and replacement with an artificial valve.

A **myocardial infarction** (heart attack) is death of heart tissue due to the sudden lack of blood flow from the coronary arteries. Doctors believe the most common cause of the blockage is a blood clot that formed at a rupture of an atherosclerotic plaque that has broken loose. The results of the heart attack are dependent on the amount of heart tissue that is damaged. With less than 10% of the heart affected, there is a reduction in the ability of the heart to pump blood, but a normal lifestyle can often be maintained. At 25%, enlargement of the heart and heart failure is a common result. If 40% or more of the heart is damaged, shock or death usually occurs.

Pericarditis is inflammation of the pericardium, usually caused by a viral infection. Although this disease can cause sharp, piercing chest pain, it is usually self-limiting and ordinarily does not lead to further problems. Pericardial effusion is a collection of fluid around the heart in the pericardial sac. If the fluid amount is great enough, it can reduce the heart's ability to expand and receive blood, reducing its efficiency. This condition is known as cardiac tamponade. A final condition of the pericardium is pericardial constriction, an abnormal inflexibility of the

pericardial membrane. Some types of pericarditis often result in this problem. If the inflexible membrane causes heart failure, it can be removed surgically.

Arrhythmias are abnormal heartbeats. Very broadly, arrhythmias can be classified into four different types: conduction system abnormalities, abnormally slow, abnormally fast, and irregular. Conduction system abnormalities are seen using **electrocardiography** units and do not directly cause an outwardly altered heartbeat. An example is some heart blocks, where the electrical signal adopts alternative paths in the heart to avoid nonconductive tissue.

Slow heartbeat (bradycardia) is the most common cause for the implantation of a pacemaker and can be caused by problems with the autonomic nervous system, the SA node, or the conduction system. Abnormally fast heartbeats (tachycardia) can be atrial flutter, the presence of an extra, abnormal pathway for electrical conduction in the heart, or ventricular tachycardia (V tach). Some common irregular heartbeats include extra beats (extrasystoles) and atrial fibrillation, where the atria stop having effective contractions and beat chaotically at several hundred times per minute.

Arterial disease

Some diseases of the arteries include atherosclerosis, arterial thrombosis, aneurysm, and arteritis. The most common cause of heart attacks, **coronary artery disease** is the blockage of one or more of the vessels that supply blood to the heart. The arteries can be obstructed by a blood clot (thrombosis), atherosclerosis, or a coronary spasm. These problems can be treated with drugs that dissolve the clot or surgical procedures that remove or circumvent the blockages, such as coronary **angioplasty** or bypass surgery.

Atherosclerosis is caused by the degradation of the lining of the arteries (endothelium) and the resultant plaque, a build-up of platelets, cholesterol, and other substances such as calcium that forms at the site. Atherosclerosis occurs to some extent in everyone and can occur in any of the body's arteries. Depending on the location, the disease can lead to other cardiovascular problems such as heart attack, leg pain, stroke, and aneurysm. Arterial thrombosis is another way that arteries can be blocked, but in this case an abnormal blood clot, called an embolus, is responsible. This condition presents with very similar symptoms to atherosclerosis. If it occurs in a coronary artery, it can cause heart attacks.

An aneurysm is an abnormally widened area of an artery. A common site for this problem is in the abdominal aorta and it is usually caused by atherosclerosis. Aneurysms can be surgically treated if detected before rupture. A final disease of the arteries is arteritis, an

KEY TERMS

Adventitia—The outer layer of the arteries containing nerves and blood vessels.

Diastole—Phase of the heartbeat where the ventricles relax and fill with blood.

Endocardium—The thin, innermost layer of the heart which is infected with endocarditis.

Epicardium—The outermost layer of the heart.

Intima—The innermost layer of the arteries containing a layer of endothelial cells that are damaged with atherosclerosis.

Media—The middle layer of arteries containing the smooth muscle.

Myocardium—The middle, working layer of the heart containing the heart muscle cells.

Pulsile—Movement in waves, a characteristic of the blood when leaving the heart and in the circulation.

Regurgitation—A defect of the heart valves that interferes with its ability to close completely, allowing blood to leak in the direction opposite of circulation.

Septum—A physical divider between chambers, found between the atria and the ventricles.

Stenosis—A stiffening of the heart valves, which narrows its opening and can interfere with function.

Systole—Phase of the heartbeat where the ventricles contract and force blood from the heart.

inflammation of the arteries. This problem is usually a part of another general disease, such as Takayasu's disease, temporal arteritis, Buerger's disease, and polyarteritis nodosa.

Venous disease

Some diseases of the veins include venous thrombosis, thrombophlebitis, pulmonary embolism, and **varicose veins**. Blockages in the veins are not usually caused by atherosclerosis, but by blood clots or venous thrombi. Venous thrombosis and the resulting inflammation, thrombophlebitis, can occur in superficial veins, usually a relatively minor problem, or in deep veins, a more serious condition where the threat of the clot breaking off and traveling to the heart or lungs is present.

These conditions are generally treated with blood-thinning drugs. If the clot does travel and get lodged in the lungs the condition is called a pulmonary embolism. This is a serious problem that often requires hospitalization. If blood-thinning drugs do not resolve the problem, surgical removal of the clot can be necessary.

Varicose veins refer to a condition where the veins become abnormally dilated and most commonly appear as soft bluish bulges in the legs. Caused by elevated pressure in the veins and the resulting damage to the valves within the vessels, varicose veins, unless severe, are a cosmetic problem. They can be treated with surgery, injections (sclerotherapy), or lasers.

Carpal tunnel syndrome

Definition

Carpal tunnel syndrome is a common disorder caused by compression at the wrist of the median nerve supplying the hand, causing numbness and tingling.

Description

The carpal tunnel is an area in the wrist where the bones and ligaments create a small passageway for the median nerve. The median nerve is responsible for both sensation and movement in the hand, in particular the thumb and first three fingers. When the median nerve is compressed, an individual's hand will feel as if it has "gone to sleep." Persistent pressure causes **pain** that may manifest as a burning or tingling sensation in the fingers (acroparesthesia). Reduced motor ability in the hand and wrist may gradually develop as well.

Women between the ages of 30 and 60 have the highest rates of carpal tunnel syndrome; they are two to five times as likely as men to develop the disorder. It is the most frequently occurring nerve compression found in the upper part of the body, and is a very significant cause of missed work days. Research has shown that the prevalence of carpal tunnel syndrome in the general population ranges from 2.1 to 4%. At least 200,000 carpal tunnel release surgical interventions are performed every year in the United States, and is the most frequently performed surgery on the hand. The costs associated with the procedure are at least \$1 billion each year. The cost to employers is also substantial because of the significant loss of work time associated with the condition.

Causes and symptoms

Compression of the median nerve in the wrist can occur during a number of different conditions, particularly those conditions which lead to changes in fluid accumulation throughout the body. Because the area of the wrist through which the median nerve passes is very narrow, any swelling in the area will lead to pressure on the median nerve. This pressure will ultimately interfere with the nerve's ability to function normally. **Pregnancy, obesity**, arthritis, certain thyroid conditions, diabetes, and certain pituitary abnormalities all predispose individuals to carpal tunnel syndrome. Other conditions which increase the risk for carpal tunnel syndrome include the presence of organic lesions, tumors, congenital malformations, and various injuries to the arm and wrist (including **fractures**, sprains, and dislocations). A type of carpal tunnel syndrome that is transmitted by hereditary means has also been found. Furthermore, activities which cause an individual to repeatedly bend the wrist inward toward the forearm can predispose to carpal tunnel syndrome. Certain jobs that require repeated strong wrist motions carry a relatively high risk of precipitating carpal tunnel syndrome. Injuries of this type are referred to as "repetitive motion" injuries, and are more frequent among people

working at computer keyboards or cash registers, factory workers, and some musicians.

Symptoms of carpal tunnel syndrome include numbness, burning, tingling, and a prickly pin-like sensation over the palmar surface of the hand, and into the thumb, forefinger, middle finger, and half of the ring finger. Some individuals notice a shooting pain going from the wrist up the arm, or down into the hand and fingers. This pain can radiate into the shoulder, neck, and chest regions, in some cases. Although pain is generally increased during repetitive movement, it is typically greatest during the night. With continued median nerve compression, an individual may begin to experience muscle weakness, making it difficult to open jars and hold objects with the affected hand. Eventually, the muscles of the hand served by the median nerve may begin to grow noticeably smaller (atrophy), especially the fleshy part of the thumb. Untreated, carpal tunnel syndrome may eventually result in permanent weakness, loss of sensation, and even **paralysis** of the thumb and fingers of the affected hand. Noticeable differences in strength and sensory perception can develop between the affected hand and the unaffected hand.

Diagnosis

The diagnosis of carpal tunnel syndrome is made in part by checking to see whether pain or paresthesia (Phalen's sign) can be brought on by holding his or her hand in position with wrist bent for about a minute. X-rays are often taken to rule out the possibility of a tumor causing pressure on the median nerve. A health practitioner examining a patient suspected of having carpal tunnel syndrome will perform a variety of simple tests to measure muscle strength and sensation in the affected hand and arm. The practitioner will likely test for Tinel's sign (tingling or shock-like pain) by tapping the surface of the wrist over the median nerve to try to produce symptoms. A similar test known as the carpal compression test, where the thumb is placed over the patient's carpal tunnel for 30 seconds, may also be performed.

Further testing might include electromyographic or nerve conduction velocity testing to determine the exact severity of nerve damage. These tests involve stimulating the median nerve with electricity and measuring the resulting speed and strength of the muscle response, as well as recording speed of nerve transmission across the carpal tunnel. A variety of conditions need to be ruled out to confirm the diagnosis of carpal tunnel syndrome. These include **osteoarthritis**, **blood** vessel compression or occlusion, other nerve compression conditions, and tendinitis.

Treatment

Carpal tunnel syndrome is initially treated with splints, which support the wrist and prevent it from flexing inward into the position that exacerbates median nerve compression. Nurses and physical therapists often instruct the patient on how to use these splints or braces. Some people get significant relief by wearing such splints at night while sleeping, whereas others will need to wear the splints all day, especially if they are performing jobs which stress the wrist. If possible, the patient should avoid the repetitive action that may have precipitated the condition initially. Elevation of the affected arm may help some patients. Nurses often provide information on how to minimize strain on the carpal tunnel during daily activities. Physical therapists and nurses can provide information on various exercises, which may help with the symptoms associated with carpal tunnel syndrome. There is some evidence that vitamin B₆ can help symptoms in some patients who have less serious symptoms, although this treatment is currently considered controversial and should be considered an alternative form of medicine. Acetaminophen, ibuprofen, or other **nonsteroidal anti-inflammatory drugs** may be prescribed to decrease pain and swelling. The clinician or pharmacist can provide advice on how to most effectively use these drugs to minimize carpal tunnel symptoms. When carpal tunnel syndrome is more advanced, injection of steroids into the wrist to decrease inflammation may be necessary. This must be carefully performed to avoid damaging the median nerve. Some patients may benefit from receiving low doses of oral **corticosteroids**.

The most severe cases of carpal tunnel syndrome may require surgery to decrease the compression of the median nerve and restore its normal function. Such a repair involves cutting the ligament that crosses the wrist, thus allowing the median nerve more room and decreasing compression. This surgery is done almost exclusively on an outpatient basis and is often performed under **local anesthesia**. Careful injection of numbing medicines (local anesthesia) or nerve blocks (the injection of anesthetics directly into the nerve) create sufficient numbness to allow the surgery to be performed painlessly, without the risks associated with **general anesthesia**. Nurses provide information on what the patient should do postoperatively. Recovery from this type of surgery is usually quick and without complications. The return of muscle strength in the affected limb occurs gradually in most patients. However, when the muscle has severely atrophied in advanced cases, complete restoration of previous muscle strength is not likely. A less-invasive surgical technique using an **endo-**

scope has been developed for this procedure and is being used to a small extent.

Health care team roles

The x-ray technologist will perform the radiography that will help the practitioner determine whether a tumor or injury has occurred in the lower arm of the patient. An x ray of the neck and upper back region of the patient can help rule out any degenerative condition of the spine that could produce some of these symptoms. Likewise, an imaging technologist performing **magnetic resonance imaging (MRI)** could help the practitioner find abnormalities in the lower arm and hand all the way up to the upper back and neck regions of the spine. Nurses can be involved at many points of the diagnostic and therapeutic process. They may assist in the initial physical diagnostic procedures performed by a physician.

Patient education

Physical therapists can design exercises that improve posture and strengthen certain muscle groups in order to alleviate or prevent carpal tunnel strain. These therapists often design rehabilitation programs for patients who have undergone carpal tunnel release surgery. These programs have the goal of restoring muscle strength to the weakened muscles of the lower arm and hand.

Nurses may provide instruction about maintaining good posture and performing exercises that reduce strain on the carpal tunnel in patients that are at the beginning stages of carpal tunnel syndrome. They may also instruct the patient on how to wear a splint or a brace and assist the practitioner in the process of steroid injection into the carpal tunnel. Nurses assist in the carpal tunnel release surgery and in the ensuing recovery process. They also play an important role in the postoperative period by providing instructions about arm elevation and other issues, such as the use of splints. Occupational therapists can play a significant role in the prevention of carpal tunnel syndrome by providing information on good posture techniques and ergonomics while working.

Prognosis

There is a wide range of outcomes in patients with carpal tunnel syndrome. A few patients have spontaneous remission of symptoms. However, most patients need to undergo some form of therapy. Continued pressure on the median nerve puts an individual at risk for permanent disability in the affected hand. Most people are able to control the symptoms of carpal tunnel syndrome using conservative methods, such as splinting and anti-inflammatory agents. Steroid injections often produce only tem-

porary improvement in symptoms. Most of these individuals have a recurrence of symptoms. Many women develop carpal tunnel syndrome in the third trimester of pregnancy, but symptoms usually disappear after the baby is born. Symptoms often reappear in later pregnancies in these women. Because symptoms generally resolve at the end of the pregnancy, surgery is not recommended in these women. In patients who do require surgery, about 95% will have complete cessation of symptoms.

Prevention

Prevention is generally aimed at becoming aware of the repetitive motions which put the wrist into a bent position. People who must work long hours at a computer keyboard, for example, may need to take advantage of recent advances in ergonomics, which position the keyboard and computer components in ways that increase efficiency and decrease stress. An interruption in the repetitive movement once an hour throughout the day may help prevent and reduce symptoms. Early use of a splint may also be helpful for people whose jobs increase the risk of carpal tunnel syndrome. Splints may also improve sleeping posture and prevent or reduce carpal tunnel symptoms.

KEY TERMS

Carpal tunnel—A passageway in the wrist, created by the bones and ligaments of the wrist, through which the median nerve passes.

Corticosteroids—Any one of several hormonal substances obtained from the adrenal gland cortex and which are classified according to biological activity.

Endoscope—A device made of a tube and an optical system for observing the inside of the body.

Electromyography—A type of test in which a nerve's function is tested by stimulating a nerve with electricity, and then measuring the speed and strength of the corresponding muscle's response.

Median nerve—A nerve which runs through the wrist and into the hand. It provides sensation and some movement to the hand, the thumb, the index finger, the middle finger, and half of the ring finger.

Osteoarthritis—A chronic disease that involves the joints and which is characterized by damaged cartilage, bone overgrowth, spur formation, and reduced function.

Tendinitis—Inflammation of a tendon.

Cast care

Definition

A cast is a rigid dressing used to immobilize a fractured bone or soft tissue injury. It is made of strips impregnated with plaster or fiberglass material. The injured area is first covered with a layer of padding made of cotton or synthetic materials to protect the skin from

irritation. The plaster or fiberglass strips are then dipped in water and applied over the padding to form the cast.

Purpose

In general, casts are applied to injured limbs to support and protect the bones and soft tissue. The cast helps to reduce the **pain**, swelling, and muscle spasms following the injury. If the bone is broken, the cast holds the fractured bone ends in correct alignment during the healing process. A cast, because of its rigid properties, will also provide protection from further injury. Body casts are used to prevent movement of the vertebrae of the back and may be used after a traumatic injury to the spine or a surgical repair of the vertebrae.

Precautions

For health professionals

Wet casts must be handled carefully, using only the palms of the hands, because a wet cast can be dented or compressed if handled too much after application. Dents or compression of the cast can cause pressure or irritation to the skin beneath the dressing, which may develop sores or ulcers.

Patients in a hip cast or body cast should be repositioned every two hours during the first 24 hours to allow even drying of the cast and every two hours when awake thereafter to avoid developing pressure sores on the skin.

For patients

The use of crutches may be recommended for patients with a leg cast or a sling for patients with an arm cast for use during the first 24–48 hours. Patients should be instructed to rest and keep the affected limb elevated on a pillow as much as possible during the first 24 hours.

Description

Materials

Of the two types of materials used for the hard supportive layer of casts, fiberglass has the advantages of being lighter, longer-wearing, and better able to “breathe” than plaster. Fiberglass is less trouble for the patient, because plaster casts are more likely to lose their shape if they become wet than fiberglass casts. It is also easier for x rays to penetrate fiberglass than plaster casts. Plaster, on the other hand, is less expensive and is easier to mold or shape to the body. A plaster cast will harden in 15–30 minutes but takes 24–48 hours to dry completely. A fiberglass cast will dry faster, in 15–30

minutes, but the force of the patient’s full body weight may cause the cast to crack in the first 24 hours after application.

Application

Casts are usually applied by physicians or orthopedic technicians, with the assistance of other health professionals. If the bone is broken, the physician will first place the fractured bone into alignment. Stockinette cut to size is applied to the limb and then cast padding (cotton batting) is wrapped around the extremity. The physician dips the casting material in water, squeezes out excess water, and then applies it wet over the cast padding to form the cast. After applying the cast, the physician will roll the stockinette over the edges of the cast to provide smooth edges at the top, bottom and any openings on the cast. The patient’s toes and fingertips are not covered by the cast. The cast is then usually placed on pillows elevated above the patient’s **heart** level for 15–20 minutes to dry.

Preparation

A health professional will assist the patient in removing any clothing that will be difficult to pull over the cast later. The patient is positioned with the affected extremity resting on a pillow. The skin around the affected area is gently cleansed and thoroughly dried. The patient may be given medication for pain as directed by the physician. After the cast has been applied, extra pillows are placed under the cast to elevate it. The patient should be kept warm and comfortable while the cast is drying. It is helpful to explain to the patient that the cast will feel warm at first but then cool and damp as the material dries.

Aftercare

Aftercare includes measuring the patient for crutches or a sling as appropriate. In addition, patients should be given aftercare instructions as follows:

- The cast should be kept dry. Water weakens plaster casts and may cause skin irritation beneath the cast. The patient should use two layers of plastic to keep the cast dry while bathing or showering.
- To decrease swelling and pain in the first 24–48 hours, the patient should place crushed ice in a plastic bag, covered with a pillow case or towel, on the cast over the injury every 15 minutes per hour while awake.
- Dirt, sand, or powder should be kept away from the inside of the cast. Cast boots can be purchased to cover the foot area of a leg cast.

- Padding should not be pulled out of the cast. In addition, the patient should not stick coat hangers, knitting needles, or similar items inside the cast in order to scratch itchy skin.
- The patient should not break off or trim the edges of the cast without consulting the physician.
- The cast should be inspected regularly. If it develops cracks or soft spots, the physician should be notified.
- The patient should never attempt to remove the cast. The physician will remove the cast at the appropriate time with a special saw that cuts through the casting material but will not damage skin.

Complications

Compartment syndrome

A serious complication that can occur after cast application is known as compartment syndrome. This is a rare phenomenon that occurs when a cast is too tight. As the affected limb swells, the cast acts as a closed compartment, tightly compressing the nerves and **blood vessels**. Compartment syndrome can cause permanent nerve damage or loss of limb due to decreased circulation and oxygen to the tissue. Patients should be instructed to call the physician *at once* if any of the following signs or symptoms appear:

- increased pain combined with the feeling that the cast is too tight
- numbness and tingling in the hand or foot
- burning and stinging sensations
- excessive swelling in the part of the limb below the cast
- inability to actively move the toes or fingers

Compromised healing

Another complication of cast application is that the injury may not heal properly. In some cases the bone endings are set incorrectly, producing a deformity; or do not unite at all. Either may require surgical correction. Delayed union of the bone endings may occur in elderly or malnourished patients; their casts may need to remain in place for a longer period of time.

Results

Cast application is an effective treatment for a fractured bone, serious soft tissue injury or surgical joint repair. Casts generally remain in place until bone healing occurs (four to six weeks). The physician will order x rays to monitor bone healing. X rays can be done through the cast. As bone healing occurs and the limb strengthens,

KEY TERMS

Compartment syndrome—A potentially serious complication of cast application, caused by pressure of the cast on the nerves and blood vessels in the injured limb.

the physician may replace the initial cast with a shorter one or a splinted cast that can be removed for bathing. When the cast is removed, the patient's skin will appear dry and the muscles of the limb may be slightly wasted. Skin care with moisturizers and special exercises to regain muscle strength or to relieve joint stiffness may be ordered by the physician.

Health care team roles

Cast application is usually performed by a physician but may be performed by a specially trained orthopaedic technician under the direction of the physician. The licensed nurse will assess the inpatient patient in a medical setting with a newly casted limb for the first 24–48 hours after cast application. In the outpatient setting, the licensed nurse will observe the patient for the first hour after cast application and instruct the patient and patients family about cast care, signs and symptoms of complications and the importance of follow-up visits with the physician for routine reassessment and cast removal.

Cataracts

Definition

The lens of the eye is normally transparent. A cataract is a condition in which the lens of the eye becomes cloudy or opaque. This cloudiness can impair **vision** and may lead to eventual blindness.

Description

The human eye has several parts. The outer layer of the eyeball consists of a transparent dome-shaped cornea and an opaque, white sclera. The cornea and sclera help protect the eye. The next layer includes the iris, pupil, and ciliary body. The iris is the colored part of the eye and the pupil is the small, dark, round hole in the center of the iris. The pupil is primarily responsible for allowing light into the eye. The ciliary body contains muscles that help the eye focus. The lens, which lies behind the pupil and iris, is covered by a cellophane-like capsule. It is normally transparent, elliptical in shape, and somewhat elastic. Due to this elasticity, the lens can focus on both near and far objects. The lens is attached to the ciliary body by fibers (zonules of Zinn). Muscles in the ciliary body act on the zonules, which then change the shape of the lens. This process is called accommodation—the lens focuses images to help make vision clear. As people age, the lens hardens and changes shape less easily. As a result, accommodation becomes more difficult, making it harder to see things up close. This normal aging condition, called **presbyopia**, generally occurs around age 40 and continues until about age 65. Individuals with this condition generally need reading glasses.

The lens is made up of approximately 35% protein and 65% water. As people age, degenerative changes in the lens's **proteins** occur. Changes in the proteins, water content, enzymes, and other chemicals are some of the reasons for the formation of a cataract.

The major areas of the lens are the nucleus, the cortex, and the capsule. The nucleus is in the center of the lens, the cortex surrounds the nucleus, and the capsule is the outer layer. Opacities can occur in any area of the lens, and cataracts can be classified according to their location (nuclear, cortical, or posterior subcapsular cataracts). The density and location of the cataract determines the amount of vision affected. If the cataract forms in the area of the lens directly behind the pupil, vision may be significantly impaired. A cataract that occurs on the outer edges or side of the lens causes less visual impairment.

Cataracts in the elderly are so common that they are thought to be a normal part of aging. Cataracts affect about 50% of individuals between the ages of 52-64, while at least 70% of those 70 and older are affected. Cataracts associated with aging (senile or age-related cataracts) are usually bilateral (occur in both eyes) with asymmetric progression (different rates of progression). Initially, cataracts may not affect vision. If the cataract remains small or at the periphery of the lens, the visual changes may be minor.

Cataracts are much less common in younger people. Congenital cataracts are rare in newborns. When they do occur, they may be due to genetic defects or an **infection** or disease in the mother during **pregnancy**. Traumatic cataracts may develop after a foreign body or trauma injures the lens or the eye. Systemic illnesses, such as diabetes, also may result in cataracts. Cataracts can occur secondary to other eye diseases—for example, uveitis or **glaucoma**. Such cataracts are called complicated cataracts. Toxic cataracts result from chemical toxicity, such as steroid use. Cataracts also can result from exposure to the sun's ultraviolet (UV) rays.

Causes and symptoms

Recent studies have investigated the effect of **nutrition** on cataract formation. The results have been mixed, with some studies finding that there is a connection between nutrition and cataract formation and other studies finding none. Much interest has been focused on the use of antioxidant supplements as a protection against cataracts. Antioxidants, such as **vitamins** A, C, E, and beta-carotene, help the body neutralize oxygen-free radicals.

Smoking and alcohol intake, however, have been implicated in cataract formation, as have the use of oral corticosteroids and antihypertensive agents. Some studies have determined that a diet high in fat increases the likelihood of cataract formation, while an increase in foods rich in antioxidants reduces the incidence. More research is needed to determine the precise role played by diet, smoking, alcohol consumption, and antioxidants in the formation of cataracts.

Some unrelated physical conditions, such as **diabetes mellitus**, also may contribute to cataracts. Eye injuries and sun exposure also are causative factors.

There are several common symptoms of cataracts:

- gradual, painless onset of blurry, filmy, or fuzzy vision
- poor central vision
- frequent changes in eyeglass prescriptions
- changes in color vision

- increased glare from lights, especially oncoming headlights when driving at night
- “second sight” improvement in near vision (no longer needing reading glasses)
- poor vision in sunlight
- presence of a milky whiteness in the pupil as the cataract progresses

Diagnosis

Ophthalmologists and optometrists detect and monitor cataract growth and prescribe prescription lenses for visual deficits. Ophthalmologists perform cataract extraction.

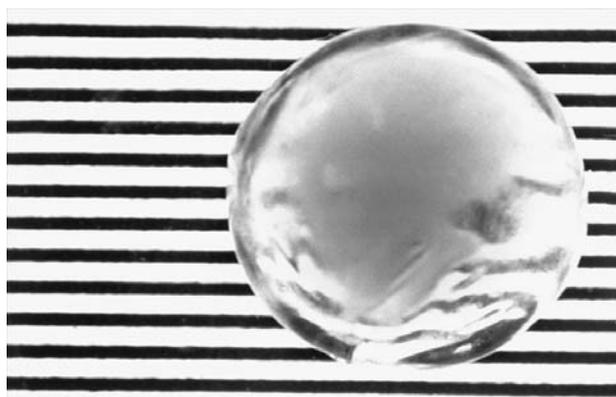

Cataract diagnosis begins with a complete eye exam. The ophthalmic assistant, technician, or nurse gathers information to determine the progression of the vision loss. It is unusual for cataracts to cause rapid vision loss, but sometimes patients believe the vision problem is acute because vision in the better eye has only recently been compromised. Patient history includes a review of refractive history, previous ocular disease, amblyopia, eye surgery, and trauma. Ophthalmic personnel also question patients about difficulties driving, reading, and performing daily activities, and record any medication the patient currently uses.

The ocular exam determines the severity of the cataract and assesses other factors that might contribute to the potential for good vision after surgery. The exam includes measurement of visual acuity under both low and high illumination, biomicroscopy with pupillary dilation, stereoscopic fundus examination with pupillary dilation, assessment of ocular motility and binocularity, visual fields, evaluation of pupillary responses, refraction, and measurement of intraocular pressure (IOP).

Treatment

No treatment may be necessary for cataracts that cause no symptoms or that cause only minor visual changes. It is important for an ophthalmologist or optometrist to continue to monitor and assess the cataract during regular office visits. Increased strength in prescription eyeglasses or **contact lenses** may be diagnostic and beneficial.

Cataract surgery—the only option for patients whose cataracts interfere with vision to the extent that their daily activities are affected—is the most frequently performed surgery in the United States. It generally improves vision in more than 90% of patients. Most cataracts are removed before the lens is completely opaque or mature. This is done to minimize the impact of

A dense cataract on the lens of an eye. (Photograph by Margaret Cubberly, Phototake NYC. Reproduced by

the cataract on the patient’s daily life and also to decrease the risk of other eye complications. Sometimes cataracts need to be removed so the surgeon can examine the back of the eye more carefully. This is important in patients with diseases that may affect the eye. If cataracts are present in both eyes, surgery is performed on one eye at a time. The first eye heals before the second cataract is removed, sometimes as soon as the following week. A final eyeglass prescription is usually given about four to six weeks after surgery. Patients will still need reading glasses. The overall health of the patient must be considered in making the decision to have undergo cataract surgery. However, age alone need not preclude effective surgical treatment of cataracts, and people in their 90s can have successful return of vision after cataract surgery.

Surgery to remove cataracts is generally an outpatient procedure. A local anesthetic is used, and some newer techniques take only minutes to complete. Removal of the cloudy lens can be accomplished with one of the three types of cataract surgery available:

- **Extracapsular cataract extraction.** In this type of cataract extraction, the lens and the front portion of the capsule are removed. The back part of the capsule remains in place.
- **Extracapsular cataract extraction by phacoemulsification.** This type of extracapsular extraction requires only a very small incision, resulting in faster healing. Ultrasonic vibration is applied to the lens to break it up into very small pieces, and the ophthalmologist then aspirates the pieces out of the eye with suction. As of 2001, this is the most commonly performed type of cataract surgery.
- **Intracapsular cataract extraction.** The lens and the entire capsule are removed. This method carries an increased risk for detachment of the retina and swelling after surgery, and, as a result, it is rarely used.

KEY TERMS

Glaucoma—Disease of the eye characterized by increased pressure of the fluid inside the eye. Untreated, glaucoma can lead to blindness.

Ultraviolet radiation (UV)—Invisible light rays that may be responsible for sunburns, skin cancers, and cataract formation.

Uveitis—Inflammation of the uvea. The uvea is a continuous layer of tissue which consists of the iris, the ciliary body, and the choroid. The uvea lies between the retina and sclera.

A replacement lens is inserted at the time of the surgery. A plastic artificial lens called an intraocular lens (IOL) is placed in the remaining posterior lens capsule of the eye. When the intracapsular extraction method is used, an IOL may be clipped onto the iris. Contact lenses and cataract glasses (aphakic lenses) are prescribed if an IOL cannot be inserted due to complications. A folding IOL is used with the phacoemulsification procedure to allow it to pass through the small incision.

Antibiotic drops to prevent infection and steroids to reduce inflammation are prescribed after surgery. An eye shield or glasses protect the eye from injury while it heals. During the night, an eye shield is worn. The patient returns to the doctor the day after surgery for assessment, with several follow-up visits over the next two months to monitor the healing process. Return visits at three and six months are optional.

Prognosis

The cataract extraction success rate is very high with a good prognosis. A visual acuity of 20/40 or better is expected as a result of cataract extraction. If an extracapsular cataract extraction was performed, a secondary cataract may develop in the remaining back portion of the capsule. This can occur one to two years after surgery. YAG capsulotomy is most often used for this type of cataract. YAG stands for yttrium aluminum garnet, the name of the laser used for this procedure. This is a painless outpatient procedure and requires no incision. The laser beam makes a small opening in the remaining back part of the capsule, allowing light through.

Complications occur in a very small percentage (3-5%) of surgical cataract extractions. Possible complications include infections, corneal **edema** (swelling), diplopia, bleeding, retinal detachment, iris prolapse or vitreous in the wound, intraocular lens dislocation, and

the onset of glaucoma. Some problems may occur one to two days, or even several weeks, after surgery. Follow-up examinations should check the patient for haziness or redness in the eye, decrease in vision, nausea, and **pain**.

Health care team roles

Skilled ophthalmic technicians and assistants record the patient history and perform many of the preliminary tests. Depending on skill level, these ophthalmic assistants may perform measurement of visual acuity under both low and high illumination, biomicroscopy with pupillary dilation, assessment of ocular motility and binocularity, visual fields, evaluation of pupillary responses to rule out afferent pupillary defects, refraction, and measurement of intraocular pressure (IOP).

Before the surgery, nurses and assistants also prepare the operating room (OR). Many ophthalmologists now have their own ambulatory surgery centers (ASCs) where skilled technicians and ophthalmic nurses play a critical role in preparing the OR and patients for the surgery. Ophthalmic nurses also assist the ophthalmologist during surgery and discuss outcomes with patients post-operatively.

Patient education

When a cataract is found, the patient should be informed, even if surgery is not immediately indicated. The optometrist or ophthalmologist should discuss the different treatment options, as well as the risks and benefits of surgery with the patient.

Prevention

The eyes should be protected from UV radiation by wearing glasses with a special coating. Dark lenses alone are not sufficient, but the lenses must be coated to filter out UV light (specifically, UV-A and UV-B). Antioxidants also may help prevent cataracts by reducing free radicals that can damage lens proteins. A healthy diet rich in sources of antioxidants, including citrus fruits, sweet potatoes, carrots, green leafy vegetables, and/or vitamin supplements, may be beneficial. When taking certain medications, such as steroids, more frequent eye exams may be necessary. Patients should also be told not to smoke.

Catheterization, female

Definition

Urinary catheterization is the insertion of a catheter through the urethra into the urinary bladder for withdrawal of urine. Straight catheters are used for intermittent withdrawals; indwelling (Foley) catheters are inserted and retained in the bladder for continuous drainage of urine into a closed system.

Purpose

Intermittent catheterization is used for the following reasons:

- To obtain a sterile urine specimen for diagnostic evaluation; to empty bladder content when the patient is unable to void (urinate) due to urinary retention, bladder distention, and obstruction, or to measure residual urine after urination.
- To instill medication for a localized therapeutic effect and to instill contrast material (dye) into the bladder through the urethral catheter for cystourethralgraphy (x ray of the bladder and urethra).
- To empty the bladder for increased space in the pelvic cavity to protect the bladder during labor and delivery and during pelvic and abdominal surgery.
- To strictly monitor the urinary output and **fluid balance** of critically ill patients.

Indwelling catheterization is:

- Indicated as palliative care for terminally ill or severely impaired incontinent patients, for whom bed and clothing changes are uncomfortable, and as a way to manage skin ulceration caused or exacerbated by incontinence.
- Used to maintain a continuous out flow of urine for patients undergoing surgical procedures that cause a delay in bladder sensation, and for persons with chronic neurological disorders that cause **paralysis** or loss of sensation in the perineal area.
- Indicated for urologic surgery, bladder outlet obstruction, and for patients with an initial episode of acute urinary retention to allow the bladder to regain its tone.

Precautions

Because the urinary tract is normally a sterile system, catheterization presents the risk of causing a urinary tract **infection** (UTI). The catheterization procedure must be sterile and the catheter must be free from **bacteria**.

Urinary catheterization aids or replaces the body's normal ability to urinate. Intermittent use of the procedure can stimulate normal bladder function, however frequent and continuous catheterization can lead to total dependency. Catheterization is invasive and has the potential of injuring the urethra and bladder, inviting urinary tract infections. Therefore aseptic techniques should be use in all catheter management activities.

The normal flow of urine from the **kidneys** through the ureters, bladder, urethra prevents the movement of bacteria up through the **urinary system**. The antibacterial properties of the bladder wall, urethra lining, and low urine pH also serve as protective barriers to urinary tract infections. Urinary tract infections occur when bacteria invade the protective barriers of one or more urinary structures.

A Foley catheter is left in place for continuous drainage of the bladder. (Custom Medical Stock Photo. Reproduced by permission.)

Infection control

Every attempt should be made to keep the urinary drainage system closed. Breaks in the system invite infections. Health care workers and patients should wash their hands before and after manipulation of the patient's catheter or collection system to control UTI. Cross-contamination is the most frequent cause of nosocomial (hospital acquired) catheter related infections. Good hand washing practices are the best prevention measure.

The extended portion of the catheter should be washed with a mild soap and warm water to keep it free of accumulated debris.

Frequent intermittent catheterization and long term use of indwelling catheterization predisposes the patient to UTI. Care should be taken to avoid trauma to the urinary meatus or urothelium (urinary lining) with catheters that are too large or inserted with insufficient use of lubricant. Patients with an indwelling catheter must be reassessed periodically to determine if alternative treatment will be more effective in treating the problem.

Description

The female urethral orifice is a vertical, slit-like or irregularly ovoid (egg shaped) opening, 4 or 5 mm in diameter, located between the clitoris and the vagina. The urinary meatus (opening) is concealed between the labia minora, which are the small folds of tissue that need to be separated in order to visualize the opening and insert the catheter. With proper positioning, good lighting and gloved hands, these anatomical landmarks can be identified. If necessary, provide perineal care to ensure a clean procedural environment.

Catheterization of the female patient is traditionally performed without the use of local anesthetic gel to facil-

itate catheter insertion. But since there are no lubricating glands in the female urethra (as found in the male urethra), the risk of trauma from a simple catheter insertion is more likely; therefore, ample supply of an anesthetic or antibacterial lubricant should be used.

Preparation

Health care practitioners performing the catheterization should have a good understanding of the anatomy and physiology of the urinary system, trained in antiseptic techniques and in catheter insertion and catheter care.

Determine the primary purpose for the catheterization and give the patient and/or caregiver a detail explanation. Patients requiring self-catheterization should be instructed and trained in the technique by a qualified health professional.

Sterile disposable catheterization sets are available in clinical settings and for home use. These sets contain most of the items needed for the procedure, such as antiseptic agent, perineal drapes, gloves, lubricant, specimen container, label, and tape. Anesthetic or antibacterial lubricant, catheter, and drainage system may need to be added. It is always wise to review the content of the pre-packaged catheterization set while assembling the materials.

Catheter choices

TYPES. Silastic catheters have been recommended for short-term catheterization after surgery because they are known to decrease incidence of urethritis. However, due to lower cost and acceptable outcomes, latex is the catheter of choice for long-term catheterization. Silastic catheters should be used for patients who are allergic to latex products.

There are also additional types of catheters:

- PTFE-coated latex Foley catheters
- hydrogel-coated latex Foley catheters
- pure silicone Foley catheters
- silicone-coated latex Foley catheter

SIZE. The diameter of the catheter is measured in millimeters. Authorities recommend the "narrowest and softest tube" that will serve the purpose. Rarely is a catheter larger than size 18 F required, and sizes 14 or 16 F are used more often. Catheters greater than size 16 F have been associated with patient discomfort and urine bypassing. A size 12 catheter has been successfully used in children and female patients with urinary restriction.

LENGTH. Female adult patients should be given the choice of a short, female length or a standard length catheter for urethral catheterization.

BALLOON SIZE. Select a catheter with a balloon-filling volume of 0.33 fl oz (10 ml) for routine drainage. Sterile water must always be used to inflate the balloon as other fluids may contain particles, which could block the inflation channel. Some indwelling catheters are manufactured pre-filled with 0.33 fl oz (10 ml) of sterile water, ready for balloon inflation after catheter insertion.

DRAINAGE SYSTEM. Review the design, capacity, and emptying mechanism of the variety of urine drainage bags with the patient. Select the system that is most adaptable to the patient's lifestyle and her ability to manage the device independently. For women with normal bladder sensation, a catheter valve for intermittent drainage may be an acceptable option.

Procedure

The standard technique for catheter insertion is:

- Explain the procedure to the patient, position the patient and ensure privacy and good lighting.
- Wash hands, remove outer tray wrapper and put on sterile gloves before opening the sterile inner packet. Prepare a sterile field and place a specimen collection vessel between the patient's legs.
- Cleanse the labia according to established guidelines and identify the urethral meatus. If an anesthetic lubricating gel is used, instill approximately 0.16 fl oz (5 ml) of 2% lignocaine hydrochloride gel into the urethra or apply the gel to the meatus to achieve surface anesthesia within three to five minutes.
- Hold the catheter in the dominant hand and gently insert it into the urethral meatus; pass it slowly through the urethra and into the bladder. If the catheter is accidentally inserted into the vagina or the tip is contaminated, discard it and take new sterile catheter before proceeding.
- Once the urine starts to flow, collect the specimen and pass the catheter an additional 2 inches (5 cm) to ensure that the balloon is in the bladder before slowly inflating the balloon with 10 ml sterile water.

Aftercare

Patients using intermittent catheterization to manage incontinence may require a period of adjustment as they try to establish a catheterization schedule that is adequate for their normal fluid intake.

Antibiotics should not be prescribed as a preventative measure for patients at risk for urinary tract infections. Prophylactic use of antibacterial agents may lead to the development of drug-resistant bacteria. Patients

who practice intermittent self-catheterization can reduce their risks for UTI by using antiseptic techniques for insertion and catheter care.

Attach the indwelling catheter to the drainage system, slightly curve the tubing, and anchor it to prevent urethral traction. In women the catheter should be secured to the anteromedial thigh with non-allergenic adhesive.

Complications

Complications that are liable to occur include:

- Trauma and/or introduction of bacteria into the urinary system, leading to infection and, rarely, septicemia.
- Trauma to the urethra and/or bladder from incorrect insertion or removal of the catheter with the balloon inflated. Repeated trauma may cause scarring and/or stricture, or narrowing of the urethra.
- Bypassing of urine around the catheter. Inserting a smaller catheter size can minimize this problem.

Sexual activity and **menopause** can also compromise the sterility of the urinary tract. Irritation of the urethra during intercourse promotes the migration of perineal bacteria into the urethra and bladder, causing UTIs. Postmenopausal women may experience more UTIs than younger women. The presence of residual urine in the bladder secondary to incomplete voiding provides an ideal environment for bacterial growth.

Results

Urinary catheterization should be avoided whenever possible. Clean intermittent catheterization, when practical, is preferable to long-term catheterization.

Catheters should not be changed routinely. When each patient is monitored for indication of obstruction, infection, or complications before the catheter is changed, some patients require catheter changes weekly, and others may need a change in several weeks. Fewer catheter changes will reduce trauma to the urethra and reduce incidence of UTI.

Health care team roles

Observation

Before commencing with the catheterization, the nurse should observe the patient's general condition, palpate the pubic area to note gross distension. The patient should be monitored for indications of infections and encourage adequate fluid intake.

KEY TERMS

Catheterization—A procedure of inserting a catheter through the urethra into the bladder to remove urine.

Catheter—A tube for evacuating or injecting fluid.

Contaminate—To make an item unsterile or unclean by direct contact.

Foley catheter—A double channel retention catheter. One channel provides for the inflow and outflow of bladder fluid, the second (smaller) channel is used to fill a balloon that holds the catheter in the bladder.

Intermittent catheterization—Periodic catheterization to facilitate urine flow. The catheter is removed when the bladder is sufficiently empty.

Perineal area—The genital area between the vulva and anus in a woman.

Urinary incontinence—The inability to retain urine or control one's urine flow.

Urinary retention—The inability to void (urinate) to discharge urine.

Urethritis—Inflammation of the urinary bladder.

The nurse should seek medical advice if the catheter cannot be inserted easily, or if the patient complains of undue **pain** or bleeding other than that associated with minor trauma.

Patient education

The patient and/or caregiver should be taught to use **aseptic technique** for catheter care. Nursing interventions and **patient education** can make a difference in the incidence of urinary tract infections in the hospital and **nursing homes** and **home care** units.

The sexuality of the patient with an indwelling catheter for continuous urinary drainage is seldom considered. If a patient is sexually active, the practitioner must explain that intercourse can take place with the catheter in place. The patient or her partner can be taught to remove the catheter before, and replace it with a new one following intercourse.

Catheterization, male

Definition

Urinary catheterization is the procedure of inserting a catheter through the urethra into the bladder to remove urine. Intermittent catheterization is performed for periodic relief of bladder distension; indwelling (Foley) catheters are inserted and retained in the bladder for continuous drainage of urine into a closed system.

Purpose

Intermittent catheterization is recommended to obtain a sterile urine specimen, to relieve urinary retention, for urologic surgery or surgery on contiguous structures, for critically ill patients requiring accurate measurement of intake and output, and for temporary obstruction of the bladder opening due to injury.

Indwelling catheterization is recommended for continuous drainage of urine when the bladder outlet obstruction can not be corrected by medical or surgical intervention; in cases of intractable skin ulceration caused or exacerbated by exposure to urine; and as palliative care for terminally ill or severely impaired incontinent patients.

Precautions

The urinary tract is normally a sterile system. The normal flow of urine from the **kidneys** through the ureters, bladder, and urethra prevents the migration of **bacteria** up through the **urinary system**. Antibacterial properties of the bladder wall, urethra, low pH of urine, and the prostatic fluid in men also inhibit bacteria growth. Urinary tract infections (UTI) usually result from bacterial invasion of the protective barriers of one or

more urinary structures. As a result, urinary catheterization should be avoided whenever possible. Precautions must be taken to keep the procedure sterile and the catheter free from bacteria. The extended portion of the catheter should be washed with a mild soap and warm water to keep it free of accumulated debris.

Frequent intermittent catheterization and long-term use of indwelling catheters predisposes the patient to UTI. Care should be taken to avoid trauma to the urinary meatus and urothelium (urinary lining) with catheters that are too large or inserted with an insufficient amount of lubricant. Further medical advice should be sought if the catheter cannot be inserted easily, or the patient complains of undue **pain** or bleeding other than that associated with minor trauma.

Every attempt should be made to keep the urinary drainage system closed. Breaks in the system invite infections. Health care workers and patients should wash their hands before and after manipulation of the patient's catheter or collection system to control UTI. Cross-contamination is the most frequent cause of nosocomial (hospital acquired) catheter related infections. Good hand washing practices are the best prevention measure. Patients with indwelling catheters should be re-evaluated periodically to determine if an alternative treatment method will be more effective.

Description

Intermittent catheterization is preferable to chronic indwelling catheterization in certain patients with bladder dysfunction. It has become the standard care for patients with **spinal cord** injuries. Elderly patients, following surgical repair of hip **fractures**, regain the ability to control urination more quickly on a program of intermittent catheterization every six to eight hours compared to the use of indwelling catheters.

Intermittent catheterization may be performed four or five times a day by the health care practitioner or caregiver. Patients who are interested in self-catheterization should be instructed and trained by a qualified health professional. This is also true for patients who require indwelling catheterization, as the procedure for insertion is similar to that for intermittent catheterization, with added responsibility of inflating the balloon.

Preparation

Health care practitioner performing the catheterization should have a good understanding of the male urinary system anatomy and physiology and should be trained in **aseptic technique**, catheter insertion technique, and catheter care.

Sterile disposable catheterization sets are available in clinical settings and for home use. These sets contain most of the items needed for the procedure, such as anti-septic agents, perineal drapes, gloves, lubricant, specimen container, label, and adhesive strips. Local anesthetic gel, antibacterial lubricant, catheter, and drainage system may need to be added. It is wise to check the content of the pre-packaged catheterization set when assembling materials and supplies.

Catheter choices

Silastic catheters have a decreased incidence of urethritis and are recommended for short-term and intermittent catheterization. Latex is the catheter of choice for long-term catheterization. Silastic catheters are recommended for patients who are allergic to latex products.

There are additional types of Foley catheters:

- PTFE-coated latex
- hydrogel-coated latex
- silicone-coated latex
- pure silicone

Select the smallest and softest catheter available. Catheters larger than 18 F are seldom used. Catheters size 14 or 16 F are used more frequently. A size 12 F catheter has been used successfully in catheterizing men with acute urinary retention. When indwelling catheters are required, select a catheter that can be inflated with 5 to 10 ml of sterile water.

Review the design, capacity, and emptying mechanism of a variety of urine drainage systems available. Select the system that is most adaptable to the patient's lifestyle and ability to manage the device independently. For patients with normal bladder sensation, a catheter valve for intermittent drainage may be an acceptable option.

Procedural precautions

Before starting the catheterization, observe the patient's general condition and palpate the suprapubic area to detect gross distension. The genital area should be washed with a mild soap and warm water and patted dry.

Phimosis is constriction of the prepuce (foreskin) so that it cannot be drawn back over the glans penis. This may make it difficult to identify the external urethral meatus. Care should be taken when catheterizing men with phimosis to avoid trauma from forced retraction of the prepuce or by incorrect positioning of the catheter.

The male urethra is longer than the female urethra and has two curves in it as it passes through the penis to the bladder, which makes catheter insertion more diffi-

cult. One curve can be straightened out by lifting the penis; the other curve is fixed. The penis should be held upright, at right angle to the patient's body when the catheter is inserted. The male urinary meatus is located at the end of the penis and is exposed by retracting the prepuce in uncircumcised patients. Men with a retracted penis can be even more difficult to catheterize. Gentle finger pressure on both sides of the penis will often cause the penis to emerge and extend from the body to facilitate the catheterization.

To perform the procedure:

- Position the patient in a horizontal recumbent position.
- Place the opened catheterization tray on the bedside stand in comfortable reaching distance.
- Retract the foreskin. Using an aseptic technique, clean the prepuce and insert anesthetic gel to anesthetize the glans penis and dilate the prepuce exposing the meatus. Anesthetic gel can then be introduced into the urethra and catheterization can commence.
- Use two or three aseptic swabs to clean the meatus with circular motion, beginning with the center of the opening and rotating outwards.
- Lubricate about 8 inches (20 cm) of the catheter.
- Hold the penis in the dominant hand and pull it upward and slightly backward to straighten the urethra.
- Gently insert the catheter with a smooth continuous motion until urine begins to flow. Do not force.
- Once the urine starts to flow, collect the specimen. Advance the catheter an additional 5 cm before inflating the balloon with 5 to 10 ml of sterile solution to hold the catheter in place.
- Connect the indwelling catheter to the drainage system. Put a slight curve in the catheter and anchor it to the upper outer thigh with hypoallergenic adhesive to prevent urethral traction.

Aftercare

Patients using intermittent catheterization as treatment of incontinence or retention will have a period of adjustment as they try to establish a catheterization schedule adequate for their normal fluid intake. The urinary drainage system should be kept closed. Breaks in the drainage unit may result in an **infection**. Avoiding cross-contamination is important in controlling catheter-related UTIs. Practitioners and caretakers should always wash their hands before and after handling a patient's catheter or urine collection unit.

The extended portion of the catheter should be washed with a mild soap and warm water to remove

accumulated debris. Patients with indwelling catheters should be re-evaluated periodically to determine if an alternative treatment method will be more effective.

Catheters should not be changed routinely. Each patient should be monitored for indication of obstruction or complications before changing the catheter. Some patients require catheter changes weekly, and others may need a change in several weeks.

In summary, the following guidelines are recommended for male catheterization:

- Catheterize the patient only when it is absolutely necessary.
- Secure the catheter properly.
- Maintain a closed sterile urine collection system and unobstructed urine flow.
- Avoid catheter irrigation unless it is needed to prevent or relieve bladder obstruction.
- Always use the smallest effective catheter.
- Do not change the catheter as an elective treatment option.
- Isolated minor episodes of UTI should not be treated with **antibiotics**. Antibiotic prophylaxis promotes emergence of drug-resistant bacteria.
- Provide continuing education in catheter care for practitioners and caretakers.

Complications

A few complications that may rise during the procedure are:

- urinary tract infections and catheter obstruction
- trauma and/or the introduction of bacteria into the urinary system, leading to infection and, rarely, septicemia
- trauma to the bladder, urethra, and meatus caused by incorrect insertion of the catheter or forceful removal with the bladder inflated by confused patients
- scarring, stricture and/or narrowing of the urethra due to repeated trauma
- urine bypass around the catheter (A smaller catheter size may minimize leakage.)
- leakage around the catheter due to forceful bladder spasms that overwhelm the catheter's drainage capacity

Results

Urinary catheterization aids or replaces the body's normal ability to urinate. Intermittent use of the procedure can stimulate normal bladder function. However frequent and continuous catheterization can lead to total

KEY TERMS

Bacteriuria—Bacteria in the urine (asymptomatic or symptomatic).

Foley catheter—A double channel retention catheter. One channel provides for the inflow and outflow of fluid; the second and smaller channel is used to fill a balloon that holds the catheter in the bladder.

Phimosis—Tightness of the foreskin, which cannot be drawn back from the glans penis.

Prepuce—A fold of cutaneous tissue over the glans penis.

Urinary catheterization—The insertion of a catheter through the urethra into a patient's bladder.

Urinary incontinence—The inability to retain urine or control one's urine flow.

Urinary retention—The inability to void (urinate) to discharge urine.

dependency. Practically every patient with chronic catheterization and frequent intermittent catheterization will develop bacteriuria. Some physicians do not recommend antibiotic therapy for asymptomatic bacteriuria. When symptomatic infections are treated in patients with indwelling catheters, the catheter is removed and a fresh urine specimen is obtained for culture to determine the source of the infection and direct the medical therapy.

Health care team roles

The physician orders the catheter and a **registered nurse** performs the procedure and provides **patient education**. Catheterization is a rather simple procedure, but female nurses are sometimes reluctant to perform urethral catheterization on male patients despite established patient care guidelines and advice on the male catheterization procedure. However, both intermittent and indwelling male catheterization is required to achieve optimum quality of life; therefore nurses should make the best possible practice and techniques available. Before commencing with the catheterization, the health care professional observes the patient's general condition, palpates the pubic area to note gross distension, monitors the patient for indications of infections, and encourages adequate fluid intake.

Patient education

The nurse usually teaches the patient and/or caregiver to use aseptic technique for catheter care. Nursing interventions and patient education can make a difference in the incidence of urinary tract infections in the hospital, **nursing homes**, and **home care** units.

The sexuality of the patient with an indwelling catheter for continuous urinary drainage is seldom considered. If a patient is sexually active, the patient or her partner can be taught to remove the catheter before intercourse, and replace it with a new one following intercourse.

Cell division

Definition

The process by which a cell distributes its genetic material (DNA) and cytoplasm to daughter cells.

Description

In higher organisms including humans, there are two types of cell division, mitosis and meiosis. Strictly speaking, mitosis and meiosis refer to division of the DNA and associated materials in the nucleus of the cell. In mitosis, the cells produced by division have exactly the same genetic information as the original cell, while in meiosis the cells produced by division have only half the genetic

information as the original cell. Both processes are accompanied by cytokinesis, the division of the cytoplasm.

Mitosis

Mitosis produces two daughter cells, each of which has the same genetic information as the parent cell. The entire process includes a series of precise steps to insure that the genetic material is accurately duplicated and distributed. The life of a cell is generally made up of two parts, interphase and mitosis. During interphase, DNA synthesis occurs. Since the process uses the original DNA as a template, the copy is exact (or nearly exact if mutations occur). After a pause, the cell then enters mitosis. Although the lifespan of a cell varies in length depending on the cell type, mitosis itself usually takes about one to two hours and involves four stages: prophase, metaphase, anaphase, and telophase.

PROPHASE. During prophase, the chromosomes, which contain the DNA, condense in length and become visible under a **microscope**. Humans have 23 chromosome pairs, for a total of 46 chromosomes. Since DNA duplication has already occurred, each of the 46 chromosomes at this stage is present in two copies referred to as sister chromatids. The two sister chromatids of a pair are attached to each other at a point called the centromere. As the chromosomes condense, the membrane surrounding the nucleus disappears, and fibers appear, which come together to form a spindle within the cell. The spindle has two opposite poles and a mid-section, the equatorial plate.

METAPHASE. At the beginning of metaphase, the chromosomes line up individually on the equatorial plate. Fibers emanating from the poles of the spindle attach to the centromeres of the sister chromatids. One member of each pair of sister chromatids is attached to a spindle fiber that radiates from one pole, and the other is attached to a fiber that radiates from the opposite pole.

ANAPHASE. After all chromosomes (92 sister chromatids in 46 pairs) have aligned on the equatorial plane of the spindle, the centromere of each chromosome splits, and the fibers begin to contract. One sister chromatid of each pair is pulled to one pole of the spindle and the other is pulled to the opposite pole.

TELOPHASE. Separate membranes form around the chromosome sets at each pole to form two nuclei. The chromosomes elongate and the spindle disappears. Cytokinesis then occurs, resulting in two daughter cells each with 46 chromosomes and roughly half the cytoplasm of the parent cell.

Function and role in human health

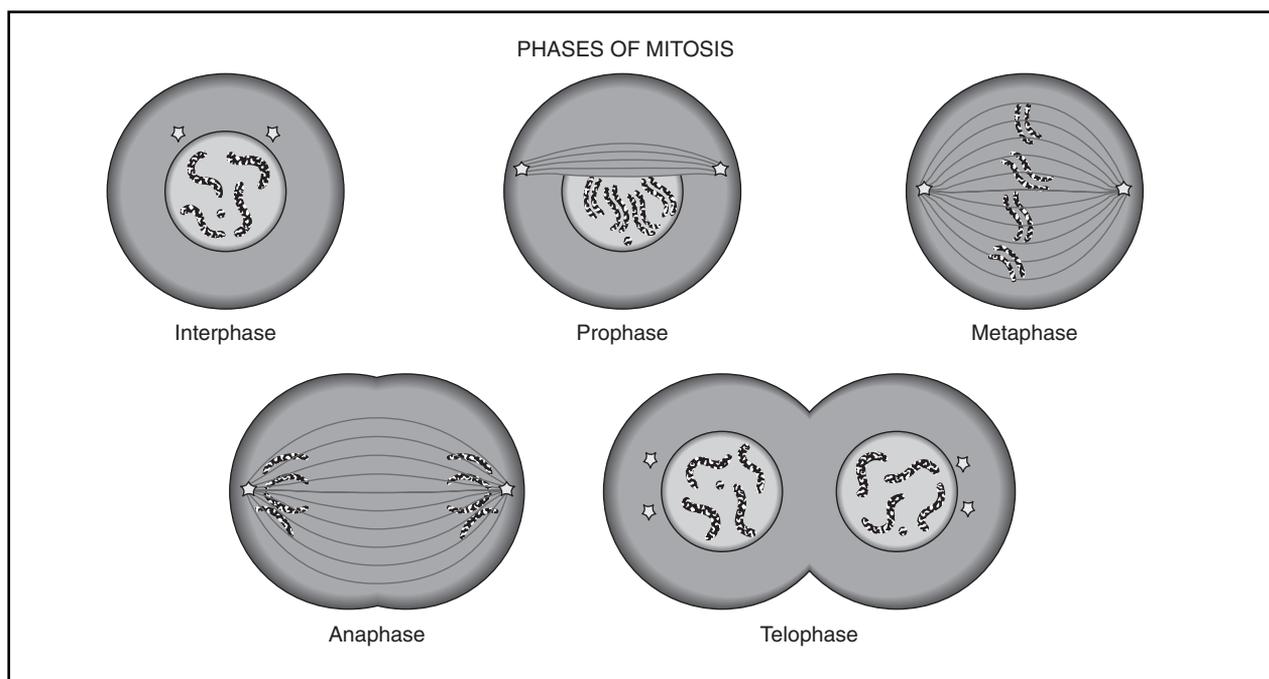

Mitosis is the process by which a single human zygote (fertilized egg cell) becomes a complex organism consisting of over 100 trillion cells. During the lifetime of an individual, mitosis continues. In some tissues such as epithelium (skin, mucous membranes), mitosis actively occurs to replace cells and repair damage. Other cell types such as nerve cells do not readily undergo mitosis after a certain point in development. Thus the capacity for mitosis is programmed into each cell type and is cell-specific. In addition, there are many molecules within the body that can influence cell division. Scientists are just beginning to learn about some of these and their possible roles in human health. For example, **cancer** occurs when the normal pattern of cell division within a tissue or organ is disrupted, and the cells begin to repeatedly undergo mitosis. Changes within the cell as well as external influences can play a part in disrupting the normal control of mitosis.

Meiosis

Meiosis is a special type of cell division that, in higher organisms, occurs only in cells of the ovaries or testes. Within these organs, cells destined to become eggs and sperm undergo meiosis in order to halve the amount of DNA that will be packaged into an egg or sperm. As with all the other cells in the body, these precursor cells are diploid; that is, they have the full complement of 46 chromosomes (23 pairs). Whereas mitosis creates two diploid cells from one existing diploid cell, meiosis results in eggs and sperm that have only one member of each pair of chromosome. Thus these cells, collectively known as germ cells, have only 23 chromosomes and are said to be haploid. At fertilization, the union of one egg and one sperm produces a diploid zygote (fertilized egg) with 46 chromosomes, half from the mother and half from the father. This zygote then begins the many mitotic divisions that will take it from a single cell to a complex, fully differentiated organism.

The steps in meiosis are similar in many ways to those in mitosis, but there are several important differences. One obvious distinction is that, unlike mitosis which includes only one division of the nucleus and cytoplasm, meiosis is actually composed of two divisions, meiosis I and meiosis II. As in a mitotic division, DNA duplication occurs during interphase before meiosis so that the cells begin meiosis I with double the diploid amount of DNA (92 sister chromatids).

MEIOSIS I PROPHASE. Prophase of meiosis I (prophase I) includes several significant features. As the chromosomes condense, chromosome pairing occurs. This is an important phenomenon that occurs only during

Phases of mitosis. (Gale Research.)

meiosis. Higher organisms receive half of their genetic material from their mother and half from their father; that is, one set of chromosomes is maternal in origin and the other set is paternal. During interphase of a cell cycle, as well as during mitotic divisions, these various chromosomes from the maternal and paternal sets do not associate in pairs. Pairing only occurs in prophase of meiosis I. This pairing brings the same chromosome from the mother and father together in close association. This pairing is essential for the important step that happens next.

A process of crossing over occurs between the maternal and paternal member of each chromosome pair. These crossover points, which can be seen through the microscope, are the places where maternal and paternal chromosomes have exchanged sections of genetic material in a process known as recombination. This essential step occurs during meiosis and serves to recombine the genetic material an individual received from their mother and father. That individual can then pass on new combinations of the genes from their parents to their offspring. This greatly increases the possible combinations of genetic traits and helps create diversity in the offspring. At the end of prophase, recombination is complete and the chromosome pairs, still attached at their cross-over points, move to the equatorial plate of the spindle that is beginning to form.

In females the process of meiosis begins while the individual herself is still an embryo. The eggs within that early embryo complete prophase I up to a certain point

and then go into an arrested state. Eggs only begin to be released from that arrest many years later after a woman has reached **puberty**. Each month as one egg is ovulated (released from the ovary), meiosis resumes.

MEIOSIS I METAPHASE. During metaphase I, the 23 chromosome pairs line up on the equatorial plate of the spindle with one member of each pair attached by a spindle fiber to one pole and the other member attached to the other pole. At this point the two members of a pair (each of which is itself composed of a pair of sister chromatids) are being held together only at the anchor points created by the cross-overs. When all chromosome pairs are properly aligned on the equatorial plate of the spindle, the anchors release and anaphase I begins.

MEIOSIS I ANAPHASE. During this stage, the two members of a chromosome pair travel to opposite spindle poles. Unlike anaphase of mitosis, the centromeres do not separate. Thus, each chromosome at a pole is composed of a pair of sister chromatids attached at their centromeres. An important point to understand is that the pairs of chromosomes do not line up on the spindle with all of the individual's mother's chromosomes pointing toward one pole and the father's pointing to the other. The alignment is random, so the function of meiosis I is similar to the shuffling of a deck of cards before dealing a hand. The half set of 23 chromosomes that collects at one spindle pole during anaphase will have chromosomes, and thus genetic information, from both the individual's mother and father. This is another way in which

KEY TERMS

Amniocentesis—A procedure performed around the fourth month of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Fetal cells in the fluid can be used to check the chromosome make-up of the baby.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at eight to 10 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells can be used to study the chromosomes of the fetus.

Chromosomes—Structures in the nucleus of a cell that contain a thread of DNA containing the genetic information (genes). Humans have 46 chromosomes in 23 pairs.

Cytoplasm—The portion of the cell that surrounds the nucleus.

DNA—Deoxyribonucleic acid, the molecule that encodes the genes.

Genetic counselor—An individual, usually with an advanced degree and board certification, who specializes in assessing genetic risk and informing patients about these risks and the options for dealing with them.

Geneticist—A individual with an advanced degree (MS, MD, PhD) in genetics. Human geneticists and medical geneticists specialize in genetic issues pertaining to humans. Many geneticists are certified by specialty boards.

Nucleus—The membrane-bound body within a cell that contains the chromosomes.

meiosis increases diversity in the offspring. When the Austrian monk Gregor Mendel put forth his principles of heredity in 1865, the process of meiosis had not been discovered. However, scientists later came to realize that the inheritance pattern Mendel described for specific traits such as color and shape in the garden pea, were due to the events of the first meiotic division.

MEIOSIS I TELOPHASE. At the poles, a separate nuclear membrane forms around each haploid chromosome set and cytokinesis occurs, resulting into two daughter cells. In females, cytokinesis produces one large cell with the bulk of the cytoplasm, and one very small

cell, the first polar body. The larger cell proceeds to meiosis II. In males, cytoplasmic division is equal and both cells enter meiosis II. Because meiosis I has reduced the diploid number of 46 chromosomes to 23, meiosis I is often referred to as the reduction division.

MEIOSIS II INTERPHASE. Unlike in mitosis, there is no further DNA duplication and interphase is brief.

MEIOSIS II PROPHASE. The nuclear membrane breaks down and a new spindle begins to form.

MEIOSIS II METAPHASE. The haploid set of 23 chromosomes, each consisting of a pair of sister chromatids, moves to the equatorial plate of the spindle. Fibers from the two poles attach at each centromere pair and exert tension to align the chromosomes.

MEIOSIS II ANAPHASE. The centromeres separate, and the sister chromatids are pulled to opposite poles. In this regard meiosis II is very similar to mitosis. In females, anaphase II is triggered by the sperm entering the recently ovulated egg.

MEIOSIS II TELOPHASE. The chromosomes begin to de-condense, a nuclear membrane forms around each set, and cytokinesis occurs. In sperm, cytokinesis is again equal and the result is the production of four haploid spermatids, which will go through a process of maturation to become sperm. In males, there is no arrest of meiosis and the entire meiotic process takes about 60 days. In females, meiosis II produces a small second polar body containing one set of chromosomes and a small amount of cytoplasm. The majority of the cytoplasm together with the other set of chromosomes comprises the ovum (mature egg). Since a sperm has already penetrated the envelope of the egg, all that remains is for the haploid chromosome sets from the egg and sperm to merge to produce the diploid zygote.

Common diseases and disorders

In humans, errors in chromosome division occur frequently during meiosis. Although these errors can take place either during the formation of the egg or the sperm, most errors occur during meiosis in the female for reasons that are not yet clearly understood. If mistakes occur during meiosis, eggs and sperm can be formed with either too many or too few chromosome. Fertilization then results in a fertilized egg than has less than or more than 46 chromosomes, a situation with major health consequences. For example, roughly 20% of all clinically recognized pregnancies result in **miscarriage**. Half of these are due to an extra or missing chromosome(s) in the developing embryo. Among live births, one in 150 infants has some type of chromosome abnormality. One of the more common is **Down syndrome**. Most cases of

Down syndrome are due to an error in meiosis that results in an extra chromosome (extra chromosome 21) being present in the fertilized egg. This condition is called trisomy 21. The individual who develops from this egg will have the clinical features of Down syndrome including mental retardation. Trisomy 21, as well as other similar chromosome errors, occurs more often in the pregnancies of women as they get older. For example, older women have a higher risk for miscarriages associated with chromosome errors. They also have a higher risk of giving birth to an infant with trisomy 21 Down syndrome or a similar chromosome abnormality. For this reason, women in their mid-30s or older are usually referred to a geneticist or genetic counselor to learn about prenatal testing options such as **amniocentesis** and **chorionic villus sampling** (CVS).

Cell membranes

Definition

A cell membrane (also known as a plasma membrane) is a thin semifluid structure that separates the contents of a cell or organelle from its surroundings.

Description

The environment inside of a cell is drastically different from that of its surroundings. Outside the cell, water-soluble ions and molecules create a harsh and toxic environment. From this, the cell must selectively absorb nutrients that are essential to its growth and function. It

must also excrete toxic byproducts of its **metabolism**. The cell membrane subsequently has two major functions:

- It acts as a barrier, enclosing and protecting the components of a cell.
- It acts as a gate, controlling the flow of molecules in and out of the cell.

Higher-level cells known as eukaryotes contain specialized components, called organelles, that play dedicated roles in its growth and development. Each organelle is surrounded by a separate membrane whose function is similar to that of plasma membranes, but with a slightly different composition that enables the organelle to perform specific tasks.

Structure

Plasma and organelle membranes are composed primarily of **lipids** (fatty acids, sterols, or other water-insoluble molecules) and **proteins** (chains of amino acids). They differ in their proportion of lipids to proteins. For example, cell membranes of structures predominantly involved in energy production (e.g., the mitochondria) have a higher percentage of proteins, while membranes acting as insulators (e.g., the Schwann cell, which insulates some nerve fibers) have a higher proportion of lipids.

LIPIDS. A membrane is actually two layers of lipids that form a shell around the cell. This lipid bilayer is composed primarily of phospholipids (lipids containing one or more phosphate groups), each with a hydrophilic (water-soluble) “head” and a hydrophobic (water-insoluble) “tail.” The bilayer is the most stable configuration for phospholipids in a water environment, with the water-repelling tails sequestered in the middle of two layers of water-soluble heads. Thus the membrane forms a stable yet flexible configuration with a certain amount of fluidity: individual phospholipids can move rapidly across the surface of the membrane, and part to allow molecules soluble in organic media (e.g., other lipids, dissolved gases, etc.) to enter the cell.

PROTEINS. One type of protein can be loosely associated with the outside of the membrane; these are called extrinsic (or peripheral) proteins. Other proteins are tightly embedded in the membrane, and may extend from one side of the membrane to the other; these intrinsic or integral proteins are difficult to remove without destroying the membrane itself.

There are two general types of membrane proteins: transporters and receptors. Although some lipid-soluble molecules can permeate the cell membrane, many of the nutrients that a cell needs to function are too large to readily enter the cell. Transporters allow the cell to be

KEY TERMS

Active transport—Movement of a substance against its concentration gradient, from a low concentration to a high concentration.

Eukaryote—An organism whose cells contain a true nucleus bound by a membrane.

Extrinsic proteins—Proteins that are loosely associated with the outside of a plasma membrane; also known as peripheral proteins.

Hydrophilic—Having an affinity for water or for absorbing water.

Hydrophobic—Lacking an affinity for or resistant to water.

Intrinsic proteins—Proteins that are tightly embedded in a plasma membrane, and might extend from one side of the membrane to the other.

Ions—Atoms with positive or negative electric charge.

Lipid—A molecule of composed fatty acids, sterols, or other water-insoluble molecules.

Metabolism—The physical and chemical processes occurring within a cell that are necessary for life.

Organelle—A specialized compartment of a cell that performs specific functions, such as a mitochondrion, lysosome, or ribosome.

Passive transport—Movement of a substance across a membrane without the expenditure of metabolic energy.

Permeation—Movement of a substance through a permeable membrane from a region of high concentration to a region of low concentration.

Receptor—An extracellular structure capable of binding specific substances.

Transporter—A transmembrane protein that transports different substances across the membrane.

selective in which molecules it allows into its cytoplasm. Examples of transporters are channels, which facilitate free movement of molecules across the membranes, and pumps, which require a certain amount of energy in order to transport molecules. Transport proteins also exist in organelle membranes; transport channels have been shown to exist in the organelles of yeast cells and are essential to cell viability.

A cell must be able to communicate with its surroundings if it is going to adapt to changing conditions. Receptors are transmembrane proteins that detect signals from the extracellular environment and translate those signals into a cellular response. An example of a signal is the compound epinephrine (also known as adrenaline). Receptors specific to epinephrine detect its presence in the environment and bind to the molecule. This binding induces a cascade of events in the cell, resulting in increased production of glucose used as energy.

Function

The cell is constantly bombarded by ions and molecules of different type and size. While lipid-soluble molecules can pass readily through the membrane, water-soluble and larger particles require another mode of entry. The plasma membrane consequently has numerous means of importing or exporting substances:

- *Permeation* occurs when a substance moves through the membrane from a region of high concentration to a region of low concentration, a process called diffusion. Only lipid-soluble molecules and some small particles (e.g., biologically important gases such as oxygen and nitrogen) can readily permeate the cell membrane.
- *Passive transport* or facilitated diffusion occurs when water-soluble molecules and ions move through the membrane with the help of transporters (also called permeases).
- *Active transport* occurs when a substance is moved against its concentration gradient, from a low concentration to a high concentration. This process requires a higher amount of energy expended by the cell.

Role in human health

Thousands of **bacteria**, protozoa, and **fungi** cause human disease. These microbial cells also have membranes that are essential to their vitality. This vulnerability is a target of the human **immune system** and some types of drugs that fight microbial diseases. For example, the polymyxin class of **antibiotics** disrupts the cell membranes of bacteria such as *Pseudomonas aeruginosa* (causes respiratory tract, burn wound, ear, and eye infections). Compromising the cell membranes of such microorganisms effectively kills them.

Common diseases and disorders

Some human diseases the result of faulty membrane transport systems. An example would be type II (adult onset) **diabetes mellitus**. Excess glucose in the bloodstream, caused by eating a meal rich in **carbohydrates**,

is usually taken up by myocytes (muscle cells) and adipocytes (fat cells). The glucose transporter GluT4 is normally present in the cell membrane in small amounts. The presence of insulin (a hormone secreted by the **pancreas** in response to high glucose levels) causes more GluT4 transporters to be exposed, increasing uptake of glucose into the cell. In type II diabetes there is resistance to the metabolic effects of insulin, either at the cell membrane or in post-receptor signaling systems. This means that little glucose can be taken up by myocytes and adipocytes, and high **blood** glucose levels are the result.

Cystic fibrosis. a genetic disease, causes an abnormality in the mucus normally found in the **lungs**, resulting in increased bacterial infections and difficulty breathing. This is caused by a defective chloride and fluid transport that decreases the water content of the mucus and causes it to be excessively thick.

Other disorders of membrane transport include Giddelman's syndrome and Liddle's syndrome, which can cause either hypo- or **hypertension**. Membrane disorders are also important causes of water and electrolyte disturbances, disorders of neural transmission, and many other syndromes.

Hazardous substances such as tetrodotoxin (produced by the puffer fish), dendrotoxin (venom of the black mamba snake), and cobrotoxin (another snake venom) affect the function of different ion channels in **neurons**, blocking signals from the nervous system to muscles. The result may be **paralysis** and in some cases, death.

Central catheter maintenance

Definition

Central venous therapy involves placing a catheter into one of the patient's central veins, with the tip situated in the superior vena cava. Central catheter maintenance includes those actions performed by a nurse or other health care professional to keep the catheter functioning properly and to minimize any negative effects on the patient.

Purpose

There are a number of reasons for a patient to require a central catheter. Sometimes a person's peripheral venous access is inadequate for the type or duration of intravenous therapy planned. In other cases, a central line allows central venous pressure to be measured and monitored.

Precautions

Several factors should be considered when deciding which type of central catheter is appropriate for a patient. The duration of therapy and the types of medications ordered, the setting in which the client will receive intravenous therapy, and the client's activity level and lifestyle will all help to determine the catheter the patient has inserted.

Description

There are several types of central catheters, which are divided into two categories: nontunneled and tunneled. They are made from a variety of materials: Teflon, polyurethane, silicone, polyvinyl chloride, and a silicone/elastomer blend called silastic. Each type has advantages and disadvantages, and each type requires specific maintenance.

Nontunneled catheters are used primarily for short-term intravenous therapy, and when quick venous access is required to administer life-saving drugs or fluids. They may be inserted at the client's bedside by the physician. One type of nontunneled catheter is the peripherally

inserted central catheter (PICC). Specially trained nurses can insert the PICC, which is suitable for the administration of any intravenous therapy in any setting. Nontunneled central catheters are easily inserted, cost-effective, and easily removed. On the other hand, they can easily be dislodged by the patient's movements, require sterile dressing changes, and must be flushed by heparin when not used continually.

Tunneled central venous catheters include the Broviac, Hickman, and Groshong. These are made from either polyurethane or silicone and can be distinguished from each other by the inside gauge of lumen and the type of catheter tips. Each of these catheters has their advantages and disadvantages.

- *Broviac*: This is a smaller-bore catheter that is anchored to the chest wall so a patient's movement is not restricted. Its small lumen makes it suitable for children and the elderly. Its disadvantages are that it requires surgical insertion, tears and kinks easily, must be removed by a physician, and is difficult to repair. Because it has a smaller gauge, it is not suitable for many patients. It also requires routine flushing with saline and heparin to maintain its patency.
- *Hickman*: This catheter is also anchored to the chest wall, and it may have multiple lumens allowing multiple uses. However, it also requires surgical insertion, is difficult to repair, and the ports must be capped and clean at all times. Routine flushing is required for the Hickman with saline and heparin.
- *Groshong*: The Groshong has some of the same advantages as the Broviac and Hickman. In addition, because of its valve at the tip, the need for daily Heparin flushes is eliminated. Instead the line can be flushed weekly with 0.9% saline solution. The Groshong is also easy to repair, and generally requires less time and cost for maintenance than the Broviac or Hickman. It too has disadvantages, however. The Groshong tears and kinks easily and must be surgically inserted and removed by a physician.

In addition to flushing, all central catheters require routine sterile dressing changes. The frequency of with which the dressing must be changed depends upon whether the patient is hospitalized or in the home environment.

Another type of central catheter is an implanted port, which consists of a portal body, a septum, a reservoir, and a catheter. The port is inserted surgically into a subcutaneous pocket in the patient's trunk, and the catheter is then threaded into the central vascular system. The septum consists of a self-sealing silicone, which is accessed by the nurse using a special noncoring needle. One of its primary advantages is that it does not require frequent flushing when not in use, and since it is implanted

KEY TERMS

Central catheter—A catheter placed into a central vein for the purpose of administering drugs, fluids, nutrients, and blood products. It may also be used to withdraw blood for laboratory testing.

Noncoring needle—Also known as a Huber needle, this special type of needle has a hole on its side rather than at the tip, and may be either straight or angled. Its special shape slices rather than punctures in the septum, reducing the chance of leakage through the opening.

Patency—Degree of openness; once inserted, catheters can become clogged unless they are flushed with heparin and/or saline to keep them clear.

Urokinase—A kidney enzyme found in urine used to dissolve blood clots.

beneath the skin, it aids in maintaining the patient's body image.

Preparation

The patient should be told why a central catheter is being placed, what care it may require afterwards, and, if possible, should consent to the procedure before it is performed. Tunneled catheters are usually placed surgically by the physician. Prior to the procedure, a sedative is often ordered to relax the patient.

Aftercare

After the catheter is placed, the placement must be confirmed by x ray prior to use.

Complications

The two primary complications with central catheters are **infection** and occlusion. Infections can be decreased with strict sterile technique when changing dressings, and monitoring the patient closely for any signs of infection, including **fever**, redness or soreness at the site of insertion, and drainage from the insertion site.

Occlusions are the most common noninfectious complication seen with central venous access devices. Thrombotic, or **blood** clot, occlusions can be prevented with regular flushing using the proper technique. A positive-pressure technique prevents blood reflux after the

flushing. Some thrombotic occlusions may require flushing with an agent like urokinase.

Mechanical occlusions can also occur if the catheter develops a kink, or if the suture holding the catheter in place is too tight. In addition, if the catheter was positioned with the tip touching the vessel wall, a partial occlusion could result that would allow infusion, but not the aspiration of blood. These types of occlusions may require the replacement of the catheter.

Results

Ideally the central catheter will stay in place for as long as it is needed without complications developing. After it is no longer needed, the catheter is removed.

Health care team roles

With the exception of PICC lines, most central catheters are inserted by a physician. These lines are normally maintained and cared for by nurses.

Central nervous system

Definition

The central nervous system (CNS) consists of the **brain** and **spinal cord**.

Description

Comprised of the brain and spinal cord, the CNS is central to the body as opposed to peripheral. It is responsible for unconscious and conscious body functions as well as intellectual functions that allow humans to think. The neuron is the basic nerve cell of the nervous system, however, the nervous system contains many types of

cells other than nerve cells. The nerve cell consists of a nucleus in a cell body, dendrites, and axons. The CNS is heavily guarded with protective features, however, this does not make it immune to disease and disorder. The CNS is cushioned with cerebrospinal fluid (CSF), protected by three layers of meninges, and protected from the body by the blood-brain barrier. The blood-brain barrier prevents harmful substances and disease-causing organisms from contaminating the bloodstream entering the CNS.

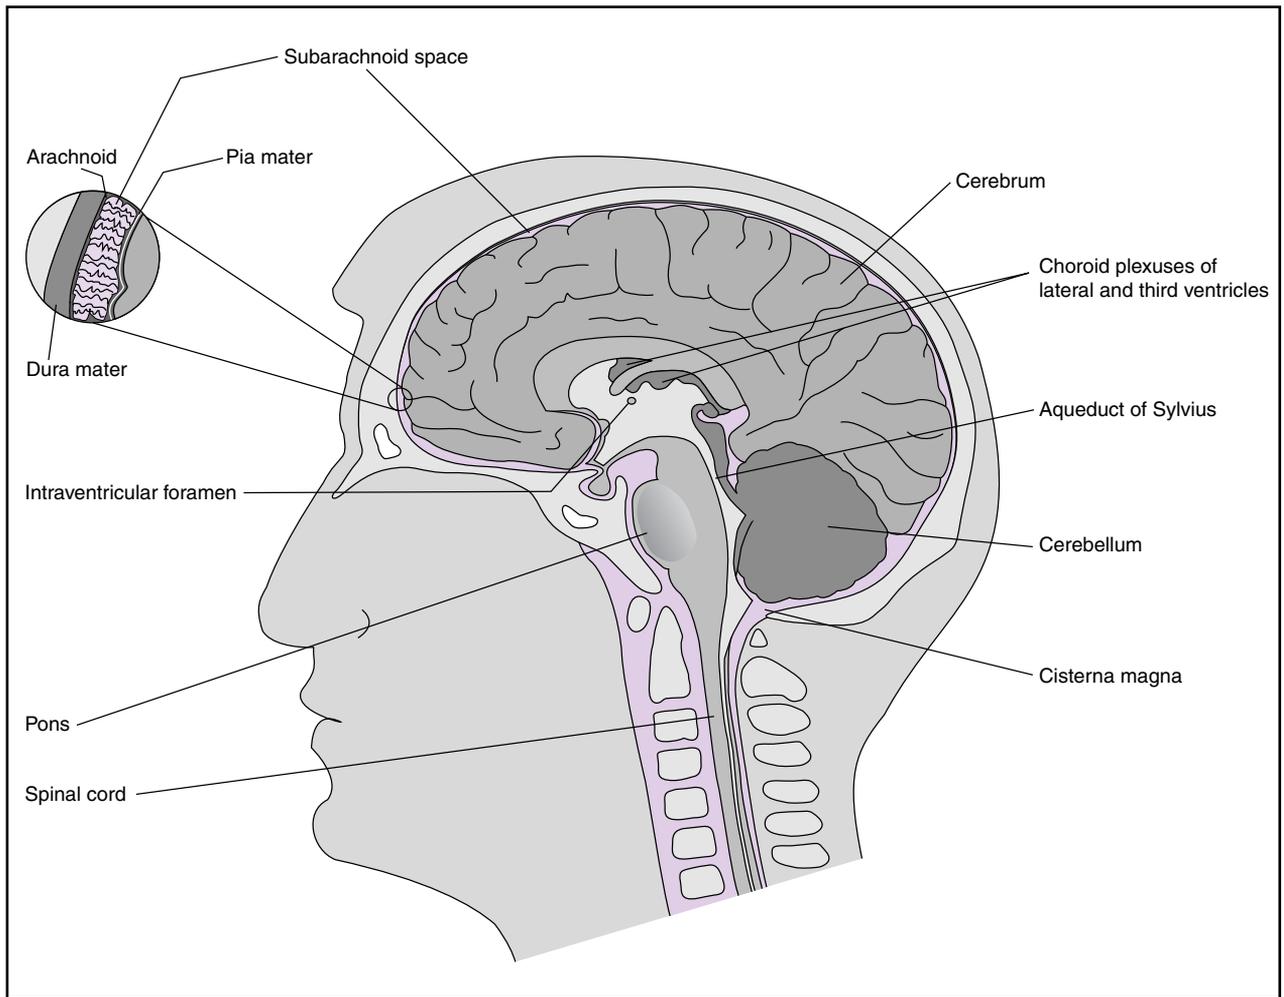

The **skull** (cranium) encloses the brain. Three main areas of the brain, the cerebrum, cerebellum, and brainstem, contain myelinated nerve fibers and white matter, in contrast to the cortex of the brain, the layer of gray matter. The cerebrum, the largest part of the brain containing the left and right hemispheres, controls conscious activities like motor functions. The cerebellum, located above the brainstem, communicates with other regions of the brain and spinal cord to control balance and coordination. The brainstem, the lowest part of the brain extending to the spinal cord, controls unconscious activities necessary for survival like breathing and **blood pressure**. The spinal cord is protected by the **vertebral column** from the cervical area to the sacrum. The spinal cord nerves relay sensory information to the brain and motor information to the body.

Function

The central nervous system (CNS) is a processing center that integrates sensory and motor activities via the brain and spinal cord. Nerves are like an electrical wire with an insulating sheath, called myelin, that facilitates the smooth, high-speed transmission of messages. Information in the nervous system is carried by brief electrical impulses that are conducted away from the body of the nerve cell along the axons. When impulses reach the tips of axons, information is transmitted to the next nerve cell in line, or to a muscle or organ. At the point of contact, or synapse, the information is carried across the gap between cells by neurotransmitters. The CNS has two-way communication. Nerve fibers either relay messages to the brain to communicate sensory stimuli, or they relay messages away from the brain to the body's tissues and organs. It is through the spinal cord that messages are sent back and forth to the brain. Spinal nerves in the spinal cord connect the message relay system to rest of the body

Role in human health

Many health care providers, neurologists, neurosurgeons, physiatrists, neuropsychologists, nurses, occupational therapists, speech language pathologists, physical

Major features of the brain and spinal cord, which comprise the central nervous system (CNS). (Delmar Publishers, Inc. Reproduced by permission.)

therapists, and vocational rehabilitation counselors play a role on the health care team and share in the responsibility of the neurologic patient. A combination of methods for assessing patients with neurologic diseases and disorders enables health care professionals to make informed treatment recommendations. These include neurologic and **physical examination**, laboratory tests such as lumbar puncture, brain-imaging scans such as MRI, neuropsychological testing, and nuclear medicine tests. Treating neurologic diseases and disorders requires active patient participation along with education and support from health care professionals. While **patient education** may be time-consuming, it is extremely important to the process of maintaining health and preventing disease.

Common diseases and disorders

There are hundreds of disabling neurological diseases and disorders that affect every age, race, and eth-

nicity. A few examples include developmental disorders (**cerebral palsy**), degenerative diseases (Parkinson's and **Alzheimer's disease**), metabolic diseases (Tay-Sachs disease), cerebrovascular diseases (stroke), autoimmune diseases (**multiple sclerosis**), and tumors (glioblastoma).

Alzheimer's disease

Alzheimer's disease (AD), a progressive, neurodegenerative disease, is the most common cause of **dementia** in later life. The course of the disease varies from person to person. Although the cause of AD is not yet known, researchers have found a familial tendency for AD. They have also implicated several possibilities including genetics, environmental factors, and biochemical changes in the brain caused by low levels of certain neurotransmitters. AD usually begins after age 65, however, it may have an early onset as early as age 40.

SYMPTOMS. The severity and progression of symptoms vary from person to person. Some of the early symptoms of AD, such as forgetfulness or loss of concentration, can easily be overlooked because they resemble signs of aging or could result from fatigue, depression, or the use of certain medications. Symptoms of AD include:

- **memory** loss, confusion, loss of concentration
- difficulty recognizing family and friends
- poor judgment, indifference
- changes in behavior and personality
- disorientation, wandering, sleep disturbance
- agitation, **anxiety**, depression

There is no specific test to confirm a diagnosis of AD. A combination of tools including brain imaging technologies, patient and family history, physical and neurological examination, and neuropsychological testing are utilized to definitively diagnose AD. There is no cure for AD and no clinically proven way to slow the progression of the disease. For some patients, medication may alleviate some of the symptoms. Treatments are intended to make the patient more comfortable.

Stroke

Stroke, also called cerebral vascular accident (CVA), occurs when the **blood** flow to part of the brain is disrupted. There are primarily two categories of stroke, ischemic and hemorrhagic. The most frequent cause of stroke is a blockage (ischemic) of a blood vessel in the brain. The blockage can have several causes but all with the same result, brain cell damage or death. Brain cells cannot survive without a blood supply of oxygen and nutrients. Blockage of blood flow in the brain can be caused by a clot in a blood vessel (thrombosis) of the brain, the movement of a clot from another part of the body (embolism) to the brain, or a severe narrowing of an artery in the brain (stenosis). In a hemorrhagic stroke, a blood vessel in the brain bursts, bleeding into the brain (intracerebral hemorrhage) or into the spaces surrounding the brain.

SYMPTOMS. The signs and symptoms of stroke depend on the areas of the brain affected and the functions they control. The right cerebral hemisphere controls the left side of the body and the left cerebral hemisphere controls the right side of the body. The symptoms of stroke may be:

- sudden numbness or weakness, especially on one side of the body
- sudden confusion, difficulty speaking, or understanding speech

- sudden difficulty seeing in one or both eyes
- sudden trouble walking
- sudden dizziness, loss of balance or coordination
- sudden severe headache
- paralysis, **pain**

Risk factors for stroke are either changeable or not. For example, a person cannot change their age or family history, but they can change behaviors, like smoking, that put them at risk for a stroke. Risk factors for stroke include:

- high blood pressure
- **heart** disease
- diabetes
- smoking
- heavy alcohol consumption
- drug abuse
- high blood cholesterol levels
- family history of stroke or TIA
- age over 55

According to the National Center for Health Statistics, stroke is the third leading cause of death in the United States. In order to improve this statistic, patients need prompt interventions. The public education campaign, “Know Stroke: Know the Signs. Act in Time,” promoted by the National Institute of Neurological Disorders and Stroke (NINDS) teaches people how to recognize the signs and symptoms of stroke and the importance of prompt medical treatment to improve recovery. Tissue plasminogen activator (t-PA), the first Food and Drug Administration (FDA) approved acute ischemic stroke treatment, needs to be given within a three-hour window of the onset of symptoms to dissolve the clot. Stroke is diagnosed by a neurological examination, blood tests, brain imaging scans, Doppler ultrasound, or arteriography.

Multiple sclerosis

Multiple sclerosis (MS) is a common neurological disease that occurs mainly in young adults. The course of the disease varies from person to person and is categorized by type. Relapsing-remitting MS (RRMS) has a course of acute attacks with full or partial recovery during remissions. Secondary progressive MS (SPMS) is initially relapsing-remitting and then becomes progressive. Primary progressive MS (PPMS) has a progressive course from the beginning of the disease with no remissions. Progressive-relapsing MS (PRMS) has a progres-

KEY TERMS

Antigen—A substance that stimulates the immune system to produce antibodies.

Autoimmune—The immune system sees self as a foreign antigen and attacks a part of the body.

Cerebrospinal fluid—Fluid surrounding and cushioning the brain and spinal cord.

Cognitive—Information processing functions carried out by the brain that include comprehension, memory, attention, planning, problem-solving, etc.

Dura mater—The outermost layer of meninges.

Exacerbation—The appearance of new symptoms or the aggravation of old symptoms.

Gene—Basic units of heredity in every cell that tell the cell how to put together different proteins.

Interferon—A naturally occurring immune system protein.

Lumbar puncture—A diagnostic procedure that uses a hollow needle to penetrate the spinal canal between the vertebrae to remove cerebrospinal fluid for analysis.

Meninges—Three layers of protective connective tissue covering the brain and spinal consisting of the pia mater, arachnoid, and dura mater.

Myelin—A protective coating made of fat and protein that insulates the nerve and enhances efficient nerve fiber conduction.

Neurotransmitter—A chemical that transmits a nerve impulse at the synapse.

sive course from the beginning with acute relapses, with or without full recovery.

MS is believed to be an autoimmune disease, where the **immune system** targets the myelin in the central nervous system. MS is the most common demyelinating disease. During an attack (exacerbation), inflammation occurs in the white matter of the central nervous system. This process is followed by destruction of myelin causing areas called plaques. Not only is the myelin damaged, but the attack may also damage or sever the nerve fibers underneath the myelin. The nerve cannot conduct or send a signal properly without the myelin sheath.

MS can be difficult to diagnose because there are other diseases with similar symptoms, and there is no specific test to confirm the diagnosis. A process of elimination may be done along with a combination of imaging

technologies such as MRI, CSF analysis, evoked potentials (EVP), medical history, and clinical examination.

SYMPTOMS. The symptoms of MS are unpredictable, can vary greatly from person to person, and come and go. The neurological symptoms of MS are the result of demyelination. Symptoms include:

- blurred, double **vision**, and blind spots
- numbness, tingling, and paresthesias (pins and needles)
- fatigue, dizziness, and vertigo
- difficulties with memory loss, concentration, and attention
- difficulty with coordination, balance, and gait
- muscle and nerve pain, muscle weakness, and tremors
- bladder and bowel problems

There are many conventional and alternative treatment therapies to alleviate the symptoms of MS, but there is no cure. However, four medications have been shown to slow down disease progression. The FDA approved Interferon beta 1b (Betaseron) in 1993, Interferon beta 1a (Avonex) in 1996, and glatiramer acetate (Copaxone) in 1996 for the treatment of RRMS. They were clinically shown to decrease the frequency and severity of attacks by approximately 30%. Mitoxantrone (Novantrone), a **chemotherapy** agent that suppresses immune function, was FDA approved in 2000 for the treatment of worsening RRMS and SPMS.

Research

Research in neuroscience and the development of new research techniques and technologies offer hope to the millions of patients and families affected by neurological diseases and disorders. Research into new treatments doesn't solve the problem, therefore, scientists are researching areas such as neurogenetics to discover how to prevent certain disorders. New treatment options and the possibility of cures can bring a sense of optimism to patients. However, the research process takes years before a treatment is available to the public. Only controlled clinical trials with human participants can determine if a treatment is safe and effective for patients.

Central nervous system stimulants

Definition

Central nervous system (CNS) stimulants are medicines that speed up physical and mental processes.

Purpose

Central nervous system stimulants are used to treat conditions characterized by lack of adrenergic stimulation, including narcolepsy and neonatal apnea. Additionally, methylphenidate (Ritalin) and dextroamphetamine sulfate (Dexedrine) are used for their para-

doxical effect in attention deficit hyperactivity disorder (ADHD).

The anorexiant, benzphetamine (Didrex), diethylpropion (Tenuate), phendimetrazine (Bontril, Plegine), phentermine (Fastin, Ionamine), and sibutramine (Meridia) are CNS stimulants used for appetite reduction in severe **obesity**. Although these drugs are structurally similar to amphetamine, they cause less sensation of stimulation, and are less suited for use in conditions characterized by lack of adrenergic stimulation.

Phenylpropanolamine and ephedrine have been used both as diet aids and as vasoconstrictors.

Description

The majority of CNS stimulants are chemically similar to the neurohormone norepinephrine, and simulate the traditional "fight or flight" syndrome associated with sympathetic nervous system arousal. **Caffeine** is more closely related to the xanthines, such as theophylline. A small number of additional members of the CNS stimulant class do not fall into specific chemical groups.

Precautions

Amphetamines have a high potential for abuse. They should be used in weight reduction programs only when alternative therapies have been ineffective. Administration for prolonged periods may lead to drug dependence. These drugs are classified as schedule II under federal drug control regulations.

The amphetamines and their congeners are contraindicated in advanced arteriosclerosis, symptomatic cardiovascular disease, and moderate to severe **hypertension** and hyperthyroidism. They should not be used to treat patients with hypersensitivity or idiosyncrasy to the sympathomimetic amines, or with **glaucoma**, a history of agitated states, a history of drug abuse, or during the 14 days following administration of monoamine oxidase (MAO) inhibitors.

Methylphenidate may lower the seizure threshold.

Benzphetamine is category X during **pregnancy**. Diethylpropion is category B. Other anorexiant have not been rated; however their use during pregnancy does not appear to be advisable. Safety for use of anorexiant has not been evaluated.

Amphetamines are all category C during pregnancy. Breast feeding while receiving amphetamines is not recommended because the infant may experience withdrawal symptoms.

There have been reports that when used in children, methylphenidate and amphetamines may retard growth.

KEY TERMS

Agranulocytosis—An acute febrile condition marked by severe depression of the granulocyte-producing bone marrow, and by prostration, chills, swollen neck, and sore throat sometimes with local ulceration.

Anorexiant—A drug that suppresses appetite.

Anxiety—Worry or tension in response to real or imagined stress, danger, or dreaded situations. Physical reactions, such as fast pulse, sweating, trembling, fatigue, and weakness may accompany anxiety.

Attention-deficit hyperactivity disorder (ADHD)—A condition in which a person (usually a child) has an unusually high activity level and a short attention span. People with the disorder may act impulsively and may have learning and behavioral problems.

Central nervous system—The brain and spinal cord.

Depression—A mental condition in which people feel extremely sad and lose interest in life. People with depression may also have sleep problems and loss of appetite, and may have trouble in concentrating and carrying out everyday activities.

Leucopenia—A condition in which the number of leukocytes circulating in the blood is abnormally low and which is most commonly due to a decreased production of new cells in conjunction with various infectious diseases, as a reaction to various drugs or other chemicals.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies, or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies, or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Withdrawal symptoms—A group of physical or mental symptoms that may occur when a person suddenly stops using a drug on which he or she has become dependent.

Although these reports have been questioned, it may be suggested that the drugs not be administered outside of school hours (because most children have behavior problems in school), in order to permit full stature to be attained.

The most common adverse effects of CNS stimulants are associated with their primary action. Typical responses include overstimulation, dizziness, restlessness, and similar reactions. Rarely, hematologic reactions, including leukopenia, agranulocytosis, and bone marrow depression have been reported. Lowering of the seizure threshold has been noted with most drugs in this class.

Withdrawal syndrome

Abrupt discontinuation following prolonged high dosage results in extreme fatigue, mental depression, and changes on the sleep EEG. This response is most evident with amphetamines, but may be observed with all CNS stimulants taken over a prolonged period of time.

Cerebral palsy

Definition

Cerebral palsy (CP) is the term used for a group of nonprogressive disorders of movement and posture

caused by abnormal development of, or damage to, motor control centers of the **brain** or, in some cases, hypoxemia (insufficient oxygen in the **blood**) during the birth process. CP is caused by events before, during, or after birth. The abnormalities of muscle control that define CP are often accompanied by other neurological and physical abnormalities.

Description

Voluntary movement (walking, grasping, chewing, etc.) is primarily accomplished using muscles that are attached to bones, known as the **skeletal muscles**. Control of the skeletal muscles originates in the cerebral cortex, the largest portion of the brain. Palsy means **paralysis**, but may also be used to describe uncontrolled muscle movement. Therefore, cerebral palsy encompasses any disorder of abnormal movement and paralysis caused by abnormal function of the cerebral cortex. However, CP does not include conditions due to progressive disease or degeneration of the brain. For this reason, CP is also referred to as static (nonprogressive) encephalopathy (disease of the brain). Also excluded from the definition of CP are any disorders of muscle control that arise in the muscles themselves or in the peripheral nervous system (nerves outside the brain and **spinal cord**).

CP is not a specific diagnosis but is more accurately considered a description of a broad but defined group of neurological and physical problems.

The symptoms of CP and their severity are quite variable. Persons with CP may have only minor difficulty with **fine motor skills**, such as grasping and manipulating items with their hands. A severe form of CP could involve significant muscle problems in all four limbs, mental retardation, seizures, and difficulties with **vision**, speech, and **hearing**.

Muscles that receive defective messages from the brain may be constantly contracted and tight (spastic), and the person with CP may exhibit involuntary writhing movements (athetosis) or have difficulty with voluntary movement (dyskinesia). There can also be a lack of balance and coordination with unsteady movements (ataxia). A combination of any of these problems may also occur. Spastic CP and mixed CP constitute the majority of cases. Effects on the muscles can range from mild weakness or partial paralysis (*paresis*), to complete loss of voluntary control of a muscle or group of muscles (*plegia*). CP is also designated by the number of limbs affected. For instance, affected muscles in one limb is called monoplegia, affected muscles in both arms or both legs is called diplegia, affected muscles in both limbs on one side of the body is called hemiplegia, and affected

muscles in all four limbs is called quadriplegia. Muscles of the trunk, neck, and head may be affected as well.

Approximately 500,000 children and adults in the United States have CP, and it is newly diagnosed in about 6,000 infants and young children each year. The incidence of CP has changed little since the 1960s and 1970s. Ironically, advances in medicine have decreased the incidence from some causes—Rh disease for example, but have increased its incidence from other causes—notably, prematurity and multiple pregnancies. (Medical advances have made it possible for more babies born prematurely or in multiple but underweight births to survive, thus allowing more time for CP to be recognized when it does occur.) No particular ethnic groups seem to be at higher risk for CP. However, people of disadvantaged background are at higher risk due to poorer access to adequate **prenatal care** and advanced medical services.

Causes and symptoms

CP can be caused by a number of different mechanisms at various times—from several weeks after conception, through birth, and into early childhood. For many years it was accepted that most cases of CP were due to brain injuries received during a traumatic birth, known as birth asphyxia. However, extensive research in 1980s showed that only 5–10% of CP could be attributed to birth trauma. Other possible causes include abnormal development of the brain, prenatal factors that directly or indirectly damage **neurons** in the developing brain, premature birth, and brain injuries that occur in the first few years of life.

Because CP has many causes, a discussion of the genetics of CP is complicated. A number of hereditary or genetic syndromes have signs and symptoms similar to CP, but usually also have problems not typical of CP. Put another way, some hereditary conditions mimic CP. Isolated CP, meaning CP that is not a part of some other syndrome or disorder, is usually not inherited.

It might be possible to group the causes of CP into those that are genetic and those that are nongenetic, but most would fall somewhere in between. Grouping causes into those that occur during **pregnancy** (prenatal), those that happen around the time of birth (perinatal), and those that occur after birth (postnatal), is preferable. CP related to premature birth and multiple pregnancies (twins, triplets, etc.) is somewhat different and considered separately.

Prenatal causes

Although much has been learned about human embryology in the latter part of the twentieth century, a

great deal remains unknown. Studying prenatal human development is difficult because the embryo and fetus develop in a closed environment, namely the mother's uterus. However, the relatively recent development of a number of prenatal tests provides a window on the process. Add to that more accurate and complete evaluations of newborns, especially those with problems, and a clearer picture of what can go wrong before birth is now possible.

The complicated process of brain development before birth is susceptible to many chance errors that can result in abnormalities of varying degrees. Some of these errors will result in structural anomalies of the brain, while others may cause undetectable, but significant, abnormalities among connections (sometimes referred to as wiring) in the cerebral cortex. An abnormality in structure or wiring is sometimes hereditary, but is most often due to chance, or a cause unknown at this time. Whether and how much genetics played a role in a particular brain abnormality depends to some degree on the type of anomaly and the form of CP it causes.

Just as a stroke can cause neurologic damage in an adult, so too can this type of event occur in the fetus. A burst blood vessel in the brain followed by uncontrolled bleeding (coagulopathy), known as intracerebral hemorrhage, could cause a fetal stroke. Alternatively, a cerebral blood vessel could be obstructed by a clot (embolism). Infants who later develop CP, along with their mothers, are more likely than other mother-infant pairs to test positive for factors that put them at increased risk for bleeding episodes or blood clots. Some coagulation disorders are strictly hereditary, but most have a more complicated basis.

A teratogen is any substance to which a pregnant woman is exposed that has the potential to harm an embryo or fetus. Links between a drug or other chemical exposure during pregnancy and a risk for CP are difficult to prove. However, any substance used by the pregnant woman that might affect fetal brain development, directly or indirectly, could increase the risk for CP. Furthermore, any substance used by the mother that increases the risk for premature delivery and low birth weight—such as alcohol, tobacco, or cocaine, among others—might indirectly increase the risk for CP.

The fetus receives all nutrients and oxygen from blood that circulates through the placenta. Therefore, anything that interferes with normal placental function might adversely affect development of the fetus, including the brain, or might increase the risk for premature delivery. Structural abnormalities of the placenta, premature detachment of the placenta from the uterine wall

(abruption), and placental infections (chorioamnionitis), are thought to pose some risk for CP.

Certain conditions in the mother during pregnancy might pose a risk to **fetal development** leading to CP. Women with autoimmune antithyroid or antiphospholipid (APA) antibodies are at slightly increased risk for CP in their children. A potentially important clue points toward high levels of cytokines in the maternal and fetal circulation as a possible risk for CP. Cytokines are **proteins** associated with inflammation, such as from **infection** or **autoimmune disorders**, and they may be toxic to neurons in the fetal brain. More research is needed to determine the exact relationship, if any, between high levels of cytokines during pregnancy and CP. A woman with high cytokine levels has some risk of developing the same complications in more than one pregnancy, slightly increasing the risk for more than one child with CP.

Serious physical trauma to the mother during pregnancy could result in direct trauma to the fetus as well. Injuries to the mother can compromise the availability of nutrients and oxygen to the developing fetal brain.

Perinatal causes

Birth asphyxia significant enough to result in CP is now uncommon in developed countries. Tight nuchal cord (umbilical cord around the baby's neck) and prolapsed cord (the cord presents through the birth canal before the baby and becomes kinked or buckled) are possible causes of birth asphyxia, as are bleeding and other complications associated with **placental abruption** and **placenta previa** (placenta lying over the cervix exit).

Infection in a mother is sometimes not passed to her fetus through the placenta but, rather, transmitted to the baby during delivery. Many of these infections are sexually transmitted diseases, such as gonorrhea, **syphilis**, and even **AIDS**. Any such infection that results in serious illness in the newborn has the potential to produce some neurological damage.

Postnatal causes

The remaining 15% of CP is due to neurologic injury sustained after birth. CP with a postnatal cause is sometimes referred to as acquired CP, but this is only accurate for those cases caused by infection or trauma.

Incompatibility between the Rh blood types of mother and child (mother Rh negative, baby Rh positive) can result in severe anemia in the baby (erythroblastosis fetalis). This occurs because the mother's blood develops antibodies to the infant's blood and attempts to destroy what it perceives as the "foreign" blood. This may lead to other complications, including severe **jaundice**, which

A physical therapist works with a child with cerebral palsy. (Lois Silver/Custom Medical Stock Photo. Reproduced by permission.)

can cause CP. Rh disease in the newborn is now rare in developed countries due to routine screening of maternal blood type and treatment of pregnancies at risk. The routine, effective treatment of jaundice due to other causes has also made it an infrequent cause of CP in developed countries. Rh blood type incompatibility poses a risk for recurrence of Rh disease with each pregnancy if treatment is not provided.

Serious infections that affect the brain directly, such as **meningitis** and encephalitis, may cause irreversible damage to the brain, leading to CP. A **seizure disorder** early in life may cause CP, or may be the product of a hidden problem that causes CP in addition to seizures. Unexplained (idiopathic) seizures are hereditary in only a small percentage of cases. Although rare in infants born healthy at or near term, intracerebral hemorrhage and brain embolism, like fetal stroke, are sometimes genetic.

Physical trauma resulting in brain injury to an infant or child, such as physical abuse, accidents causing impact to the head, or near drowning/suffocation, might cause CP. Likewise, ingestion of a toxic substance such as lead, mercury, poisons, or certain chemicals could cause neurological damage. Accidental **overdose** of cer-

tain medications might also cause similar damage to the **central nervous system**.

Prematurity and multiple pregnancy

Advances since the 1980s in the medical care of **pre-mature infants** have dramatically increased the rate of survival of these fragile newborns. However, as gestational age at delivery and birth weight of a baby decrease, the risk for CP dramatically increases. A term pregnancy is delivered between 37 and 41 weeks of gestation. The risk for CP in a preterm infant (32–37 weeks) is increased about five-fold over the risk for an infant born at term. Survivors of extremely preterm births (less than 28 weeks) face as much as a 50-fold increase in risk. About 50% of all cases of CP being diagnosed are in children who were born prematurely.

Two factors are involved in the risk for CP associated with prematurity. First, premature babies are at higher risk for various CP-associated medical complications, such as intracerebral hemorrhage, infection, and difficulty in breathing, to name a few. Second, the onset of premature labor may be induced, in part, by complications that have already caused neurologic damage in the fetus.

A combination of both factors almost certainly plays a role in some cases of CP. The tendency toward premature delivery tends to run in families, but the genetic mechanisms are far from clearly understood.
